ABSTRACT: Trimethylacetic acid (TMAA) adsorption on stoichiometric and oxygen-deficient CeO$_2$(111) surfaces was investigated using density functional theory that accounts for the on-site Coulomb interaction via a Hubbard term (DFT +U) and long-range dispersion correction. Both the molecular state and dissociative state (TMAA → TMA$^-$ + H$^+$) were identified on stoichiometric and oxygen-deficient CeO$_2$(111) surfaces. For the stoichiometric surface, two thermodynamically favorable configurations with adsorption energies of the order of $\sim$30 kcal/mol are identified; one is a molecule adsorption state, and the other one is a dissociative state. For the oxygen-deficient surface, dissociative states are more favorable than molecular states. The most favorable configuration is the dissociative adsorption of TMAA with the adsorption energy of the order of $\sim$77 kcal/mol. The dissociated TMA moiety takes the position of oxygen vacancy, forming three Ce–O bonds. The signature vibrational frequencies for these thermodynamically stable structures are reported as well as their electronic structures.

The effects of long-range dispersion interactions are found to be negligible for geometries but important for adsorption energies.

1. INTRODUCTION

CeO$_2$ is an important material with wide applications, including use as a catalyst and electrolyte and in solar cells because of its ability to accommodate varying charge states and facilitate relatively facile surface oxidation–reduction that allows it to mediate oxygen concentration. It is well-known that the concentration of Ce$^{3+}$ ions increases with the reduction of the size of CeO$_2$ nanoparticles, and consequently oxygen exchange and redox reactions occur easily. Because of this unique property, CeO$_2$ nanoparticles have been recently identified for a wide range of biomedical applications in which the ligand–nanoparticle interactions are of paramount importance in controlling the required properties. For instance, CeO$_2$ nanoparticles coated with appropriate ligands can work as effective drug carrier and delivery agents. Because their efficiency depends on the binding stability of the nanoparticles with the ligands, it is vital to understand the chemistry between the anchoring groups on ligands and the surfaces of CeO$_2$ nanoparticles. One of the most commonly used anchoring groups is carboxylate; thus, the chemical adsorption of carboxylic acids on the nanoparticle surface is of great interest. Because of the complexity of nanoparticle surfaces, researchers have been using solid surfaces to study various facets of CeO$_2$ nanoparticle surfaces. Carefully designed experimental studies have been undertaken on the adsorption of carboxylic acids and carboxylates, such as formic acid, acetic acid, and formate, on the CeO$_2$(111) surface, which has been determined both theoretically and experimentally to be the most stable low-index surface. The three general adsorption modes being studied are monodentate, bridging bidentate, and chelating bonding, shown in Scheme 1. However, concerning the most stable configuration of carboxylic acid on the CeO$_2$(111) surface, varying results were reported. Stubenrauch et al. studied the reactions of formic and acetic acids on CeO$_2$(111) and CeO$_2$(100) surfaces using temperature-programmed desorption (TPD) and high-resolution electron energy loss spectroscopy (HREELS). They found that carboxylic acids were dissociated on both surfaces to form surface carboxylates and hydroxyl groups and identified stable surface.
