Abstract. Rust fungi are some of the most devastating pathogens of crop plants. They are obligate biotrophs, which extract nutrients only from living plant tissues and cannot grow apart from their hosts. Their lifestyle has slowed the dissection of molecular mechanisms underlying host invasion and avoidance or suppression of plant innate immunity. We sequenced the 101-mega-base pair genome of *Melampsora larici-populina*, the causal agent of poplar leaf rust, and the 89-mega-base pair genome of *Puccinia graminis* f. sp. *tritici*, the causal agent of wheat and barley stem rust. We then compared the 16,841 predicted proteins of *M. larici-populina* to the 18,241 predicted proteins of *P. graminis* f. sp. *tritici*. Genomic features related to their obligate biotrophic life-style include expanded lineage-specific gene families, a large repertoire of effector-like small secreted proteins (SSPs), impaired nitrogen and sulfur assimilation pathways, and expanded families of amino-acid, oligopeptide and hexose membrane transporters. The dramatic upregulation of transcripts coding for SSPs, secreted hydrolytic enzymes, and transporters *in planta* suggests that they play a role in host infection and nutrient acquisition. Some of these genomic hallmarks are mirrored in the genomes of other microbial eukaryotes that have independently evolved to infect plants, indicating convergent adaptation to a biotrophic existence inside plant cells.

Rust fungi (Pucciniales, Basidiomycota), is a diverse group of plant pathogens composed of more than 120 genera and 6,000 species and are one of the most economically important groups of pathogens of native and cultivated plants (1, 2). *Puccinia graminis*, the causal agent of stem rust, has caused devastating epidemics wherever wheat is grown (3) and a new highly virulent strain (Ug99) threatens wheat production worldwide (4). Similarly, major epidemics of poplar leaf rust, caused by *Melampsora* spp., is a major constraint on the development of bioenergy programs based on domesticated poplars (5) due to the lack of durable host resistance (6,7). Rust fungi are obligate biotrophic parasites with a complex life cycle that often includes two phylogenetically unrelated hosts (2; Fig. S1). They have evolved specialized structures, haustoria, formed within host tissue to efficiently acquire nutrients and suppress host defense responses (8). Molecular features driving adaptations to an obligate biotrophic association with plant hosts are unknown. Whether the convergent biotrophic adaptation observed in bacterial parasites (9) and other lineages of microbial eukaryotes (e.g. microsporidia) (10) has lead to functional specializations at the genome level (i.e. gene gain or loss, regulation of gene expression) remains to be determined. The recent report of the genome sequence of *Blumeria graminis*, an ascomycete biotroph pathogen responsible for Barley powdery mildew revealed a genome size expansion due to transposons proliferation concomitant with dramatic reduction in gene content, i.e. genes encoding sugar-cleaving enzymes, transporters and assimilatory enzymes for inorganic nitrate and sulfur (11). Similar gene losses were observed in the genome of the oomycete *Hyaloperonospora arabidopsidis*, a biotroph parasite infecting *Arabidopsis thaliana*, and the diversification of genes encoding RXLR-effector-like secreted proteins (12). Despite their

phylogenetic distance, these two pathogens forming haustoria seems to share striking adaptation convergences to biotrophy. To determine the genetic features underlying pathogenesis and biotrophic ability of rust pathogens, we report here the genome sequences of the rust fungi *M. larici-populina* and *P. graminis* f.sp. *tritici*.

Results and Discussion

Genome sequencing, gene family annotation and expression analysis. We have sequenced the diploid genomes of the poplar leaf rust fungus, *Melampsora larici-populina* and of the wheat stem rust fungus, *Puccinia graminis* f. sp. *tritici*, by Sanger whole-genome shotgun strategy (*SI Text*). The overall assembly sizes of the haploid genomes of *M. larici-populina* and *P. graminis* f. sp. *tritici* are 101.1 Mb and 88.6 Mb, respectively (Table S1). These genomes are much larger than the other sequenced basidiomycete genomes (13,14), but no evidence for whole-genome duplication or large scale dispersed segmental duplications was observed. The expanded size results from a massive proliferation of transposable elements (TEs), which account for nearly 45% in both assembled genomes (Fig. S4, Tables S4 and S5). Class I long-terminal-repeat (LTR) retroelements are more abundant in *M. larici-populina*, whereas class II TIR (Terminal Inverted Repeat) DNA transposons are prominent in *P. graminis* f. sp. *tritici*. Timing of TE activity using sequence divergence of extant copies suggests that a major wave of retrotransposition in the *M. larici-populina* and *P. graminis* f. sp. *tritici* lineages occurred <1 million years ago (Fig. S8).

We predicted 16,841 and 18,241 protein-coding genes in *M. larici-populina* and *P. graminis* f. sp. *tritici*, respectively. The size of these proteomes is similar to the symbiotic basidiomycete *Laccaria bicolor* (14), but strikingly larger than the corn smut fungus, *Ustilago maydis*, a pathogenic biotroph that only possesses ~6,500 proteins (15). Among the predicted proteins, only 41 and 44% in *M. larici-populina* and *P. graminis* f. sp. *tritici*, respectively, showed significant sequence similarity to documented proteins (BLASTP $\leq$ e-value 10^{-5}) (Fig. S9 and 10). *M. larici-populina* and *P. graminis* f. sp. *tritici* possess a large set of lineage-specific gene pairs showing high similarity levels (80-100%) (Fig. S11 and S15). To investigate protein evolution in *M. larici-populina* and *P. graminis* f. sp. *tritici*, we constructed families containing both orthologs and paralogs from a diverse set of ascomycetous and basidiomycetous fungi. The two genomes shared 3,273 orthologous Tribe-MCL families (*SI Text*) which comprised 5,709 *P. graminis* f. sp. *tritici* genes and 6,117 *M. larici-populina* genes; ~30% of the predicted proteins are lineage-specific, whereas 854 gene families were unique to these two rust fungi. Expansion of protein family sizes was prominent in both *M. larici-populina* and *P. graminis* f. sp. *tritici* (Fig 1, Fig. S13, Tables S7-9); several expanded gene families are lineage-specific, suggesting that important protein-coding innovation occurred in these lineages. Of the 4,858 *M. larici-populina* genes that have an orthologue in *P. graminis* f. sp. *tritici* (Best Reciprocal Hit, e-value $\leq 10^{-3}$), very few show conservation of neighbouring orthologues (synteny) (Fig S14). This is likely due to the expansion of the TE and massive reshuffling of the genome as a result. In addition, within the rust fungi, *M. larici-populina* and *P. graminis* f. sp. *tritici* represent very divergent phylogenetic lineages (1). Marked gene family expansions also occurred in those genes coding for alpha-kinases (Fig

S21), oligopeptide membrane transporters (OPT) (Table S19), copper/zinc superoxide dismutase (Table S24), and several groups of predicted transcription factors (Fig S13).

Seventy and 54% of the predicted genes of *M. larici-populina* and *P. graminis* f. sp. *tritici*, respectively, were detected by custom microarray transcript profiling of resting and germinating urediniospores, as well as infected leaves (Fig S17). A significant proportion of the detected transcripts (18%) is differentially expressed (fold-ratio $\geq$ 10.0, $P<0.05$) in infected leaves (Fig S16), whereas only ~8.0% are specifically expressed *in planta* (Fig S17). Transcripts coding for secreted peptidases and lipases, transporters of hexoses, amino-acids and oligopeptides, and carbohydrate-cleaving enzymes, such as chitin deacetylase and cutinase (Tables 1 and 2, Tables S13 and S17), are strikingly enriched ($\geq$ 10-fold) *in planta*. However, the most highly upregulated transcripts *in planta* ($\geq$ 100-fold) are mainly comprised of species-specific transcripts, including those coding for small secreted proteins (SSPs) (Tables S11 and S15). These *in planta*-induced, lineage-specific genes are likely involved in the specific relationship established between these rusts and their respective hosts.

Rust fungi secretomes contain candidate novel rust effectors. Microbial pathogens have evolved highly advanced mechanisms to engage their hosts in intimate contact and sabotage host immune responses by secreting effector proteins into host cells to target regulators of defense (16,17,18). Most SSPs that are specifically produced during plant infection are likely to be effectors that manipulate host cells to facilitate parasitic colonization, such as by suppressing plant innate immunity or enhancing nutrient availability (17). *In silico* gene prediction and manual annotation of SSPs in *M. larici-populina* genome identified a set of 1,184 SSPs (Table S18), of which 74% are species-specific. Homologs of known effectors from *M. lini*, such as haustorially expressed secreted proteins (HESPs) and the avirulence factors *AvrM*, *AvrL567*, *AvrP123*, *AvrP4* from the flax rust fungus *M. lini* (8,17), and the rust-transferred protein RTP1 from the bean rust pathogen (18), are present in highly upregulated *M. larici-populina* transcripts (Table 1, Tables S11-S13). At least 43% of *M. larici-populina* SSPs are expressed in infected leaves at 96 hours post infection. *P. graminis* f. sp. *tritici* contains a similar number of 1,103 SSPs, of which 85% are species-specific. In *P. graminis* f. sp. *tritici*, PGTG_17547 matches the highest number of haustorial ESTs, and is similar in sequence to a predicted secreted protein (ADA54575) from the wheat stripe rust fungus, *P. striiformis* (19). In both rust species, one protein in this group (PGTG_13212, JGI ID# 85525), is similar in sequence to a haustorially expressed protein from the flax rust pathogen, HESP-735 (17) (Tables S11 and S15). Fifty and 29 SSPs belong to the top 100 most highly transcriptionally up-regulated in infected poplar and wheat leaves compared to *M. larici-populina* and *P. graminis* f. sp. *tritici* urediniospores, respectively (Tables S11 and S15). Most upregulated SSP transcripts *in planta* were species-specific, as only 16% have an ortholog in both rust species, suggesting that these sequences are evolving at a very high rate. It remains to be determined whether upregulated SSPs are expressed in infection hyphae and/or haustoria, and whether they remain in the cell-wall, the extra-haustorial matrix, or are addressed to specific compartments of the host cell where they interact with their target proteins as showed for avirulence proteins in *M. lini* (8,17). In *M. larici-populina*, a total of 844 SSPs are organized in 91 families of 3 to 111 members (Table S18); the largest family contains a highly conserved ten-cysteine pattern (Fig. S18).

In *P. graminis* f. sp. *tritici*, a total of 1,105 SSPs are organized in 164 families of 2 to 38 members; the largest family contains a highly conserved eight-cysteine pattern. Four of these proteins show evidence of haustorial expression, suggesting they could be potential effectors.

Rust fungi Carbohydrate-Active Enzymes set. Gene families encoding host-targeted, hydrolytic enzymes acting on plant biopolymers, such as proteinases, lipases, and several sugar-cleaving enzymes (CAZymes)(20), are highly upregulated in both rust pathogen transcriptomes *in planta* (Tables 1 and 2, Tables S13 and S17), suggesting that the invading hyphae is penetrating the host cells by using these degrading enzymes. The comparison of the glycoside hydrolase (GH), glycosyltransferases, polysaccharide lyase (PL) and carbohydrate esterase (CE) of 21 sequenced fungi (Fig. 2) however revealed that *M. larici-populina* and *P. graminis* f. sp. *tritici* have a relatively smaller set of GH-encoding genes (173 and 158 members, respectively) (Table S20); similar to the basidiomycete symbiont *L. bicolor* (14), but much fewer than hemibiotrophic or necrotrophic phytopathogens (e.g., *Magnaporthe grisea*) and saprotrophs (e.g., *Neurospora crassa*; *Podospira anserina*). This set of CAZymes is strikingly larger than the repertoire of the biotroph *Ustilago maydis* (100 members) (15). In evolving a biotrophic lifestyle, the rust fungi have lost several secreted hydrolytic GH and PL enzymes acting on plant cell wall (PCW) polysaccharides (Fig. 2) and they are lacking the cellulose-binding CBM1 module. However, they show a moderate expansion of a few GHs cleaving plant celluloses and hemi-celluloses (e.g., GH7, GH10, GH12, GH26 and GH27) compared to the biotroph *U. maydis* or the hemibiotroph *M. grisea*. These enzymes, together with *in planta* upregulated and expanded alpha-mannosidase (GH47) and beta-1,3-glucanase (GH5) transcripts (Tables S13 and S17), may play a key role in the initial stages of host colonization, i.e. penetration of the parenchyma cells. On the other hand, induced chitin deacetylases (CE4) present in *P. graminis* f. sp. *tritici*, *M. larici-populina* and the symbiont *L. bicolor* (14) are likely involved in fungal cell wall remodelling and may play a role in the alteration of the fungal cell wall surface during infection to conceal the hyphae from the host (21).

Expanded rust transporters gene families are expressed during host infection. A process that is crucial to the success of rust pathogen biotrophic interactions is the acquisition of nutrients (carbohydrates and amino acids) by invading hyphae from its host plant through the haustoria (17,22,23). The repertoire of membrane transporters (Table S19) in *M. larici-populina* and *P. graminis* f. sp. *tritici* contains homologs of the hexose transporter HXT1, amino-acid transporters AAT1, AAT2 and AAT3 and H⁺-ATPases from the bean rust pathogen (*Uromyces fabae*), known to be highly upregulated during the interaction with its host plant. In addition, *M. larici-populina* and *P. graminis* f. sp. *tritici* genomes display an increased genetic potential for peptide uptake with 22 and 21 oligopeptide transporter (OPT) genes, respectively, whereas other basidiomycete genomes only contain five to 16 OPT genes (Table S19). OPT genes, that are transcriptionally upregulated *in planta* (Tables S13 and S17), are likely involved in the transport of peptides released by the action of the induced proteinases (aspartic peptidase, subtilisin) expressed in infected leaf tissues. The Major Facilitator Superfamily (MFS) gene family is reduced in the *M. larici-populina* and *P. graminis* f. sp. *tritici* genomes compared to other basidiomycetes (Table S19), but many MFS transcripts are however highly expressed *in planta* including two HXT1 homologs. Consistent with *in planta* expression of *M. larici-populina* and *P. graminis* f. sp.

tritici invertase genes (Tables S13 and S17), no homolog of the sucrose transporter Srt1 recently described in *U. maydis* (22) was identified, supporting the preferential uptake of host hexoses by invading rust pathogen hyphae (23). The increased activity of membrane transporters provides the needed fuel for the high primary metabolism activity observed in the invading rust fungi (Tables S13 and S17).

Nitrate and sulfate assimilation pathways deficiencies in rust fungi. Based on the inability of rust fungi to grow *in vitro* we hypothesized that the *M. larici-populina* and *P. graminis* f. sp. *tritici* genomes may lack genes typically present in saprotrophic basidiomycetes. Major anabolic pathways of primary metabolism were manually inspected for potential deficiencies. Although the enzymes of the NH_4^+ assimilation pathway were identified, several genes involved in nitrate assimilation were lacking in both rust pathogen gene repertoires. The nitrate/nitrite porter and the nitrite reductase (NiR) are missing from the nitrate assimilation gene cluster found in other fungi (Fig. 3) (24). Genes required to perform the primary sulfate assimilation were identified in *M. larici-populina* whereas they were lacking in *P. graminis* f. sp. *tritici*. The latter fungus lacks both alpha- and beta-subunits of sulfite reductase (SiR), whereas the *M. larici-populina* beta-subunit of SiR is missing the transketolase domain present in other fungal SiRs. The apparent lack of nitrate and sulfate assimilation enzymes in both rust fungi is consistent with their obligate biotrophic life style, as they depend on reduced nitrogen (either NH_4^+ or amino acids) and sulfur from plant cells. These metabolic deficiencies have also been found in plant pathogens that represent two independent evolutionary lineages of obligate biotrophy in the oomycete (*H. arabidopsidis*) and ascomycete (*Blumeria graminis*) lineages (11,12).

Conclusions

The obligate biotroph status of rust fungi has limited studies to understand how they invade their hosts and avoid or suppress defense responses. The genome sequences of the poplar leaf and wheat stem rust fungi are an unparalleled opportunity to address questions related to the obligate biotrophy lifestyle. The genetic changes that brought about the evolution of obligate biotrophy from biotrophic progenitors remain obscure. Our comparisons of *M. larici-populina* and *P. graminis* f. sp. *tritici* to other saprotrophic, pathogenic and symbiotic basidiomycetes indicate that the developmental innovations in the lineages of rust fungi did not involve major changes in the ancestral repertoire of proteins with known function. On the other hand, the large set of lineage-specific, expanding gene families may provide a key source of developmental innovation and adaptation. Our analysis shows that the colonization of the host leaf, differentiation of pathogenic structures and control of the plant immune system can be associated with a large-scale invention of lineage-specific proteins. For example, the rich repertoire of candidate effector-like SSPs could underline the co-evolution and adaptation of these obligate pathogens to the plant immune system. Contrary to obligate bacterial biotrophs and microsporidian fungal parasites which often undergo gene loss and genome compaction (9,10), the rust pathogen genomes are amongst the largest fungal genomes sequenced so far showing expanded gene families and massive proliferation of TEs. No massive gene loss was observed in *M. larici-populina* and *P. graminis* f. sp. *tritici*, but

irreversible deletion of genes not essential for the obligate biotrophic life-style (e.g., N and S assimilation), together with a lower set of plant cell wall polysaccharide degrading enzymes are genomic hallmarks of rust fungi and other biotrophic pathogens (11,12).

A deeper understanding of the complex array of factors, such as effector-like SSPs, affecting host–pathogen interactions and co-evolution could ensure efficient targeting of parasite-control methods in agricultural and forest ecosystems.

Material and Methods

Genome sequencing, assembly and annotation. The dikaryotic *M. larici-populina* 98AG31 and *P. graminis* f.sp. *tritici* CDL 75-36-700-3 (race SCCL) strains were sequenced by whole-genome sequencing (WGS) and were assembled into predicted 101.1Mb and 88.6 Mb genomes respectively (*SI Text*). The protein coding-genes (16,841 for *M. larici-populina* and 18,241 for *P. graminis* f.sp. *tritici*) were predicted with a combination of gene callers using ESTs produced from each rust fungus (*SI Text*). Reduced gene sets were considered to perform multigene families analyses (14,527 and 15,680 predicted genes for *M. larici-populina* and *P. graminis* f.sp. *tritici* respectively) by removing gene models presenting overlaps with specific repeats/TE fragments to avoid creation of biased gene families (*SI Text*). The *M. larici-populina* genome sequence can be accessed at <http://genome.jgi-psf.org/Mellp1/Mellp1.home.html> and the *P. graminis* f.sp. *tritici* genome sequence can be accessed at http://www.broadinstitute.org/annotation/genome/puccinia_group/MultiHome.html.

Microarray analysis of gene expression in urediniopores and rust-infected plants. For both *M. larici-populina* and *P. graminis* f.sp. *tritici*, gene expression was assessed in resting and *in vitro* germinating urediniopores of the sequenced rust strains as well as in respective host plant tissues at late stages of infection using specific custom 70-mer oligoarrays (*SI Text*). Methods for RNA isolation, probes synthesis and hybridization, data capture and analysis are described in *SI Text* and data have been deposited in GEO (GSE23097 for *M. larici-populina* and GSE25020 for *P. graminis* f.sp. *tritici*).

ACKNOWLEDGEMENTS. The work conducted on *M. larici-populina* by the Joint Genome Institute of the U.S. Department of Energy is supported by the Office of Science of the U.S. Department of Energy under contract No. DE-AC02-05CH11231. This project was also funded by grants from the INRA and the Région Lorraine Council to F.M. and S.D.; a grant from Natural Resources Canada to R.C.H. The sequence of *P. graminis* f. sp. *tritici* was funded by the US National Science Foundation and conducted by the Broad Institute Sequencing Platform. The work of Y-CL, P.R. and Y.VdP was supported by IUAP P6/25 (BioMaGNet). We thank Marie-Pierre Oudot-LeSeq for the initial *M. larici-populina* TE annotation, Benoît Hilselberger for database construction, Carine Commun and Hélène Hirzel for the annotation of the *M. larici-populina* secretome and mating-type genes, respectively, and Jerry Johnson for technical assistance.

Up-regulation in poplar infected leaves is assessed by comparing transcripts profiles to those from resting urediniospores (USp). Poplar leaves were infected by *M. larici-populina* urediniospores and left for 96 hpi Under controlled conditions. At this stage, poplar rust pathogen has formed many haustoria in planta and sporulation has not yet occurred. Expression values are the means of three biological replicates for 96 hpi and USp. Based on statistical analysis of normalized fluorescence levels, a gene was considered significantly regulated if it met two criteria: (1) t-test Pvalue, 0.05 (ArrayStar, DNASTar); infected poplar leaves at 96 hpi versus urediniospores fold-change > 10. Genes were selected on the basis of homology to a function, and hypothetical proteins or genes without homology of unknown function (exception of small secreted proteins representing candidate rust pathogen effectors) were discarded. The complete list of significantly regulated genes is detailed in Table S13. Genes presented here are a selection of in planta highly up-regulated rust genes falling in the small secreted proteins,

lipases, proteases, transporters, carbohydrate active enzymes, metabolism-related genes categories. A grey cell indicates an expression value below background expression level.

Table 2. Selection of *Puccinia graminis* f. sp. *tritici* genes strongly upregulated during wheat infection (see Table S17 for complete list)

Up-regulation in infected wheat is assessed by comparing transcripts profiles to those from resting urediniospores (USp). Wheat leaves were infected by *P. graminis* f.sp. *tritici* urediniospores and left for 8 days post-inoculation under controlled conditions. At this stage, wheat rust pathogen has started to sporulate and macroscopic flecking are visible. Expression values are the means of three biological replicates for 8 dpi and USp. Based on statistical analysis of normalized fluorescence levels, a gene was considered significantly regulated if it met two criteria: (1) t-test *P*-value, 0.05 (using matthes in Matlab); infected wheat at 8 dpi versus USp fold-change > 10. Genes were selected on the basis of homology to a function, and hypothetical proteins or genes without homology of unknown function (exception of small secreted proteins representing candidate rust pathogen effectors) were discarded. The complete list of significantly regulated genes is detailed in Table S17. Genes presented here are a selection of in planta highly up-regulated rust genes falling in the small secreted proteins, lipases, proteases, transporters, carbohydrate active enzymes, metabolism-related genes categories. A grey cell indicates an expression value below background expression level.

Legends of Figures

Fig. 1. Predicted pattern of gene families gain and loss in representative fungal genomes. The figure represents the total number of protein families in each species or node estimated by Dollo parsimony principle. The numerals on the phylogenetic tree branches show numbers of expanded (left, black), contracted (right, red) or inferred ancestral (oval) protein families along lineages by comparison to the putative pan-proteome. For each species, the number of gene families, orphan genes and the total non-TE gene number are indicated on the right.

Fig. 2. Double clustering of the carbohydrate-cleaving families (19) from representative fungal genomes. Top tree: the fungi named are *Aspergillus nidulans* (A_nidu), *Aspergillus niger* (A_nige), *Aspergillus oryzae* (A_oryz), *Cryptococcus neoformans* (C_neof), *Gibberella zeae* (G_zeae), *Hypocrea jecorina* (H_jeco), *Laccaria bicolor* (L_bico), *Magnaporthe grisea* (M_gris), *Malassezia globosa* (M_glob), *Melampsora larici-populina* (M_lari), *Nectria haematococca* (N_haem), *Neurospora crassa* (N_cras), *Penicillium chrysogenum* (Pe_chr), *Phanerochaete chrysosporium* (Ph_chr), *Podospira anserina* (P_anse), *Postia placenta* (P_plac), *Puccinia graminis* f. sp. *tritici* (P_gram), *Saccharomyces cerevisiae* (S_cere), *Schizosaccharomyces pombe* (S_pomb), *Tuber melanosporum* (T_mela) and *Ustilago maydis* (U_mayd). Left tree: the enzyme families are represented by their class (GH, glycoside hydrolase; PL, polysaccharide lyase) and family number according to the carbohydrate-active enzyme database (27). Right side: known substrate of CAZy families (most common forms in brackets): BPG, bacterial peptidoglycan; CW, cell wall; ESR, energy storage and recovery; FCW, fungal cell wall; PCW, plant cell wall; PG, protein glycosylation; U, undetermined; α -gluc, α -glucans (including starch/glycogen); α -man, α -mannan, β -glyc, β -glycans; β -1,3-gluc, β -1,3-glucan; cell, cellulose; chit, chitin/chitosan; dext, dextran; hemi, hemicelluloses; inul, inulin; N-glyc, N-glycans; N-/O-glyc, N- / O-glycans; pect, pectin; suc, sucrose; and treh, trehalose. Abundance of the different enzymes within a family is represented by a colour scale from 0 (white) to 33 occurrences (red) per species.

Fig. 3. Structure of the nitrate assimilation cluster among Basidiomycetes. Phylogram based on the MS277 and MS456 genes (25) from eight Basidiomycete fungi was obtained using the minimum evolution method implemented in MEGA4 (26), with the complete deletion option for handling alignment gaps, and with the Poisson correction model for distance computation. Bootstrap tests were conducted using 1000 replicates. Branch lengths (drawn in the horizontal dimension only) are proportional to phylogenetic distances. Description of open reading frames coding nitrate/nitrite porter (green), nitrate reductase (purple) and nitrite reductase (red) is given. Numbers indicate the start and stop codons for each ORF. Grey rectangles indicate proteins that are not functionally related to nitrate assimilation.
