26 **Abstract**

27 Zika virus (ZIKV), an arbovirus of global concern, remodels intracellular membranes to form
28 replication sites. How ZIKV dysregulates lipid networks to allow this, and consequences for
29 disease, is poorly understood. Here, we performed comprehensive lipidomics to create a lipid
30 network map during ZIKV infection. We found that ZIKV significantly alters host lipid
31 composition, with the most striking changes seen within subclasses of sphingolipids. Ectopic
32 expression of ZIKV NS4B protein resulted in similar changes, demonstrating a role for NS4B in
33 modulating sphingolipid pathways. Disruption of sphingolipid biosynthesis in various cell types,
34 including human neural progenitor cells, blocked ZIKV infection. Additionally, the sphingolipid
35 ceramide redistributes to ZIKV replication sites and increasing ceramide levels by multiple
36 pathways sensitizes cells to ZIKV infection. Thus, we identify a sphingolipid metabolic network
37 with a critical role in ZIKV replication and show that ceramide flux is a key mediator of ZIKV
38 infection.

48 **Introduction**

49 Zika virus (ZIKV), an enveloped positive-strand RNA virus of the family
50 Flaviviridae, has recently emerged as a significant global human health threat¹.
51 Following its rapid expansion into the Americas, ZIKV was found to possess a unique
52 combination of virulence traits, including the ability to cross the human placental barrier
53 and cause microcephaly and other congenital abnormalities². Like other positive-strand
54 RNA viruses, ZIKV is highly dependent on host cell machinery for the production of new
55 virions^{3,4}. The resulting disruption of cellular networks can directly contribute to clinical
56 disease, raising the need for systems biology methods to elucidate host-virus
57 interactions within and between all host tissue compartments^{5,6}.

58 The development of genome-scale CRISPR/Cas9 knockout screens has
59 tremendously advanced investigations into genetic factors that affect disease⁷.
60 Knockout screens for genes required for flavivirus-induced cell death have identified a
61 number of novel targets, including multiple components of the endoplasmic reticulum
62 (ER) protein processing and quality-control pathways^{8,9}. While such screens are
63 powerful tools for elucidating host factors in infection, they have important limitations:
64 knockouts in genes that are not essential for virus-induced cell death may escape
65 detection, as may knockouts in host pathways with genetic or functional redundancy
66 that can continue to function in the absence of individual gene products. To date, host
67 factors identified in gene-editing experiments have thus far clustered around ER protein
68 complexes essential for flavivirus genome replication and translation, while metabolic
69 pathways with important roles during infection have been mostly underrepresented.

70

71 ZIKV's distinct tropism and pathology, and lack of readily apparent disease mechanism,
72 has prompted efforts to systematically map the interaction of ZIKV infection with host
73 cells¹⁰. While studies of the ZIKV-infected host proteome³, transcriptome^{4,9,11}, and
74 protein-protein interactome¹² have yielded new insights into ZIKV biology, the
75 mechanistic basis of ZIKV pathogenesis remains largely unknown.

76 Like other flaviviruses, ZIKV carries out each stage of its replication cycle in close
77 association with cellular membranes, including the synthesis of new genome copies and
78 assembly of viral particles within specialized replication complexes (RCs) formed from
79 extensively remodeled endoplasmic reticulum (ER) membranes¹³. These steps appear
80 to require a specific lipid milieu, as flaviviruses presumably modify various host lipid
81 pathways to create this milieu¹⁴⁻¹⁶. A rapidly growing body of knowledge on the
82 importance of lipids in cell organization, signaling networks, and viral disease outcomes
83 therefore led us to investigate how ZIKV perturbs cellular lipid metabolic networks to
84 establish and promote infection^{17,18}.

85 To systematically map the host lipid-virus interaction networks in an unbiased
86 manner, we carried out a global lipidomic survey in ZIKV-infected human cells. We also
87 performed similar lipidomic profiling in cells that ectopically express NS4B, one of the
88 non-structural proteins of ZIKV known to be involved in forming viral replication sites¹⁹.
89 We found that ZIKV infection as well as NS4B expression significantly alters the lipid
90 composition of human cells, with the most striking pattern of changes seen within
91 sphingolipids. Ceramide, a bioactive sphingolipid implicated in signaling and apoptosis,
92 is recruited to ZIKV replication sites and strongly associate with the ZIKV non-structural
93 protein NS4B. We used pharmacological inhibition and genetic knockouts of enzymes

94 involved in sphingolipid biosynthesis in various cell types, including neural progenitor
95 cells to show that sphingolipids are required for ZIKV replication, but not for binding to
96 or entering host cells. Conversely, genetic knockout of sphingomyelin synthesis
97 drastically increased cellular permissiveness to ZIKV, indicating that ceramide or its
98 derivatives, rather than sphingomyelin, are required for ZIKV infection. Together, our
99 study identified a sphingolipid metabolic network with a novel pro-viral role in ZIKV
100 replication.

112 **Results**

113 **ZIKV alters the lipid landscape of host cells**

114 To understand how cellular lipid metabolism is altered by ZIKV infection, we carried out
115 a global lipidomic survey of the model Huh7 human hepatic carcinoma cell line²⁰ infected for 24
116 or 48 hours with Asian lineage ZIKV strain FSS13025 (Fig. 1a). Lipids extracted from
117 populations of mock and infected cells ($n = 5$ biological replicates per condition) were analyzed
118 with electrospray ionization tandem mass spectrometry (LC-ESI-MS/MS) (Supplementary Data
119 1 and Supplementary Fig. 1a-f). We identified 340 lipid species spanning the phospholipid,
120 sphingolipid, glycerolipid, and sterol classes for which pairwise comparisons of normalized
121 abundance between mock and infected cells could be made (Supplementary Data 1). Of these,
122 80 species (23.5%) showed significant changes in abundance by 24 hours post-infection (hpi)
123 and 172 species (50.6%) were significantly altered by 48 hpi ($P < 0.05$, ANOVA or g-test)
124 (Supplementary Data 1). Principal component analysis (PCA) of these observations confirmed
125 that infection status (mock or ZIKV) and timepoint (24 or 48 hpi) accounted most of these
126 changes, with changes in lipid composition between mock and infected cells increasing over
127 time (Fig. 1b).

128 Next, we examined how ZIKV-induced changes in host lipid composition broke down by
129 subclass and species (Fig. 1c, d). A map of the pairwise correlations of all 340 species at 48 hpi
130 (Supplementary Fig. 2a) revealed that lipid subclasses largely fell into two groups of species
131 that were either enriched or depleted in abundance (Supplementary Fig. 2b), suggesting that
132 individual metabolic pathways are up- or down-regulated to create a specific lipid milieu around
133 the events of the viral replication cycle. Supporting this, many of the trends we observed were
134 consistent with earlier reports of functional roles for lipids during flavivirus infection. In line with
135 evidence that lipid droplets are consumed as an energy source during flavivirus replication,
136 most triglycerides (TG) declined over the course of infection, though TG species with 22:6 acyl

137 chains increased. All cholesterol esters (CE) were enriched in ZIKV-infected cells, reproducing
138 trends seen during dengue virus (DENV) infection. Trends among phospholipid subclasses
139 varied: cardiolipin (CL), phosphatidylserine (PS), and phosphatidylethanolamine (PE) species
140 were mostly depleted at 24 and 48 hpi and phosphatidylcholine (PC) species were enriched. A
141 notable exception was the phosphatidylinositol (PI) subclass, which went from largely depleted
142 to largely enriched between 24 and 48 hpi. The role of PI signaling in regulating numerous
143 cellular functions is well established, and our data supports findings that PI pathways are
144 upregulated to block apoptosis late in flavivirus infection.

145

146 **Expression of ZIKV NS4B enriches host sphingolipids**

147 The flavivirus genome encodes three structural (capsid [C], envelope [E] and membrane
148 [prM]) and seven nonstructural (NS) proteins (NS1, NS2A, NS2B, NS3, NS4A, NS4B and NS5).
149 Structural ZIKV proteins carry out the entry and membrane fusion steps of the viral life cycle²¹,
150 while NS proteins cooperatively remodel ER membranes to form replication sites and
151 synthesize viral RNA²². Despite their limited size and number, the functions of most of the NS
152 proteins are poorly characterized²³, as are their interactions with host lipids²⁴ and potentially
153 hundreds of unique proteins^{3,12,25}. While the enigmatic nature of the ZIKV NS proteins and their
154 interactions presented challenges to defining a mechanistic basis for our lipidomics results, two
155 lines of evidence led us to investigate NS4B as potentially important in altering lipid metabolism.
156 First, NS4B is a transmembrane protein that produces the strongest ER stress and autophagic
157 response of the ten flavivirus proteins when individually expressed^{26,27}, and lipid metabolism is
158 coordinately regulated with these pathways during periods of stress²⁸⁻³¹. Second, the NS4B of
159 the closely related *Flaviviridae* member Hepatitis C virus (HCV) dysregulates lipid metabolism to
160 permit viral replication³², which may directly contribute to liver disease³³. Like *Flavivirus* NS4B³⁴,
161 HCV NS4B is an integral component of the viral replication complex and can both remodel ER

162 membranes into replication site-like structures³⁵ and induce a potent ER stress response³⁶ when
163 individually expressed.

164 To examine whether ZIKV NS4B could similarly regulate global lipid metabolism, we
165 performed a second lipidomic survey of HEK293T cells transfected with ZIKV NS4B-FLAG or an
166 empty vector control (Fig. 2a and Supplementary Fig. 3a-d). Supporting its role as a major factor
167 in host-virus interactions, NS4B caused significant down- or up-regulation ($P < 0.05$, one-way
168 ANOVA) in 44% of the 318 lipid species identified relative to the control (Fig. 2b and
169 Supplementary Data 2). Furthermore, many of these changes were comparable to or exceeded
170 those of similar species in ZIKV-infected cells, especially in the negative direction (Fig. 2c).

171 We analyzed the relationship between NS4B transfection and ZIKV infection for the set
172 of lipid species ($n = 98$) that appeared in both datasets and found a weak but highly statistically
173 significant positive correlation between the two conditions ($P < 0.05$, Pearson correlation
174 coefficient) (Fig. 2d). Strikingly, ceramides were the only species that were significantly enriched
175 by over a log in both conditions (Fig. 2d). When we repeated our analysis for individual lipid
176 classes, sphingolipids were even more strongly correlated than total lipids, or phospholipids and
177 glycerolipids alone (Fig. 2e). Together, our results support a causal relationship between NS4B
178 expression and targeted regulation of sphingolipid metabolism, along with previously described
179 stress-signaling pathways.

180

181 **Depletion of cellular sphingolipids inhibits ZIKV propagation**

182 De novo sphingolipid biosynthesis begins in the ER with the condensation of L-serine
183 and palmitoyl CoA catalyzed by serine palmitoyltransferase (SPT) (Fig. 3a). Further reactions
184 yield dihydrosphingosine, which is converted by ceramide synthase (CerS) to dihydroceramide,
185 then to ceramide (Cer), the precursor to SM and other downstream sphingolipids. To determine
186 if ZIKV could replicate in the absence of sphingolipids, we used the small-molecule inhibitors
187 myriocin and fumonisins B1 (FB1) to block the activity of SPT and CerS, respectively (Fig. 3a).

188 Inhibition of sphingolipid synthesis was confirmed by pulse-chase experiments using the SM
189 precursor [¹⁴C]-serine (Supplementary Fig. 4a, b) and LC-ESI-MS/MS confirmed that inhibitor
190 treatment effectively reduced overall levels of sphingolipids without perturbing levels of PS
191 (Supplementary Fig. 4c-f), while cell growth rate and morphology was not affected
192 (Supplementary Fig. 5a, b).

193 Next, we examined the ability of ZIKV to propagate in inhibitor-treated cells. Huh7 cells
194 treated with myriocin or FB1 and infected at an MOI of 0.1 showed a 30-fold reduction in
195 infectious virions released into the culture supernatant 24 hours after infection, a difference that
196 increased to over 100-fold after 72 hours (Fig. 3b). To control for the possibility that the
197 inhibitors reduced ZIKV particle infectivity, we performed RT-qPCR to quantify the number of
198 ZIKV genomes released into the supernatant of treated and untreated Huh7 cells (Fig. 3c).
199 Myriocin or FB1 treatment caused reductions in levels of extracellular viral RNA comparable to
200 the losses in infectious titer we found by plaque assay, indicating that inhibition of sphingolipid
201 biosynthesis caused a defect in ZIKV particle biogenesis. Similarly, propagation of ZIKV in
202 myriocin or FB1-treated Vero cells, a primate epithelial cell line highly permissive to flavivirus
203 infection³⁷, resulted in decreased load of E glycoprotein at 72 hpi (Fig. 3d). We concluded that
204 depletion of cellular sphingolipids blocked ZIKV propagation in human and non-human primate
205 cells.

206 To confirm this finding in a genetic model, we tested ZIKV propagation in two cell lines
207 negative for SPTLC2: human haploid HAP1 cells³⁸ with a CRISPR-mediated knockout
208 (*SPTLC2*^{-/-}), and knockout murine dendritic DC2.4 cells (*Sptlc2*^{-/-})³⁹. HAP1 cells, which are
209 generally excellent genetic models for studies of the virus life cycle⁴⁰⁻⁴³, yielded a nearly
210 hundred-fold decrease in viral shedding in SPTLC2^{GT} cells by 48 hpi (Fig. 3e). Though
211 immunocompetent murine cells are highly restrictive to ZIKV⁴⁴, we observed a ten-fold reduction
212 in ZIKV production from *SPTLC2*^{-/-} DC2.4 cells at 24 hpi similar to that timepoint in our other cell
213 lines (Fig. 3f); both WT and knockout DC2.4 cells appeared to clear the infection at later

214 timepoints as previously reported *in vivo*⁴⁴, further suggesting that sphingolipids are required for
215 fundamental aspects of flavivirus biology rather than interactions with specific cell types or
216 antiviral immunity.

217

218 **Sphingolipids are required for ZIKV infection of neural progenitor cells**

219 ZIKV is known to be neurotropic and mainly infects neuronal cells within the central
220 nervous system to cause microcephaly². Recent studies have used iPSC-derived human neural
221 progenitor cells (NPCs) for their studies as a proxy to physiologically relevant primary cells^{3,45-47}.
222 Therefore, we decided to use iPSC-derived NPCs to validate our key findings by manipulating
223 sphingolipid levels in these cells using myriocin and FB1. Inhibitor-treated cells showed a
224 significantly reduced level of viral shading as compared to untreated cells, showing roles for
225 sphingolipids in ZIKV infection in neuronal primary cells (Fig. 3g). In addition to iPSC-derived
226 NPCs, we also employed the human neuroblastoma cell line SH-SY5Y to validate our initial
227 findings further. Consistent with the Huh7 and NPCs, both myriocin and FB1 significantly
228 reduces the amount of ZIKV production (Fig. 3h) as compared to the control cells. These data
229 demonstrate roles for sphingolipid in ZIKV infection and validate our initial observations.

230

231 **Sphingolipids are required for ZIKV replication**

232 Both the sphingolipid metabolic network and flavivirus replication cycle are distributed
233 throughout the cell, leading us to investigate where and when the essential ZIKV-sphingolipid
234 interactions suggested by our inhibitor experiments occur. To test whether sphingolipids are
235 required ZIKV binding or entry as has been reported⁴⁸ for other positive-strand RNA viruses⁴⁸, we
236 incubated monolayers of Vero cells pretreated with myriocin or FB1 with ~100 ZIKV PFUs on
237 ice for 0-45 min, then washed away unbound virions and overlaid the cells with methylcellulose
238 overlay media that did not contain inhibitors. After three days, viable cells were stained with
239 crystal violet and numbers of plaques counted (Fig. 4a). Inhibitor-pretreated Vero cells showed

240 no losses in absolute levels or rate of plaque formation, indicating that myriocin inhibition of
241 sphingolipid synthesis did not significantly affect ZIKV binding or internalization.

242 To investigate whether ZIKV requires sphingolipids during genome replication in the
243 replication factory, we used RT-qPCR to compare levels of intracellular viral RNA in Huh7 cells
244 treated with myriocin or FB1 relative to a vehicle control. Supporting the results of our entry
245 assay, levels of ZIKV RNA bound to cells at 0 hpi were not significantly changed by sphingolipid
246 depletion (Fig. 4b). After the initiation of RNA replication by 3-4 hpi, levels of RNA in
247 sphingolipid-depleted cells more than 60% relative to vehicle-treated cells, and remained over
248 30% lower by 20 hpi (Fig. 4b). To confirm that these differences were due to decreased RNA
249 replication rather than defects at other stages of the viral life cycle, we treated infected
250 sphingolipid-depleted and normal cells with an inhibitor of ZIKV RNA polymerase (TPB)⁴⁹ and
251 measured intracellular replication relative to non-TPB-treated cells at 8 hpi (Fig. 4c). ZIKV RNA
252 in both sphingolipid-depleted and vehicle cells decreased by approximately tenfold under TPB
253 treatment, ruling out a pre-replication viral requirement for sphingolipids. We concluded that
254 sphingolipids are dispensable for ZIKV entry into host cells, but are required for viral replication.

255

256 **The Cer-SM network is a key determinant of ZIKV infection**

257 Of the thousands of known sphingolipid structures⁵⁰, which specific categories of species
258 are required for ZIKV replication? Our findings that SM and Cer, despite opposing trends during
259 infection, are linked by a single enzymatic step in the sphingolipid metabolic network (Fig. 5a)
260 prompted us to study their relationship more closely. First, we calculated ratios of normalized
261 lipid levels for all possible pairs of SM and Cer species in our dataset (Supplementary Data 4),
262 382 of which varied significantly across experimental conditions ($P < 0.01$, one-way ANOVA).
263 We then used recursive feature elimination with cross-validation (RFECV) to define a subset of
264 250 lipid pairs with the features of greatest biological interest (Supplementary Data 5). PCA of
265 these ratios (Fig. 5b) revealed a pattern of infection- and time-dependent separation similar to

266 the overall distribution of lipid species observed previously, indicating that the SM-Cer metabolic
267 network is strongly perturbed by ZIKV infection. Furthermore, hierarchical clustering of the lipid
268 pairs resulted in near-complete separation, as measured by identity of nearest neighbor, by ratio
269 type (Cer/Cer, SM/SM, or Cer/SM) (Fig. 5c). Remarkably, every Cer/SM ratio without exception
270 decreased from 24 to 48 hpi in mock cells and increased in infected cells, suggesting that flux
271 between ceramide and SM is highly regulated during ZIKV replication.

272 While the trend of ceramide enrichment relative to SM was consistent across ceramide
273 species, there was considerable variation among ceramide species in both our ZIKV and NS4B
274 experiments (Fig. 2d). To identify relationships of biological interest between ceramide species,
275 we tested RFECV-identified ratios that fell above the stringent cutoffs of component score > 0.1
276 and F-score > 50 . This yielded four Cer/Cer ratios ($P < 0.01$, one-way ANOVA) (Fig. 5d-g);
277 Strikingly, each of these high-interest ratios contained the (dihydro)ceramide Cer(d18:0/16:0) or
278 Cer(d18:1/16:0), which was the single most enriched lipid by both ZIKV and NS4B (Fig. 2d).
279 Recently, it has been shown that the six mammalian ceramide synthases (*CERS1-6*)
280 preferentially catalyze the formation of ceramide species with different acyl chain lengths and
281 degrees of saturation^{51,52}, and that the signaling properties of ceramides are influenced by acyl-
282 chain identity⁵³. Our data indicates that ZIKV infection, and NS4B expression, increases the
283 production of Cer(d18:1/16:0) relative to other ceramide species.

284 Three major pathways control ceramide levels in mammalian cells: (1) de novo synthesis
285 in the ER, (2) degradation of SM by a family of sphingomyelinases (SMases), and (3) salvage of
286 sphingolipid catabolism products via conversion to sphingosine (Fig. 5a). Because SM is the
287 most abundant sphingolipid in mammalian cells and represents a major outlet for newly
288 synthesized ceramides, we reasoned that flux between SM and Cer likely contributed to ZIKV-
289 driven increases in Cer/SM ratios. To test this hypothesis, we infected KBM7 cells bearing a
290 gene-trap mutation for SGMS1, the major human sphingomyelin synthase^{54,55}. KBM7 SGMS1^{GT}
291 cells displayed higher Cer/SM ratios than did WT or reconstituted mutant cells (KBM7

292 SGMS1^{GT}+SGMS1), recapitulating the trend seen in the Cer/SM ratios identified by RFECV⁵⁶.
293 Indeed, KBM7 SGMS1^{GT} cells were over 100-fold more permissive to ZIKV infection than WT or
294 SGMS1^{GT}+SGMS1 cells (Fig. 6a), suggesting that even modest increases in pools of
295 intracellular ceramide could dramatically enhance viral replication.

296 Having increased virus production by blocking the conversion of Cer to SM, we predicted
297 that blocking the SMase pathway of Cer synthesis would have the opposite effect. When treated
298 with the neutral SMase inhibitor GW4869, infected KBM7 SGMS1^{GT}+SGMS1 cells displayed a
299 70% reduction in ZIKV shedding without altering cell viability, while SGMS1^{GT} cells were
300 unaffected (Fig. 6b and Supplementary Fig. 6a, b). To validate our KBM7 experiments in Huh7
301 cells, we again used GW4869 to block conversion of SM to Cer, and exogenously added
302 recombinant SMase to increase Cer flux. GW4869 treatment reduced viral shedding and SMase
303 treatment modestly increased permissiveness to ZIKV infection (Fig. 6c and Supplementary Fig.
304 7a-c). Taken with our findings that depletion of all sphingolipids reduces viral replication (Fig.
305 6d), these data show that ZIKV targets the SM-Cer flux to successfully establish infection in the
306 host cells.

307 Dysregulation of lipid metabolism contributes to diverse human diseases⁵⁷, including
308 sphingolipidoses such as Niemann-Pick disease and hereditary sensory neuropathy^{58,59}. The
309 physical interactions between lipids, proteins, and other macromolecules are increasingly the
310 focus of efforts to systematically map the biological networks underlying disease^{60,61}. These
311 maps have provided evidence that disorders which are unrelated in origin but similar in
312 phenotype can share overlapping patterns of genetic and metabolic perturbations, forming
313 distinct disease modules within the human interactome⁶²⁻⁶⁴.

314 Having shown the importance of the sphingolipid network in ZIKV replication, we asked if
315 it interacted with known disease modules that were clinically similar to the symptoms of ZIKV
316 infection. To accomplish this, we built a metabolic network containing the biosynthesis pathways
317 of each subclass in our lipidomics dataset (Supplementary Fig. 8a) then surveyed the network

318 for metabolites associated with seven Medical Subject Heading (MeSH) terms selected for their
319 similarity to clinical outcomes of ZIKV infection⁶⁵⁻⁶⁷. As a consequence of including all
320 compounds and genes from the constituent lipid biosynthesis pathways in our metabolic model
321 (Supplementary Data 5), nearly every node of the resulting disease-metabolite network was a
322 non-lipid compound capable of participating in other aspects of cellular metabolism (Fig. 6e).
323 Remarkably, however, the two network nodes with the greatest number of connections to MeSH
324 disease terms were the sphingosine and sphinganine, which differ by only a single double bond
325 (Fig. 6f). In addition to forming the sphingoid bases incorporated into all other sphingolipids,
326 sphinganine and sphingosine are immediate neighbors of SM and Cer, with which they can be
327 readily interconverted (Fig. 6f and Fig. 5a).

328

329 **Ceramide is redistributed to ZIKV replication membranes**

330 The set of network perturbations we defined left open the function of ceramide's role
331 during ZIKV replication. Our results suggested that the defects in production of new ZIKV RNA
332 and proteins in the replication factory (Fig. 3d and Fig. 4b, c), rather than their assembly or
333 maturation (Fig. 3c and Fig. 4a), caused reduced viral shedding from sphingolipid-depleted
334 cells, leading us to hypothesize that ceramide was physically recruited to membranes of the
335 ZIKV replication site. Providing a remarkable link to our lipidomics results, superresolution
336 microscopy revealed a close association between ceramide and replication complex marker
337 NS4B (Fig. 7a, g). As a control, we also measured overlap between ceramide and E protein,
338 which is produced at replication sites but not thought to be present in replication vesicles; further
339 supporting a specific function for ceramide in replication vesicles, we observed no correlation
340 with E protein (Fig. 7b, g)¹³.

341 Sphingomyelin is enriched in the *trans*-Golgi network (TGN), PM, and vesicle transport
342 system⁶⁸, while the events of ZIKV replication occur in the ER. Because we had shown that
343 hydrolysis of SM to ceramide by neutral SMase was partially responsible for the activity of

344 ceramide during viral replication, we asked whether SM was recruited to replication sites to
345 serve as a source of ceramide species during infection. To visualize the intracellular distribution
346 of SM in mock and infected cells, we utilized Eqt-SM-GFP, a genetically encoded probe capable
347 of binding diffuse pools of sphingomyelin^{68,69}. We did not observe correlation between Eqt-SM-
348 GFP and NS4B or E (Fig. 7c, d and g). This did not prevent enrichment of ceramide in the ER
349 during ZIKV infection (Fig. 7e, f and h), suggesting that multiple pathways in sphingolipid
350 biosynthesis and transport are coopted to support ZIKV replication.

370 Discussion

371 Following the explosive outbreak of Zika virus in South and Central America and
372 subsequent discovery of a startling array of novel virulence traits and modes of transmission,
373 systems biology approaches have provided a wealth of insights into the host-virus interactions
374 underlying ZIKV disease. While these studies have opened promising avenues for further
375 investigation, a major limitation their focus on genetically encoded host factors, leaving the
376 landscape of ZIKV-host metabolite interactions relatively uncharacterized. To fill in this gap in
377 knowledge, we performed a global lipidomic survey in ZIKV-infected human cells and found that
378 ZIKV alters cellular sphingolipid metabolism to selectively increase production of ceramides,
379 which are then enriched at viral replication sites. We confirmed that this relationship benefited
380 ZIKV replication through targeted perturbations of sphingolipid metabolism in human neural
381 progenitors and other cell types, resulting in enrichment or depletion of certain species and
382 corresponding increases or decreases in ZIKV RNA synthesis, virion biogenesis, and viral
383 shedding. In summary, we have mapped a host-virus wiring diagram of sphingolipid metabolism
384 in human cells.

385 Our findings present several avenues to fill in the circuitry of this wiring diagram and
386 connect it to other maps of the molecular factors of ZIKV pathogenesis. From a mechanistic
387 standpoint, it is now clear that individually expressed ZIKV proteins can regulate specific cellular
388 processes^{27,70-75}, and that minor changes in genome sequence can greatly affect ZIKV
389 infectivity and virulence⁷⁶⁻⁷⁸. We show here that ectopic expression of ZIKV NS4B, a
390 transmembrane protein integral to the *Flaviviridae* replication complex²², causes changes in
391 sphingolipid metabolism similar to what we observed during full viral infection, implying a causal
392 relationship between NS4B and dysregulation of sphingolipid homeostasis. It is notable that this
393 relationship is specific to sphingolipids, as other regulation of other lipid classes showed only
394 modest correlations between NS4B and ZIKV infection; future work could address whether

395 similar links exist for other ZIKV NS proteins and lipid networks, and the extent to which these
396 mechanisms are conserved across viral clades.

397 The biosynthesis, degradation, and intracellular distribution of ceramides is tightly
398 controlled through a complex regulatory circuit⁷⁹⁻⁸⁴, including glycosylation to form complex
399 sphingolipids or conversion to the highly abundant sphingomyelin⁸⁵. We observed increasing
400 ratios of ceramide to sphingomyelin over the course of infection, essentially reversing
401 homeostatic trends in both lipids. To test this experimentally, we infected a KBM7 cell line
402 containing an inactivating mutation for SGMS1, the enzyme responsible for most SM synthesis
403 in mammalian cells^{54,86}, and observed significant enhancement of ZIKV infection in SGMS1^{GT}
404 cells. Ceramide can be obtained through *de novo* synthesis in the ER or directly through the
405 degradation of sphingomyelin by a family of SMases. We observed that GW4869-mediated
406 inhibition of SMase activity decreased virus production in genetically complemented KBM7
407 SGMS1^{GT} cells, while exogenous addition of SMase enhanced it; in contrast, uncomplemented
408 KBM7 SGMS1^{GT} cells were unaffected by either treatment. Therefore, the SMase degradation
409 pathway represents a major pipeline in ZIKV ceramide recruitment. Further work is required to
410 characterize how other modes of ceramide homeostasis, including conversion to complex
411 sphingolipids, are coopted by ZIKV.

412 The challenges of studying lipidomic rather than genetic or proteomic factors of disease
413 have been discussed in detail⁸⁷, yet the results we present here in human cells and by others in
414 the flavivirus arthropod vector⁸⁸⁻⁹⁰ argue strongly for the equal importance of lipids in questions
415 of ZIKV pathogenesis. Our evidence that sphinganine and sphingosine are strongly linked to
416 diseases with phenotypes that are clinically similar to ZIKV syndrome further implicates the
417 sphingolipid network as contributing to the molecular processes underlying ZIKV virulence.
418 Indeed, the role of sphingolipid signaling in regulating cell death, including during neural
419 development, has been extensively described⁹¹⁻⁹³. Further work is needed to validate lipidomic
420 trends during ZIKV infection in clinical samples, as has recently been shown for Ebola virus^{94,95}.

421 A variety of nontoxic pharmacological modulators of sphingolipid metabolism exist, including
422 one that is FDA-approved, raising the possibility that sphingolipid metabolism could be targeted
423 as part of a host-directed therapeutic strategy in infected patients^{96,97}.
424

425 **Methods**

426 **Cell culture and transfections**

427 Huh7, Vero, and HEK 293T cells were maintained in DMEM; HAP1 cells and KBM7 cells were
428 maintained in IMDM. Both media contained 10% FBS, 100 units/mL penicillin, 100 µg/mL
429 streptomycin, and 1% non-essential amino acids. C6/36 cells were maintained in MEM
430 containing 5% FBS, 100 units/mL penicillin, 100 µg/mL streptomycin, and 1% non-essential
431 amino acids. Mammalian cell lines were maintained at 37°C and 5% CO₂; C6/36 cells were
432 maintained at 32°C and 5% CO₂.

433 **Transfections.** C-FLAG pcDNA3 plasmids containing ZIKV NS4B were generously provided by
434 the Hirsch Lab. Low-passage HEK 293T cells were seeded at a density of 350,000 cells per well
435 in 6-well plates. Transfections were carried out the next day using Lipofectamine 3000
436 transfection reagent (Invitrogen) as per manufacturers suggested protocol, with 5 µg of plasmid
437 DNA used per transfected well. Wells were transfected with C-flag NS4B vector or with equal
438 quantities of empty vector. Media was changed 6 hours after transfection. After 48 hours post
439 transfection, individual wells were harvested for lipid purification as mentioned in lipidomics
440 sample preparation protocol. Cells were also fixed with 4% PFA, then stained with an Alexa
441 Fluor 488-conjugated anti-FLAG antibody (Cell Signaling Technology #5407) to confirm high
442 levels of transfection efficacy. For Eqt-SM-GFP sphingomyelin probe, Huh7 cells were seeded
443 at a density of 25,000 cells per 24-well TC plate. Transfections were carried out with
444 lipofectamine 3000 transfection reagent as per manufacturer's instructions after infection or
445 mock infection of cells with ZIKV (see below), using 1 µg of plasmid DNA used per transfected
446 well. After 24 hours post transfection, cells were fixed with 4% PFA before imaging.

447 **Stem cells.** Human iPSC (XCL-1)⁹⁸-derived neural progenitor cells (hNPCs) were purchased
448 commercially (StemCell Technologies, Cat #70901, Lot #17080) and maintained up to ten
449 passages according to the manufacturer's instructions. Briefly, hNPCs were grown on Matrigel-

450 coated culture plates in Neural Progenitor Medium 2 (StemCell Technologies) up to 95-100%
451 confluency, then detached using Accutase and seeded at a density of 80,000-100,000
452 cells/cm².

453

454 **Viruses**

455 Zika virus strain FSS1302536 was propagated in C6/36 or Vero cells, and viral stocks and
456 experimental samples were titrated on Vero cells by plaque assay (ZIKV) as described
457 previously⁹⁹.

458

459 **Infections**

460 For infections of Huh7, Vero, or DC2.4 cells, ZIKV stocks were diluted to the desired MOI in
461 DMEM or RPMI containing 2% FBS and added to cells for 1 hr at 37°C and 5% CO₂ with
462 constant rocking. The virus-containing supernatants were then aspirated and the infected cells
463 washed three times with PBS before addition of culture media and continued growth under
464 normal conditions until the desired timepoints. For KBM7 suspension cells, 500,000 cells per
465 replicate were centrifuged for 5 min at 300 x g at room temperature, and resuspended in 1 mL
466 IMDM containing 2% FBS and ZIKV. Cells were rocked for 1 hr at 37°C and 5% CO₂ in six well
467 plates, then centrifuged as before and resuspended in PBS three times. After aspiration of the
468 final wash, cells were resuspended in culture media and grown under normal conditions until the
469 desired timepoints.

470

471 **Lipidomics**

472 **Sample collection.** Huh7 cells were seeded at a density of 1.2 million cells in 15-cm dishes and
473 infected the next day with ZIKV FSS13025 at an MOI ~ 50 PFU/cell to ensure that all cells were
474 infected. At 24 and 48 hpi, mock and infected cells were washed three times with ice-cold PBS
475 and detached by scraping. A small fraction of the cell suspension was retained for protein

476 content determination by BCA assay (Supplementary Data 1); the remaining volume was
477 transferred into glass sample tubes on ice and centrifuged for 5 min at 500 x g and 4°C. After
478 aspiration of the PBS supernatant, cell pellets were resuspended with 1 mL ice-cold methanol
479 and stored at -80°C.

480 **Lipid extraction.** Using a modified Folch extraction¹⁰⁰, chloroform and water were added to
481 samples for a final ratio of 8:4:3 chloroform:methanol:water. The samples were vortexed to mix,
482 chilled on ice for 5 min, then vortexed again. The samples were incubated at 4°C for 2 hrs to
483 allow for the separation of the phases. The lower organic lipid containing layer was removed,
484 dried in vacuo then stored at -20°C in 2:1 chloroform:methanol (v/v) until analysis.

485 **LC-MS/MS analysis and lipid identification.** LC-MS/MS parameters and identifications were
486 conducted as outlined¹⁰¹. A Waters Aquity UPLC H class system interfaced with a Velos-ETD
487 Orbitrap mass spectrometer was used for LC-ESI-MS/MS analyses. Lipid extracts were dried in
488 vacuo, reconstituted in 10 µl chloroform plus 540 µl methanol, injected onto a reversed phase
489 Waters CSH column (3.0 mm x 150 mm x 1.7 µm particle size), and lipids were separated over
490 a 34 min gradient (mobile phase A: ACN/H₂O (40:60) containing 10 mM ammonium acetate;
491 mobile phase B: ACN/IPA (10:90) containing 10 mM ammonium acetate) at a flow rate of 250
492 µl/min. Samples were analyzed in both positive and negative ionization modes using HCD
493 (higher-energy collision dissociation) and CID (collision-induced dissociation) to obtain high
494 coverage of the lipidome. The fragment ions used for lipid identifications were used as
495 previously outlined¹⁰¹. The LC-MS/MS raw data files were analyzed using LIQUID whereupon all
496 identifications were manually validated by examining the fragmentation spectra for diagnostic
497 ions and fragment ions corresponding the acyl chains. In addition, the precursor mass isotopic
498 profile and mass ppm error, extracted ion chromatograph, and retention time for each
499 identification was examined. To facilitate quantification of lipids, a reference database for lipids
500 identified from the MS/MS data was created and features from each analysis were then aligned
501 to the reference database based on their identification, m/z and retention time using MZmine

502 2^{102} . Aligned features were manually verified and peak apex intensity values were exported for
503 statistical analysis.

504 **QC, normalization, and statistical comparison methods.** Data from positive and negative ion
505 modes were analyzed separately using MATLAB version R2016b (MathWorks). Any
506 unobserved lipid values were recorded as missing (NAs), and the data were \log_2 -transformed.
507 The rMd-PAV algorithm¹⁰³ was used to identify potential outliers on the basis of their correlation,
508 median absolute deviation, and skew; confirmation of outlier biological samples was achieved
509 via Pearson correlation between the samples. All lipids were assessed for having at least two
510 observations across all samples and enough observations for performing either qualitative or
511 quantitative statistical tests¹⁰³; none failed to meet these requirements and thus all lipids were
512 retained for further analysis. The data were normalized using global median centering, in which
513 each sample was scaled by the median of its observed abundance values. This approach has
514 been described previously^{104–107} and utilized in a number of other studies^{108–110}. Lipids were
515 evaluated using analysis of variance (ANOVA) with a Dunnett test correction to compare
516 infected to mock at each timepoint (24 hours and 48 hpi). Yellowbrick¹¹¹ was used to perform
517 recursive feature extraction.

518

519 **Cell culture treatments**

520 Myriocin, FB1, and GW4869 were purchased from Cayman Chemical. Myriocin was dissolved in
521 DMSO to make 15 mM stock solutions, and added to culture media at 1:500 for a final
522 concentration of 30 μM ; because myriocin is not fully soluble at 15 mM, stocks were thawed at
523 room temperature, then heated for 15 min at 55°C immediately before addition to media. FB1
524 was dissolved in 1:1 acetonitrile:DI water to make 5 mM stocks, then added 1:1,000 to culture
525 media for a final concentration of 5 μM . Myriocin and FB1 treatments were carried out for 72 hrs
526 before experimental manipulations; we did not observe significant differences in growth rate or
527 morphology over that period (Supplementary Fig. 2). GW4869 was added to culture media for

528 24 hrs at a final concentration of 10 μ M, and stocks were prepared as previously outlined¹¹². No
529 significant toxicity was observed by CellTiter Glo assay (Promega) (Supplementary Fig. 4). All
530 inhibitor stocks were stored at -20°C. Neutral sphingomyelinase from *Bacillus cereus* (Sigma-
531 Aldrich) was supplied at 2.5 units/mL (one unit is defined as hydrolyzing 1 μ M of TNPAL-
532 sphingomyelin per min at pH 7.4 and 37°C) in 50% glycerol containing 50 mM Tris-HCl, pH 7.5.
533 SMase was diluted in culture media to a final concentration of 0.1 units/mL and added to cells
534 immediately after infection with ZIKV before supernatants were collected for titration by plaque
535 assay at 24 hpi.

536

537 **Sphingomyelinase activity assay**

538 Huh7 cells were seeded in 96 well plates at a density of 20,000 cells per well. Cells were
539 treated with GW4869 as described above, then lysed in PBS with 1% Tritonx-100 and 1mM
540 PMSF. Sphingomyelinase activity in cell lysates in presence and absence of 10 μ M GW4869
541 was determined with the Amplex Red Sphingomyelinase Assay (Invitrogen) as per
542 manufacturer's instructions. (Supplementary Figure 7)

543

544 **RT-qPCR**

545 To measure intracellular viral replication, Huh7 cells were treated with 30 μ M myriocin, 5 μ M
546 FB1, or 1:500 (v/v) DMSO for at least 72 hrs before seeding in six well plates (200,000 cells per
547 well). Cells were incubated for 24 hrs in freshly treated media containing 20 μ M TPB47
548 (ChemBridge) or an additional DMSO vehicle control, then infected with ZIKV at a MOI of 20. At
549 0, 4, 8, 12, and 24 hpi, cells were lysed with Trizol reagent (Invitrogen) and stored at -80°C.
550 RNA was harvested using a Trizol phenol-chloroform extraction according to the manufacturer's
551 protocol, and converted to cDNA with a High-Capacity RNA-to-cDNA kit (Applied Biosystems)
552 using random hexamers. Real-time PCR was performed with a StepOnePlus Real-Time PCR
553 system (Applied Biosystems) using TaqMan primer/probe sets (Thermo Fisher) against ZIKV48

554 (Assay ID APH6AE9) and beta-Actin (Assay ID Hs99999903_m1) according to the
555 manufacturer's protocol. ZIKV signal was normalized to beta-Actin, and relative comparisons
556 between treatments were made with the $2^{-\Delta\Delta CT}$ method¹¹³. For measurements of viral shedding,
557 RNA was isolated from culture supernatants with Trizol according to the manufacturer's
558 protocol, and absolute quantification was performed by constructing a gBlock (IDT) standard
559 curve as described previously¹¹⁴.

560

561 **Fluorescence microscopy**

562 **Sample preparation.** Huh7 cells were seeded on glass coverslips in 24-well plates at a density
563 of twenty thousand cells per well and grown overnight. The next day, cells were infected with
564 ZIKV at a MOI of 10 and/or transfected as needed, and grown another 24 hrs before fixation
565 with 4% paraformaldehyde in PBS for 15 min at room temperature. After washing with PBS,
566 cells were blocked/permeabilized in blocking buffer (10% normal goat serum, 0.1% Triton X-100
567 in PBS) for 1 hr. Incubations with primary and Alexa Fluor-conjugated secondary antibodies
568 diluted in blocking buffer (see Reporting Summary for list of antibodies and dilution information)
569 were performed for 1 hr at room temperature, separated by three 5 min washes with PBS. DAPI
570 (4',6-diamidino-2-phenylindole) was used to visualize nuclei. Coverslips were mounted on glass
571 slides with ProLong Glass antifade reagent (ThermoFisher).

572 **Image acquisition.** Images were acquired with a Zeiss LSM 880 laser scanning confocal
573 microscope in Airyscan mode using a 63x/1.4 NA oil objective. Fluorophores were excited
574 sequentially by 405/488/561/633 nm lines, and imaging conditions were optimized to minimize
575 bleed-through. Z-stacks were taken with a 0.18 μm interval between slices. Airyscan processing
576 was performed in Zeiss Zen software using the default settings.

577 **Image analysis.** Pearson's correlation coefficients (PCC) were measured from z-stacks in
578 Imaris 9.3.1 (Bitplane) using the included Coloc module, after thresholding the signals to reduce

579 background as indicated in the Source Data. PCC values were calculated from at least ten cells
580 per condition, pooled from two or three independent experiments.

581

582 **Immunoblotting**

583 Vero cells were seeded in 10-cm dishes at a density of one million cells per dish and infected
584 the next day with ZIKV at a MOI of 0.1. At 48 and 72 hpi, cells were washed three times with
585 PBS to remove extracellular virus and lysed with 1% SDS in PBS, followed by three rounds of
586 heating (95°C for 5 min) and manual vortexing to complete lysis. Protein levels were determined
587 on a NanoDrop spectrophotometer (Thermo Fisher Scientific); equal amounts of protein were
588 subjected to SDS-PAGE and transferred to a PVDF membrane (Amersham). Samples blocked
589 with 5% dried milk in TBST and probed with monoclonal antibodies for flavivirus E protein (4G2)
590 (1:500) and GAPDH (1:1,000), followed by incubation for 1 hr with HRP-conjugated secondary
591 antibodies (1:1,000). Blots were visualized with SuperSignal West Pico chemiluminescent
592 substrate (Thermo Fisher Scientific) on an ImageQuant LAS 4000 imager (GE Life Sciences).

593

594 **Binding and entry assay**

595 Vero cells were seeded in six-well plates at approximately 250,000 cells per well so they were
596 80-90% confluent the next day. These monolayers were washed three times with ice-cold PBS
597 to inhibit endocytosis, and inoculated with 100 PFUs of ZIKV diluted in ice-cold Opti-MEM
598 containing 2% FBS (0.5 mL inoculum per well). Cells and virus were incubated at 4°C with
599 rocking. After 0, 10, 20, and 45 minutes, the inoculums were aspirated and the cell layers
600 washed three times with ice-cold PBS before addition of Opti-MEM containing 2% FBS and 1%
601 methylcellulose. Plates were incubated for three days at 37°C and 5% CO₂. After that period,
602 the overlay media was removed through repeated PBS washes, and the cells were fixed with
603 4% paraformaldehyde and stained as for plaque assays as described above.

604

605 **Metabolite-disease module network**

606 To generate a Cytoscape network model of the lipid subclasses identified in our lipidomics
607 experiment, we input a curated list of gene or compound identifiers from KEGG (Supplementary
608 Data 5) into the MetScape 3 Cytoscape app as previously described^{115,116}. To determine
609 whether any of the network nodes had been associated in the literature with disorders that were
610 phenotypically similar to ZIKV syndrome, we used the MetDisease Cytoscape app¹¹⁷ to query
611 the Metab2MeSH database¹¹⁸ for seven Medical Subject Heading (MeSH) terms ('macular
612 degeneration', 'optic nerve diseases', 'pregnancy complications', 'virus diseases', 'brain
613 diseases', 'congenital abnormalities', 'testicular disease') arbitrarily selected for this purpose.

614

615 **Flow Cytometry**

616 Huh7 cells were seeded at a density of 350,000 cells per well in six well plates, then incubated
617 in untreated DMEM or DMEM containing GW4869 at a concentration of 10 μ M as above. After
618 18 hours of treatment, Huh7 cells were harvested for staining and flow cytometry analysis. Cells
619 were washed with PBS, stained with Zombie Violet Fixable Viability Kit (BioLegend) for 10
620 minutes. For ceramide labeling, cells were fixed with 4% PFA at RT for 15 minutes, blocked and
621 permeabilized for 10 minutes with blocking buffer (FCS 5%, triton X-100 0.1%, PBS), then
622 stained for 30 minutes at RT with mouse anti-ceramide primary (1:100 in blocking buffer) and
623 Alexa Fluor 555 anti-mouse secondary (1:100 in blocking buffer). Alexa Fluor 555 secondary
624 staining was used as an isotype control. All samples washed twice with FACS buffer before
625 analysis. Data acquisition carried out with BD FACSymphony flow cytometer with CellQuest (BD
626 Bioscience) software, FlowJo (FlowJo LLC software was used for data analysis and figure
627 construction.

628

629 **Statistics**

630 Analysis of lipidomics datasets was performed as described above. All other statistical analyses
631 were performed using Prism 8.0 (GraphPad). Unless otherwise stated, hypothesis testing was
632 performed using unpaired two-tail t tests, with $P < 0.05$ considered statistically significant.

633

634 **Data availability**

635 All mass spectrometry datasets generated during this study have been deposited at the Mass
636 Spectrometry Interactive Virtual Environment (MassIVE) at the University of California at San
637 Diego, (<https://massive.ucsd.edu/ProteoSAFe/static/massive.jsp>), under the ID code
638 MSV000083079.

654 Erika M. Zink (PNNL) for providing technical support; Stefanie K. Petrie, Aurelie Snyder, and
655 Brian Jenkins (OHSU Advanced Light Microscopy Core) for their help in designing and

656 analyzing the confocal microscopy experiments; and Lenette L. Lu (University of Texas
657 Southwestern Medical Center) for substantial comments on the manuscript.

658

659 **Author contributions**

660 F.G.T and H.C.L. conceived of the study; J.E.K., K.G.S., L.M.B., and J.L. performed and
661 analyzed the lipidomics experiments with input from T.O.M.; J.B.W. performed flow cytometry
662 and transfections; J.B.W. and H.C.L. performed RT-qPCR; D.K. and J.B.W. performed
663 immunoblotting and microscopy experiments; A.R.N. and E.A.D. performed pilot lipidomics
664 experiments, which were analyzed by E.G.T.; T.H. generated the HAP1 mutant cell lines; J.B.W.
665 and H.C.L. performed infection assays, cell culture, propagated viruses; H.C.L. performed
666 Airyscan microscopy and prepared the Cytoscape model; H.C.L. prepared figures and wrote the
667 manuscript with input from W.B.M., E.B., and F.G.T.

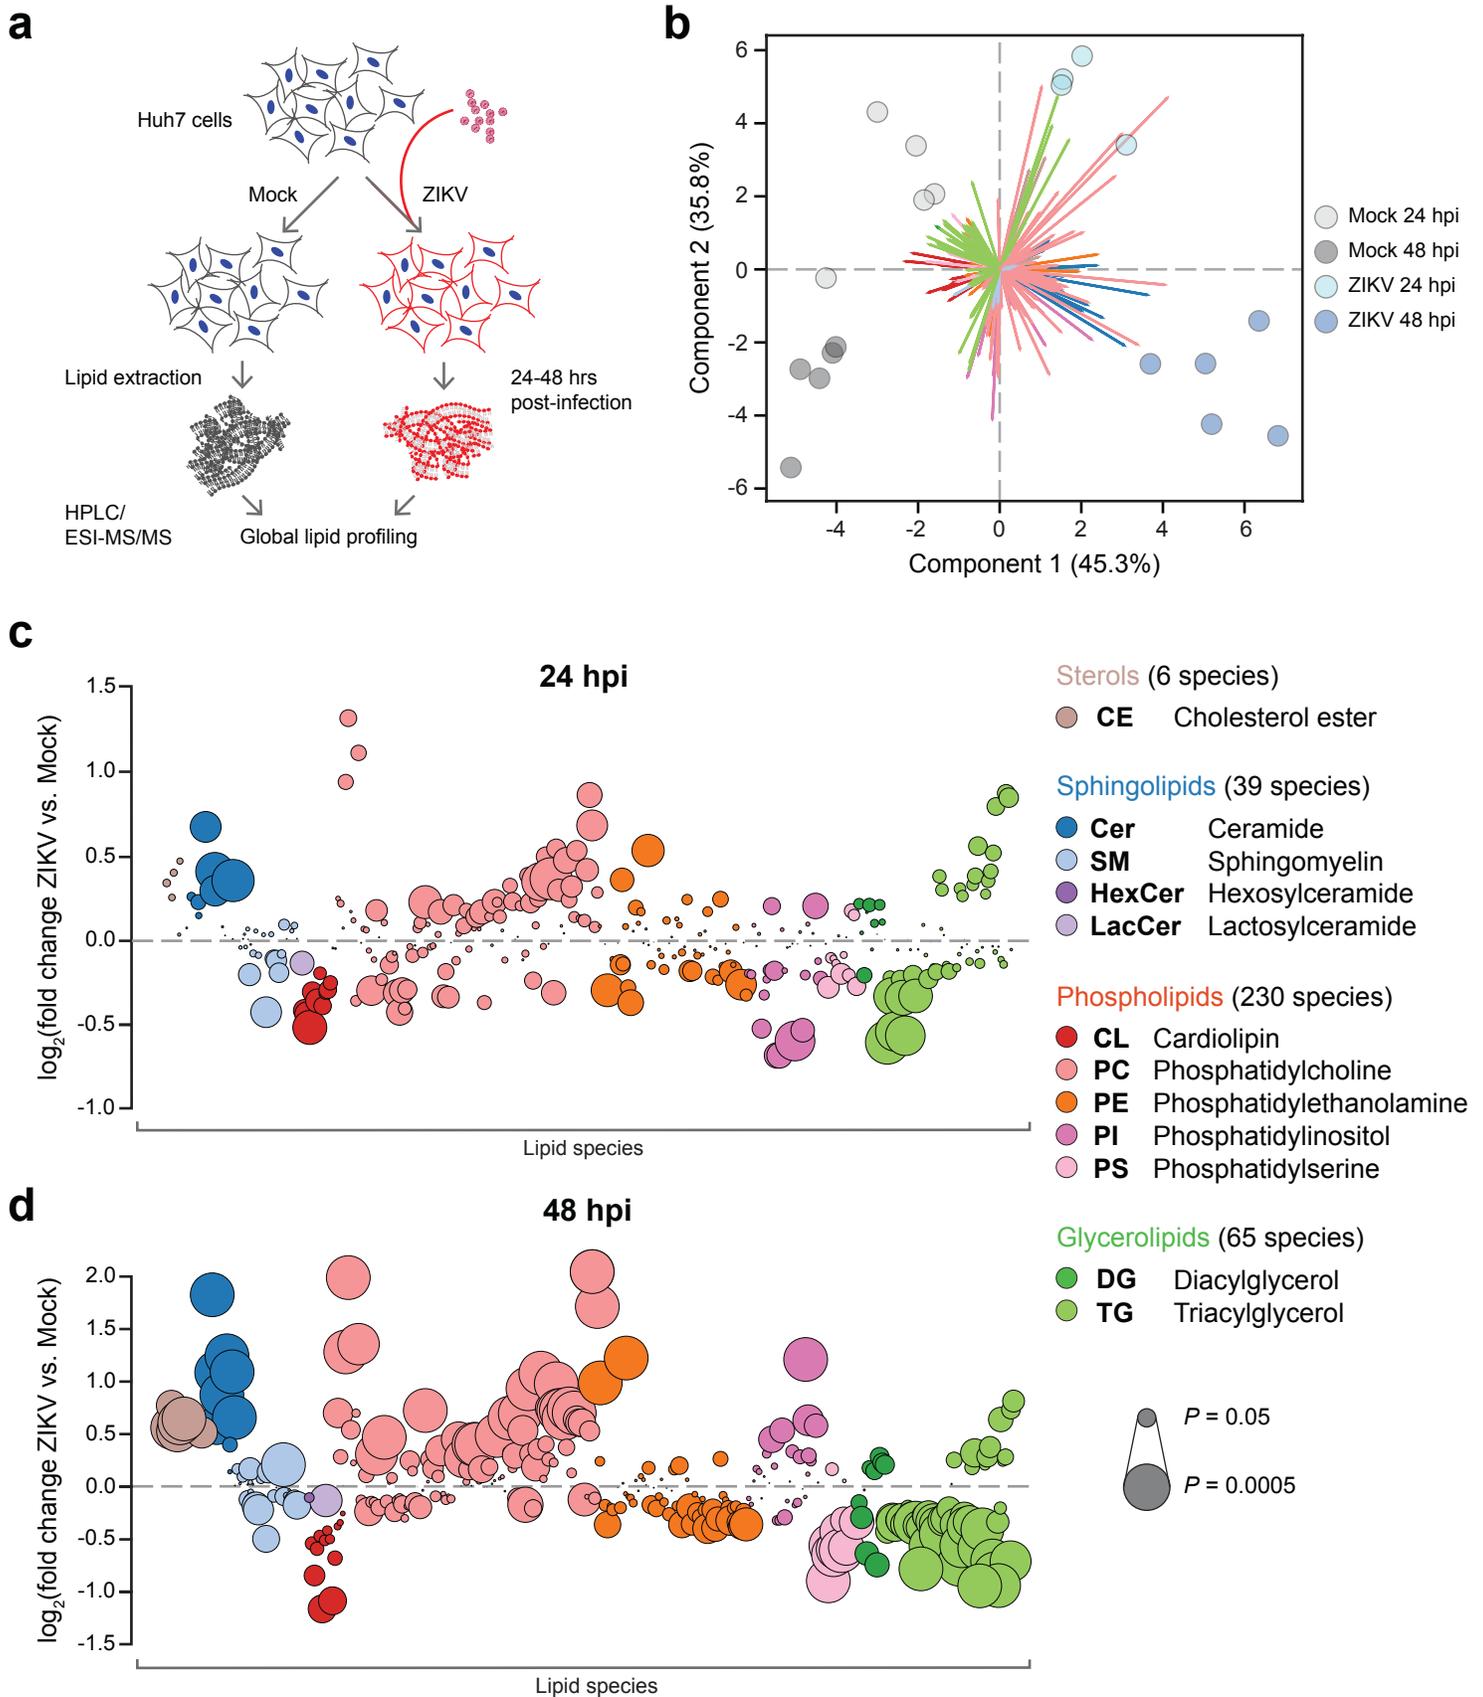

Fig. 1 Global lipidomics of ZIKV-infected human cells. **a** Study overview. Huh7 cells were infected with ZIKV strain FSS13025 for 24 or 48 hrs. Each experimental condition (Mock 24 hpi, ZIKV 24 hpi, Mock 48 hpi, and ZIKV 48 hpi) had $n = 5$ replicates for a total of 20 biological samples, 19 of which were included in our final analysis. **b** Principal component analysis (PCA) of the lipidomics dataset. Colored arrows represent individual lipid species. **c, d** Bubble plots of \log_2 fold changes in abundance of lipid species in ZIKV-infected cells relative to mock at 24 hpi (c) and 48 hpi (d). Bubble size represents P value from one-way ANOVA or g-test. See also Supplementary Fig. 1, Supplementary Data 1, and the Source Data file.

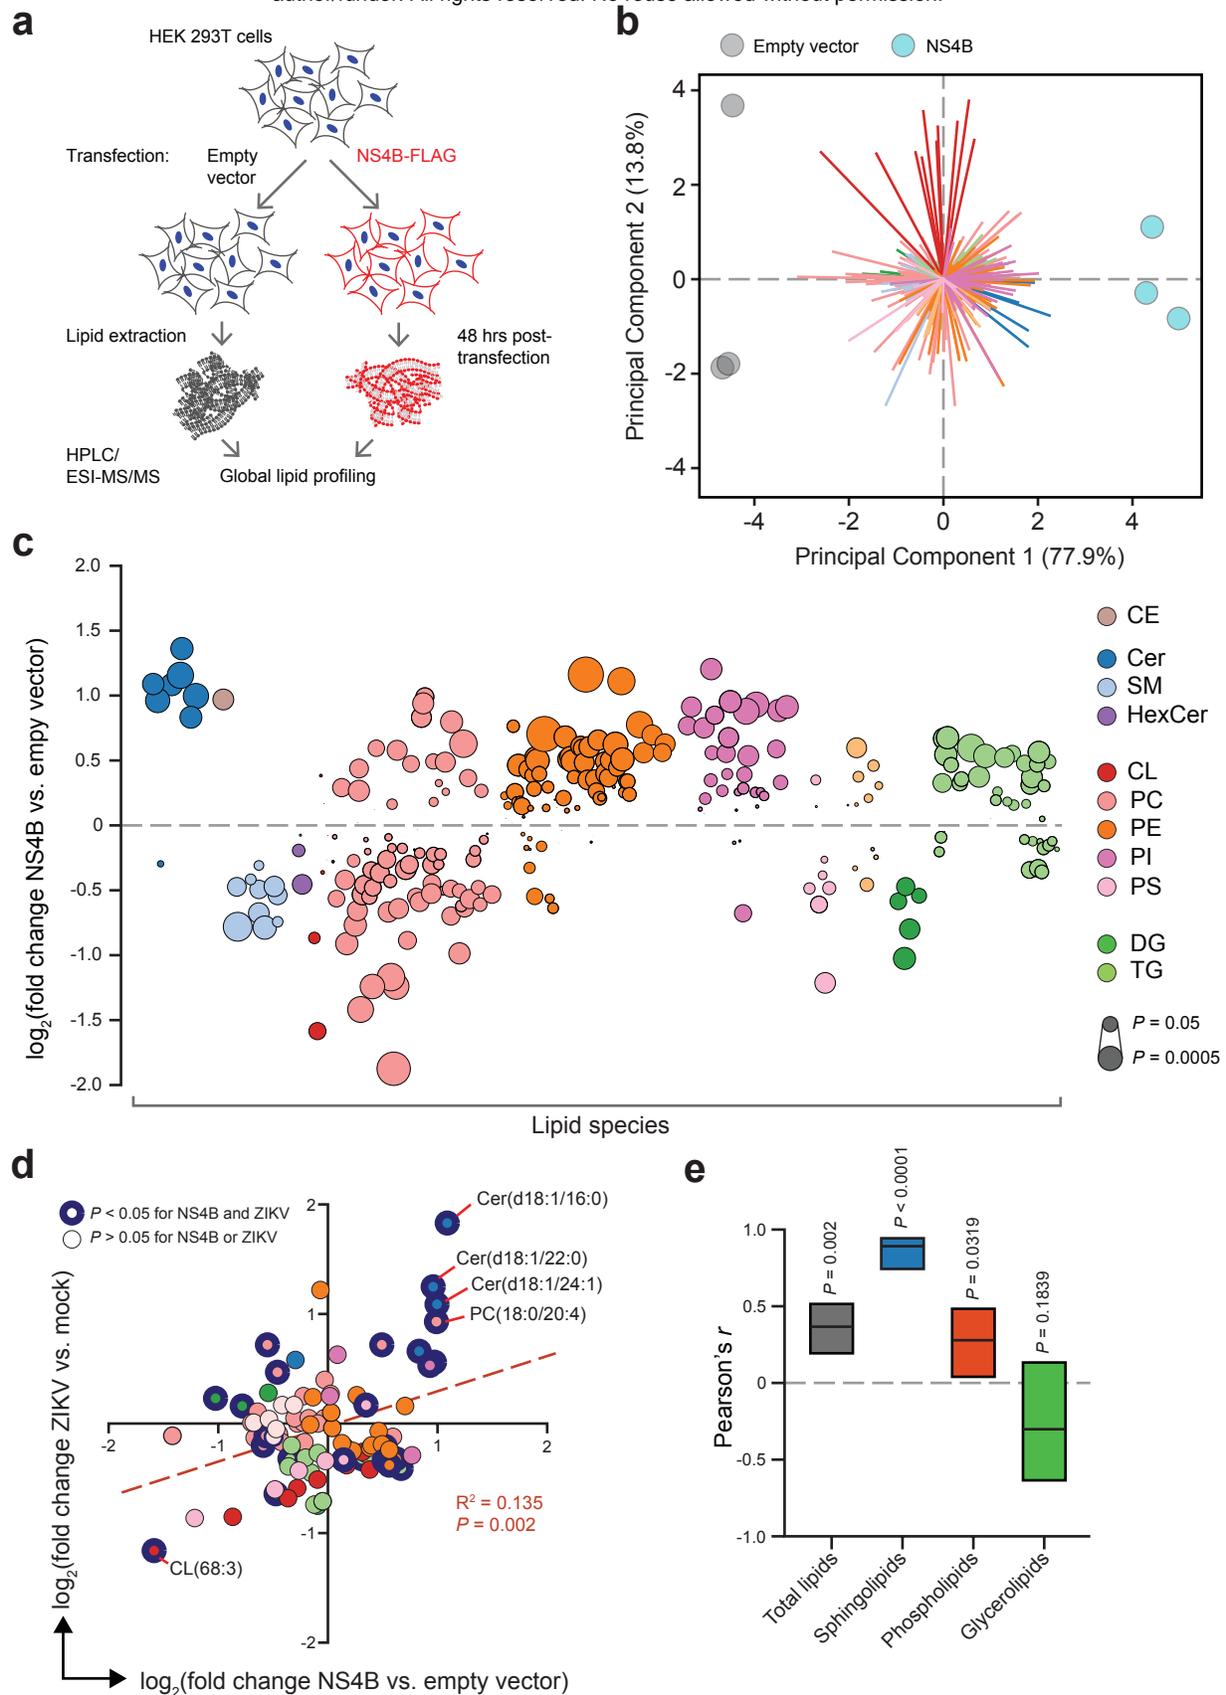

Fig. 2 ZIKV NS4B dysregulates host lipid metabolism. **a** Design of transfection experiment. Total lipids were extracted from HEK 293T cells transfected with NS4B or an empty vector control; $n = 3$ biological replicates per condition. **b** PCA of the lipidomics dataset. Colored arrows represent individual lipid species. **c** Bubble plots of \log_2 fold changes in abundance of lipid species in ZIKV-infected cells relative to mock 24 hpi. Bubble size represents P value from one-way ANOVA or g-test. **d** Correlation of \log_2 fold-change values of lipid species ($n = 95$) identified in both ZIKV-infection and NS4B-transfection experiments (see Supplementary Data 1 and 2, respectively). Linear regression best-fit line ($y = 0.3212x - 0.02533$), R^2 , and P values are shown. **e** Pearson's correlation coefficient (r) for total or subclasses of lipid pairs. Lines and bars are r values with 95% CI, respectively. See also Supplementary Fig. 3, Supplementary Data 2, and the Source Data file.

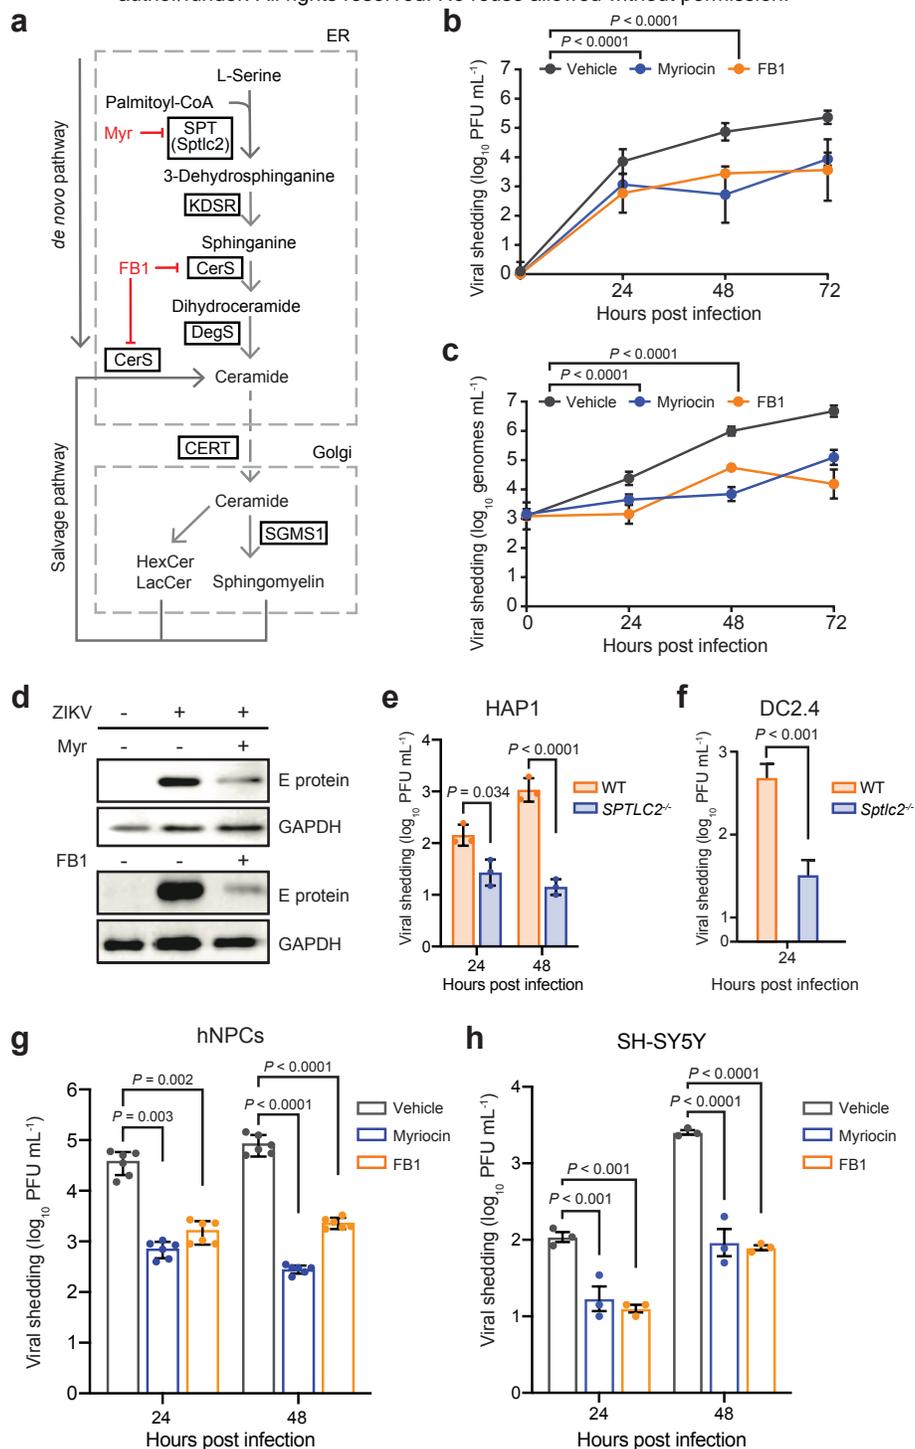

Fig. 3 Spingolipids are essential for ZIKV infection. **a** Overview of sphingolipid biosynthesis. SPT, serine palmitoyltransferase; KDSR, 3-ketodihydrosphingosine reductase; DegS, Delta 4-desaturase, Sphingolipid; CerS, ceramide synthase; SGMS1, sphingomyelin synthase 1; CERT, ceramide transfer protein. **b, c** Huh7 cells treated with myriocin, FB1, or a vehicle control were infected with ZIKV (MOI = 0.1). At the indicated times post-infection, culture supernatants were collected and analyzed by plaque assay (**c**) or RT-qPCR (**d**); $n = 3$ independent experiments. Two-way ANOVA with Dunnett's multiple comparisons test. **d** Vero cells treated with myriocin, FB1, or vehicle were infected with ZIKV (MOI = 0.1). At 72 hpi, intracellular levels of ZIKV E protein were assessed by immunoblotting. Blot is representative of 2 independent experiments. **e, f** HAP1 human (**e**) and DC2.4 murine dendritic (**f**) WT and *SPTLC2*-knockout cells were infected with ZIKV (MOI = 0.1). At the indicated timepoints, culture supernatants were collected and analyzed by plaque assay; $n = 3$ independent experiments. Two-way ANOVA with Sidak's multiple comparisons test (**e**) and two-tailed Student's *t*-test (**f**). **g** iPSC-derived human neural progenitor cells (hNPCs) treated with myriocin, FB1 or vehicle were infected with ZIKV (MOI = 0.1). At the indicated times post-infection, culture supernatants were collected and analyzed by plaque assay; $n = 3$ independent experiments. Two-way ANOVA with Tukey's multiple comparisons test. **h** SH-5Y5Y human neuroblastoma cells were treated with inhibitors, infected with ZIKV (MOI = 0.1) and analyzed by plaque assay. Two-way ANOVA with Tukey's multiple comparisons test. Data are mean \pm SD. See also Supplementary Data 3, Supplementary Fig. 4, Supplementary Fig. 5, and the Source Data file.

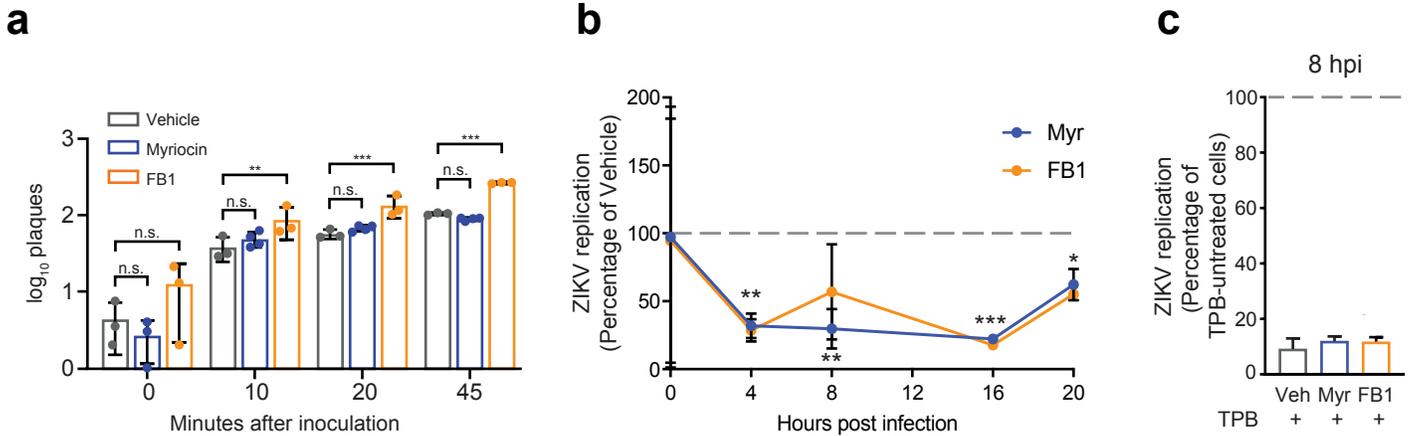

Fig. 4 SpHINGOLIPIDS are required for ZIKV replication. **a** Monolayers of Vero cells pretreated for three days with myriocin, FB1, or a vehicle control were incubated on ice for the indicated times with 100 PFUs before washing and overlay with media without the inhibitors. Plaques were counted after three days; $n = 3$ or 4 independent experiments, each performed with at least 5 technical replicates. Two-way ANOVA with Tukey's multiple comparisons test. **b** Huh7 cells pretreated for three days with myriocin, FB1, or a vehicle control were infected with ZIKV (MOI = 20). Intracellular ZIKV replication in myriocin or FB1-treated cells was measured at the timepoints shown and plotted relative to vehicle. **c** Huh7 cells treated with inhibitors as in (b) were pretreated for 24 hrs with the RNA polymerase inhibitor TPB, infected as before, then maintained in TPB and inhibitor/vehicle treated media for 8 hrs. At 8 hpi, intracellular replication in TPB-treated cells was measured relative to non-TPB-treated cells for each condition. Data are mean \pm SD; n.s., not significant, * $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$, two-tailed Student's t -test. See also the Source Data file.

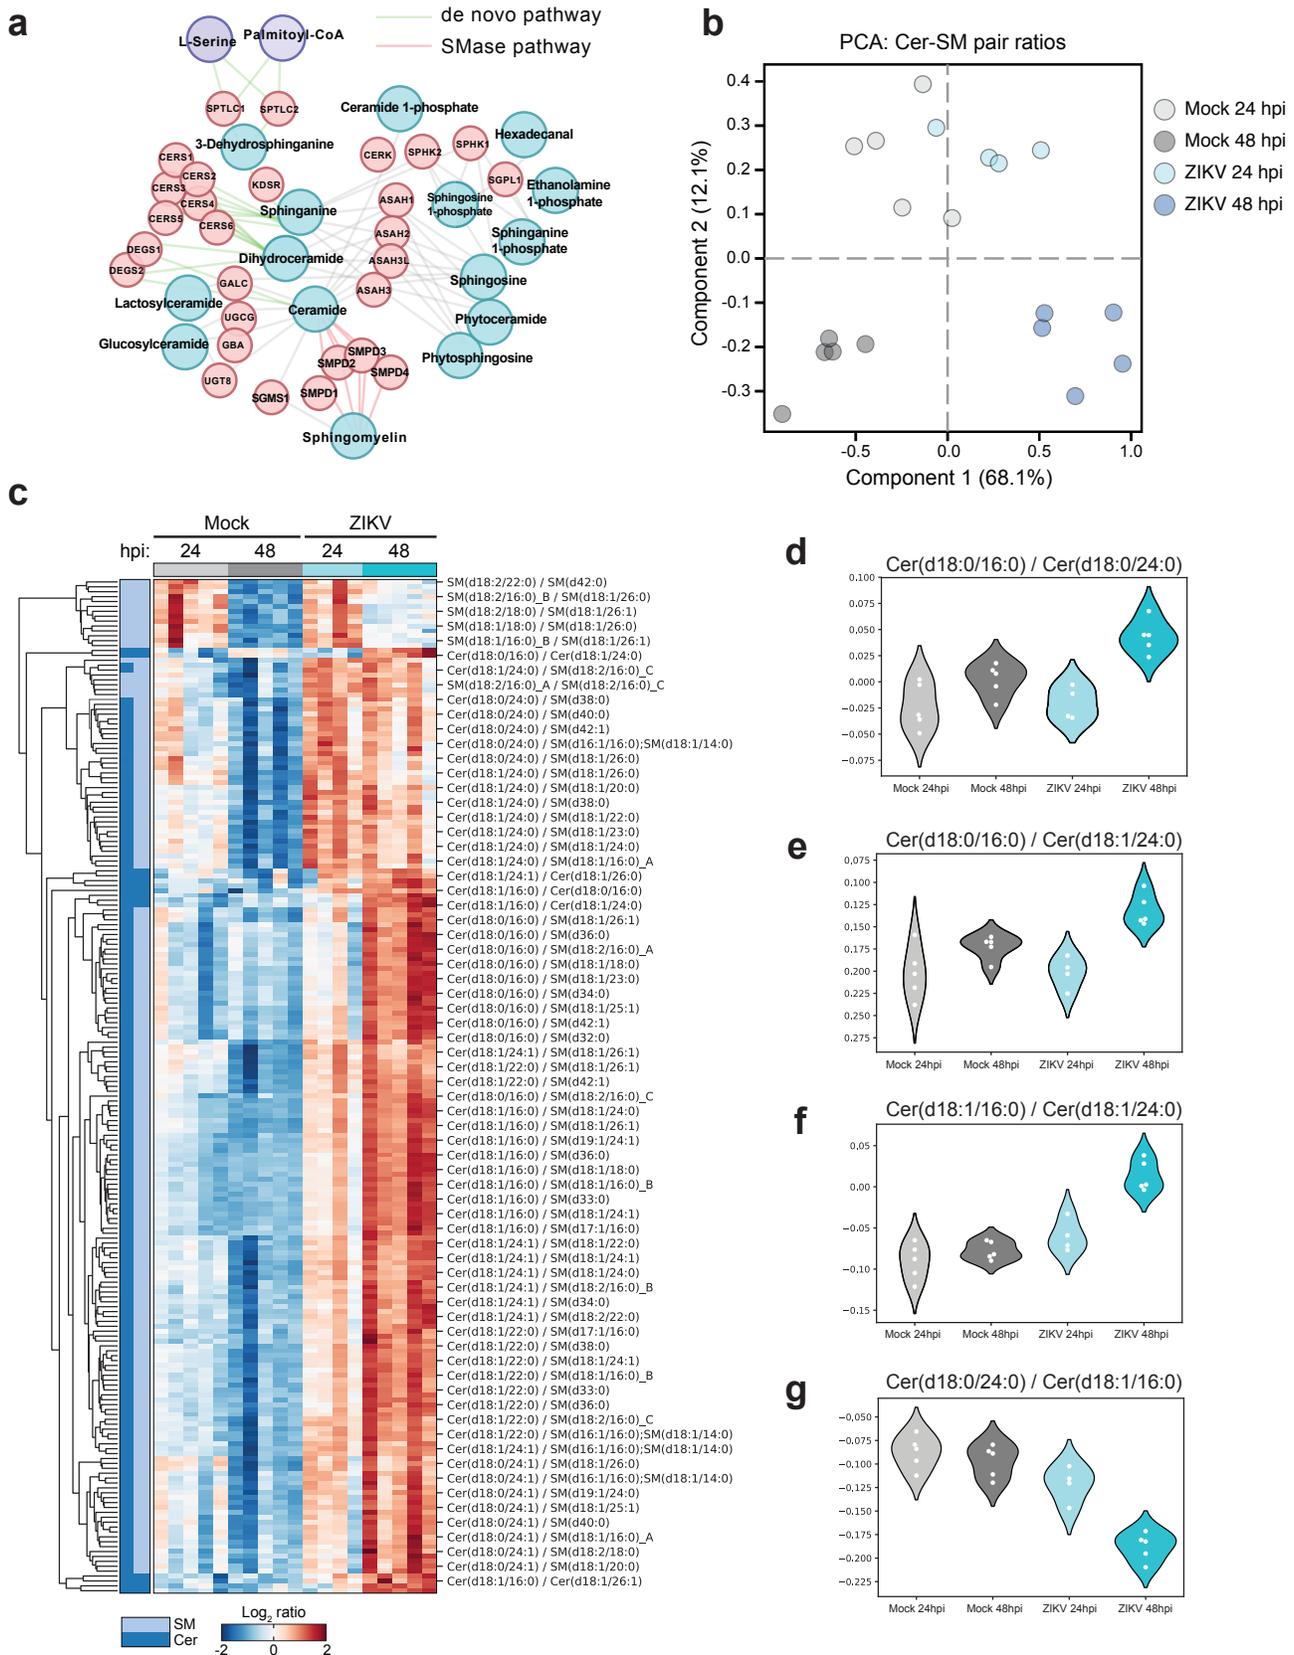

Fig. 5 Targeted regulation of sphingolipid metabolism by ZIKV. **a** Overview of the ceramide metabolism network. **b** Ratios of normalized lipid levels were calculated for all combinations of SM and Cer species in our dataset. Ratios that varied significantly across conditions ($n = 382$, $P < 0.01$, one-way ANOVA) were analyzed with recursive feature elimination with cross-validation, and the resulting high-interest Cer/SM pairs ($n = 250$) were analyzed with PCA. **c** Heatmap of clustered \log_2 SM/Cer ratios identified in (b). Each column represents a single biological sample. **d-g** \log_2 ratios from (b) that met the following criteria: PC length > 0.1 , F-score > 50 , and $P < 0.01$. SM, sphingomyelin, Cer, ceramide. See also Supplementary Data 4 and the Source Data file.

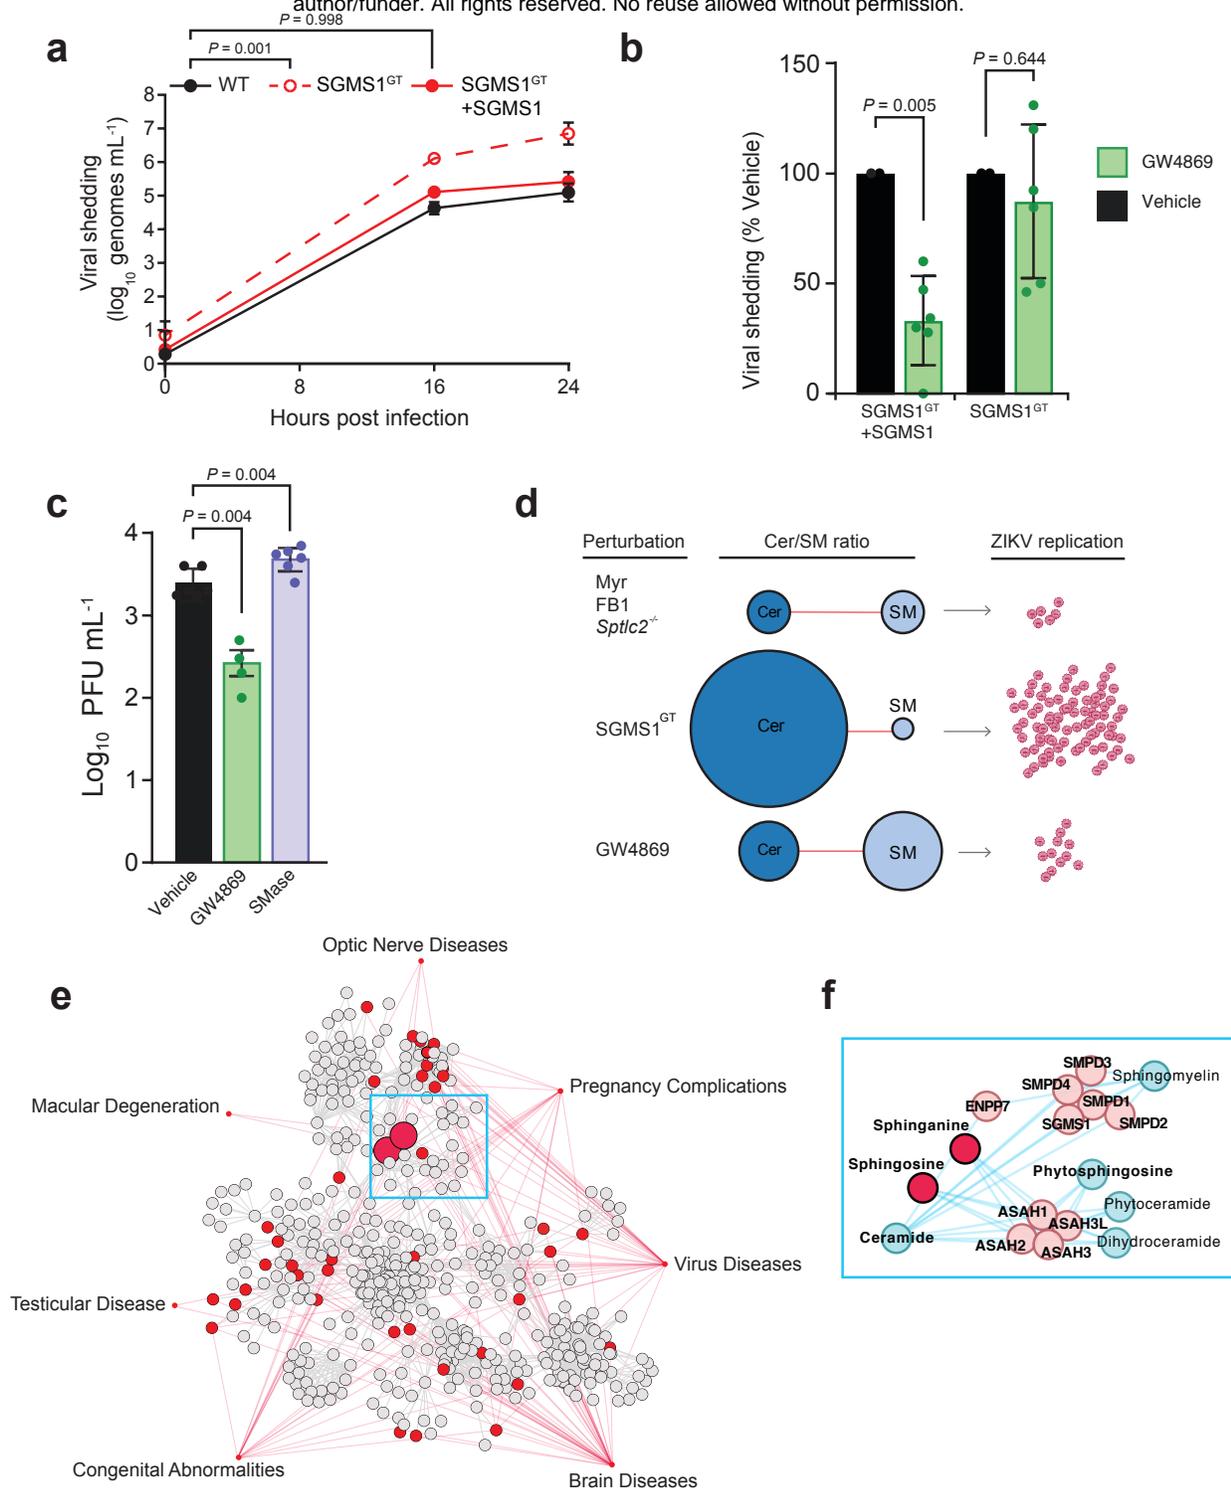

Fig. 6 Elevated ceramide levels increase ZIKV infection. **a** KBM7 WT, SGMS1^{GT}, and SGMS1^{GT}+SGMS1 cells were infected with ZIKV (MOI = 1). At the indicated timepoints, culture supernatants were collected and titrated by plaque assay; $n = 8$ biological replicates. Two-way ANOVA with Dunnett's multiple comparisons test. **b** KBM7 SGMS1^{GT} and SGMS1^{GT}+SGMS1 cells were infected with ZIKV (MOI = 1) and treated with 10 μM GW4869 or vehicle. At 24 hpi, supernatants were collected and analyzed by plaque assay; $n = 3$ independent experiments. Two-tailed Student's *t*-test. **c** Huh7 cells were infected with ZIKV (MOI = 1) and treated with 10 μM GW4869 or recombinant neutral sphingomyelinase (SMase). At 24 hpi, culture supernatants were analyzed by plaque assay; $n = 2$ independent experiments. One-way ANOVA with Dunnett's multiple comparisons test. **d** Model of experimental perturbations to the Cer/SM metabolic network and their effects on ZIKV replication. **e** Network of associations between disease modules similar to congenital ZIKV syndrome and lipid metabolism pathways. A metabolic network connecting the lipid subclasses identified by lipidomics was mapped to seven medical subject heading (MeSH) disease terms selected for their phenotypic similarity to clinical ZIKV syndrome. Nodes represent enzymes, lipids, and other metabolites in lipid biosynthesis, and grey lines represent reactions. Red nodes are metabolites associated with the MeSH ontologies linked by red lines. **f** Inset panel showing the metabolic neighborhood of the sphingolipids sphinganine and sphingosine. Data are mean \pm SD. See also Supplementary Fig. 6-8, Supplementary Data 5, and the Source Data file.

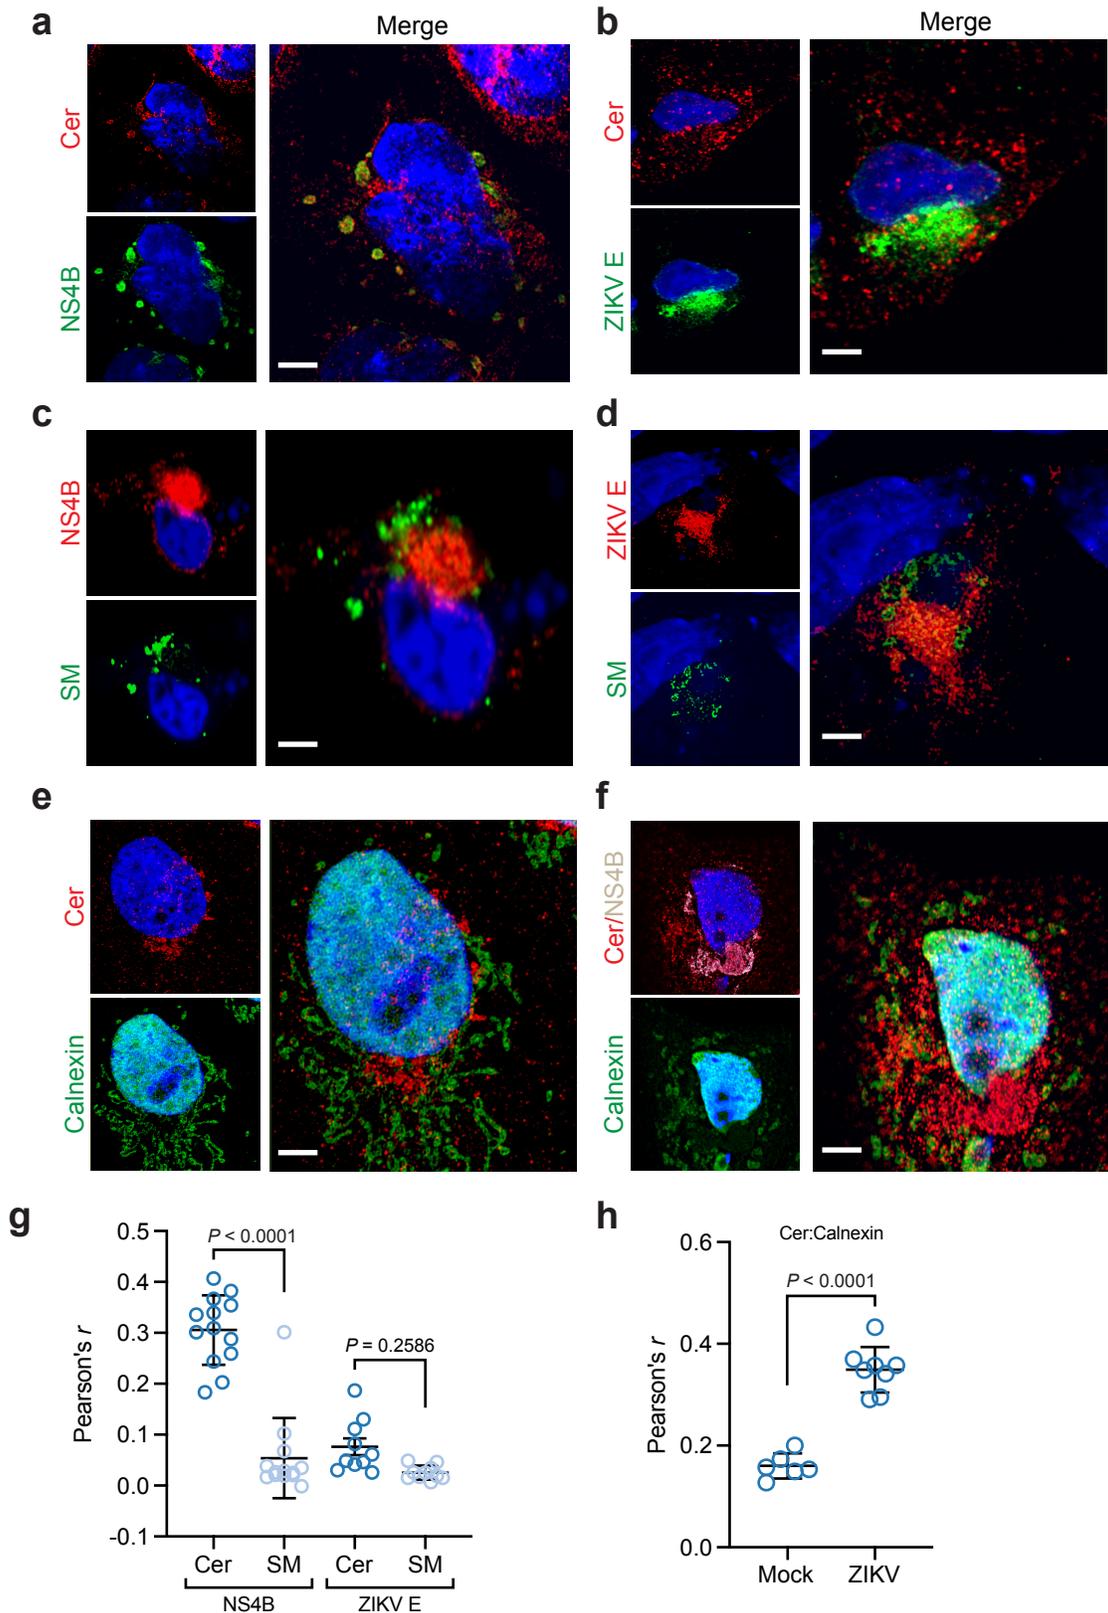

Fig. 7 Ceramide redistributes to ZIKV replication sites. Huh7 cells were infected with ZIKV (MOI = 10). At 24 hpi, mock and infected cells were fixed, co-stained with the indicated antibodies and visualized with Airyscan superresolution light microscopy. **a, b** Cells were co-stained with antibodies against ceramide and ZIKV replication marker NS4B (**a**) or E protein (**b**). **c, d** Huh7 cells were transfected with SM-Eqt-GFP immediately following infection, then fixed, stained with antibodies against ceramide and NS4B (**c**) or E protein (**d**), and visualized as before. **e, f** Mock (**e**) and infected (**f**) cells were stained with antibodies against ceramide, NS4B, and the ER marker calnexin. **g, h** Pearson's correlation coefficient was calculated for the indicated pairs of signals ($n = 10$ cells per condition; each dot represents r from a single field of view containing one or more cells, from 4 independent experiments). Scale bar, 10 μm .
