ABSTRACT

We investigate the potential of future TeV linear e^+e^- colliders to observe singly-charged Higgs bosons (H^\pm) via the coupling $H^\pm W^\mp Z$, which would signal the existence of exotic Higgs representations. In the context of a Higgs-triplet model compatible with the electroweak oblique parameters, we estimate the cross section for producing charged Higgs-triplet bosons that couple predominantly to W and Z bosons in 0.5–2 TeV- e^+e^- colliders. The principal backgrounds are evaluated and the viability of the signal is discussed and illustrated.

MASTER

The physics potential of a TeV- e^+e^- collider, such as the proposed next linear collider (NLC) planned to operate with a centre-of-mass energy of 500 GeV [1], includes the exploration of the parameter space of theories beyond the minimal Standard Model (SM). Theories beyond the SM usually predict the existence of charged Higgs bosons (H^\pm) [2]. In particular, if charged Higgs bosons are produced via a *sizeable* $H^\pm W^\mp Z$ coupling, this alone can reveal the origin of the charged Higgs boson, *i.e.*, as a member of a Higgs-triplet realization beyond the SM. In extensions of the SM with Higgs doublets and singlets, the coupling $H^\pm W^\mp Z$ vanishes at tree level and can only be generated at one-loop level [3, 4]. The reason for the vanishing of the $H^\pm W^\mp Z$ coupling in the Lagrangian is rather technical and depends upon the hypercharge (Y) and weak-isospin assignments of the Higgs representations introduced in the model. In fact, the W^\pm and Z bosons couple through the covariant derivative to the charged Higgs and would-be Goldstone (G^\pm) bosons, and a tree-level coupling to the singlet Higgs fields ($Y = 0$) is therefore prohibited. On the other hand, in models with complex Higgs doublets Φ_i ($Y = 1$), the vertex $H^\pm W^\mp Z$ is proportional to $T_- \langle \Phi_i \rangle$ and hence vanishes [$T_\pm = \frac{1}{2}(\sigma_1 \pm \sigma_2)$, with the Pauli matrices denoted by $\sigma_{1,2,3}$], whereas $G^\pm W^\mp Z \propto T_+ \langle \Phi_i \rangle$ is non-zero as should be the case in a renormalizable extension of the SM. In multi-Higgs doublet models, the resulting strength of the loop-induced $H^+ W^- Z$ -coupling turns out to be rather small of the order of 10^{-2} relative to the SM vertex HW^+W^- . A large $H^\pm W^\mp Z$ coupling is therefore an indicator of exotic triplet or higher Higgs representations beyond the SM; searches for experimental signatures of this coupling will offer unique tests for the presence of such exotic representations.

In the context of theories containing $Y = 2$ Higgs-triplet fields, our aim is to show that TeV- e^+e^- colliders are capable of differentiating whether the charged Higgs bosons belong to a triplet or doublet representation after taking into account the SM background. Such a distinction is harder to achieve at hadron colliders; searches there for doublet charged Higgs bosons have been discussed [5]. Complex triplet representations also predict doubly charged Higgs bosons (*i.e.* H^{++}); we shall not address their signatures here, but refer the reader to Ref. [6] for H^{++} signals at hadron colliders and Ref. [7] for H^{--} production at e^-e^- linear colliders.

In models with Higgs triplets, one has to face difficulties coming from large contributions to the electroweak parameters S , T , and U [8] (generalized to V , W , and X [9]).

Especially, compatibility with the Veltman parameter ρ ($\propto T$) [10] and the absence of large flavour-changing neutral currents suggest that the neutral component of the left-handed triplet should possess an unnaturally small vacuum expectation value of the order of eV. An interesting scenario that avoids this problem was considered by Galison [11], and Georgi and Machacek [12]. They introduced more than one triplet field into the model and imposed an $SU(2)$ custodial symmetry on the vacuum expectation values and hypercharges of the Higgs multiplets to ensure $\rho = 1$ at tree level. This scenario was further analyzed by Chanowitz and Golden [13], who examined stability conditions of the $SU(2)$ custodial symmetry in the Higgs potential under higher order quantum corrections. To be more precise, the model under discussion consists of the usual SM $Y = 1$ complex doublet Φ , plus one real $Y = 0$ and one complex $Y = 2$ triplet given by

$$\Delta = \begin{pmatrix} \delta^0 & \chi^+ & \delta^{++} \\ \delta^- & \chi^0 & \delta^+ \\ \delta^{--} & \chi^- & \delta^{0*} \end{pmatrix}. \quad (1)$$

Among the various Higgs fields that the model predicts, there exist charged Higgs-triplet bosons H^\pm (sometimes denoted as H_5^\pm), which have no-tree level couplings to fermions. In addition to H^\pm , the model also contains charged Higgs-doublet bosons H'^\pm (also called H_3^\pm) that do not couple to gauge bosons in the Born approximation. Specifically, after diagonalizing the charged Higgs-boson matrix by assuming that the $SU(2)$ custodial symmetry is preserved, they are identified as

$$H^\pm = \sqrt{\frac{1}{2}}(\delta^\pm - \chi^\pm), \quad H'^\pm = c_H \sqrt{\frac{1}{2}}(\delta^\pm + \chi^\pm) - s_H \phi^\pm, \quad (2)$$

where ϕ^\pm is the charged-field component of the Higgs doublet Φ and $s_H = \sqrt{1 - c_H^2}$ is the sine of a doublet-triplet mixing angle defined as

$$s_H = \sqrt{\frac{8v_T^2}{v_D^2 + 8v_T^2}}, \quad (3)$$

with $v_D/\sqrt{2} = \langle \phi^0 \rangle$ and $v_T = \langle \delta^0 \rangle = \langle \chi^0 \rangle$. The SM vacuum expectation value is then related to v_D and v_T via $v^2 = v_D^2 + 8v_T^2$. The corresponding vertex H^+W^-Z is then given by [14]

$$\mathcal{L}_{int} = -g_w \frac{s_H}{c_w} M_W H^+ W^-_\mu Z^\mu + H.c., \quad (4)$$

where g_w is the usual $SU(2)_L$ electroweak coupling constant, $c_w^2 = 1 - s_w^2 = M_W^2/M_Z^2$ and $s_w^2 = \sin^2 \theta_w$ is the sine-square of the Weinberg angle. Due to electromagnetic gauge invariance, the coupling $H^\pm W^\mp \gamma$ is absent at tree level. As emphasized earlier, we are interested in a large $H^\pm W^\mp Z$ coupling that will unavoidably signify the triplet nature of the charged Higgs bosons H^\pm . This can only be the case if $s_H \sim 1$ or equivalently $v_T \sim v_D$, which is considered to be a natural scenario. In the limit of our interest ($s_H \rightarrow 1$), the only interactions of H^\pm with other fields that survive in the Lagrangian are those between the so-called fiveplet members ($H_5^{--}, H^-, H_5^0, H^+, H_5^{++}$ in the notation of [15]), *i.e.*, the couplings $H_5^0 H^- W^+$, $H^+ H_5^{--} W^+$, $H^+ H^- Z$, $H^- H^+ \gamma$, and the one given by Eq. (4). There is also a tri-Higgs vertex $H^+ H'^- H_3^0$, which depends crucially on the details of the Higgs potential. Thus, for some specific choice of parameters, H_3^0 can be heavier than H^+ and $H^+ \not\rightarrow H'^+ H_3^0$. An exhaustive list of the Feynman rules containing all the Higgs particles involved in this model can be found in Ref. [15]. Furthermore, as an effect of the $SU(2)$ custodial symmetry, all fiveplet members are degenerate in mass and so the only dominant decay mode is $H^+ \rightarrow W^+ Z$. The partial width of this decay channel is given by

$$\Gamma(H^+ \rightarrow W^+ Z) = \frac{\alpha_w}{16} \left(\frac{s_H^2}{1} \right) M_H \lambda^{1/2}(M_H^2/M_W^2, 1/c_w^2, 1) \left[1 + x_W^2 + x_Z^2 - 2x_W - 2x_Z + 10x_W x_Z \right], \quad (5)$$

with $\alpha_w = g_w^2/4\pi$, $\lambda(x, y, z) = (x - y - z)^2 - 4yz$, $x_W = M_W^2/M_H^2$, and $x_Z = M_Z^2/M_H^2$. Of course, if such a scenario were embedded in a grand unified theory (GUT), one would have to cope with the known gauge-hierarchy problem or problems related to the existence of a unification point at the GUT scale M_X . Solutions to these problems may be achieved by considering a supersymmetric GUT version that contains our low-energy model [15]. One may therefore expect that additional supersymmetric scalars will be present in the theory and give rise to new decay modes for a very heavy charged Higgs boson with mass of order 1 TeV. For our present illustrations, however, it is reasonable to consider a scenario in which $B(H^+ \rightarrow W^+ Z) \simeq 1$ for charged Higgs masses $M_H \lesssim 600$ GeV and $s_H \simeq 1$.

There are two preferred channels for hunting the charged-triplet Higgs at TeV- e^+e^- colliders: (i) $e^+e^- \rightarrow Z^* \rightarrow W^- H^+$ and (ii) $e^+e^- \rightarrow W^{+\ast} Z^* e^- \bar{\nu}_e \rightarrow H^+ e^- \bar{\nu}_e$ (illustrated in Fig. 1), both of which depend on the $W^\pm Z H^\mp$ vertex.

(i) *The Bjorken-type process $e^+e^- \rightarrow Z^* \rightarrow W^- H^+$*

The Feynman diagram is depicted in Fig. 1(i). The total cross section for $e^+e^- \rightarrow Z^* \rightarrow W^\pm H^\mp \rightarrow f\bar{f}' H^\mp$, where W^\pm denotes an off-shell W boson and $f\bar{f}'$ is any fermion pair from the W decay, is given by

$$\sigma_{tot}(s) = \frac{\alpha_w^3 N_c s_H^2}{192 c_w^4 s} \frac{(1 + v_e^2) M_W^2}{(s - M_Z^2)^2 + M_Z^2 \Gamma_Z^2} I(s, M_H^2), \quad (6)$$

where $v_e = 1 - 4s_w^2$, the colour factor $N_C = 3$ (1) for quarks (leptons), and

$$\begin{aligned} I(s, M_H^2) &= \text{Re} J(2M_H \sqrt{s}, s + M_H^2 - M_W^2 - i\Gamma_W M_W, s + M_H^2) \\ &\quad + \frac{M_W}{\Gamma_W} \text{Im} J(2M_H \sqrt{s}, s + M_H^2 - M_W^2 - i\Gamma_W M_W, s + M_H^2). \end{aligned} \quad (7)$$

The function $J(\alpha, \beta, \gamma)$ is defined as

$$\begin{aligned} J(\alpha, \beta, \gamma) &= \int_{\gamma}^{\alpha} dx \frac{\sqrt{x^2 - \alpha^2}}{x - \beta} = -\sqrt{\gamma^2 - \alpha^2} - i\pi \sqrt{\beta^2 - \alpha^2} + (\beta + \sqrt{\beta^2 - \alpha^2}) \ln \alpha \\ &\quad - \beta \ln(\gamma + \sqrt{\gamma^2 - \alpha^2}) - \sqrt{\beta^2 - \alpha^2} \ln \left(\frac{\beta\gamma - \alpha^2 - \sqrt{\beta^2 - \alpha^2} \sqrt{\gamma^2 - \alpha^2}}{\gamma - \beta} \right). \end{aligned} \quad (8)$$

In case of complex arguments, the function $J(\alpha, \beta, \gamma)$ should be continued analytically. In Fig. 2, we have plotted the total cross section (summing H^+ and H^- channels) as a function of the charged Higgs mass at center-of-mass energies $\sqrt{s} = 0.5, 1, 1.5$ and 2 TeV. We also summed over all the fermion pairs $f\bar{f}'$. Since H^\pm decays into W and Z bosons, the process of interest is $e^+e^- \rightarrow f\bar{f}' W^\pm Z$, in which the vector bosons may be identified via their leptonic decays into electrons and muons. Obviously, the irreducible background is the SM production of $e^+e^- \rightarrow W^+ W^- Z$. The leptonic branching fractions are:

$$B(W^- \rightarrow e^-, \mu^- + X_\nu) \simeq 0.26, \quad B(Z \rightarrow e^- e^+, \mu^- \mu^+) \simeq 0.067, \quad (9)$$

where we have included the modes $W^- \rightarrow \tau^- \bar{\nu}_\tau \rightarrow e^- / \mu^- \bar{\nu}_e / \mu^- \nu_\tau \bar{\nu}_\tau$, so the quantity X_ν denotes either one or three neutrinos. From these branching fractions and the cross sections of Fig. 2, we see that pure leptonic signals from charged Higgs production via this process are very small, and decrease as c.m.s. energy \sqrt{s} increases as indicated by the $1/s$ factor in Eq. (6). We shall therefore henceforth focus our attention mainly on the more promising WZ fusion process, but we will take account of small contributions from the Bjorken process at $\sqrt{s} = 0.5$ TeV, where they are not negligible.

(ii) The fusion process $e^+e^- \rightarrow W^{+\ast}Z^{\ast}e^-\bar{\nu}_e \rightarrow H^+e^-\bar{\nu}_e$

This reaction depicted in Fig. 1(ii) offers larger signals than the previous process. The total cross section can be written

$$\sigma_{tot}(s) = \frac{1}{1024\pi^4 s^2} \int \frac{ds_2 dt_1 dt_2 ds_1}{\sqrt{-\Delta_4(s, s_1, s_2, t_1, t_2)}} |\overline{\langle T \rangle}|^2, \quad (10)$$

where the squared transition element averaged over the spins of the initial states is

$$|\overline{\langle T \rangle}|^2 = \frac{g_w^2 M_W^2 s_H^2 g_L^{(w)2}}{c_w^2 (t_1 - M_Z^2)^2 (t_2 - M_W^2)^2} \left[g_L^{(z)2} s(s - s_1 - s_2 + M_H^2) + g_R^{(z)2} (s - s_1 + t_2)(s - s_2 + t_1) \right], \quad (11)$$

and the coupling constants $g_L^{(w)}$, $g_{L,R}^{(z)}$ are given by

$$\begin{aligned} g_{L,R}^{(i)} &= g_V^{(i)} \mp g_A^{(i)}, \quad i = w, z \\ g_V^{(w)} &= -g_A^{(w)} = \frac{g_w}{2\sqrt{2}}, \quad g_V^{(z)} = -\frac{g_w}{4c_w} (1 - 4s_w^2), \quad g_A^{(z)} = \frac{g_w}{4c_w}. \end{aligned} \quad (12)$$

Here, the superscripts (w) and (z) refer to the production vertices of a virtual W and Z boson, respectively. Furthermore, s , s_1 , s_2 , t_1 , and t_2 in Eq. (11) are the usual Mandelstam variables defined as follows:

$$\begin{aligned} s &= (k_{e^-} + k_{e^+})^2, \quad t_1 = (p_{e^-} - k_{e^-})^2, \quad t_2 = (p_\nu - k_{e^+})^2, \\ s_1 &= (p_{e^-} + p_H)^2, \quad s_2 = (p_\nu + p_H)^2. \end{aligned} \quad (13)$$

The phase-space limits of the Mandelstam variables listed in Eq. (13) as well as the definition of the kinematic function Δ_4 in Eq. (10) can be found in Ref. [16]. In Fig. 3, we show the computed total cross section as a function of the charged Higgs boson mass M_H at $\sqrt{s} = 0.5, 1, 1.5$, and 2 TeV. Unlike the Bjorken-type process this channel has a cross section increasing with \sqrt{s} .

The signal of interest is $e^+e^- \rightarrow e^\mp \nu H^\pm \rightarrow e^\mp \nu W^\pm Z$ with leptonic decays; we therefore concentrate on the channel

$$e^+e^- \rightarrow e\nu WZ \rightarrow e\nu(\ell\nu)(\ell'\bar{\ell}'), \quad (14)$$

where ℓ, ℓ' denote e or μ . It is understood that decays $W \rightarrow \tau\nu \rightarrow \ell\nu\nu\nu$ are always included, since they are practically impossible to be distinguished experimentally from the

direct leptons in $W \rightarrow \ell\nu$, but decays $Z \rightarrow \tau\tau \rightarrow \ell\ell\nu\nu\nu\nu$ can be excluded because the dilepton invariant mass is generally much less than M_Z . The WZ -fusion process then has net branching fraction 0.017, that multiplies the cross section of Fig. 3 to give the cross section in this leptonic channel.

The main characteristics of the WZ -fusion four-lepton signal are: three hard central leptons from W and Z decay; one scattered beam e^\pm ; two of the leptons reconstruct the Z boson; and the two undetectable neutrinos give large missing p_T . Note that the Bjorken process also contributes in this channel, albeit at a low level, and must be added to the final signal.

We must now discuss the main SM backgrounds in the above channel, together with possible kinematic cuts to reduce them with minimal loss of signal. These backgrounds are:

- (a) $e^+e^- \rightarrow W^+W^-Z$, with one W boson decaying to e or μ and the other only to e . This background cannot easily be removed and must be calculated in detail, though the cross section decreases as \sqrt{s} increases. It is part of the annihilation channel $e^+e^- \rightarrow W^+W^-Z^* \rightarrow W^+W^-\ell\bar{\ell}$ ($\ell = e, \mu$). Actually, it can also be viewed as part of $e^+e^- \rightarrow W^-ZW^+ \rightarrow W^-Z\ell^+\nu$, or $e^+e^- \rightarrow W^+ZW^- \rightarrow W^+Z\ell^-\bar{\nu}$. To avoid double counting we include it in the $e^+e^- \rightarrow W^-ZW^+ \rightarrow W^-Z\ell^+\nu$ calculation.
- (b) $e^+e^- \rightarrow e^+e^-W^+W^-$ with leptonic W decays. This background refers only to the scattering channel contribution; the annihilation channel is already included in process (a). The total cross section of this production is very large, of order 2 pb at $\sqrt{s} = 1.5$ TeV due to the double photon-exchange diagrams. Fortunately, this huge cross section can be substantially reduced by requiring both the scattered beam electron and positron to be away from the beam direction (*e.g.* requiring $|\cos\theta_e| < 0.98$), and by constraining the invariant mass of one lepton pair to be around the Z mass while the invariant mass of the other pair is larger than $M_Z + 10$ GeV. After all these requirements this background remains non-negligible, so we include it in our analysis.
- (c) $e^+e^- \rightarrow e^\pm W^\mp Z\nu$, followed by the subsequent decays $W^\pm \rightarrow e^\pm, \mu^\pm X_\nu$ and $Z \rightarrow ee, \mu\mu$. The Feynman graphs of this SM reaction may be found in Fig. 4 of Ref. [17]. This process refers only to the scattering channel, while the annihilation channel is already included in

process (a). The total cross section of this process is also very large due to the photon-exchange diagrams. The cross section can be reduced by excluding electrons close to the beam, but the reduction is less than in $e^+e^- \rightarrow e^+e^-W^+W^-$ and it remains a major background to our signal. Since this process [17, 18] has very similar features to our signal a more sophisticated investigation of kinematic variables is needed. Thanks to the difference that there are no resonance graphs with a heavy charged Higgs boson in this background, we can exploit the invariant mass of the three charged leptons that decay from the WZ . While the background should be smooth in this distribution, the signal should be concentrated in a limited range depending on the charged Higgs-boson mass.

(d) $e^+e^- \rightarrow ZZ$ with leptonic Z decays. The case where both Z decay directly to e or μ pairs can be suppressed by requiring that only one pair has invariant mass near M_Z , and by requiring a large missing transverse momentum \cancel{p}_T . There remains a contribution where the second Z decays via $Z \rightarrow \tau^+\tau^- \rightarrow ee, e\mu + X_\nu$; this is important only at $\sqrt{s}=0.5$ TeV, where $\sigma_b \simeq 0.2$ fb, and can be removed completely by requiring that the second pair of leptons have invariant mass greater than M_Z .

(e) $e^+e^- \rightarrow Ze^+e^-$ with Z decaying directly to ee or $\mu\mu$. This background refers to the scattering channel (process (d) already includes the major annihilation channel). The total production cross section is of order 1 pb at $\sqrt{s} = 0.5 - 2$ TeV [7], including the Z decay branching ratio. It is reduced to the level of 1 fb by cutting out leptons at small beam angles, and can be finally eliminated by a missing transverse momentum cut.

(f) $e^+e^- \rightarrow ZZZ^*, ZZ\gamma^*$. These annihilation processes are of higher order than process (d) and therefore generally smaller. If the final Z bosons and/or the off-shell photon go to $\ell^+\ell^-$, $\nu\bar{\nu}$ and e^+e^- , respectively, they contribute to the same final states as (g) and (h) below.

(g) $e^+e^- \rightarrow ZZe^+e^-$ scattering, with one Z decaying invisibly. This can fake signal events but is at least an order of magnitude smaller than (c) and the small-angle cut on both the scattered e^+ and e^- reduce it to a negligible level. For example, at 1.5 TeV this background is only of order 10^{-3} fb.

(h) $e^+e^- \rightarrow ZZ\nu\nu$ scattering, with one Z boson decaying via τ leptons into $e^+e^-\nu\nu\nu\nu$ or $e\mu\nu\nu\nu\nu$. This background can be removed by requiring the invariant mass of $e^+e^-/e\mu$ to

be larger than M_Z .

Thus the only major backgrounds are (a), (b), and (c).

Our strategies to select the signal and minimize these backgrounds are as follows.

- We select events with exactly four charged leptons in the final state (no hadrons), at least one of which must be e^\pm , and impose the following lepton acceptance cuts:

$$p_T^\ell > 10 \text{ GeV} \quad \text{and} \quad |\cos \theta_\ell| < 0.98 \quad (15)$$

where θ_ℓ is the angle between the lepton and the beam direction.

- Since two of the four charged leptons should come from a Z boson, we require one pair of oppositely charged leptons of the same flavour to reconstruct the Z mass in the range

$$M_Z - 10 \text{ GeV} < M(\ell^+ \ell^-) < M_Z + 10 \text{ GeV} . \quad (16)$$

- For the other pair of leptons (which should come from W decay and a scattered e^-/e^+), we require them to have opposite charges, one of them to be e^\pm , and their invariant mass $M(e\ell)$ to be above the Z range:

$$M(e\ell) > M_Z + 10 \text{ GeV} . \quad (17)$$

- We impose a missing transverse momentum cut

$$\cancel{p}_T > 30 \text{ GeV} . \quad (18)$$

- We attempt to form the invariant mass of the two leptons, which reconstruct the Z boson, plus the lepton from the W decay. For $e\mu Z$ final states it is uniquely determined that $M(\mu Z)$ is the correct combination. But for eeZ final states (half of our signal) the choice is ambiguous; here we choose the minimum of the two invariant masses $M(eZ)$, denoted by $M(\ell\ell\ell - \min)$. In the case of the signal, $M(\ell\ell\ell - \min)$ turns out to have a distribution very similar to the “correct” invariant mass $M(\mu Z)$ in the $e\mu Z$ channel; both have the same sharp upper limit

$$M^2 < \frac{1}{2}[M_H^2 + M_Z^2 - M_W^2 + \lambda^{1/2}(M_H^2, M_Z^2, M_W^2)] < M_H^2 \quad (19)$$

The lower limit on $M(\mu Z)$ is found by reversing the sign of $\lambda^{1/2}$ above. This variable is intended to distinguish further between signal and background.

A possible additional strategy would be to select only $e\mu Z$ in the final state. This would trivially remove some of the backgrounds and would remove the need for the $M(\ell\ell\ell - \min)$ variable. However, the signal would then be halved and the major backgrounds would remain, reduced by no more than the same factor 2. We do not choose this option here.

We have computed the triplet-Higgs signal and the main backgrounds with the above acceptance criteria, using Monte Carlo methods. The signal calculations are based on spinor trace techniques; the $H^\pm \rightarrow W^\pm Z \rightarrow \ell^\pm \nu \ell' \bar{\ell}'$ decay trace is analogous to the production trace, with appropriate crossings; the effects of $W \rightarrow \tau \nu \rightarrow \ell \nu \nu \nu$ cascade decays are included by the methods of Ref.[19]. The background calculations are based on helicity amplitude techniques, extending the codes originally developed in Ref.[17]. We have restricted ourselves to masses $M_H > M_W + M_Z$, for which on-shell $H^\pm \rightarrow W^\pm Z$ decays are possible. Our integrated cross section results are exhibited in Table 1. Several comments should be made.

- (i) The signals do not rise monotonically with energy, unlike the uncut cross sections in Fig. 3. This is mostly because of the angular cut on the scattered beam electron or positron, that removes a larger fraction of electrons at higher energy. The signal would increase if this cut were relaxed, and ideally one might consider different cuts for different energies; however, the background would increase even more (and there are also practical difficulties in detecting at small angles in linear colliders), so we have not pursued this option.
- (ii) The other cuts do not cost more at higher energy. The cut on the two non- Z lepton invariant mass is in fact the most costly at the lowest energy, $\sqrt{s} = 0.5$ TeV, where it typically halves the signal; this is understandable, because the scattered beam electron is less energetic at lower s .
- (iii) The Bjorken process contributes significantly at the lowest energy only, giving 20% (60%) of our signal for $M_H = 175$ GeV (350 GeV) there.
- (iv) $W \rightarrow \tau \nu \rightarrow \ell \nu \nu \nu$ decays give between 4% and 12% of our signal, losing a larger fraction to the cuts, especially at lower energies.

Are such signals detectable above the backgrounds? Assuming annual luminosity 50 fb^{-1} at each energy, and a net lepton identification efficiency of 60% or more per event, we see the possibilities at $\sqrt{s} = 0.5$ TeV are rather limited; however, charged Higgs-triplet bosons with masses up to about 400 GeV might eventually be detectable for large values

of the mixing angle s_H , at the higher energies. For example, at $\sqrt{s} = 1.5$ TeV with $M_H = 175 - 400$ GeV and $s_H \sim 1$, there would be about 8-12 signal events on top of 9 background events per year, giving a somewhat significant excess in one year.

If the presence of a signal can be detected as an excess of events over the expected background, its origin as a WZ resonance can be confirmed and the Higgs mass extracted by a study of the trilepton invariant mass distributions. In Fig. 4, we illustrate the $M(\ell\ell\ell - \min)$ distribution at $\sqrt{s} = 1.5$ GeV, for triplet Higgs masses 200, 300, 400, 500 GeV; the case of $M(\mu Z)$, that can only be defined in $e\mu Z$ channels, is rather similar. We see that the signal and background have quite different distributions. In the case $M_H = 200$ GeV, the narrow signal peak between $M(\ell\ell\ell - \min) = 100$ and $M(\ell\ell\ell - \min) = 180$ GeV is particularly striking, compared to the broad background continuum. For higher Higgs masses, the signal peak is broader but nevertheless has a sharp upper limit and changes the net distribution shape in a very significant way. For estimating the significance of the signal, we should compare only with the background events directly under the signal peak; this improves the numerical significance of our signal. For example, for $M_H = 200$ GeV at $\sqrt{s} = 1.5$ TeV with 50 fb^{-1} luminosity, we should compare 12 signal events in the Higgs peak with about 4 background events under this peak (see Fig. 4), rather than the total of 9 background events altogether.

We now briefly discuss the effects of initial state radiation (bremsstrahlung and beamstrahlung), that are not included in our analysis above. Both bremsstrahlung and beamstrahlung reduce the center-of-mass energy \sqrt{s} to an effective center-of-mass energy $\sqrt{\hat{s}}$, while beamstrahlung at e^+e^- colliders also increases the effective luminosities. The effect of beamstrahlung on the effective luminosities at various e^+e^- collider designs can be found in Ref. [20]; the increase in luminosities varies from a factor of 1.3 to 3.3 and is favourable to our signal. The reduction in the effective center-of-mass energy does not have such an adverse effect on our signal as one might at first suppose; although the uncut signal cross section decreases with $\sqrt{\hat{s}}$, this is compensated by the effect of the cuts, at least at the higher energies (see Table 1). Furthermore, although bremsstrahlung is inevitable, standard, and independent of the collider designs, the beamstrahlung can always be minimized by designs, *e.g.* by using a ribbon-shaped beam. Thus initial state radiation has only a marginal effect in our analysis, and can even increase the signal.

Finally, we remark briefly on the possibility of using the hadronic decays of $WZ \rightarrow (jj)(jj)$, where j denotes a hadronic jet, to identify the charged Higgs boson. The advantages of the hadronic mode are the much larger branching fraction and the full reconstruction of the charged Higgs boson. The increase in branching ratio is more than a factor of 25. However, the same is true for the backgrounds, and might be even worse due to additional QCD backgrounds; also it is impractical to distinguish event-by-event between the W and Z bosons using the hadronic mode, since they give very similar dijet invariant masses. Therefore, we have to face much larger backgrounds from $e^+e^- \rightarrow e^+e^-W^+W^-$ and e^+e^-ZZ . There are also complications due to the other charged Higgs bosons H'^{\pm} , which do not decay into WZ but mainly into quark jets. However, if we can reconstruct the hadronic W and Z bosons fairly cleanly, it should still be possible to distinguish between H'^{\pm} and H^{\pm} production. This possibility might be worth exploring in the future.

In conclusion, we have investigated the feasibility of using the WZ fusion process, $e^+e^- \rightarrow W^+Ze\nu \rightarrow H^{\pm}e^{\mp}\nu$, to detect an exotic charged Higgs boson. If the coupling $W^{\pm}ZH^{\mp}$ is large enough, *e.g.*, the case when H^{\pm} belongs to a Higgs-triplet and the mixing angle s_H is close to 1, the production of H^{\pm} by WZ fusion, followed by $H^{\pm} \rightarrow W^{\pm}Z \rightarrow \ell^{\pm}\nu\ell'\bar{\ell}'$, give a sizeable number of signal events above a few SM background events. In addition, we have shown that the invariant mass distribution $M(\ell\ell\ell - min)$ is a good indicator to test for the existence of such a singly-charged triplet-Higgs boson.

Figure and Table Captions

- Fig. 1: Feynman diagrams responsible for producing the singly-charged Higgs-triplet boson: (i) $e^+e^- \rightarrow Z^* \rightarrow W^- H^+$ and (ii) $e^+e^- \rightarrow W^{+\ast} Z e^- \bar{\nu}_e \rightarrow H^+ e^- \bar{\nu}_e$.
- Fig. 2: Production cross section of the charged Higgs-triplet boson via the Bjorken-type process $e^+e^- \rightarrow Z^* \rightarrow W^{\mp\ast} H^\pm \rightarrow f \bar{f}' H^\pm$ for different c.m.s. energies: $\sqrt{s} = 500$ GeV (solid line), 1 TeV (dashed line), 1.5 TeV (dash-dotted line), and 2 TeV (dotted line). It is summed over all possible $f \bar{f}'$ pairs.
- Fig. 3: Production cross section of the charged Higgs-triplet boson via the WZ fusion process $e^+e^- \rightarrow H^\pm e^\mp \nu$ for c.m.s. energies $\sqrt{s} = 500$ GeV (solid line), 1 TeV (dashed line), 1.5 TeV (dash-dotted line) and 2 TeV (dotted line).
- Fig. 4: Histogram estimates indicating the excess of the leptonic signal from $WZ \rightarrow H^\pm$ fusion (shaded area) above the background at $\sqrt{s} = 1.5$ TeV, as a function of the leptonic invariant mass $M(l\bar{l} - min)$ defined in the text, with charged Higgs-boson masses: (a) $M_H = 200$ GeV, (b) $M_H = 300$ GeV, (c) $M_H = 400$ GeV, and (d) $M_H = 500$ GeV.
- Tab. 1: Production cross section σ/s_H^2 (in fb) of charged Higgs bosons in the channel $e^+e^- \rightarrow H^{\pm\ast} e^\mp \nu \rightarrow W^\pm Z e^\mp \nu$; $W \rightarrow e\nu, \mu\nu, e\nu\nu\nu, \mu\nu\nu\nu$, and $Z \rightarrow ee, \mu\mu$ as a function of M_H after the kinematic cuts discussed in the text. At the end of the table, we also present results for the background processes (a), (b), and (c) in fb.
