**FINAL REPORT**

DOE Award No:	DE-FC26-08NT0005643
Name of recipient:	University of North Dakota Department of Petroleum Engineering 243 Centennial Drive, Stop 8154 Grand Forks, ND 58202-8154
Project title:	Geomechanical Study of Bakken Formation for Improved Oil Recovery
Principal investigators:	Kegang Ling, Zhengwen Zeng
Date of report:	December 31, 2013

## **DISCLAIMER**

This report was prepared as an account of work sponsored by an agency of the United States Government. Neither the United States Government nor any agency thereof, nor any of their employees, makes any warranty, express or implied, or assumes any legal liability or responsibility for the accuracy, completeness, or usefulness of any information, apparatus, product, or process disclosed, or represents that its use would not infringe privately owned rights.

Reference herein to any specific commercial product, process, or service by trade name, trademark, manufacturer, or otherwise does not necessarily constitute or imply its endorsement, recommendation, or favoring by the United States Government or any agency thereof. The views and opinions of authors expressed herein do not necessarily state or reflect those of the United States Government or any agency thereof.

## **ACKNOWLEDGEMENTS**

This report is based upon work supported by the U.S. Department of Energy National Energy Technology Laboratory under Award Number DE-FC26-08NT0005643.

The project team at The University of North Dakota would like to thank U.S. Department of Energy National Energy Technology Laboratory for sponsoring this study, and the Wilson M. Laird Core and Sample Library, The North Dakota Geological Survey for providing core samples and other information for this study.

We also wish to express gratitude to Department of Petroleum Engineering and Department of Geology and Geological Engineering at The University of North Dakota for various administrative support to this project.

## EXECUTIVE SUMMARY

On October 1, 2008 US DOE-sponsored research project entitled “Geomechanical Study of Bakken Formation for Improved Oil Recovery” under agreement DE-FC26-08NT0005643 officially started at The University of North Dakota (UND). This is the final report of the project; it covers the work performed during the project period of October 1, 2008 to December 31, 2013.

The objectives of this project are to outline the methodology proposed to determine the in-situ stress field and geomechanical properties of the Bakken Formation in Williston Basin, North Dakota, USA to increase the success rate of horizontal drilling and hydraulic fracturing so as to improve the recovery factor of this unconventional crude oil resource from the current 3% to a higher level. The success of horizontal drilling and hydraulic fracturing depends on knowing local in-situ stress and geomechanical properties of the rocks. We propose a proactive approach to determine the in-situ stress and related geomechanical properties of the Bakken Formation in representative areas through integrated analysis of field and well data, core sample and lab experiments. Geomechanical properties are measured by AutoLab 1500 geomechanics testing system. By integrating lab testing, core observation, numerical simulation, well log and seismic image, drilling, completion, stimulation, and production data, in-situ stresses of Bakken formation are generated. These in-situ stress maps can be used as a guideline for future horizontal drilling and multi-stage fracturing design to improve the recovery of Bakken unconventional oil.

# 1. INTRODUCTION

## 1.1. Background

The objectives of this five-year research project are to determine the in-situ stresses and to measure the geomechanical properties of the Bakken Formation in Williston Basin, North Dakota, USA to increase the success rate of horizontal drilling and hydraulic fracturing so as to improve the recovery factor of this 200-400 billion original oil in place (OOIP) unconventional crude oil resource from the current 3% to a higher level. Horizontal drilling with hydraulic fracturing is a required well completion technique for economic exploitation of crude oil from Bakken Formation in the North Dakota Williston Basin. The success of horizontal drilling and hydraulic fracturing depends on knowing local in-situ stress and geomechanical properties of the rocks. Currently some areas experienced low success rate in drilling and multistage fracturing due to wellbore instability and unsuccessful fracturing with the cost of 5-10 million dollars per well due to the limited knowledge of in-situ stresses and geomechanical properties of the Bakken Formation. To increase the success rate of drilling and fracing, we determined the in-situ stress and related geomechanical properties of the Bakken Formation in representative areas through integrated analysis of field and well data, core sample, and lab experiments. By integrating lab testing, core observation, numerical simulation, well log, drilling and completion, and production data, in-situ stresses were modeled and the in-situ stress maps were generated. A database of geomechanical properties of the Bakken formation rocks in the studied areas was generated. The results of this research can be used as a guideline and reference to optimize horizontal drilling and fracturing design to increase estimated ultimate recovery (EUR) in unconventional shale oil and gas productions.

The Bakken Formation in North Dakota is a significant portion of the largest contiguous oil reserve ever discovered in the lower 48 states. The U.S. Geological Survey's original study of the Bakken Formation found 4.3 billion barrels of recoverable oil in the Montana and North Dakota portion of the Williston Basin. According to federal testimony provided by the director of the North Dakota Department of Mineral Resources, hydraulic fracturing is a critical component of developing the Bakken Formation, indeed every shale play throughout the U.S. and Canada. Without hydraulic fracturing, under regulation of the states, this resource could not be produced. Hydraulic fracturing is the process of improving the ability of oil to flow through a rock formation by creating fractures. The process involves pumping into the fractures a mixture of water and additives that include various sizes of sand or ceramic particles called proppants that are designed to "prop" the fractures open, creating greater conductivity for fluids flowing to the wellbore. However, within the Bakken Formation, field data suggest that operators are unable to sustain propped fractures spatially or temporally (Vincent, 2011), resulting in decreased oil production. This research sought an improved understanding of performance and the factors that contribute to optimize horizontal drilling and hydraulic fracturing in the Bakken Formation.

## 1.2. Williston Basin

The Williston Basin is a roughly oval-shaped, sub-surface sedimentary basin with the deepest point near Williston, ND. The Williston Basin, an intracratonic basin, is a major structural feature of central North America that covers surface areas between 120,000 and 240,000 square miles (Landes, 1970). The basin reaches approximately 475 miles north-south from southern Saskatchewan to northern South Dakota and 300 miles east-west into western North Dakota and eastern Montana. It underlies most of North Dakota, western Montana, northwestern South Dakota, southeastern Saskatchewan and a small section of southwestern Manitoba (Heck et al., 2002). The Williston Basin began to subside during the Ordovician Period, around 495 million years ago and underwent episodic subsidence throughout the rest of the Phanerozoic Eon. The Phanerozoic Eon extends from approximately 600 million years ago to the present. Although the Williston Basin was subsiding, marine sediments were not deposited in it continuously. The basin contains a complete rock record compared to many basins (Heck et al., 2002). All sedimentary systems from Cambrian through Quaternary are presented in the basin, with a rock column more than 15,000 ft thick in the deepest section (Heck et al., 2002). This nearly continuous deposition of sediments shown in the geologic record makes the Williston Basin one of only a handful of basins worldwide with that distinction.

### 1.3. Bakken Formation

Several companies explored for oil starting in 1917, and although several wells hit shallow gas, it was not until 1951 that Amerada's Clarence Iverson No. 1 well struck commercial quantities of oil south of Tioga, ND at a depth greater than 11,000 feet below the surface. This discovery led to a boom in leasing and drilling activities in the Williston Basin, especially along the prolific Nesson Anticline. The discovery well was completed in the Silurian Interlake Formation but subsequent development on the anticline focused on the Mississippian Madison Group. The basin became a major oil province in the 1950s. It has been experiencing a steady and substantial increase in oil production since 2004, when the application of horizontal drilling technologies and stage fracturing facilitated the ability to extract oil from previously unviable deposits, the Bakken shales. The Bakken Formation, a large subsurface formation within the Williston Basin, is known for its rich petroleum deposits. Currently, the Bakken formation is considered the main reservoir and source of a large portion of the oil generated and produced in the Williston Basin. Formed during the late Devonian and early Mississippian age, Bakken shale is a thin, naturally fractured and considered both a source and reservoir. The Bakken formation consists of three members: the upper shale, the lithologically variable middle member, and the lower shale. The upper and lower shales have rich organic content with greater than one percent carbonaceous material, and are the source rocks for oil and gas in the Bakken Formation. In North Dakota,

the middle member is mainly gray interbedded siltstones and sandstones with a maximum thickness of 85 ft occurring at depths of approximately 9,500 to 10,000 ft (Heck et al., 2002). Located above the Bakken is the Lodgepole Formation, and below is the Three Forks formation. Although the Bakken Formation is very thin compared to other oil producing horizons, it has recently attracted much attention because its extremely high carbon content places it among the richest hydrocarbon source rocks in the world. Estimates of original oil in place (OOIP) range from 200 to more than 400 billion barrels (Price, 2000). For comparison, excluding these Bakken Formation reserves, so far the total US discovered OOIP is less than 600 billion barrels, of which only less than 200 billion barrels has been produced. With the growth rate of demand outpacing that of new reserves on oil and gas, the importance of these unconventional reserves in the Bakken Formation becomes increasingly important. Since 2001, a significant amount of oil has been successfully produced from the Bakken Formation in Richland County, Montana, USA. However, application of similar well construction technologies to the Bakken Formation in the North Dakota part of the basin has not achieved the expected success. This report presents part of the ongoing efforts in improving the success rate of horizontal drilling and hydraulic fracturing in this thin, naturally fractured tight shale formation through geomechanical study.

From 1953 to 1987, vertical wells were drilled to recover the crude oil from Bakken Formation. Successful wells were those that encountered natural fractures which displayed high production at the beginning and soon dropped rapidly to a steady, low level production rate. The Bakken shale is oil-wet, and could not be waterflooded. Acidizing is prohibited because the injected fluid may react with the pyrite presented in the shales, forming an iron hydroxide precipitate.

#### ***1.4. Horizontal Drilling and Fracturing Technology***

The small formation thickness, the limited chance of hitting the natural fractures in a vertical well, the problem with hydraulically fracturing the vertical wells, and the restriction on using water flooding and acidizing led to the application of horizontal drilling (Joshi, 1987; Breit et al, 1992; Reisz, 1992). From 1987 to 2001, horizontal drilling was extensively practiced in the Bakken Formation (Carlisle et al., 1996). These wells performed quite well in the “Bakken Fairway” area in North Dakota. Due to the high investment, horizontal wells are usually drilled for two purposes: increasing the drainage area in thin layers, and/or connecting more fractures in naturally fractured reservoirs (Economides and Boney, 2000). The success of horizontal well depends on two factors: (1) vertical permeability and (2) wellbore orientation with respect to natural fractures (Karcher et al, 1987; Mukherjee and Economides, 1991; Hudson and Matson, 1992). Using horizontal drilling improved the performance, to a certain degree, especially with the successful production of oil from the upper shale. However, horizontal wells also encountered new challenges: borehole instability and wellbore interference. The large investment and high risk in drilling horizontal wells in the Bakken Formation kept the exploration and production activities at a low level until 2000 when new well construction technique was developed in Richland County, Montana (Lantz et al., 2007), which later extended to western North Dakota. This new technique combines horizontal drilling with hydraulic fracturing. However, in-situ stress field and geomechanical properties change not only along the axis of those horizontal wells that extends several thousand feet, but also from location to location in the basin. Well orientation with respect to the in-situ stresses is one of the controlling factors to the success of hydraulic fracturing and wellbore stability during drilling and production. Therefore, it is vitally important to know the in-situ stress field and fundamental geomechanical parameters for selecting the appropriate orientation of horizontal wells and for designing successful hydraulic fracturing treatment.

## **2. GOALS AND OBJECTIVES**

The objectives of the project are to determine the in-situ stresses and to measure the geomechanical properties of the Bakken Formation in Williston Basin, North Dakota, USA to increase the success rate of horizontal drilling and hydraulic fracturing so as to improve the recovery factor of this 200-400 billion OOIP unconventional crude oil resource from the current 3% to a higher level.

### ***2.1. Challenges in Exploration and Production***

Since the first Bakken discovery well was drilled in the 1950s (Anderson, 1953), thousands of wells have been drilled to produce oil from this formation (NDIC, 2008a). The Bakken Formation in the North Dakota Williston Basin is a thin layer of interbedded, naturally fractured low permeability black shale, siltstone, silty sandstone and silty carbonate rocks at about 10,000 ft depth (LeFever, 2005). Due to the high total organic carbon (TOC) content in the upper and lower shales, it is estimated to have 200 - 400 billion barrels of OOIP (Price, 2000). However, an April 2008 assessment by the US Geological Survey indicated that technical recoverable reserve is about 3.6 billion barrels of crude oil (Pollastro et al., 2008). A more recent research report released by North Dakota Geological Survey assessed the current recoverable reserve is 2.1 billion barrels (Brimberry, 2008a). Although there is a big gap between these two assessments, both indicate a recovery factor of about 3%, which is much lower than the US domestic average recovery factor of 30% (Lake, 1989; Green and Willhite, 2003).

The success of horizontal drilling and hydraulic fracturing depends on the local in-situ stress and geomechanical properties of formation rocks. Only limited information on these aspects is available. The geology heterogeneity and the special features of the Bakken Formation makes it impossible to drill and complete the well successfully without knowing the in-situ stress and geomechanical properties of the formation rocks. Currently some areas experienced success rate of less than 10% in drilling this type of wells due to wellbore instability and unsuccessful fracturing, each of these wells costing 3-6 million dollars.

### ***2.2. Current State-of-the-Art***

Currently horizontal drilling followed by hydraulic fracturing stimulations are being applied to produce the Bakken crude oil in the North Dakota Williston Basin. In building the horizontal wells, multilateral (single, dual and tri lateral) technologies were used. Similarly, different completion techniques (perforated liner or open hole, cased and cemented) were tried (Brimberry, 2008b). Corresponding to the above well schemes, different types of well spacing have been used, including: (1) long single lateral 1280 acres, (2) single 640 acres, (3) coplanar dual and tri lateral 1280 acres, and (4) coplanar 640 acres (Helms, 2007). In the hydraulic fracturing stimulation, both longitudinal and transverse fractures were tried. Different combinations of wellbore azimuth, length, and placement were tested (Cox, et al., 2008).

### ***2.3. Benefits and Inadequacies of Current Technology***

Maximum thickness of Bakken Formation is about 145 ft, including about 20 ft in Upper Bakken, 85 ft in Middle Bakken, and 40 ft in Lower Bakken. The Middle Bakken is further divided into 5 Lithofacies L1~5. Bakken oil is produced mainly from two central Lithofacies, L2, interbedded shale and silty sandstone, and L3, sandstone. These two Lithofacies are about 10 to 20 ft thick (LeFever, 2005). It is believed, and confirmed by recovered cores, that the Bakken Formation is naturally fractured due to the action of in-situ stress fields and internal pressure when hydrocarbon was generated in the low permeability shales. Combination of horizontal wells and hydraulic fracturing in the Bakken Formation has the following benefits:

- (1) Horizontal wells increase the exposure to reservoir rock in thin formations. Vertical wells have only limited exposure to the reservoir rock, which is the formation thickness. Instead, exposure of horizontal wells equals the length of the horizontal sections.

- (2) Horizontal wells increase the connection between wellbore and the natural fractures, and those laterally isolated fractures. Because horizontal wells have larger exposure to reservoir rock, it is more likely that they hit and connect more natural fractures in comparing with vertical wells.
- (3) Hydraulic fracturing stimulation increases the reservoir drainage volume and speeds up the recovery, because the Bakken Formation has very low permeability.

However, due to the complex geological conditions in the Bakken Formation, the above technology has some serious limitations:

- (1) Improper well orientation will cause wellbore instability (Roegiers, 2008a). In order to have the most stable wellbore, the optimized orientation is the one that has the most homogeneous stress distribution, or minimum stress difference, around the wellbore. Finding this optimized orientation needs the information of in-situ stresses: both orientation and magnitude.
- (2) Improperly selected wellbore orientation may greatly reduce the well performance. Because one of the purposes of using horizontal wells is to connect laterally isolated natural fractures, which usually follow a patterned distribution controlled by in-situ stresses.
- (3) Improperly designed hydraulic fracturing treatment may not only ruin the well, but also affect the nearby wells, and lose the reserves in the targeted drainage volume (Roegiers, 2008b). The orientation of the hydraulically induced fractures is controlled by local in-situ stresses. The geometry is partly controlled by the geomechanical properties of both the target formation (Bakken Formation) and the boundary formations.

## ***2.4. Problems to be Addressed***

In comparing to the success in producing crude oil from the Bakken Formation in eastern Montana, the horizontal drilling with hydraulic fracturing stimulation technology suffered many more difficulties in western North Dakota, and new completion and fracturing technologies were developed (LeFever, 2005; Powell et al, 2007; Phillips et al, 2007). The biggest challenges include: (1) the horizontal well could not hit the natural fracture, and (2) the hydraulically generated fractures did not develop longitudinally as designed, but more than often transversely instead (Wiley, 2004; Besler et al, 2007). This was attributed to the lack of in-situ stress knowledge and the geological heterogeneity in the Bakken Formation in the North Dakota portion (Powell et al, 2007). Recently, the US Geological Survey updated the technically recoverable crude oil reserve in the Bakken Formation from 151 million barrels to 3.65 billion barrels of oil (Pollastro et al, 2008). In the same report, the Bakken Formation was divided into five assessment units (AU): (1) Elm Coulee-Billings Nose AU, (2) Central Basin-Polar Dome AU, (3) Nesson-Little Knife Structural AU, (4) Eastern Expulsion Threshold AU, and (5) Northwest Expulsion Threshold AU, as shown in Figure 2-1. The boundaries of these assessment units are consistent with the major structures in this area, and support the aforementioned geological heterogeneity.

We propose an active approach to attack these problems: determine the in-situ stress and related geomechanical properties of the Bakken Formation in representative areas (five assessment units in Figure 2-1) through integrated analysis of field and well data, core sample, and lab experiments. We use well data, core analyses, and lab testing to determine the direction and magnitude of the in-situ stresses. Geomechanical properties are measured using suggested methods by International Society for Rock Mechanics (ISRM). A large scale in-situ stress field map of the targeted region is developed. A database of geomechanical properties of the Bakken formation rocks in the studied areas is generated.

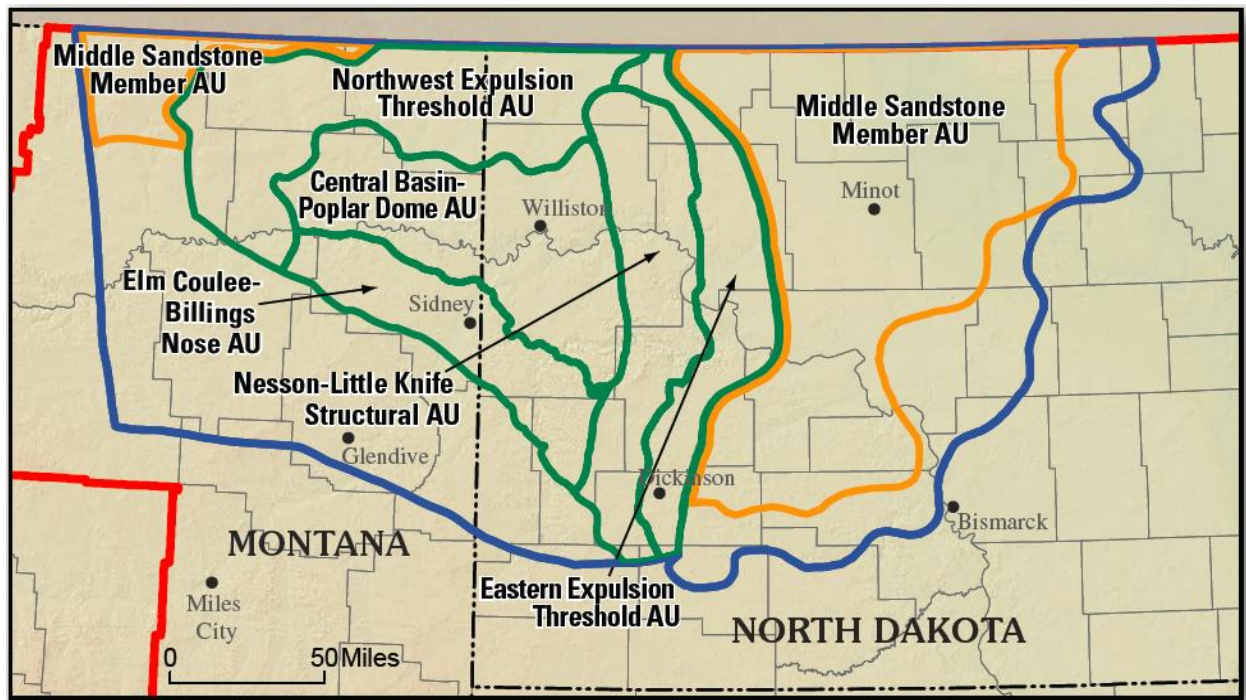

Figure 2-1. The five continuous assessment units of the Bakken Formation (Pollastro et al, 2008).

### In-situ Stress Determination

Knowing the in-situ stress field is vitally important to any underground excavation, including petroleum drilling, mining, and tunneling (Jaeger et al, 2007). Many efforts have been made to determine the direction and magnitude of in-situ stresses (Hudson, 1993). Consequently many different methods were developed. After carefully reviewing the existing techniques and our conditions, we use the following methods to determine the orientation and magnitude of the in-situ stresses.

**Stress orientation from analyzing discontinuities:** When the rock is subjected to load, it deforms. When the load exceeds a certain limit, it fractures or fails. The failure surface is called discontinuity of the rock. The failure plane and the stress orientation have a certain relationship (Narr et al, 2006). Following the geological guidelines, the feature of the discontinuity, i.e., tensile failure (joint) or shear failure (fault) or bedding plane, can be identified from core sample observation (Davis and Reynolds, 1996). Using the relationship between the in-situ stresses and the discontinuities, part of the directions of the principal stresses can be derived. Similar method can be also applied to characterizing naturally fractured reservoirs by using surface lineaments and fractures (Guo et al, 1999). Recent development in this area is a new type of acoustic log for determining principal stress direction using the split waves (Nihei et al, 2002). Because the Bakken Formation in Williston Basin is at about 10,000 ft depth, no surface access is available. The North Dakota Geological Survey Core Library, which is located on the University of North Dakota campus, has a large collection of Bakken Formation core samples from the petroleum drilling activities, including some oriented core samples. With the recent booming drilling in the Bakken Formation, more samples are being delivered.

**Geomechanical Properties of Bakken Formation:** Geomechanical properties of rocks are important parameters for well design to avoid instability and for a hydraulic fracturing treatment plan (Fjaer et al, 1992; Zeng, 2002). However, the Bakken Formation hasn't been investigated very much in this aspect; only one reference was found with limited data (Kuhlman et al, 1992; Zhou et al, 2008); this is far behind the research on the petroleum geology of the Bakken Formation (LeFever, 1991; Webster, 1992; Gosnold, 1999). We conduct geomechanical experimental investigation on Bakken Formation rocks, including measurement of the following properties: (1) Uniaxial compressive and tensile strengths, (2) Cohesion and angle of internal friction, (3) Young's modulus and Poisson's ratio, (4) Triaxial strength at three different confining pressures, and (5) Biot's coefficient. We also measure rock porosity, permeability, and sonic velocity. International Society for Rock Mechanics' (ISRM)

suggested methods and other related guidelines are followed in specimen preparation and experiment (Zeng et al, 2004). Most of the testing methods for all these rock properties have been well developed.

**Uniaxial compressive strengths, Young's modulus, Poisson's ratio and in-situ stresses:**

Uniaxial compressive strength is measured together with Young's modulus, and Poisson's ratio. Axial load, axial and lateral deformations are measured during the compression until failure of the specimen. Load-deformations curves are converted to stress-strain curves using the specimen's geometry, from which the Young's modulus and Poisson's ratio are obtained using the linear portion. Because the Williston Basin is very flatting, we can assume that one of the three principal stresses will be parallel to the vertical direction. With this assumption, using the measured historic stresses in three different directions in the bedding plane allows the determination of the two principal stresses in the bedding plane.

**Tensile strength:** Point load test or direct extension method are used to measure the tensile strength.

**Triaxial strength, cohesion and angle of internal friction:** Triaxial strength under three different confining pressures is measured. Using these results and the uniaxial compressive and tensile strengths, a Mohr envelope of this rock is developed, from which the cohesion and angle of internal friction is determined.

**Biot's coefficient:** Biot's coefficient defines the relationship among total stress, effective stress and pore fluid pressure (Biot and Willis, 1957; Geertsma, 1957). It describes how soon the matrix stress will respond when the pore fluid pressure is changed. It is more important to low permeability rocks, such as the Bakken Formation. This parameter is used in hydraulic fracturing treatment design and wellbore stability. It is measured using triaxial and hydrostatic compression (Azeemuddin et al, 2002).

## ***2.5. Impact on the U.S. Oil and Gas Industry***

Using the results from this research, the success rate of horizontal drilling and hydraulic fracturing will be greatly increased. For each saved well, the direct impact is 3-6 million dollars. More importantly, optimized well alignment in the Bakken Formation, due to the knowledge of in-situ stresses, will not only improve primary recovery, but also allow future application of enhanced oil recovery technology, such as CO<sub>2</sub> flooding. An increase of 1% in recovery (a modest goal) will lead to increase of 2 - 4 billion barrels of domestic production, a direct impact of 200 - 400 billion dollars reduction in trade deficit at current oil price. New job opportunities and other benefits will be even larger.

Results from this research project will directly serve the technical demand on recovering oil and gas from the Bakken Formation in North Dakota Williston Basin. These results can also be used to help oil and gas development in many other naturally shale formations, such as the Antrim shale in the Michigan, the New Albany shale in Illinois, and the Eastern Devonian shale in Appalachian region (Kentucky, West Virginia, Ohio, and Pennsylvania), and Pierre shale in Colorado. In fact, it is the PI's belief that using the technologies developed in this project to improve gas recovery in the above mentioned shale formations will have huge impact on domestic gas supply and reduction of greenhouse gas emission, due to the fact that those formations are close to big population centers.

### 3. PETROLEUM GEOLOGICAL MODEL OF BAKKEN FORMATION

The petroleum geological model provides an understanding to the hydrocarbon resources and special structural features of the Bakken Formation. It serves as a platform for future research works. Based on the investigation to the fundamentals on the aspect of geomechanics, geophysics, reservoir features, and recovery plan, the project targets at finding solutions which is suitable for the unique features of exploration and production in the Bakken formation (Figure 3-1). To build the geological model, geological, geophysical, petrophysical, geomechanical, and engineering data are analyzed, Laboratory test of core and fluid and field stress data are collected. The model constructed in this project can be further developed as more works will add information and more understandings will be obtained to update and calibrate the existing model.

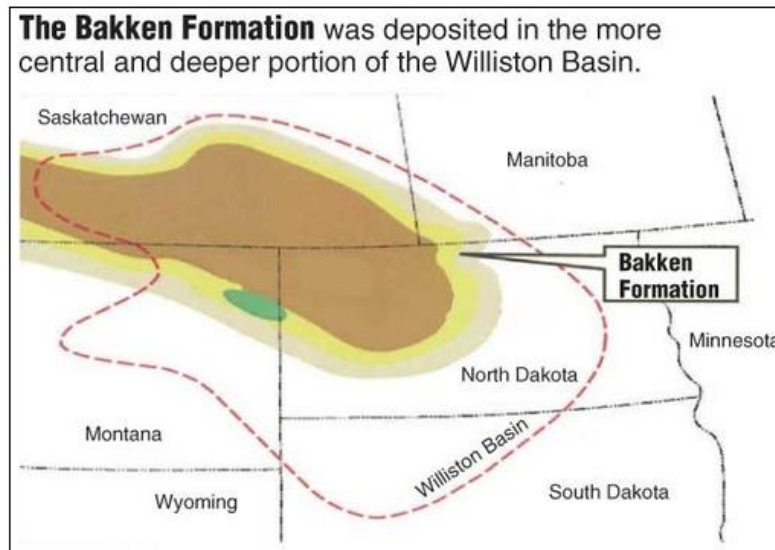

Figure 3-1: Map of the Bakken Formation (USGS, <http://bakkenshale.com/home/attachment/bakken-formation-map-usgs-2/>)

#### 3.1. Study Area and Wells Used for Geological Model

The work is based on information from 65 wells drilled in five assessment units in the Williston Basin (Figure 3-2). The corresponding North Dakota Industrial Commission (NDIC) file# to Map# for these 65 wells are listed in Table 3-1. These wells are mainly located in the west side of North Dakota, most along the Nesson Anticline and north side of the Billings Anticline.

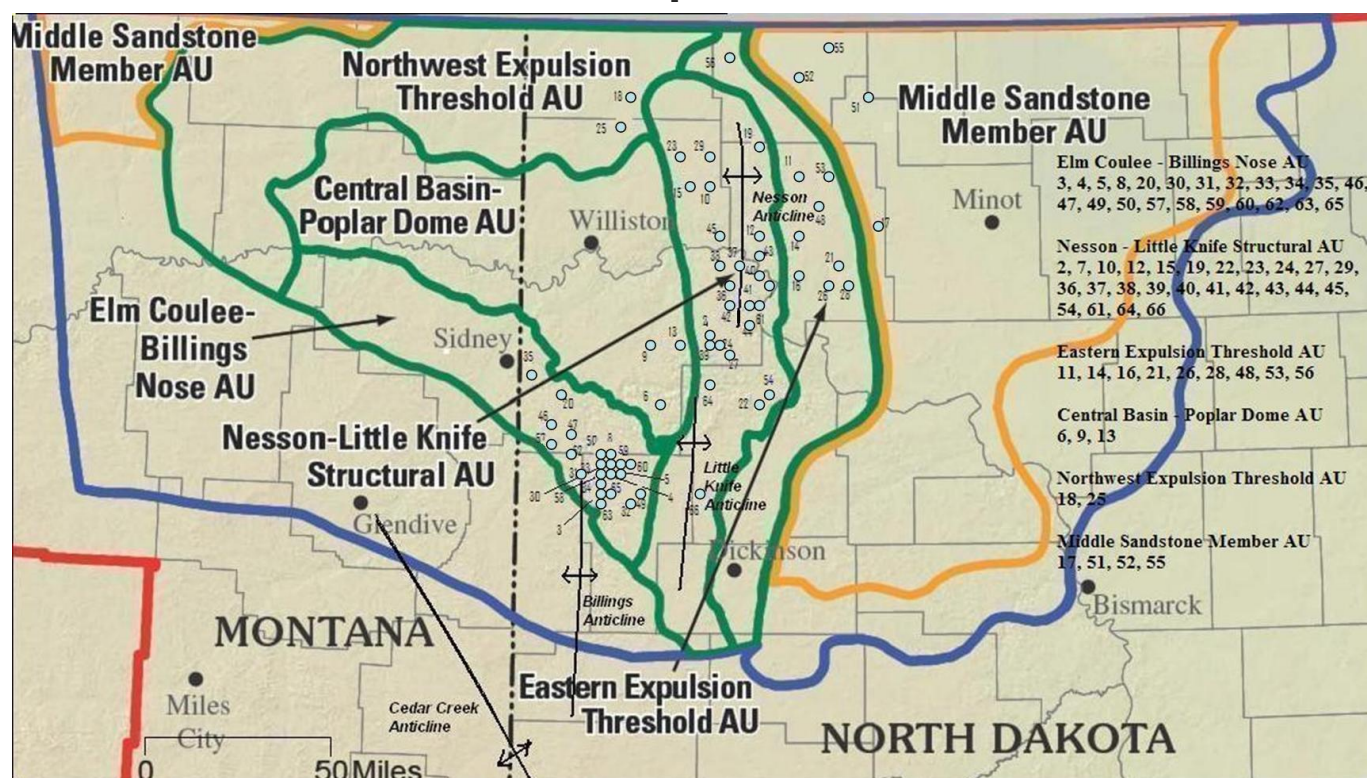

Figure 3-2: Location of the 65 wells and five assessment units in Williston Basin

Table 3-1. List of the corresponding NDIC file# to Map# in Figure 3-2 for 65 wells used in this study

## 3.2. Work Procedure

### 3.2.1 Data Collection

We have screened and collected available data for representative areas and wells within the study area. The data used in this project is mainly obtained from the information provided by companies who once drilled production wells and wildcat wells. Data collected include cores, core images, digitized geophysical well logs, monthly production, and available petrophysical testing results. A database containing information of the selected 65 wells is established. The database includes basic information of wells (longitude, latitude, depth, formation intervals, well path, core analytical data, sample lithology descriptions, and well logs), and derived results (lithology, porosity, hydrocarbon saturation, and water saturation). Most of this information can be accessed via the Premium Services on the website of North Dakota Department of Mineral Resource (DMR) (<https://www.dmr.nd.gov/oilgas/>), and Wilson M. Laird Core and Sample Library of the North Dakota Geologic Survey (Figure 3-3). RQD measurements of all the 65 wells are also conducted.

Figure 3-3: Photo of the core samples (<https://www.dmr.nd.gov/oilgas/>)

Well logs listed on the DMR website include gamma, resistivity, neutron, sonic, and density. However, it should be noticed that most of these 65 wells do not have all the above logs, and 45 wells' logs are originally in the form of image instead of digit format. These image files are digitized by using the Petra software (Figure 3-4), and the generated LAS files are ready to be read in Interactive Petrophysics software. The Interactive Petrophysics calculates parameters like clay volume, porosity, and saturation based on these log files. The second way to get the core parameters is collecting data from the well reports submitted by operators. Available core parameters in the well report are read and recorded in ASCII format, and imported into the database of Interactive Petrophysics. The core parameters obtained through the two approaches are compared and provide reference for later analysis. Details of the work using Interactive Petrophysics are described in the following parts.

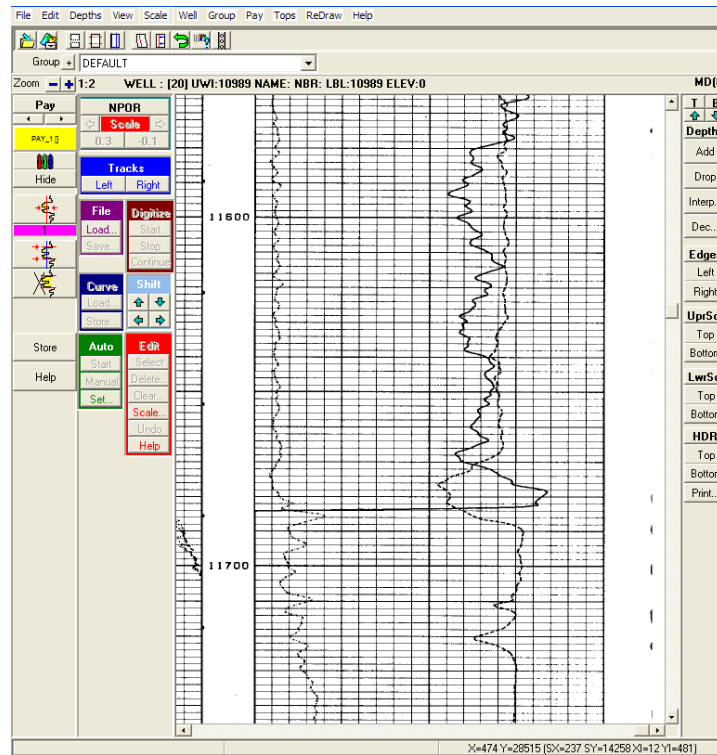

Figure 3-4: Digitizing of well logs

### 3.2.2 Data Analysis

We analyze field and well data to build a geological model of the study area to include factors affecting in-situ stresses such as structural features and basin stress history. Commercial software is used to analyze well logs. Interactive Petrophysics a product is developed by Schlumberger and is an ideal tool for well log interpretation and analysis. Using the gamma ray, density, sonic, neutron, resistivity curves, the software is able to calculate porosity, water saturation, and analyze lithology. The detail process follows 6 steps.

#### *Identification of three member of the Bakken formation*

The depth intervals are initially split into zones based on the gamma ray curve. The Bakken Formation is split into three zones: upper, middle, and lower, as the different compositions among the middle sandstone and the upper and lower shale (Figure 3-5). To build the 3D skeleton model, the middle Bakken is divided into 5 layers, and the upper and lower members are kept as single layer for each.

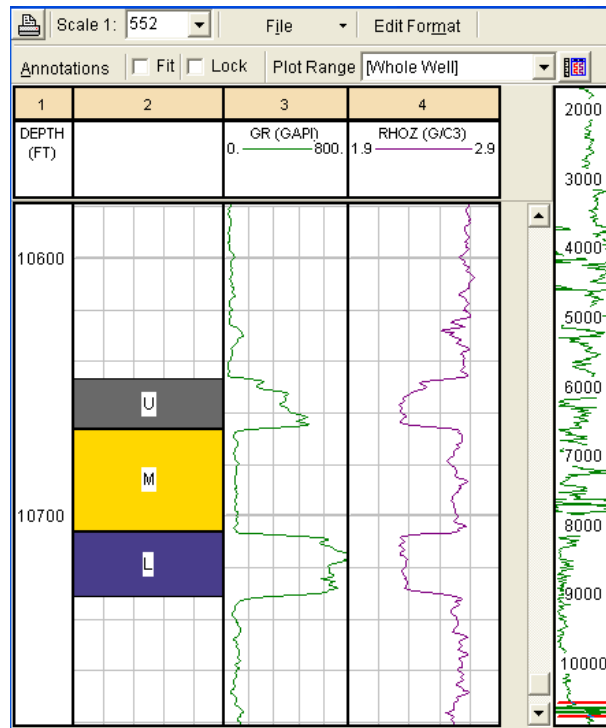

Figure 3-5: Identifying top and bottom for three members of the Bakken formation based on GR

### Normalization of well logs

Well logs of different wells are recorded in various ranges. In order to setup a common basis for comparison, the well logs are normalized. Knowing the value of gamma ray of the pure sandstone and the pure shale, wells curves are normalized using the “normalize” function in the histogram module. Figure 3-6 shows the histograms of a gamma ray before and after normalization.

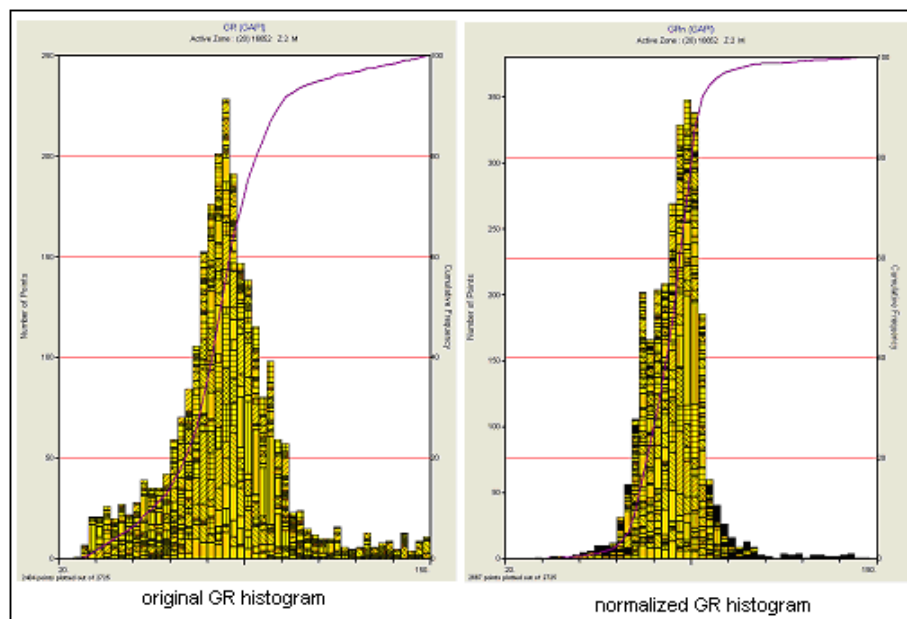

Figure 3-6: Histograms of GR before and after normalization

### Calculation of clay volume

The volume of clay is a parameter for analyzing porosity and water saturation. Gamma ray is a good indicator and all wells have gamma ray curve, so it was used to analyze clay volume through:

$$VCL = \frac{GR - GR_{sand}}{GR_{shale} - GR_{sand}} \dots\dots\dots(3-1)$$

where VCL is the volume of the clay, GRsand is the gamma ray value of pure sandstone and GRshale is gamma ray value of pure shale. If one well has other logs like neutron, density and sonic curves, besides gamma ray, a function named “Dural Clay Indicator” can be used to analyze the volume of clay. Combining pairs include neutron/density (Figure 3-7), neutron/sonic, or density/sonic. However, using the combinations and equations also requires knowing the log values for pure sandstone and pure shale.

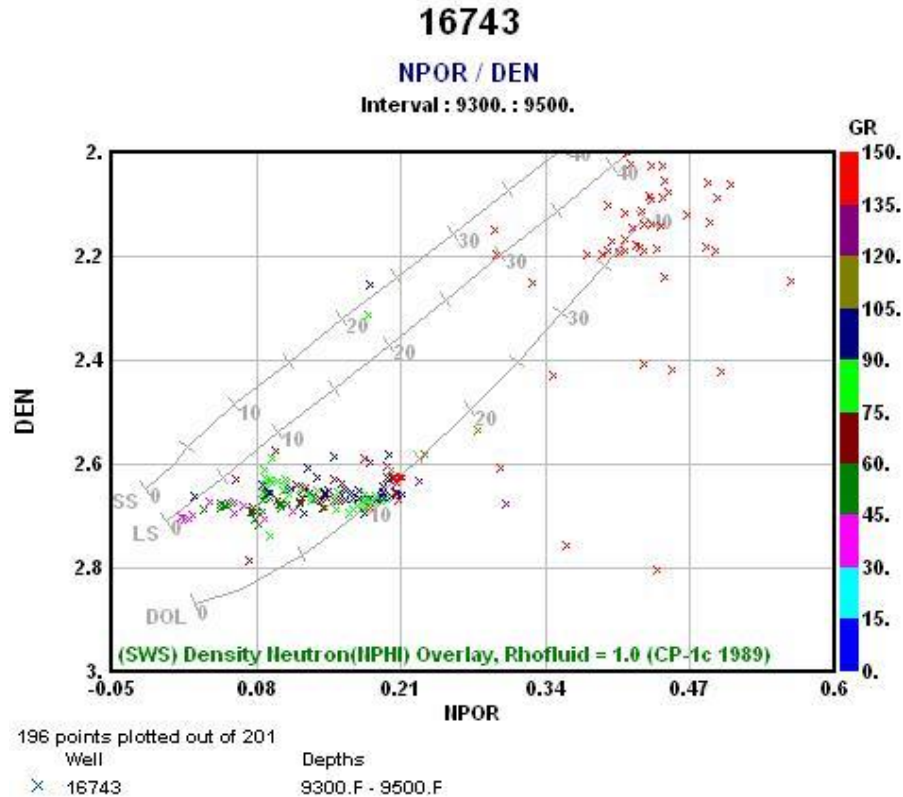

Figure 3-7: Neutron/density cross plot of Well#16743

### Lithology and porosity analysis

The rock lithology and porosity can be determined by using the cross plots module. The cross plot function has different equations for calculation, such as Schlumberger Neutron/Sonic or Western Atlas Den/Neutron (Figure 3-8). Choosing of equations is based on available logs of each well. If more than one equation is available, multiple results are obtained and compared with the core analysis data given in the well report to determine the most suitable equation.

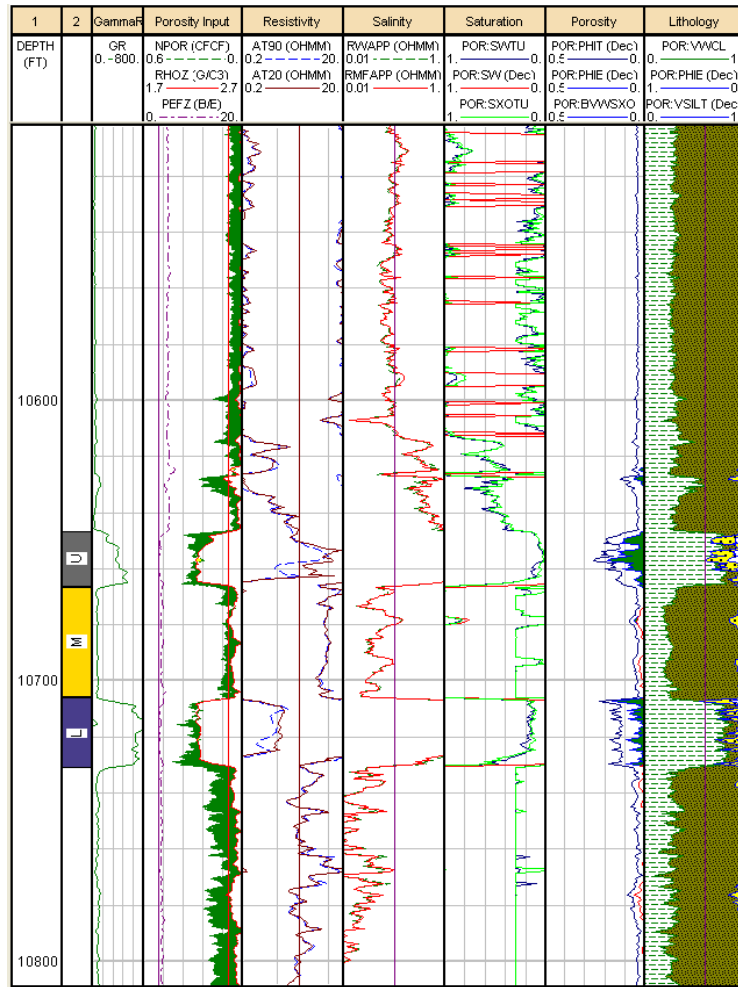

Figure 3-8: Well logs interpretation results: lithology, porosity, and saturation

### Saturation analysis

The water saturation is determined by the resistivity/porosity cross plots and the Archie equation.

$$S_w = \left[ \left( \frac{a}{F^m} \right) \left( \frac{R_w}{R_t} \right) \right]^{1/n} \quad (3-2)$$

where  $S_w$  is water saturation;  $F$  is porosity;  $R_w$  is formation water resistivity;  $R_t$  is bulk resistivity,  $a$  is a constant (often taken to be 1);  $m$  is cementation factor (varies around 2); and  $n$  is saturation exponent (generally 2).

### Permeability analysis

The Interactive Petrophysics does not have a function to calculate the permeability. But some of core analysis records in the well reports contain the permeability values and we have measured core permeability in this study. In order to calculate the permeability values of all wells and the entire formation, a correlation (Equation 3-3) between the porosity and permeability is developed using experimental data. This correlation is used as an empirical equation to calculate Bakken formation permeability.

$$k = 0.0394 \text{Exp}(0.5412\phi) \quad (3-3)$$

## 3.3. Geological Modelling

### 3.3.1 Data input and 3D skeleton model construction

First, the data of well tops are input into the Petrel. As divided by Petrophysics, there are 3 zones contained in the well data: upper, middle, and lower Bakken. Once the top data are loaded into Petrel, two isodepth maps are generated: one is the top of the Upper Bakken, the other is the bottom of the Lower Bakken. Then the 3D skeleton model is created based on these two isodepth maps as shown in **Figure 3-9**. The 3D skeleton model has three horizons. The top and bottom horizons are actually the two isodepth maps. The middle horizon is generated automatically by the Petrel and bounded by the upper and lower horizons. **Figure 3-10** shows the isopachous map of Bakken formation. Each of the three horizontal surfaces is gridded by a pattern of 500×500. It should be noticed that the 3D skeleton model is just a physical model before any rock properties are loaded. The 3D skeleton serves as a platform for further modeling works.

**Figure 3-9.** The 3D skeleton model

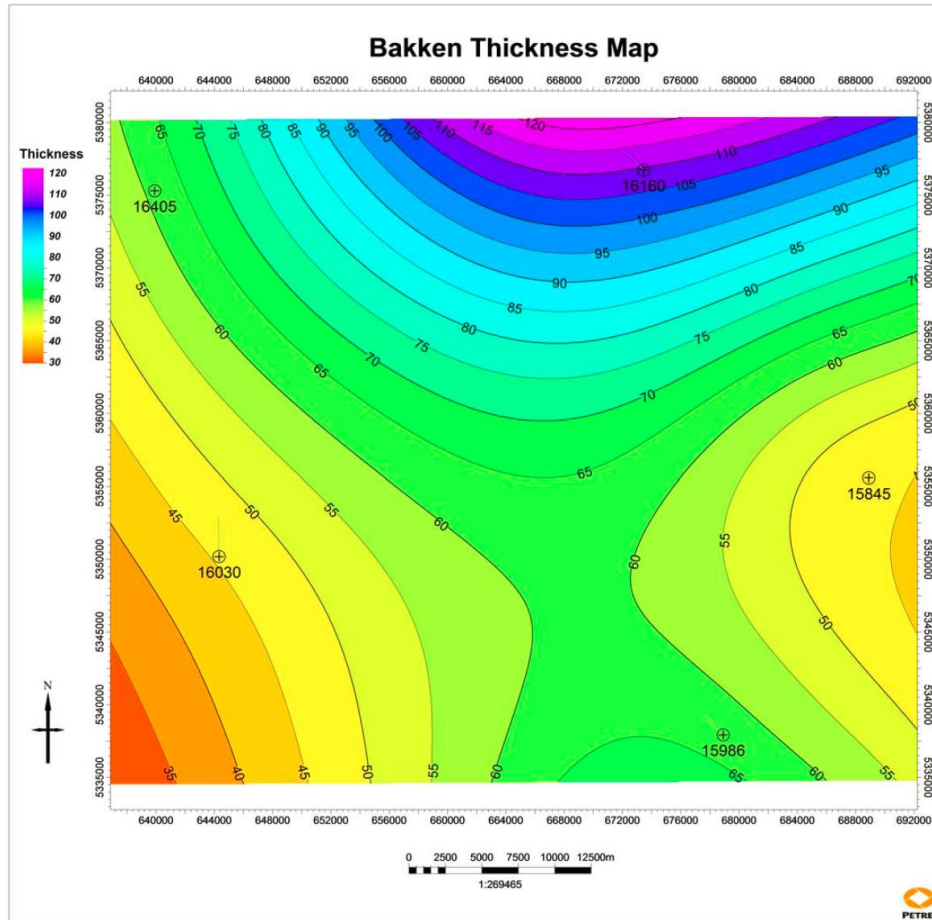

Figure 3-10. The isopachous map of Bakken formation

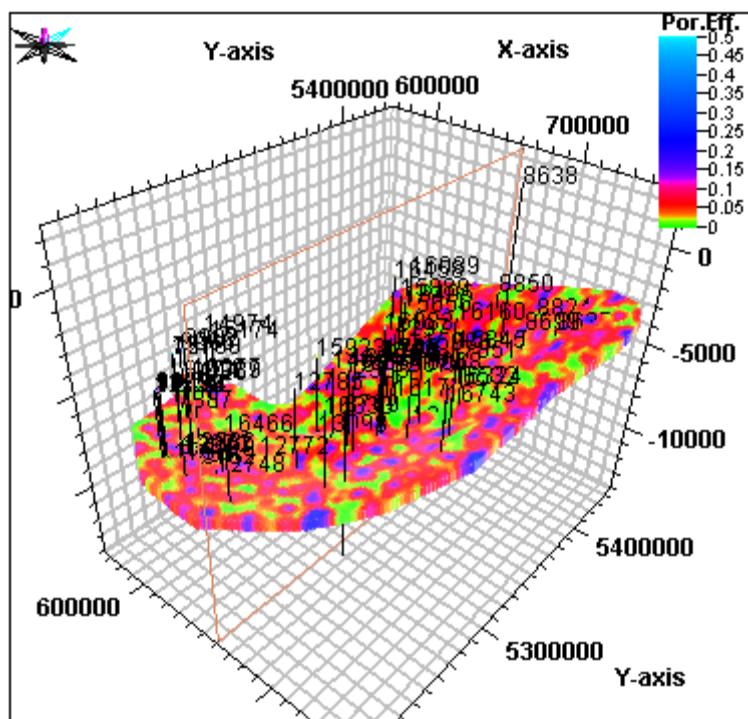

### 3.3.2 Geological modelling results

In this work, the Middle Bakken is again split into 5 layers, with the upper Bakken and lower Bakken are kept as one integrated layer, respectively, so there are 7 layers in total. However, the Lower Bakken Member pinches out in some south parts of the formation, 7 is not a fixed number for the layers in the model. The formation model is later inserted with the rock and fluid parameters exported from Interactive Petrophysics. The parameters of each 65 wells are first added into the cells that are exactly located in the wells' position, and then the Petrel populates these parameters into all cells in the 3D grid based on the simulated formation geometry and on-site conditions. Currently, the parameter added in the model is porosity (Figure 3-11). In the future, more data including permeability, oil saturation, gas saturation, water saturation, fractures, et al, can be loaded into the model. The model can be updated as new data available.

## 4. MINOR AND MICRO STRUCTURES ANALYSIS

### 4.1. RQD Based Bakken Formation Minor and Micro Fracture System

#### 4.1.1 The RQD Index

The Bakken formation is a tight reservoir with extremely low matrix permeability. Fractures in the formation can significantly improve the permeability and therefore increase the oil production rate. Fractures and cracks are observed in the borehole cores from the Bakken Formation. These fractures and cracks can be either natural fractures or induced ones due to drilling and handling. In most cases, these induced cracks occur on the planes of weakness. Therefore, similar natural and induced fractures should also exist in the productions wells penetrating through the Bakken formation. Referring to the concept of Rock Quality Designation (RQD) in geomechanics, we have collected the statistic information about the fractures and cracks on the Bakken core samples, calculated the RQD index, and visualized the results in the Petrel 3D model. The RQD index is defined as the borehole core recovery percentage incorporating only pieces of solid core that are longer than or equal to 10cm in length measured along the centerline of the core. Expressed mathematically, RQD is

$$RQD = 100 \sum_{i=1}^n \frac{x_i}{L} \% \quad \text{.....(4-1)}$$

where  $x_i$  = length of cores greater than 10 cm (standard RQD distribution) or 5 cm (non-standard RQD distribution);  $n$  = the number of these core that are greater than 10 cm or 5 cm intersected by a borehole core or scanline of length  $L$ . The higher value of the RQD index, the higher integrity the core has. On the other hand, the lower RQD index values mean the rock tends to be broken or weak. In this project, we have two sets of RQD index:  $x_i$  greater than 10 cm, and  $x_i$  greater than 5 cm. Using the International Society for Rock Mechanics (ISRM) proposed method, the 10-cm based, standard rock quality designation (RQD) of 89 wells in the study area are measured. In addition, 5-cm based, non-standard RQD are determined.

#### 4.1.2 Data Collection

The RQD information was collected from 89 Bakken borehole cores stored the Wilson M. Laird Core and Sample Library of the North Dakota Geologic Survey (Figure 4-1). Top depth of each piece of core that is longer than 10 cm is recorded in ft. The length of cores is recorded in cm. The measured data were input into the Excel sheet, and converted to the RQD index. The “L” in the RQD equation is set to be 100 cm, so the calculated interval for RQD is 100 cm. The calculation starts at the top of the measured sample, and the interval is moved down at a step of 5 cm, until the bottom of the sample. Through the calculation, a continuous RQD value along the depth was obtained for each core sample and the RQD index is presented in a form similar to the well logs used in reservoir modeling (Figure 4-2).

Figure 4-1. Photo of the borehole cores

Figure 4-2. Example of RQD index log along the depth of a core sample

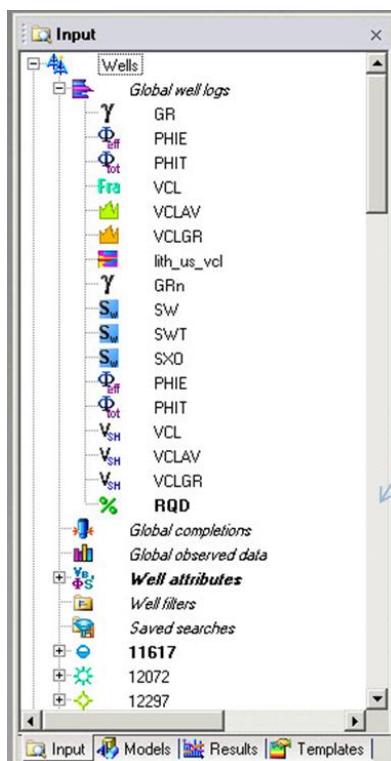

#### 4.1.3 Calculation Procedure

The steps to calculate RQD index and generate the RQD log are as follows:

- 1) The records of core size were input to the Excel. There are 2 column values: one is the depth and another is core size.
- 2) It should be noted that recovery efficiency for coring is equal or less than 100%. Under the condition of <100% recovery efficiency, some cores were lost. To be able to calibrate the total core length to penetration footage during the coring operation, which is recorded in drilling operation, lost cores are assumed to be converted to cutting and are not collected as drilling cores in the operation. It is reasonable to assume the lost cores' sizes are less than 5 cm.
- 3) The RQD is the total length of the rocks whose length are great or equal than 10 cm (or 5 cm) in the 100 cm range of penetration footage.
- 4) The first RQD index is calculated using step 3 from the top of the core interval. The RQD index is assigned in the middle of the 100cm range. Then changing the position through adding 5cm to get another RQD index.
- 5) Repeat step 4 until last RQD index is calculated.

#### 4.1.4 Populating and Visualization in Petrel 3D Model

Two sets of the RQD index ( $x_i > 5$  cm and  $x_i > 10$  cm) of the 89 core samples were then input to the 3D Model of the Bakken formation which was constructed earlier in Petrel. The RQD logs were input as a continuous property (Figure 4-3). After inserting the RQD index along the corresponding well path (Figure 4-4), Petrel upscale the value into the cells located in the well path (Figure 4-5), and then populates the parameters into all cells in the 3D grid based on the simulated formation geometry (Figure 4-6).

*RQD's unit is percent(%)*

#### 4.1.5 RQD Results

##### *10 cm based model*

The statistical results of the RQD index of the 10 cm based model are summarized in Table 4-1. Figures 4-7, 4-8, and 4-9 show the RQD index presented in the 3D model for the upper, middle and low Bakken members, respectively. Figure 4-10 is the RQD profile of North-South cross-section view and Figure 4-11 is the RQD profile of West-East cross-section view.

Table 4-1. Statistic results of RQD index, 10 cm based

Member	Mean RQD	Std RQD
Upper Bakken	37%	25%
Middle Bakken	51%	25%
Lower Bakken	27%	24%
Total Bakken	35%	24%

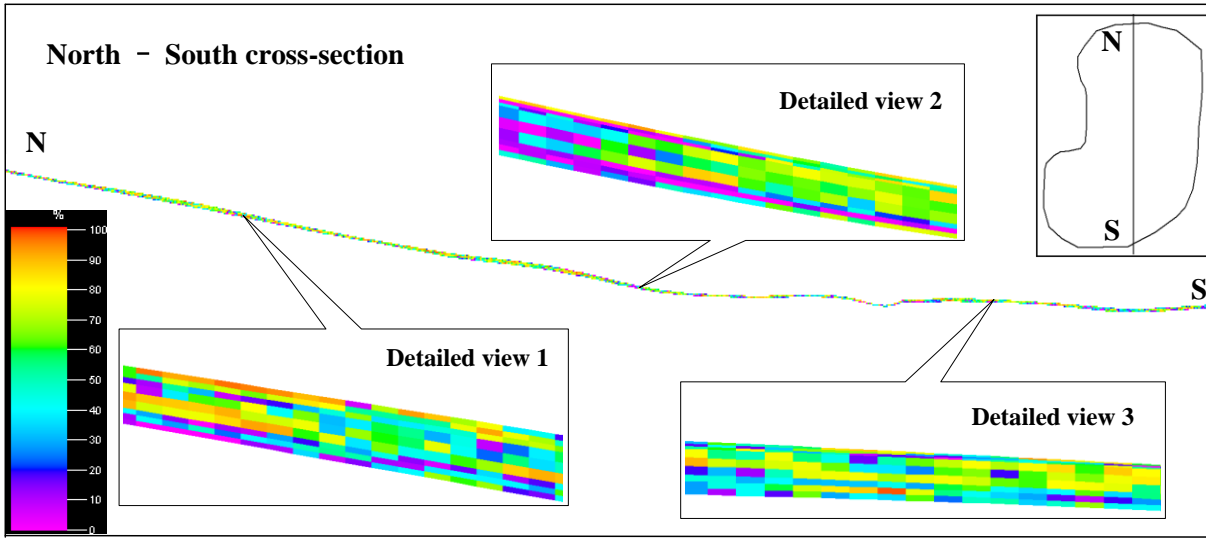

Figure 4-15. North-South cross-section view, 5cm based RQD index

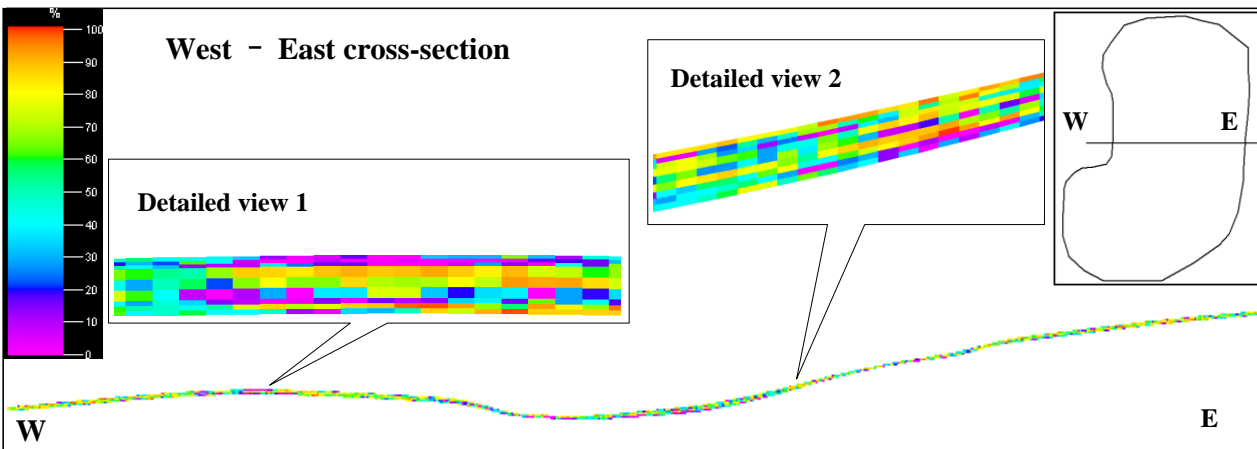

Figure 4-16. West-East cross-section view, 5cm based RQD index

#### 4.1.6 Analysis of 3D RQD Model for Bakken Formation.

In the vertical direction, RQD index is low in upper and lower Bakken formations, while middle Bakken has the highest RQD index (Figure 4-17). It should be noted that upper and lower Bakken formations are black shale and middle Bakken formation is interbedded with limestone, siltstone, and dolomite. Therefore, it is reasonable that upper and lower Bakken formations contain more discontinuity (or lower RQD index) than middle formation. From the RQD index point of view, the lower Bakken formation is the “poorest rock” or the most uncompetitive rock and should be the target of multistage fracturing in the horizontal well completion to achieve economical oil and gas production rate. However, we notice that the RQD index in this study represents the discontinuity surface in horizontal direction. In other words, it is easier to create horizontal fracture in upper and lower Bakken than in middle Bakken. Considering the depth of Bakken formation in Williston Basin as target for multistage fracturing ranges from 7000 ft to 13000 ft, the artificial fractures generated from well stimulation are mainly vertical or high angle fracture with rare case of horizontal fracture. We also observe that as a result of the lithology and mineralogy differences, upper and lower Bakken become more brittle and weaker due to dehydration and weathering after the cores are extracted from subsurface, which can cause fracture or crack along the dispositional bedding. Therefore, RQD index developed in this study should not be applied without any calibration to each unique well when RQD is used to design fracturing stimulation in Bakken formation. Based on the observation and experience in the core plug preparation, we conclude that it is easier to drill the core plug or generate fracture in vertical direction for middle

Bakken than for upper and lower Bakkens. This is one of the reasons that the industry is targeting middle Bakken formation even it is more competitive than upper and lower Bakken formations. Of course, a higher permeability in middle Bakken than those in upper and lower Bakken is another driven force.

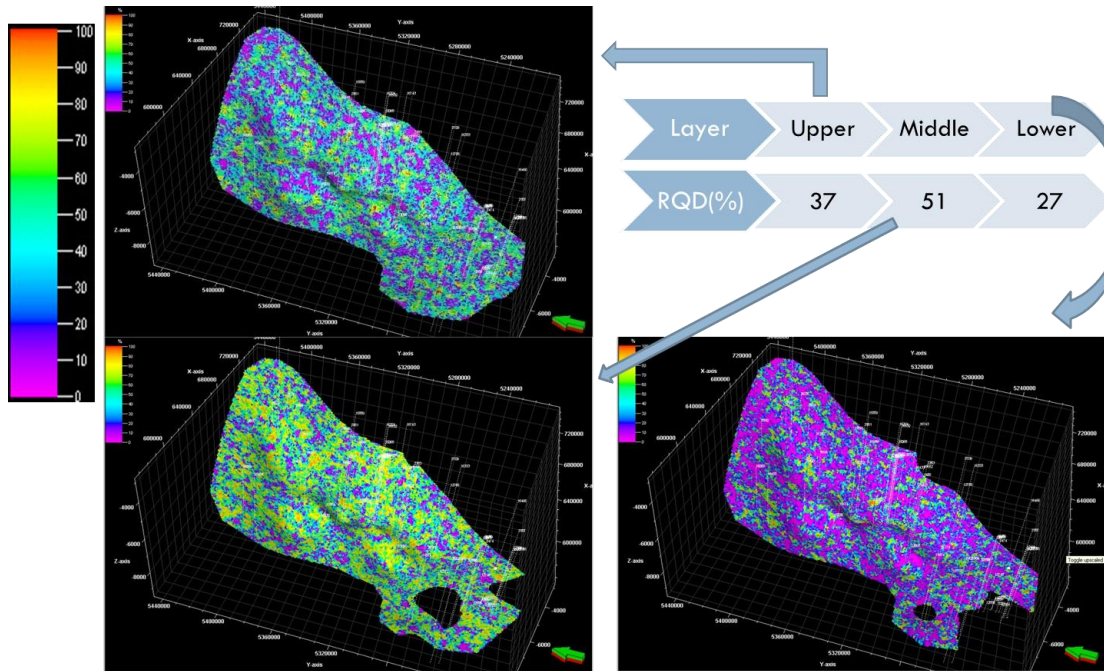

Figure 4-17. RQD index for upper, middle, and lower Bakken formations

In the horizontal direction, RQD index is low in the northern portion than in the southern portion as shown in (Figure 4-18). It should be noted that formation dip angle in north is higher than that in south, or the deformation in north is larger than that in the south, which agrees with the RQD index.

Figure 4-18. RQD index in north is lower than in south for Bakken formations

#### 4.1.7 Correlating RQD to production history.

RQD index at the downdip (or flank) of the structure is lower than that at the updip (or the structure high). Figures 4-19 and 4-20 show the 2D and 3D structure map overlapped by RQD index. We believe the flank of the structure is

more productive than the updip of structure for Bakken formation. Two wells, Well#15923 drilled at the flank of structure and Well#13098 drilled at the top of structure (Figure 4-21), are compared to show that the structure is not the key element for well targeting Bakken formation. It is shown that Well#15923 is productive while Well#13098 is dry (Table 4-3). Horizontal well (Well#15845) has a higher cumulative production than that of vertical well (Table 4-4) because horizontal well contact more discontinuity surface comparing with vertical well. It seems that drilling along the long axis of anticline (Well#16532) results in a higher productivity than drilling along the short axis of anticline (Well#16333) as depicted in Figure 4-22 and Table 4-5.

## 4.2. Bakken Wells Production Performance and RQD

### 4.2.1 Decline Curve Analysis

Decline curves are one of the most extensively used forms of data analysis employed in evaluating oil and gas reserves and predicting future production. The decline curve analysis technique is based on the assumption that the past production trend with its controlling factors will continue in the future and, therefore, can be extrapolated and described by a mathematical expression. The method of extrapolating a “trend” for the purpose of estimating future performance must satisfy the condition that the factors which caused changes in the past performance, i.e., decline in the flow rate, will operate in the same way in the future. These decline curves are characterized by three factors (Ahmed and McKinney, 2005):

- (1) Initial production rate or the rate at some particular time;
- (2) Curvature of the decline;
- (3) Rate of decline.

These factors are a complex function of numerous parameters within the reservoir, wellbore, and surface-handling facilities. Certain conditions must prevail before we can analyze a production decline curve with any degree of reliability. The production must have been stable over the period being analyzed; that is, a flowing well must have been produced with constant choke size or constant wellhead pressure and a pumping well must have been pumped off or produced with constant fluid level. These indicate that the well must have been produced at capacity under a given set of conditions. The production decline observed should truly reflect reservoir productivity and not be the result of external causes, such as a change in production conditions, well damage, production controls, and equipment failure (Ahmed and McKinney, 2005). Stable reservoir conditions must also prevail in order to extrapolate decline curves with any degree of reliability. This condition will normally be met as long as the producing mechanism is not altered. However, when action is taken to improve the recovery of oil, such as infill drilling, fluid injection, fracturing, and acidizing, decline curve analysis can be used to estimate the performance of the well or reservoir in the absence of the change and compare it to the actual performance with the change. This comparison will enable us to determine the technical and economic success of our efforts (Ahmed and McKinney, 2005). Production decline curve analysis is used in the evaluation of new investments and the audit of previous expenditures. Associated with this is the sizing of equipment and facilities such as pipelines, plants, and treating facilities. Also associated with the economic analysis is the determination of reserves for a well, lease, or field. This is an independent method of reserve estimation, the result of which can be compared with volumetric or material balance estimates (Ahmed and McKinney, 2005).

The basic concept in decline curve analysis is that the “curvature” in the production rate versus time can be expressed mathematically by one of the hyperbolic family of equations. Arps (1945) recognized the following three types of rate decline behavior (Ahmed and McKinney, 2005):

- (1) Exponential decline;
- (2) Harmonic decline;
- (3) Hyperbolic decline.

Nearly all conventional decline curve analysis is based on empirical relationships of production rate versus time given by Arps (1945) as:

$$q_t = \frac{q_i}{(1 + nD_i\Delta t)^{1/n}} \quad \dots\dots\dots (4-2)$$

where:

$q_t$  = gas flow rate at time  $t$ , MMscf/day

$q_i$  = initial gas flow rate, MMscf/day

$t$  = time, days

$D_i = bq_i^n$  = initial decline rate, 1/day

$b$  = decline coefficient, 1/ (day (STB/day)  $^n$ )

$n$  = Arps's decline curve exponent

Arps introduced this empirical relationship for a gas well, but with the use of linear and nonlinear regression techniques we can also use it for an oil well. The mathematical description of these production decline curves is greatly simplified with the use of the instantaneous (nominal) decline rate  $D$ . This decline rate is defined as the rate of change of the natural logarithm of the production rate, i.e.,  $\ln(q)$ , with respect to time  $t$  (Ahmed and McKinney, 2005):

$$D = -\frac{d(\ln(q))}{dt} = \frac{-1}{q} \frac{dq}{dt} \quad \text{..... (4-3)}$$

The parameters determined from the classical fit of the historical data, namely the decline rate  $D$  and the exponent  $n$ , can be used to predict future production. This type of decline curve analysis can be applied to individual wells or the entire reservoir. The accuracy of the entire reservoir application is sometimes better than for individual wells due to smoothing of the rate data. Based on the type of rate decline behavior of the hydrocarbon system, the value of  $n$  ranges from 0 to 1 and, accordingly, Arps's (1945) equation can be conveniently expressed in the following three forms (Ahmed and McKinney, 2005).

**Table 4-6** Different types of rate-time relationship

Case	$n$	Rate-time relationship	
Exponential	$n = 0$	$q_t = q_i \times e^{-D_i \Delta t}$	(3)
Harmonic	$n = 1$	$q_t = \frac{q_i}{(1 + D_i \Delta t)}$	(4)
Hyperbolic	$0 < n < 1$	$q_t = \frac{q_i}{(1 + n D_i \Delta t)^{1/n}}$	(5)

where  $q_t$  is the oil production rate at time  $t$ ,  $q_i$  is the initial oil production rate, and  $D_i$  is the initial decline rate (at  $t=0$ ).

In this study we use the first two methods to analyze the relation between RQD and the decline trend of the wells producing from Bakken formation in Williston Basin. The use of hyperbolic method to analyze the decline rate of the Bakken wells failed because of the divergence of the solutions. The main characteristics of these decline curves are discussed below and can be used to select the flow rate decline model which is appropriate for describing the rate-time relationship of a hydrocarbon system:

In Williston Basin 25 wells, which are producing from Bakken formation, are studied in this research (the rest of the wells either lacked some data or were not Bakken-related). First, RQD data of the wells were obtained from the core laboratory measurements. Then, the decline curve analysis was done for estimating the decline trend of each well. Efforts were made to correlate the RQD measurements with the decline rate coefficient of the wells. It's been expected that the higher the RQD, the less prolific the well (no matter horizontal or vertical well). In the following, this hypothesis is examined through the use of sophisticated mathematical methods.

**Table 4-7** Values of total RQD and Decline coefficient for each well

Well Name	10077	12160	12331	12494	12873	15674	15845	15889	15923
RQD_t	0.48	0.06	0.98	0.47	0.45	0.34	0.33	0.47	0.51
b	2.77E-05	2.97E-05	2.15E-05	2.63E-05	8.82E-05	2.08E-05	4.55E-05	1.10E-04	2.14E-04

15986	16030	16068	12162	16803	16089	16160	16174	16405
0.51	0.47	0.45	0.37	0.40	0.38	0.51	0.58	0.43
1.39E-04	1.16E-04	1.80E-05	7.85E-05	1.65E-05	9.11E-05	5.36E-04	1.61E-04	1.95E-04

16458	16532	16652	5656	7579	8251	8474	8709
0.17	0.19	0.38	0.14	0.39	0.36	0.29	0.26
1.74E-04	8.26E-06	5.38E-05	9.24E-05	3.24E-05	6.60E-05	1.57E-05	4.80E-04

#### 4.2.2 Exponential Decline Analysis

A straight-line relationship will result when flow rate is plotted versus time on a semilog scale and also when the flow rate versus cumulative production is plotted on a Cartesian scale. Regarding exponential decline, using linear regression technique we may have:

$$D = b$$

$$x_i = \Delta t$$

$$y_i = \ln\left(\frac{q_t}{q_i}\right)$$

$$y_i = -bx_i \quad \dots\dots\dots (4-4)$$

The parameter  $b$  is approximated in such a way that the error function becomes minimal (least square method).

$$s = \sum_{i=1}^N (y_i + bx_i)^2 \quad \dots\dots\dots (4-5)$$

$$\frac{\partial s}{\partial b} = \sum_{i=1}^N (y_i x_i + bx_i^2) \quad \dots\dots\dots (4-6)$$

Hence,  $b$  can be calculated by the following formula:

$$b = -\frac{\sum_{i=1}^N y_i x_i}{\sum_{i=1}^N x_i^2} \quad \dots\dots\dots (4-7)$$

#### 4.2.3 Harmonic Decline Analysis

Harmonic decline equation in **Table 4-6** describes the rate-time relationship in harmonic decline case. Since it is not possible to build any linear relationship between rate and time neither in Cartesian nor in logarithmic system, we have to use another technique to approximate the decline coefficient of the wells. The method of nonlinear regression is used to determine the decline rate and the decline coefficient by analyzing the production data since the time point

at which the production rate of the wells started to decline. Therefore, the time difference ( $\Delta t$ ) is defined as any time increment from that time onward. The following mathematical procedure has been coded by computer programs to obtain the decline coefficient for all the wells:

$$\begin{aligned} D_i &= bq_i \\ x_i &= \Delta t \\ y_i &= \frac{q_t}{q_i} \end{aligned} \dots\dots\dots (4-8)$$

where  $b$  is the decline coefficient, and  $D_i$  is the initial decline rate to be determined. We should obtain  $D_i$  such that the series in Equation 4-10 becomes minimal. This is the basic element of nonlinear regression technique. To obtain such value for  $D_i$  the following calculations are established:

$$s = \sum_{i=1}^N \left( y_i - (1 + D_i x_i)^{-1} \right)^2 \dots\dots\dots (4-9)$$

$$\frac{\partial s}{\partial D_i} = f(D_i) = \sum_{i=1}^N \left( \frac{x_i \left( y_i - (1 + D_i x_i)^{-1} \right)}{(1 + D_i x_i)^2} \right) \dots\dots\dots (4-10)$$

The Jacobian matrix of the objective function is also obtained by applying Equation 4-11.

$$J = \left[ \frac{\partial f}{\partial D_i} \right] = \left[ \sum_{i=1}^N x_i^2 \frac{\left( 1 - 2(1 + D_i x_i) \left( y_i - (1 + D_i x_i)^{-1} \right) \right)}{(1 + D_i x_i)^4} \right] \dots\dots\dots (4-11)$$

and here is the objective function to be minimized:

$$f(D_i^*) = \sum_{i=1}^N \left( \frac{x_i \left( y_i - (1 + D_i x_i)^{-1} \right)}{(1 + D_i x_i)^2} \right) = 0 \dots\dots\dots (4-12)$$

$$D_i^* = D_i + dD_i \dots\dots\dots (4-13)$$

$D_i$  is the first guess and  $dD_i$  is the difference between the first guess and the first result which can be obtained from Equation 4-15. To obtain this difference we use the Taylor series (in the following equations [ ] refers to matrix):

$$\begin{aligned} f(D_i^*) &= f(D_i) + \frac{\partial f(D_i)}{\partial D_i} \times dD_i = f(D_i) + \left[ \frac{\partial f(D_i)}{\partial D_i} \right] [dD_i] = 0 \\ \Rightarrow [f(D_i)] &= - \left[ \frac{\partial f(D_i)}{\partial D_i} \right] [dD_i] \end{aligned}$$

where :

$$\left[ \frac{\partial f(D_i)}{\partial D_i} \right] = Jacob = J \dots\dots\dots (4-14)$$

From these equations we may have:

$$\begin{aligned}
[f(D_i)] &= -J[dD_i] \\
\Rightarrow [dD_i] &= -J^{-1}[f(D_i)] \\
\text{where:} \\
[dD_i] &= [D_i^*] - [D_i] \\
\Rightarrow [D_i^*] - [D_i] &= -J^{-1}[f(D_i)] \dots\dots\dots (4-15)
\end{aligned}$$

where the definitions of  $[D_i]$  and  $[D_i^*]$  are as follows:

$$\begin{aligned}
[D_i] &= [D_i]^k \quad \text{the first guess!} \\
[D_i^*] &= [D_i]^{k+1} \quad \text{the first result!} \\
[D_i]^{k+1} - [D_i]^k &= -J^{-1}[f(D_i)] \dots\dots\dots (4-16)
\end{aligned}$$

Therefore, the following trial-error relationship can be established between the guesses and the results in many iterative steps of calculations:

$$[D_i]^{k+1} = [D_i]^k - J^{-1}[f(D_i)] \dots\dots\dots (4-17)$$

where  $J^{-1}$  is the inverse of Jacobian matrix, and  $k$  denotes the number of calculation steps after assuming a starting guess. This iterative computation is repeated until the relative difference between the values of  $D_i$  at any two consecutive computation steps becomes smaller than a specified value. To check this relative error the following is used:

$$\begin{aligned}
\text{norm} &= \sqrt{\sum_{i=1}^N f_i^2} \\
\text{here } N &= 1 \\
\Rightarrow \text{norm} &= f \dots\dots\dots (4-18)
\end{aligned}$$

If the norm is higher than a specified value, the calculations proceed until an acceptable norm is achieved. There is also another criterion which should be fulfilled, that is:

$$\begin{aligned}
\text{norm}_2 &= f([D_i]^{k+1}) \\
\text{norm}_1 &= f([D_i]^k) \\
\Rightarrow \\
\text{norm}_2 &\prec \text{norm}_1 \dots\dots\dots (4-19)
\end{aligned}$$

At any step this condition should hold, unless otherwise Equation 4-17 should be modified as the following:

$$[D_i]^{k+1} = [D_i]^k - J^{-1} s [f(D_i)]$$

$$s = \frac{\sqrt{1+6\eta} - 1}{3\eta}$$

where

$$\eta = \frac{norm_2}{norm_1}$$

.....(4-20)

This process has been programmed in MATLAB, and this procedure has been accomplished for all the wells listed in Table 4-7 and the results of a handful of the wells are illustrated in Figures 4-23 through 4-28 (in these figures  $q_o$  is oil production rate and  $q_{oi}$  is the initial oil production rate).

Figure 4-23. Real data vs. Exponential and Harmonic decline approach (well 15674)

Figure 4-24. Real data vs. Exponential and Harmonic decline approach (well 15674)

Figure 4-25. Exponential vs. Harmonic decline approach (well 15674)

The same results for another well (well 15986) are obtained and are shown below:

Figure 4-26. Real data vs. Exponential and Harmonic decline approach (well 15986)

Figure 4-27. Real data vs. Exponential and Harmonic decline approach (well 15986)

Figure 4-28. Exponential vs. Harmonic decline approach (well 15986)

Using Equation 4-3 and rearranging harmonic decline equation, led us to Equation 4-21. From this we may conclude that the more the decline coefficient ( $b$ ), the more the decline rate ( $D$ ). This is clearly illustrated in Figure 4-29.

$$D = \frac{b q_{oi}}{(1 + b q_{oi} \Delta t)} \dots\dots\dots (4-21)$$

Figure 4-29. Effect of Decline coefficient on decline rate

#### 4.2.4 Relation between Production Decline and RQD

Due to the reasons mentioned above, we may expect that the more the decline coefficient, the higher the RQD of a well. This makes sense since the higher RQD generally means the less number of fractures or fissures along the centerline of the core. In Figure 4-30 this hypothesis is investigated.

Figure 4-30. Decline coefficients of wells vs. RQD

In Figure 4-30  $b$  is the decline coefficient which is shown on the ordinate. The values of this parameter for all the wells were obtained and are plotted versus their corresponding RQD values in Figure 4-30. The trend line in this graph is calculated by the linear curve fit method. It is clear that the relationship between decline coefficient and RQD conforms well to the linear trend line. It means that the higher RQD, the higher decline coefficient and the higher decline rate, accordingly.

Based on the study described above, we can now conclude that the value of RQD of the wells- producing from Bakken formation is related reversely to the wells performance. It might be applicable to delineate the degree of fracturing in the Bakken wells along with to make comparisons among the producing wells.

## 5. MAPPING OF PALEO IN-SITU STRESSES

### 5.1. Geological Settings

The Bakken formation is a tight oil play with continuous oil accumulation. Fractures play an important role in both exploration and production of the oil. As considered to be one of the most promising plays in the world, oil production from the Bakken largely depends on presence of natural or artificially-created fractures. There also exist arguments about the oil migration patterns in and out of the Bakken. This study reviews the tectonic history of the Williston basin, North Dakota, USA, and a numerical model of the study area has been built to reconstruct the paleostress under the far-field effect of the Laramide orogeny in late Cretaceous. The modeling results show that tensile horizontal stress was developed in most parts around the Nesson master fault in the study area during the Laramide event, and tensile fractures are very likely to be generated in the north and south sides of the fault. These tensile fractures could enhance the reservoir quality in both porosity and permeability. Zones of possible fracture development are identified based on the stress profile. In the fault zone, the paleostress has a lower magnitude of compressive stress than that in the host rock, so driving force may be provided to push the oil migrate from the host rock to the fault zone. However, after the hydrocarbon accumulated in the fault, fractures presented around the fault may function as additional pathways for migration again.

The Nesson anticline is a major north-trending structural feature located near the center of the Williston Basin (Figure 5-1). The anticline is created by a drag fold and its deformation is controlled mainly by movement on a major normal fault beneath the west side of the anticline crest. The Nesson anticline is about 175 km long, with nearly continuous production along a north-south line from just south of Canadian border (T163N) to the Killdeer Mountains (T146N), south of the Missouri River. Nesson master fault bounds the structure from Beaver Lodge Field (T156N) to just south of T150N, with its west side downthrown. (Lindsay et al., 1988). The Nesson anticline has a large bifurcation on its southeast side – the Antelope anticline (Figures 5-1 and 5-2). The Antelope anticline trends NW-SE, with a much smaller size comparing to the Nesson anticline. Antelope fault occurs along the northeast side of the Antelope anticline, with its northeast side downthrown. The Antelope fault is thought to have affected Devonian and younger strata (Lindsay et al., 1988).

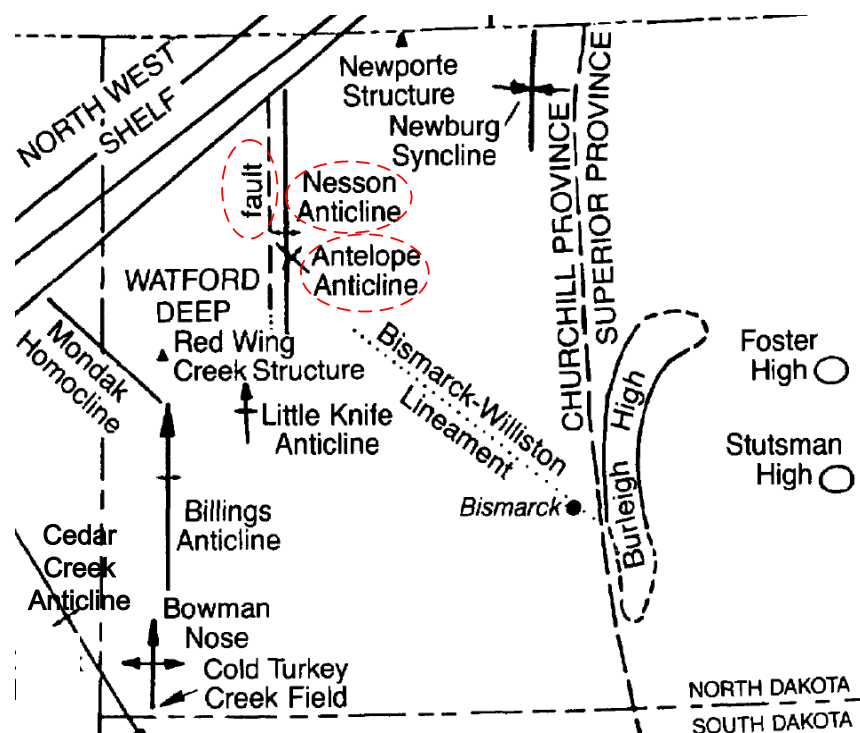

Figure 5-1. Major structural features of the Williston basin, North Dakota portion (After Gerhard et al., 1990).

Figure 5-2. Cross section view of the Nesson anticline and Antelope anticline (after Meissner, 1978).

Presences of the Nesson master fault and the Antelope fault can influence the local in situ stress field. Both the magnitude and the direction of the in situ stress in the fault zone differ from those in the host rock (Gudmundsson et al., 2010). The Nesson anticline area has the most intensive oil production in the Williston basin. Horizontal drilling and hydraulic fracturing are extensively applied in this area. It is of great interest to understand the distribution of the natural fractures and the in situ stress in this region.

The characteristics of the natural fractures, especially origination mechanisms, in the Bakken formation have been investigated by many researchers (Pitman et al., 2001; Meissner 1978; Murray 1968; Druyff, 1991; Mullen et al., 2009; Stockton, 2009; Warner, 2011). As early as 1968, Murray (1968) applied the curvature method to study the fracture development in the Devonian Sanish pool in the Antelope field, and the contribution of the natural fractures to reservoir quality. In general, natural fractures in the Bakken formation can be categorized into three types according to different origination mechanisms: 1) fractures caused by tectonic stress; 2) fractures as a result of regional stress; and 3) fractures associated with super-lithostatic pressure increase due to the hydrocarbon expulsion during maturation. The Bakken is also regionally overpressured and featured with a very high pore pressure. Documented fluid-pressure gradient is as high as 0.73psi/ft (16.5 kPa/m) in the Antelope filed. These high pressures are discretely confined to the Bakken interval Meissner (1978) and are beneficial for oil production.

## 5.2. Tectonic History of the Basin

The Williston Basin is one of the four cratonic basins in North America (Bally, 1989). They are different from the other two types of most basins were formed due to extensional and/or compressional deformation of the sedimentary rocks. Cratonic basins were formed mainly due to large scale deposition of sedimentary rocks that covers one or more cycles of complete marine transgressive-regressive process.

The basin is neither structurally complicated, nor tectonically active. To better understand the basin, it is essential to study its tectonics. From tectonic point of view, the Williston Basin is composed of two parts: the hard basement and the relatively soft sedimentary top deposits. The structural geology and part of the geomechanical properties (i.e., in-situ stress) of the sedimentary formations, including Bakken formation, are largely influenced (controlled) by the geological features of the basement.

### 5.2.1 The Basement

The Williston basin basement includes five major components. From east to west in a plan view, these five components are (Green, 1985; Fischer et al., 2005): (1) the Superior craton, (2) the Archean- Proterozoic Thompson boundary zone, (3) the Proterozoic island arc massifs, (4) the Trans-Hudson orogenic belt, and (5) the Wyoming craton, as shown in Figure 5-3.

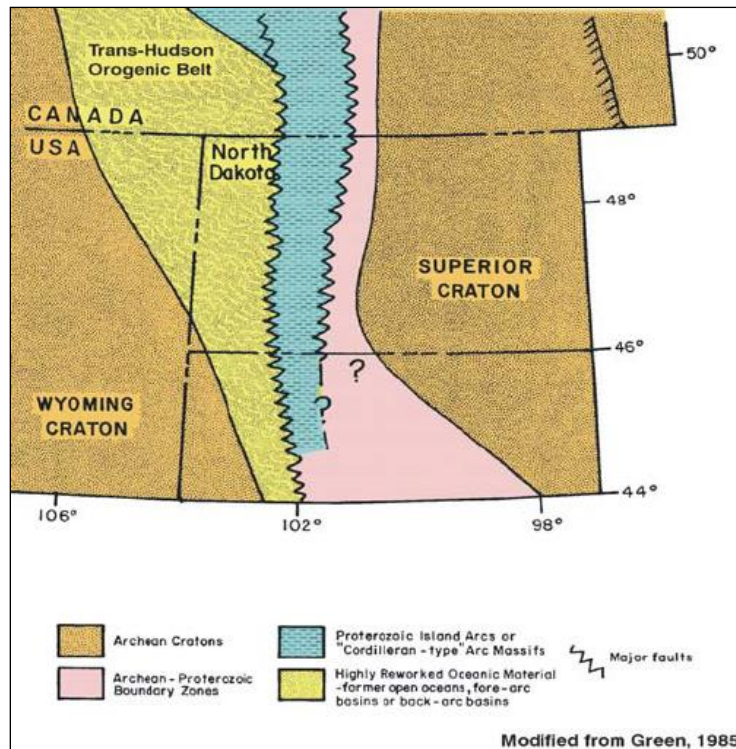

Figure 5-3. Basement terrain of the Williston basin (after Fischer et al., 2005).

The two cratons are of Archean Eon and represent proto-continents. They are separated by oceanic sediments in the Archean- Proterozoic Thompson boundary zone, the Proterozoic island arc massifs, and the Trans-Hudson orogenic belt. Rocks of the Superior craton underlie most of eastern North and South Dakota, as well as Manitoba, and consist primarily of granites and greenstones. The Wyoming craton underlies eastern Montana, western Saskatchewan, western South Dakota, and southwestern North Dakota. It consists of quartz-rich rocks, including gneisses. Both cratons are approximately the same age.

The Archean- Proterozoic Thompson boundary zone and the Trans-Hudson orogenic belt underlie most of western North Dakota. Sediments of these two components are composed of oceanic materials that accreted between the active continental margins the two cratons (Green et al., 1985).

The Proterozoic island arc massifs represent highly reformed oceanic materials from former open oceans and fore-arc or back-arc basins as well as rocks believed to be associated with island arc formation. Basement rocks in these massifs are interpreted as representing the initially rifting between the two cratons, and later their collision, which clearly shows the instability of the craton during that time. The collision formed a north-south oriented structure that comprises an underlying vertical and sub-vertical faulting system etching on the basement. The relatively strong massifs formed subsurface highs which initiated the anticlines in the overlying sedimentary rocks.

## 5.2.2 The Lineament Structures

The basement is can be further divided into blocks by a series of tectonic features, referred to as lineaments (Figure 5-4). Lineaments are best defined as linear zones of structural weakness. Similar to faults, lineaments are believed to be responsible for the origin of structures and depositional patterns within the sedimentary formations in the basin. Lineaments are important component in the formation of the basin. They were formed in response to external stresses and, once formed, served as conduits to transmit and release stresses through deformation.

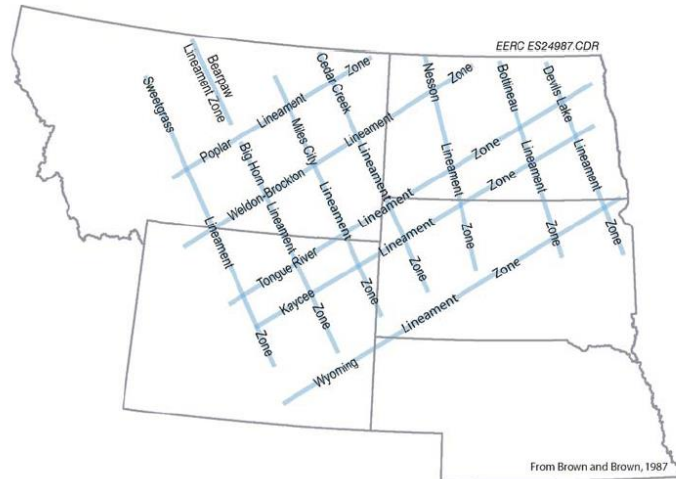

Figure 5-4. Major Paleozoic structural lineaments (after Fischer et al., 2005).

The Williston basin may have formed as a sag on the cratons in response to a left lateral shearing movement between two regional lineaments: the Weldon–Brockton and the Wyoming lineaments (Gerhard et al., 1982). Some in-depth study shows major structural lineaments were observed on the Landsat image with orientations of 70 degrees and 120 degrees (Figure 5-5). These observations confirmed the lineaments in Figure 5-4. The lineaments are surface expressions of major structural features in deep basement rocks of the Williston basin.

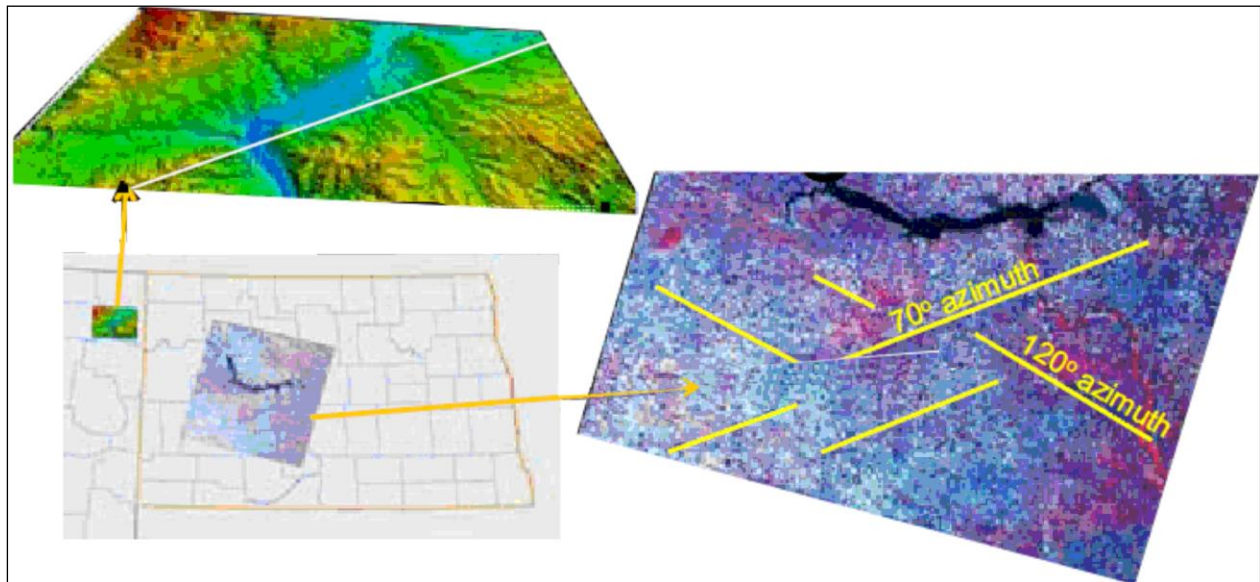

Figure 5-5. Major structural lineaments in satellite imagery (after Abbott et al., 2009).

Other tectonic features in the Williston basin include faulting and folding. These features formed in response to either subsidence or the sporadic movement of individual linearly-bounded basement blocks.

### 5.2.3 The Faults

Due to the cratonic feature, faulting in the Williston basin is less intensive in comparing to other Rocky Mountain basins. Some faults, such as those on the west flank of the Cedar Creek Anticline (Clement, 1987), the west flank of the Nesson Anticline, and the Heart River Anticline, are identifiable on a seismic survey (Figure 5-6). Seismic image

shows that these faults are near vertical. Clement (1987) further reported that faults along the Cedar Creek Anticline have undergone recurrent near-vertical shearing.

There might be two mechanisms for the vertical and sub-vertical faulting. The two cratons and the massifs are relatively strong terrains. While the two cratons defined the east and west boundaries of the basin, the massifs formed the subsurface highs. The Thompson boundary zone and the Trans-Hudson Orogenic belt are relatively soft rock bodies. Differential vertical movements might have been occurring during the Paleozoic eon in responding to the adjustment of the five basement components. On the other hand, during the deposition process, differential compaction of the sediments on top of the subsurface highs (massifs) and lows (the Thompson boundary zone and the Trans-Hudson Orogenic belt) could have been existing.

Figure 5-6. Seismic image across Heart River Anticline, Stark County, North Dakota (after Fischer et al., 2005).

### 5.2.4 The Folds

As mentioned above, the subsurface highs formed in the basement have initiated the formation of folding structures such as the Nesson Anticline, the Little Knife Anticline, the Billings Anticline, the Cedar Creek Anticline, and the Poplar Dome (Figure 1-1). Throughout time, the basin might have responded to local and regional orogenic events to further shape these folding structures.

## 5.3. Tectonic History of the Nesson Anticline

Different explanations have been proposed about the tectonic history of anticlines in the Williston basin. Redly and Hajnal (1995) proposed that these foldings are formed as a result of the subsidence of the basin. They considered that subsidence of a circular segment of a spherical surface, such as the Williston basin, gave rise to two types of folding:

circular folding at the dynamic rim, and radial folding at the central part. According to their description, the Cedar Creek anticline, with a proven ENE dipping (basin center direction) western boundary fault, is an example of circular folding. The Nesson anticline, which is toward to the center of the basin, is a radial folding. However, most of other studies consider that the fold structures in the basin are the result of deep basement-linked normal faults reactivated several times during the Paleozoic. We tend to agree with this explanation and follow this explanation in the modeling process presented in this paper. The tectonic history of the Nesson anticline is given as following.

The Nesson anticline is created by a drag fold and its deformation is controlled mainly by the vertical movement along the normal Nesson master fault beneath the west side of the anticline crest (Figure 5-1). This fault system has been present and active since Precambrian time. The Nesson anticline underwent periodic deformations through the history of the Williston basin. The most recent and strongest reactivation of the fault occurred in response to the Laramide orogeny during late Cretaceous (Gerhard et al., 1990; Lindsay et al., 1988; Meissner, 1978; Warner 2011; Thomas, 1974; Brown and Brown, 1987; Gerhard et al., 1987). This event is thought to have largely resulted in the current structure of the anticline, and the tectonic stress may have induced natural fractures. The detailed stress model used to explain the behavior of the fault and consequent deformation is described below.

In the Williston basin, a series of basement-weakness zone, represented as lineament at the surface, trend northeasterly and northwesterly. These weakness zones define a framework of basement blocks. These basement blocks and bounding weakness zones appear to have influenced the development of structural features in the basin. The Nesson fault is located on the Weldon basement which trends northeasterly (Figure 5-7). In late Cretaceous, the Laramide orogeny provided regional compressive stresses from the southwest, and the response of the basement blocks to the Laramide tectonics can be analyzed by analogy to a hypothesized cardboard model (Figure 5-8). According to the simple shear model proposed by Thomas (1974) and the wrench-style deformation model proposed by Brown (1978), the regional stress regime created the dominant left-lateral adjustment on the northwesterly trending blocks, and the subordinate right-lateral adjustment on the northeasterly trending blocks. Therefore, the Weldon block, where the Nesson anticline is set, subjected to a right-lateral adjustment and experienced right-lateral stress and tensile stress during the Laramide event (Figure 5-8). This stress profile in the block rejuvenated the vertical displacement along the Nesson master fault (Figure 5-9). Gerhard et al. (1987) described that during the event, the master fault has a down-to-the-west displacement of about 120 m, while the Antelope fault appears to have been relatively quiescent. The vertical offset resulted in the fold-drag deformation and set the current structure of the anticline. It is worthy of noticing the descriptions given by Pilcher et al. (2009) that the structural features with NW-SE trend, such as the Antelope and Cedar Creek anticlines, were oriented optimally and strongly inverted by the Laramide tectonics. However, in this modeling work, we consider that the Antelope anticline is relative quiescent with minor displacement.

Figure 5-7. Basement blocks of the Williston-Blood Creek basin. Highlighted by the red dash lines is the northeasterly trending Weldon block, where the Nesson anticline lays on (After Warner, 2011; Thomas, 1974).

Figure 5-8. Regional stress applied on the basement blocks during the Laramide orogeny, and response of the northeasterly trending blocks and northwesterly trending blocks, according to the simple shear model (After Thomas, 1974).

Figure 5-9. The Laramide orogeny tectonics rejuvenated the vertical movement of the Nesson master fault, and resulted in the drag-fold deformation.

It is also believed that, during late Cretaceous, or even until early Tertiary, the Bakken was buried to its maximum depth within the oil window, as shown in Figure 5-10 (Pitman et al., 2001; Flannery and Kraus, 2006; Warner, 2011). It is very possible that the fold deformation and oil maturation occurred at the same time, and it is likely that tensile fractures could be generated during the Laramide event. Comparing to shear fractures, tensile fractures are more beneficial to reservoir quality due to their higher conductivity. On the other hand, the presence of the Nesson master fault and Antelope fault would change both the direction and magnitude of the local principal stresses, influencing the distribution and orientation of natural fractures around the faults. The tensile fractures would also function as pathways for mature hydrocarbon to migrate out of the Bakken. This paper uses finite element method (FEM) to reconstruct the paleostress during the Laramide event in Nesson anticline area based on the information from previous studies. With the simulated paleostress profile, possibility of development of natural fractures is discussed.

## 5.4. Elastic Properties

### 5.4.1 Overview of previous testing

#### *Wells cored for testing*

In order to study the geomechanical parameters of the Bakken formation: (1) uniaxial compressive strength (UCS); (2) cohesion and angle of internal friction; (3) Young's modulus and Poisson's ratio; (4) triaxial strength under different confining pressures; (5) Biot's coefficient; (6) fracture gradient; (7) dynamic elastic parameters; and (8) elastic wave velocities., we must select the specimen from different wells at different depth so as to make profound insights into this aspect. Among all the screened wells, Bakken shales in seven wells were cored and tested. The cored specimens from four wells were used for all-purpose parameter testing, and the core specimen from the other three wells were adopted to do the express geomechanical testing to gain UCS. **Figure 5-11** indicate the geographic location of each testing well.

**Table 5-1** Test contents for each well

Well #	Well Name	Testing contents	Well completion report
WT1	SARAG BARSTAD 6-44H	UCS*	15889 (NDIC, 2007a)
WT2	J.HORST 1-11 H	UCS	15986 (NDIC, 2006)
WT3	ANDERSON SMITH 1-26H	UCS	16083 (NDIC, 2007b)

### 5.4.2 Overview of testing methods and instruments

#### *Procedures for triaxial compressive strength test with ultrasonic velocities*

The general procedures for triaxial compressive test with ultrasonic velocities are summarized in the following:

- (1) A right cylindrical plug is cut from the sample core and their ends ground parallel according to International Society for Rock Mechanics (ISRM) and American Society for Testing and Materials (ASTM) standards. A length to diameter ratio of 2:1 is recommended, to obtain representative geomechanical properties of the sample. Physical dimensions of the specimen are recorded and the specimen is saturated with simulated formation brine.
- (2) The specimen is then placed between two endcaps and a thermal-shrink jacket is placed over the specimen.
- (3) Devices for axial and radial strains are mounted in the endcaps and on the vertical surface of the specimen, respectively.
- (4) The specimen assembly is placed into the pressure vessel and brought into contact with a loading piston that allows application of axial load.
- (5) Confining pressure is applied to the desired hydrostatic testing pressure.
- (6) Ultrasonic velocities are measured at the hydrostatic confining pressure.
- (7) Increase axial load at a constant rate until the specimen fails or axial strain reached a desired amount of strain while confining pressure is held constant.
- (8) Reduce axial stress to the initial hydrostatic condition after sample fails or reaches a desired axial strain.
- (9) Reduce confining pressure to zero and disassemble sample.

#### *Core-Based Strength (CBS) logging test*

Benefits of using Brinell Hardness (BH) in identifying Core-Based Strength (CBS) logs include:

- (1) Generates the relative strength along the length of the core;
- (2) Identifies the weakest areas over large depth intervals;
- (3) Provides a non-destructive strength profile vs. depth;
- (4) Provides high resolution logs with multiple rock mechanical parameters (UCS, BH);
- (5) A helpful guide in determining which areas require additional core analysis;

The Brinell Hardness test can be performed on samples with a variety of shapes and sizes. Brinell Hardness is a measure of the resistance of the rock to indentation and has a direct correlation to rock strength. The test apparatus is shown in **Figure 5-12**. The Brinell hardness test is performed by applying measured load to a spherical steel-ball (indenter) that is in contact with the sample. The depth of ball penetration is recorded along with applied load. The hardness value is determined from the ratio of applied load to the indentation area and is expressed as  $\text{kg/mm}^2$  or in other units.

Figure 5-18. Shear and Mohr-Coulomb analysis for sample set 2-24VRM from WT7 (NDIC, 2010)

To check if there exists depth-dependent distribution of the measured geomechanical properties and depths, these properties are plotted against depth. Figures 5-19 through 5-25 show these results.

Figure 5-19 Uniaxial compressive strength vs. depth

Figure 5-20. Elastic modulus vs. depth

Figure 5-21. Poisson's ratio vs. depth

Figure 5-22. Biot's coefficient vs. depth

Figure 5-23. Dynamic modulus vs. depth

Figure 5-24. Dynamic Poisson's ratio vs depth

Figure 5-25. Ultrasonic wave velocities vs. depth

According to the analysis, all the measured geomechanical properties are rather scattered. There is no correlation between the properties and depth directly. Because lithology and ingredients vary unpredictably, the scattering of all these parameters surely is the result of variation of lithology and anisotropy of the rock mass around these test wells. The ranges of these geomechanical properties of the Bakken shales are as follows.

- (1) For UCS of Bakken shale, the value varies between 4,000 and 6,000 psi.
- (2) For the triaxial compressive strengths, the value varies between 20,000 and 45,000 psi under confining pressures that corresponding the core depths.
- (3) For the static Young's modulus determined with triaxial tests, the value varies between  $3.5 \times 10^6$  and  $6.5 \times 10^6$  psi.
- (4) For the Poisson's ratio determined with triaxial tests, the values fall between 0.25 and 0.45.
- (5) For the Biot's coefficient, although only limited number of values are available, most values are between 0.7 and 0.8.
- (6) For the dynamic Poisson's ratio, most values are between 0.25 and 0.35.
- (7) For the dynamic modulus, the shear modulus varies within a narrow range from  $2 \times 10^6$  to  $4.5 \times 10^6$  psi, but the dynamic bulk and Young's moduli vary in a rather large range.
- (8) For the elastic wave velocities, the shear wave velocity varies between  $0.7 \times 10^4$  and  $1.1 \times 10^4$  ft/sec, and the compressional wave velocity varies between  $1.4 \times 10^4$  and  $2.1 \times 10^4$  ft/sec.

Other works to measure in-situ stress and related properties of the Bakken formation include Jia et al., 1996; Chu et al., 2008; Fu et al., 2009; Beekman et al., 2000; Zhao and Muller, 2001; Gundmumdsson et al., 2010. Comparing the current experimental results on Bakken samples obtained by our group and other available information (Crammer, 1992; Spikes, 2011; Haven, 2011; Kuhlman et al., 1992; Reynolds et al., 2002; Wang and Zeng, 2011), Young's modulus and Poisson's ratio used in this model are determined as in Table 5-5.

Table 5-5. Elastic properties of different materials used in the model

Material No.	Geological portion	Young's modulus	Poisson's ratio
1	Fault core	5 GPa	0.32
2	Damage zone	10 GPa	0.27

3	Host rocks	45 GPa	0.27
---	------------	--------	------

### 5.5. Modeling of the Paleo In-Situ Stress

The finite element modeling package ANSYS (2010) is used in this study. The shell element provided by ANSYS can well model the stress and strain profile of the geological formation. In numerical modeling, the fault usually is modeled as a weak zone, with a lower Young's modulus and higher Poisson's ratio comparing to the host rock. Gundmundsson et al. (2010) suggest that a fault zone can be modeled as a core in the center, sandwiched by damage zones on both sides. The modeling area should be set large enough to offset the impact of boundary conditions to the results. The main modeling part of the three dimensional model is a rhomboid in plan view with a side length of 120 km, and a rectangle in side view with a thickness of 1 km, starting from the basement of the basin to the top of the Bakken formation. The structure of the main block is shown in Figure 5-26. As the cardboard model described above (Figure 5-8), the blocks in the basin interacted with each other under the far-field effect of the Laramide tectonics. The Weldon block would subject to compressive and frictional forces from its neighboring blocks. Therefore, two rectangular blocks, A and B, are added and contact with to rhombic block on its north and south sides. The two additional blocks provide compressive and frictional effects from the neighboring blocks (Figure 5-27).

The Nesson master fault (about 60 km long) and the Antelope fault (about 25 km long) are put in the center of the model. The Nesson fault is represented by a fault core sandwiched by two damage zones. The Antelope fault is modeled as a damage zone because of its smaller size. Material attributes are listed in Table 5-5 and shown in Figure 5-28. In the model, 6-node and 8-node shell elements are used.

Displacement constraints on X and Y directions are applied on the northeast and southwest corners of the additional blocks. A vertical pressure of 70 MPa is applied to simulate the overburden pressure. Horizontal stress is applied on the three lateral faces of the additional blocks A and B. Therefore, right lateral force, or frictional forces can be provided on the contact surface between the main rhombic block and the additional blocks. To account the driving force from the corners of neighboring blocks, we add four concentrated forces at each corner of the main block, pointing to the SE, SW, NW and NE directions respectively (Figure 5-27). The applied stresses and forces are adjusted until the offset between the east and west of the Nesson master fault reaches about 120 m as described in the literature (Gerhard et al., 1987).

Figure 5-26. Structure of the main rhombic block in the three dimensional model, with exaggeration in the Z (vertical) direction.

## 5.6. Modeling Results

The modeling results show that, during the Laramide event, the maximum principal stress is in the vertical direction, and the other two principal stresses are horizontal. Figure 5-29 shows the contour maps of the minimum horizontal stress, maximum horizontal stress, vertical stress and stress intensity. The stress intensity is defined as  $(\sigma_1 - \sigma_3)$ , corresponding to two times of the maximum shear stress in geological convention (ANSYS, 2010). For the horizontal stress from Figures 5-29a, 5-29b, 5-29c, and 5-29d, it can be seen that tensile stress (negative value) was developed in most parts around the fault. Stresses of lower magnitude (larger tensile stress) appear in north and south of the Nesson master fault. The lowest value (maximum tensile stress) is less than -12 MPa just next to the north and south ends of the fault. There is an obvious change of the stress magnitude in and out of the fault zone. The presence of the faults, especially the Nesson master fault, has a significant impact to the magnitude of the vertical and horizontal stresses. In general, stresses in the fault zone have a lower value than those in the host rock. This is consistent to other researchers' modeling results (Gudmundsson et al., 2010).

According to Kuhlman and Claiborne (1992) and Haven (2011), it can be assumed that the tensile strength of the Bakken shale is about 6 to 9 MPa. Based on the magnitude of the minimum horizontal stress, zones of possible tensile fracture development can be recognized. Due to the accuracy of the model, it is hard to say that fracture zones can be accurately identified. However, it is fair to say that the lower the tensile stress value, the more likely the tensile fractures could be generated. Therefore, we classify the possible fractural zones as Class I and II (Figure 5-31). Class I refers to areas with the very low value of minimum horizontal stress ( $< -6$  MPa), so tensile fractures are developed in this zone. Class II refers to areas with minimum principal stress between -3 and -6 MPa. Tensile fractures are less developed in this zone. In zones of Class I and II, porosity and permeability could be enhanced by the fractures, and these zones are likely form "sweet spots" in the reservoir. For other areas with minimum principal stress of negative values, some tensile fractures probably exist in this zone, but not in large scale.

Figure 5-29c. Contour map of vertical stress.

Figure 5-29d. Contour map of stress intensity.

Figure 5-31. Possible zones for natural tensile fracture development.

Figures 5-32 to 5-34 show the maps of trajectories of maximum horizontal stress in areas around the north, middle and south portions of the Nesson master fault respectively. Due to the existence of the lateral force, the direction of the principal stresses varies across the study area. However, in general the maximum horizontal stress is in NNW direction, and the minimum horizontal stress is in ENE direction. Therefore, if any possible tensile fractures were generated under the effect of the Laramide event, the fracture should be in the NNW direction, parallel to the maximum horizontal paleostress. This modeling result agrees with the hydraulic fracturing test result conducted by the Bakken Research Consortium (Headington Oil LLC and XTO Energy Inc, 2008; Dow, 1974). The project area is in Section 36-T156N-R95W in eastern Williams County, North Dakota, which is on the eastern flank of Nesson anticline, next to the Nesson master fault on its northeast. Three horizontal wells were drilled and a hydraulic fracturing test was conducted. Natural fractures encountered in the drilling are primarily in the NW direction.

Figure 5-34. Trajectories of the maximum horizontal stress, south part of the Nesson master fault.

## 5.7. Discussion and Conclusion

The deformation of the Nesson anticline is controlled by the Nesson master fault beneath the west side of its crest. The vertical movement of the fault under the far-field effect of the Laramide orogeny largely determined the deformation of the fold. On the other hand, the Nesson master fault, and a secondary fault – the Antelope fault, have an obvious influence on the local in situ stress. The paleostress profile during the Laramide event has been reconstructed by using a three-dimensional finite element elastic model, which treats the geological formation as shell elements. The modeling result indicates that, in late Cretaceous, horizontal tensile stress was probably generated in areas around the Nesson master fault, and vertical stress was the maximum principal stress. On the north and south ends of the fault, the minimum principal stress reaches its lowest value; hence tensile fractures are very likely developed. As a continuous, tight, self-sourced reservoir, natural tensile fractures can form “sweet spots” and greatly enhance the reservoir quality in terms of both porosity and permeability. According to the vector map of the principal stresses, the natural tensile fractures around the Nesson anticline should be in the NNW direction.

The modeling result also provides information for discussion of the oil migration and accumulation pattern. The Bakken shale is an excellent source rock in the Williston basin. There have been arguments that if the generated oil is confined in Bakken or the Bakken shale is also the source rock for other Mississippian reservoirs in the basin

(Meissner, 1978; Webster, 1984; Price et al., 1984; Osadetz and Snowdon, 1986; Price and LeFever, 1994). As shown in the contour maps of principal stresses (Figure 5-28), the fault zone generally present as an area of low stress magnitude comparing to the host rock. If the modeled paleostress regime had lasted until the post-maturation of hydrocarbon in the source rock, the stress regime should have an impact to the oil migration. It is known that the Bakken shale in the area around the Nesson anticline has generated the largest volume of oil comparing to other areas in the basin (Figure 5-35). The high compressive stresses in the host rock could provide driving force pushing the mature hydrocarbon to the low-stress zone in the fault from both sides. As the hydrocarbon accumulated in the fault zone, the vertical fractures may provide additional pathways for outward migration to overlying formations and other areas in the basin until suitable cap rock is encountered.

In previous literature, horizontal fractures on the Bakken core samples are reported, and it is doubted that these fractures were generated by the super-lithostatic pressure due to the hydrocarbon expulsion in the shale rocks when it reached the maturation window. Since the direction of the fractures is orthogonal to the minimum principal stress, the vertical stress had to be the minimum principal stress so that the horizontal fractures could be generated when the hydrocarbon reached maturation during late Cretaceous. Nevertheless, there is no sound evidence by far that the minimum stress was vertical stress during that time. Warner (2011) suspected that the contemporaneous Laramide orogeny far-field tectonics probably generated a maximum horizontal stress regime, then joint propagation in the Bakken at that time would have likely been horizontal. However, the modeling results in this study show that the vertical stress was the maximum principal stress under the effect of Laramide orogeny. Therefore, these reported horizontal fractures are probably generated by other mechanisms, or just caused by pressure-release during coring.

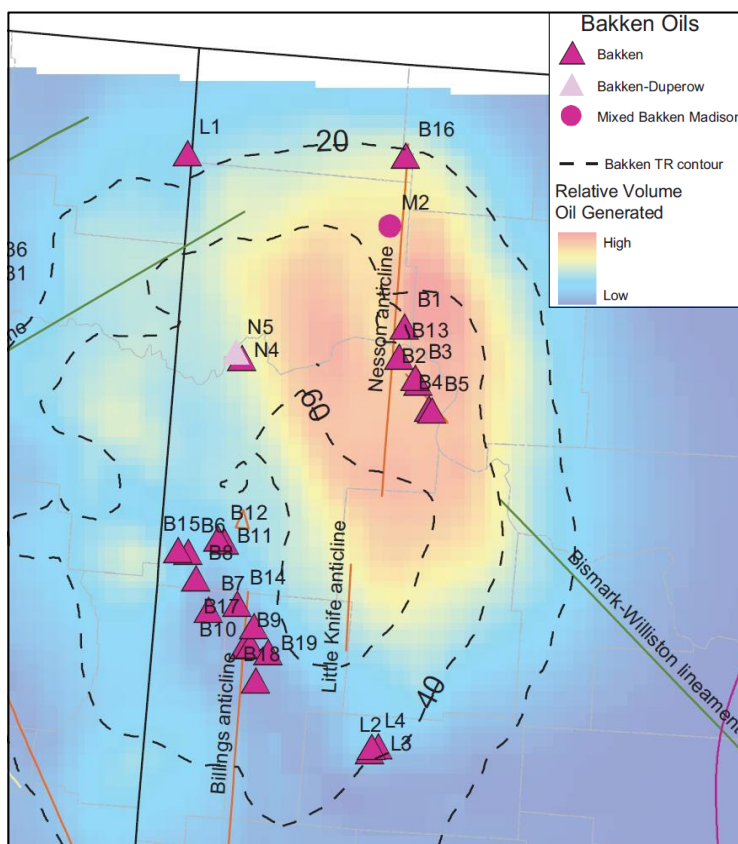

Figure 5-35. Relative volume oil generated from the Bakken shale (after Flannery and Kraus, 2006).

The modeling work presented in this study provides an alternative approach to reconstruct the paleostress in the Williston basin. As mentioned early in the above section, natural fractures in the Bakken have been generated by different mechanisms at different times in the history. This modeling work focus on the late Cretaceous period and gives an image where the tensile fractures were probably developed, as well as possible hydrocarbon migration

patterns based on the paleostress profile. The model can be improved if a more accurate three dimensional geological model could be built with seismic profile and a better well control. It is also suggested that some laboratory test can be carried out to investigate the effect of stress difference on hydrocarbon migration in tight formations.

## 6. MAPPING OF CURRENT IN-SITU STRESSES

According to existing literature, in-situ stresses of the Bakken formation have not been investigated systematically. The objective of this study is to screen for geomechanical properties from exiting references and perform a research on the in-situ stress characteristics. The overall goal is to increase the success rate of horizontal drilling and hydraulic fracturing to expand the access to reservoir rocks, and consequently to improve the ultimate recovery factor of this 200-400 billion barrels unconventional crude oil resource. The following aspects related to the in-situ stresses of the Bakken formation in the Williston basin, North Dakota are touched: (1) the basin tectonics, (2) the orientation and magnitude of the principal stresses, and (3) distribution of in-situ stresses in the Bakken formations, and (4) stress concentration around a horizontal well at different orientations.

### 6.1. Geological Settings

The geological settings of the study area have been discussed in previous section.

### 6.2. Tectonic History of the Basin

The tectonic history of the Williston basin has been discussed in aforementioned section.

### 6.3. Tectonic History of the Nesson Anticline

The tectonic history of the Nesson anticline has been discussed in aforementioned section.

### 6.4. Elastic Properties

A review of literature has been conducted to investigate the modeling approach as discussed in aforementioned section.

There is not much information about the in situ stress data in the Williston Basin available. Most of the available data only give either the magnitude or direction of the principal stresses (Wang and Zeng, 2011; Kuhlman et al., 1992; Phillips et al., 2007; Cipolla et al., 2009; Heidbach et al., 2008). For this modeling work, we consider that the best information is the result of a hydraulic fracturing test provided by the Bakken Research Consortium (Headington Oil LLC and XTO Energy Inc, 2008; Sturm and Gomez, 2009). The project area is in Section 36-T156N-R95W in eastern Williams County, North Dakota, which is on the eastern flank of Nesson anticline. Three horizontal wells were drilled and hydraulic fracturing test was conducted. Figure 6-1 shows pump plot of two of the three wells. The horizontal principal stresses can be estimated using the equations of suggested calculation for stress determination (Hudson and Harrison, 1997; Kim and Franklin, 1987):

$$P_s = \sigma_h \dots\dots\dots (6-1)$$

$$P_B = 3\sigma_h - \sigma_H + \sigma_t \dots\dots\dots (6-2)$$

where  $P_s$  is the shut-in pressure,  $P_B$  is the break pressure,  $\sigma_t$  is the tensile strength of rock,  $\sigma_h$  is the minimum horizontal stress, and  $\sigma_H$  is the maximum horizontal stress.

The tensile strength is assigned a value of 1192 psi (8.2 MPa) according to Kuhlman et al. (1992). Using Equations (6-1) and (6-2), we estimated that the maximum horizontal principal stress is 41.4 MPa, and minimum horizontal principal stress is 27.6 MPa. Depth of the wells is between 10,200 and 10,400 ft, therefore the vertical stress is assumed to be 70 MPa, or about 10,200 psi. Directions of the maximum horizontal stress determined by tests on these three wells are NE 41°, 34° and 45° respectively.

Figure 6-1. Pump plot of the hydraulic stimulation test (after Headington Oil LLC and XTO Energy Inc, 2008).

Elastic properties have appeared in previous literature (Crammer, 1992; Spikes, 2011; Haven, 2011; Kuhlman et al., 1992; Reynolds et al., 2002; Wang and Zeng, 2011). Over 200 core specimens have been tested at the University of North Dakota. The tested wells are selected to represent a decent geographical coverage. The test results were the database of elastic properties in the modeling work. In the modeling work, the modeled area was divided into several areas. Each area was assigned with its elastic properties based on the laboratory test results of nearby wells. Comparing the current experimental results on Bakken samples obtained by our study and other available information Young's modulus and Poisson's ratio used in this model are shown in Table 6-1.

Table 6-1. Elastic properties of different materials used in the model

Reference well	Material No.	Geological portion	Young's modulus, GPa	Poisson's ratio

## 6.5. Modeling of the Current In-Situ Stresses

The numerical modeling package ANSYS is used in this study. ANSYS has already extensively been used in different fields of mechanical engineering, chemical engineering and civil engineering. It provides sound solutions for structure design, bridge and tunneling engineering, aviation and aerospace simulation etc. The shell element provided by ANSYS can well model the stress and strain profile of the geological formation.

In this study, the three-dimensional model has a thickness of 95 meters. The satellite map of the modeling area is shown in Figure 6-2. The lower Bakken member is 30 m thick; the middle Bakken member is modeled as 50 m thick, and the upper Bakken member is modeled as 15 m thick. To eliminate the impact of the boundary condition to the results, the area is set as a square of 200\*200 km<sup>2</sup>. The Nesson fault and the Antelope fault are put at the center

of the model. The Nesson fault and the Antelope fault are modeled as damage zones of weak elastic properties. Material attributes are listed in Table 6-1. 8-node solid-shell elements are used. After meshing, the central part of the model, including the two faults, is shown in Figure 6-3. Figure 6-4 shows the different materials used for the elements.

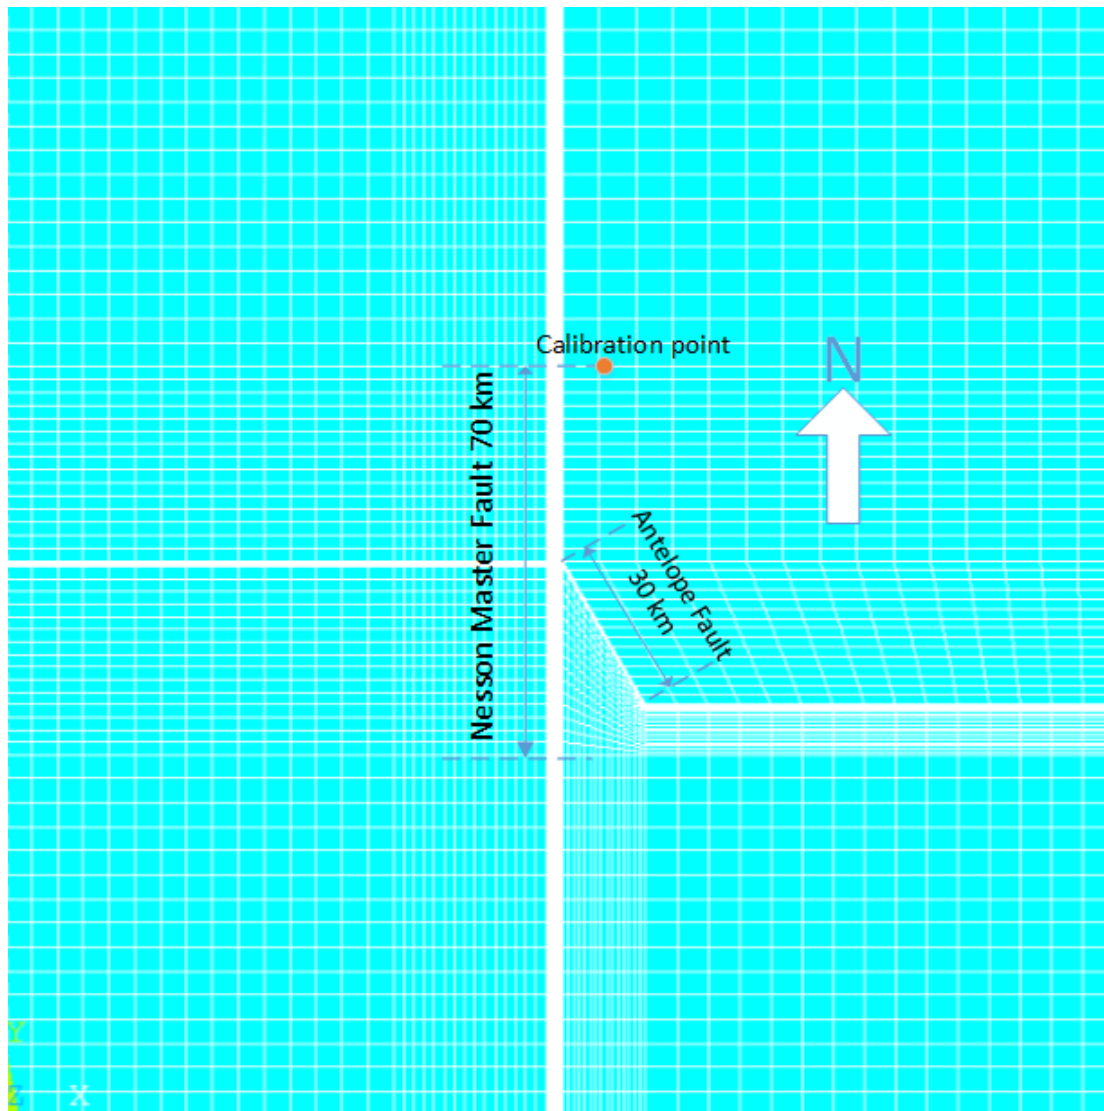

Figure 6-2. Satellite map of the modeling area

(b) 3D model

Figure 6-3. Meshed model

(a) 2D model

(b) 3D model

Figure 6-4. Different materials used for the elements. Different colors represent different materials in the model.

A vertical pressure of 70 MPa is applied on the model to simulate the vertical stress. Pressure is applied on the NE and SW boundaries of the model at the direction of NE 40°. The NW and SE boundaries are fixed. The boundary pressure is adjusted until the values of the principal stresses on the calibrated point (Section 36-T156N-R95W, Williams County, ND) matches the measured values mentioned above.

## 6.6. Modeling Results

The contour maps of the minimal horizontal stress, maximum horizontal stress and vertical stress are shown in Figures 6-5, 6-6, and 6-7, respectively. It can be seen that due to the existence of the fault zone, the magnitude of the principal stresses varies from the faults to the host rocks. In general, the stresses in the fault zone have a lower value than those in the host rock. This is consistent with the description of other researchers' modeling results.

The vector map of the maximum horizontal stress is shown in Figure 6-8. Figures 6-9 to 6-11 are plan views of the detailed vector map in the North, Central and South portions of the Nesson Anticline. It can be seen that there is a minor rotation of the direction of the maximum horizontal stress around the fault zone.

## 7. EXPERIMENTAL METHODS

Middle, Upper, and Lower Bakken Formation cores were cut into cylinder-shape for performing rock property test. These samples were cut using a gas jet to attain the proper geometry.

### 7.1. Core Sampler and Rock Geomechanics Test System

Bakken core samples, supplied by the North Dakota Geological Survey's Wilson M. Laird Core and Sample Library, were chosen as the specimens to represent the tight rocks. Due to the fragile nature of the core, we drilled the core plug with liquid N<sub>2</sub> as coolant (Figure 7-1). The core plugs are cylindrical with dimension of one inch in diameter and two inches long.

Figure 7- 1 Core plug sampling system used in this study

The equipment that is used to perform our experiments is AutoLab-1500, which is made by New England Research Inc. AutoLab 1500 supports a comprehensive suite of physical rock properties measurements as a function of the state of stress and temperature (AutoLab 1500, 2009). The system conveniently runs most standard rock mechanics test regimens, such as hydrostatic compression, pure shear, unconfined compression, confined compression, creep, and uniaxial strain. Each of these tests can be performed at pore pressures and temperatures representative of reservoir conditions. The system can also measure rock permeability, sonic velocity, and resistivity. Figure 7-2 is an image of AutoLab 1500 used in this study. Figure 7-3 presents the experimental setup and hydraulic diagram of AutoLab-1500. The cylindrical core plug was covered with copper sheet (Figure 7-4) in order to make a gas-tight seal on the cylindrical wall of the sample, and for applying radial confining pressure. Then the core plug was

mounted in a sample holder with flexible rubber sleeves at both ends of the plug (Figure 7-5). At last, the sample holder was put into a pressure vessel flooded with mineral oil, in which the sample can be hydrostatically compressed by applying force to plug by hydraulic means.

Figure 7-2 is an image of AutoLab 1500 used in this study.

Figure 7-2 AutoLab 1500 used in this study.

Figure 7-3 Experimental setup for permeability measurement under stresses

Figure 7-4 Images of core and core holder for rock properties test

Figure 7-5 Images of the end caps (left: downstream cap, right: upstream cap)

Figure 7-5 shows that the two end caps contain two axial ports for transporting test fluid to and from the sample and each of them has radial and circular grooves for distributing fluid to its entire surface. The upstream end-cap connects to a servo-controlled hydraulic intensifier, which is used to control and monitor the upstream pressure ( $p_1$ ). The downstream pressure at the other end of the sample is monitored by a miniature pressure transducer, which is located in the downstream end-cap.

The experimental procedure is as follows:

- 1) A specimen of core plug was prepared using the core plug sampling system shown in Figure 7-1.
- 2) The dimension of core plug is measured and the volume of core plug is calculated
- 3) The weight of core plug is measured and the dry bulk density was calculated.
- 4) Porosity is measured using the facility shown in Figure 7-6.
- 5) Permeability, sonic velocity, uniaxial and triaxial strength (non-destructive), Biot's coefficient, and uniaxial and triaxial strength (destructive) are tested using AutoLab 1500.

The following is a step-by-step procedure for conducting the experiment in AutoLab 1500.

- 1) Prepare the specimen as a right circular cylinder and measure its dimensions.
- 2) Measure the dry bulk density of the specimen.
- 3) Measure the porosity of the specimen.
- 4) Insert the specimen into a pliable jacket. Cut the jacket approximately 20 mm longer than the test specimen. Insert the sample in the jacket and secure it to a transducer assembly using a double wrap of steel wire.
- 5) Insert the transducer assembly with the jacketed specimen into the pressure vessel.
- 6) Set the servo-controllers to panel mode. Turn the control knobs fully counterclockwise.
- 7) Turn on the hydraulic power supply.
- 8) Fill the pressure vessel with mineral oil.
- 9) Advance the axial piston inside the vessel approximately 5 mm and close the valve between the intensifier and the vessel.
- 10) Increase the confining pressure to desired level.
- 11) Expel air from the pore pressure lines to the sample assembly.
- 12) Fully charge both pore pressure intensifiers.
- 13) Connect the upstream and downstream pore pressure tubes to the specimen.
- 14) Open the valve on the upstream pore pressure system so that fluid can be injected into the specimen.
- 15) After several minutes or so, fluid will begin to flow out the downstream pore pressure reservoir. This indicates that all of the tubing and the specimen are fully saturated with pore fluid.

- 16) Wait for pressure reach equilibrium; adjust the upstream and downstream pressure to desired level
- 17) Close inlet valve at upstream reservoir.
- 18) Switch the servo-controls for both the confining pressure and pore pressure to computer. control. The system is fully charged now and ready to begin an experiment.

## 7.2. Porosity

Porosity is a measure of the void spaces in a rock, and is a fraction of the volume of voids over the total rock volume. For oil and gas reservoirs, porosity provides the space to store the fluid subsurface and is important to the permeability of rock. Porosity measurements were conducted to evaluate the storage ability of Bakken Formation. Gas compression method is used to measure the porosities of core plugs in this research. Helium is used as the test fluid due to its small molecular size and inertial property. Figure 7-6 (He et al., 2013) shows the setup to measure rock porosity. The system consists of gas source, three pressure gauges, and two chambers. The core is put in Chamber 2.

Figure 7-6. Schematic of facility to measure rock porosity

### Measurement Principle

The measurement principle is based on real gas law. Followings are the derivation of governing equation to measure the core porosity.

Firstly, the sum of the volume of Chamber 1 and pipeline volume between Gas Inlet Valve and Gas Outlet Valve is denoted as Volume 1,  $V_1$ .

$$V_1 = V_{\text{chamber 1}} + V_{\text{pipeline between Gas Inlet Valve and Gas Inlet Valve}} \dots\dots\dots (7-1)$$

Similarly, the sum of the volume of Chamber 2 (without core) and pipeline volume between Gas Outlet Valve and Gas Vent Valve is denoted as Volume 2,  $V_2$ .

$$V_2 = V_{\text{chamber 2}} + V_{\text{pipeline between Gas Outlet Valve and Gas Vent Valve}} \dots\dots\dots (7-2)$$

The bulk volume of core is denoted as  $V_{\text{bulk, core}}$ , which is calculated by

$$V_{bulk,core} = \frac{\pi}{4} D_{core}^2 h_{core} \dots\dots\dots (7-3)$$

Initially the pressure in Chamber 1 is  $p_1$  and pressure in Chamber 2 is  $p_2$ , where  $p_1 > p_2$ . Then Gas Outlet Valve is open to allow gas flow from Chamber 1 to Chamber 2 and reach equilibrium. The equilibrium pressure,  $p_3$ , is recorded. According to real gas law we have

$$p_1 V_1 = z_1 n_1 R T_1 \dots\dots\dots (7-4)$$

$$p_2 [V_2 - V_{bulk,core} (1 - \phi)] = z_2 n_2 R T_2 \dots\dots\dots (7-5)$$

$$p_3 \{ [V_2 - V_{bulk,core} (1 - \phi)] + V_1 \} = z_3 (n_1 + n_2) R T_3 \dots\dots\dots (7-6)$$

The temperature is kept constant and pressure is changed in a narrow range. Therefore we have

$$z_1 \cong z_2 \cong z_3 \dots\dots\dots (7-7)$$

Equations (7-4), (7-5), and (7-6) can be simplified into

$$p_1 V_1 = z_1 n_1 R T_1 \dots\dots\dots (7-8)$$

$$p_2 [V_2 - V_{bulk,core} (1 - \phi)] = z_1 n_2 R T_1 \dots\dots\dots (7-9)$$

$$p_3 \{ [V_2 - V_{bulk,core} (1 - \phi)] + V_1 \} = z_1 (n_1 + n_2) R T_1 \dots\dots\dots (7-10)$$

Summing Equations (7-8) and (7-9) we obtain

$$p_2 [V_2 - V_{bulk,core} (1 - \phi)] + p_1 V_1 = z_1 (n_1 + n_2) R T_1 \dots\dots\dots (7-11)$$

Comparing the right-hand-sides of Equations (7-10) and (7-11) gives us

$$p_2 [V_2 - V_{bulk,core} (1 - \phi)] + p_1 V_1 = p_3 \{ [V_2 - V_{bulk,core} (1 - \phi)] + V_1 \} \dots\dots\dots (7-12)$$

Rearranging Equation (7-12) yields

$$\phi = 1 - \frac{V_2}{V_{bulk,core}} + \frac{(p_1 - p_3) V_1}{(p_3 - p_2) V_{bulk,core}} \dots\dots\dots (7-13)$$

Equation (7-13) is the governing equation to measurement rock porosity. Three pressures are recorded in the measurement. Volume 1,  $V_1$ , and Volume 2,  $V_2$  can be determined using standard volume samples made of stainless steel (zero porosity). The approach is also based on real gas law. The bulk volume of core can be readily calculated from core diameter and height.

### **Measurement Procedure**

The measurement of porosity of a specimen includes following steps:

- 1) Put the core into Chamber 2, close Gas Vent Valve, and open Gas Inlet Valve and Gas Outlet Valve to allow gas from gas tank fill Chambers 1 and 2 until pressure reaches 100 psig
- 2) Open Gas Vent Valve and allow gas from gas tank purge Chambers 1 and 2, Wait for 10 to 20 minutes until the purity of gas in Chambers 1 and 2 is high enough.
- 3) Close Gas Vent Valve, Gas Inlet Valve, and Gas Outlet Valve, record the pressure of Chamber 2,  $p_2$ .
- 4) Keep Gas Vent Valve and Gas Outlet Valve close, Open Gas Inlet Valve and allow gas from gas tank fill Chamber 1 until its pressure reaches target pressure, close Gas Inlet Valve and record the pressure of Chamber 1,  $p_1$ .

- 5) Open Gas Outlet Valve to allow gas flow from Chamber 1 to Chamber 2 (because  $p_1 > p_2$ ), wait until pressure reaches equilibrium, or pressure at Pressure Gauge 3 equates pressure at Pressure Gauge 2, record equilibrium pressure,  $p_3$ .
- 6) Now we finish the porosity measurement of specimen. Porosity can be calculated by Equation (7-13).

### **7.3. Permeability**

Rock permeability is one of most important rock properties for fluid flow in reservoir according to Darcy's law. It is a measure of the ease with which a fluid, such as gas, oil and water in petroleum engineering, can move through a porous rock. Permeability is an inherent characteristic of the porous media only. It depends on rock type, the textural of rock, effective porosity, pore throat size, geometry of the pore, and connection and distribution of pore. Conventional methods of measuring permeability in the laboratory utilize steady-state flow. Steady-state flow, or a constant pressure gradient flow, is established through the core plug, and the permeability is calculated from the rate of the measured flow and the pressure gradient. But this method is not adequate when measuring permeability in the low permeability Bakken samples. Not only the low flow rates across the core plug are difficult to be measured and controlled, but the tests are also quite time consuming. Because of the disadvantage of the steady-state flow, unsteady state flow, a condition under which the pressure gradient is a function of time, was used. With the measurements of the volumetric flow rate, upstream, and downstream pressures, the permeability can be calculated. Three unsteady-state methods, which are oscillating pulse method, pulse decay method, and radius-of investigation method had been developed to measure permeability in this project.

#### ***Oscillating Pulse Method***

The oscillating pulse method estimates rock permeability by interpreting the amplitude attenuation and the phase retardation in the sinusoidal oscillation of the pore pressure as it propagates through a sample. At the beginning of the experiment, the sample pore pressure, the upstream pressure, and the downstream pressure are stabilized. Then a sinusoidal pressure wave is generated in the upstream and propagates through a core plug. Using the information of the amplitude attenuation and phase shift between the upstream pressure wave and the derived downstream pressure wave at the downstream side of the sample, the permeability can be obtained (Figure 7-7). This method can measure the permeability of tight rock in a relative short time without destroying rock sample. The accuracy of permeability obtained from this method relies on the signal-to-noise ratio and data analysis techniques. The optimum frequency of the oscillation and the ratio of the downstream to upstream pore pressures depend upon the sample size and the magnitude of permeability (Kranz et al., 1990). Therefore, the calculated permeability contains large uncertainty when measured under the condition of low signal-to-noise ratio. Moreover, different analysis techniques can result in different permeabilities in the same experiment.

Figure 7-7 Changes of the pressure during a sinusoidal oscillation pulse method

### Pulse Decay Method

The pulse decay method is a transient method. The experimental arrangement is shown schematically in Figure 7-8. The sample has both upstream reservoir and downstream reservoir with the initial condition of uniform pore, upstream and downstream pressures. When a pressure pulse is applied at the upstream end of a core plug and propagates through core to the downstream reservoir, the pressure pulse will decay over time. The decay characteristics depend on the permeability, size of the sample, volumes of upstream and downstream reservoirs, and physical characteristics of the fluid. Permeability is estimated by analyzing the decay characteristics of the pressure pulse.

Figure 7-8 Schematic diagram for pulse decay permeability system

Figure 7-9 Changes of upstream and downstream pressures in pulse decay method

To calculate the permeability from the build-up curve of the measured downstream pressure, the solution of the diffusivity Equation (7-14) needs to be known. According to the solution of this problem from Hsieh et al. (1981) and Dicker and Smits (1988), the exact solution for the pressure in the downstream reservoir is

$$\frac{\partial^2}{\partial x^2} [m(p)] = \frac{\phi \mu c_t}{k} \frac{\partial}{\partial t} [m(p)] \quad \dots\dots\dots (7-1)$$

$$\frac{m[p_2(t)] - m[p_2(0)]}{m[p_1(0)] - m[p_2(0)]} = \frac{b}{a + b + ab} + 2 \sum_{m=1}^{\infty} \frac{e^{-t_D \theta_m^2} (ab^2 - b \theta_m^2)}{[\theta_m^4 + \theta_m^2 (a + a^2 + b + b^2) + ab(a + b + ab)] \cos \theta_m} \quad \dots\dots\dots (7-2)$$

where  $\theta_m$  can be calculated from the following equation

$$\tan \theta = \frac{(a + b) \theta}{\theta^2 - ab} \quad \dots\dots\dots (7-3)$$

where  $a$  is the ratio of the sample pore volume ( $V_p$ ) over the upstream reservoir volume ( $V_1$ ), and  $b$  is the ratio of the sample pore volume over the downstream reservoir volume ( $V_2$ ), ( $a = \frac{V_p}{V_1}$ ,  $b = \frac{V_p}{V_2}$ ).

In the Equation (7-15) the dimensionless time,  $t_D$ , is defined as:

$$t_D = \frac{kt}{\phi \mu c_t L^2} \quad \dots\dots\dots (7-17)$$

The setup of the permeability test system in this study and measurement pressure and temperature allow us simplify Equation (7-15) to:

$$\frac{p_1^2(0) - p_2^2(t)}{p_1^2(0) - p_2^2(0)} = e^{-t_D \theta_i^2} \cdot \left( 2 \frac{b \sqrt{\theta_i^4 + \theta_i^2 b^2}}{\theta_i^4 + \theta_i^2 (b + b^2)} \right) \dots\dots\dots (7-4)$$

Let  $\Delta p(t) = p_1^2(0) - p_2^2(t)$ , we get

$$\frac{\Delta p(t)}{\Delta p(0)} = \left( 2 \frac{b \sqrt{\theta_i^4 + \theta_i^2 b^2}}{\theta_i^4 + \theta_i^2 (b + b^2)} \right) \cdot e^{-t_D \theta_i^2} \dots\dots\dots (7-5)$$

which can be written as

$$\Delta p(t) = \left( 2 \Delta p(0) \cdot \frac{b \sqrt{\theta_i^4 + \theta_i^2 b^2}}{\theta_i^4 + \theta_i^2 (b + b^2)} \right) \cdot e^{-t_D \theta_i^2} \dots\dots\dots (7-6)$$

Taking the natural log of Equation (7-20) yields

$$\ln[\Delta p(t)] = \ln \left( 2 \Delta p(0) \cdot \frac{b \sqrt{\theta_i^4 + \theta_i^2 b^2}}{\theta_i^4 + \theta_i^2 (b + b^2)} \right) + (-t_D \theta_i^2) \dots\dots\dots (7-7)$$

Substituting  $t_D$  from Equation (7-17) into Equation (7-21), we get

$$\ln[\Delta p(t)] = \ln \left( 2 \Delta p(0) \cdot \frac{b \sqrt{\theta_i^4 + \theta_i^2 b^2}}{\theta_i^4 + \theta_i^2 (b + b^2)} \right) - \frac{\theta_i^2 k}{\phi \mu c_i L^2} t \dots\dots\dots (7-8)$$

The determination of the permeability is a three-step process, namely installing the core plug into AutoLab-1500, running the test, and analyzing the resultant data.

### 1) Installing the core plug into AutoLab-1500

First, the core holder is placed into the vessel, then the vessel is filled with mineral oil and the confining pressure is increased to the desired level ( $p_c$ ). The valve between the core plug and the upstream reservoir is closed. Dry nitrogen is used to fill the upstream reservoir and the upstream pressure is increased to the desired level ( $p_1$ ). The downstream pressure is atmospheric pressure. Notice that the confining pressure must be greater than the upstream pressure.

### 2) Running the test

The starting time is recorded when the valve between the core plug and the upstream reservoir is opened. During the whole test, the upstream and the confining pressures are constant. The pressures are monitored and recorded at both the upstream and downstream ends of the sample. The test is end when the downstream pressure is equal to the upstream pressure, which is shown in Figure 7-9.

### 3) Analyzing the resultant data

First the pressure difference is calculated in a logarithm scale from equation:. Then form the plot by function fitting (Figure 7-10), we get the slope,  $s$ . Finally, using Equation (7-23), we can obtain the permeability of the rock.

$$k = \frac{2\phi\mu c_i L^2 s}{3 - 3 \sqrt{1 + \frac{4\phi AL}{3V_2}}} \dots\dots\dots (7-23)$$

Figure 7-10  $\ln(\Delta p)$  vs. time plot for core sample permeability measurement using pulse decay method

### ***Radius-of-Investigation Method***

Based on the radius-of-investigation concept (Lee, 1982), we proposed a new laboratory core permeability measurement method (Ling et al., 2013). When doing the permeability test using the downstream pressure build-up method, we observed that the downstream pressure did not increase immediately when the upstream reservoir connected with the core plug. The lower the permeability is, the longer delay time is observed. Based on this phenomenon, a correlation can be found between the permeability and the delaying time. Through this correlation, the permeability can be measured in a much shorter time (Figure 7-11) when compared with the previous method.

Figure 7-11 Changes of the downstream pressures while maintaining constant upstream pressure  
The upstream pressure ( $p_1$ ) is constant, and the downstream pressure ( $p_2$ ) builds up through the time.

In our research, we discovered that the radius-of-investigation concept could be useful for uncovering the relationship between the permeability of rock and the waiting time before the downstream pressure increases. Radius of investigation is the distance that a pressure disturbance moves into a formation when it is caused from the well. Lee pointed out that it is possible to calculate the maximum distance that a pressure disturbance can reach at any time, if we know the properties of rock and fluid, such as the rock permeability and porosity, fluid viscosity, and the compression of both rock and fluid. This means that the maximum distance of pressure disturbance is a function of permeability and time, when other parameters are constants. Thus, the time that a pressure disturbance spends in a rock is a function of the permeability of the rock, if we know the length of the rock. Our hypothesis is that we can calculate the low permeability in laboratory by measuring the delaying time, which is the time that the pressure disturbance propagates from the upstream end of the core plug to the downstream end (in case pressure disturbance is generated in upstream), or the pressure disturbance propagates from the downstream end of the core plug to the upstream end (in case pressure disturbance is generated in downstream). Permeability can be calculated for given porosity, viscosity, total compressibility, location, and time, which is

$$k = \frac{\phi \mu c_t x^2}{2t_m} \dots\dots\dots (7-24)$$

Converting Equation (7-24) into the U.S. field units we have

$$k = \frac{1896 \phi \mu c_t x^2}{t_m} \dots\dots\dots (7-25)$$

where permeability  $k$  is in mD, porosity  $\phi$  is dimensionless (in fraction), viscosity  $\mu$  is in cp, total compressibility  $c_t$  is in  $\text{psi}^{-1}$ , time  $t_m$  is in hour, and location (or distance)  $x$  is in ft. Equations (7-24) and (7-25) are the governing equations to measure the rock permeability. They are used to calculate the permeability of any rock that meets the aforementioned assumptions and can be used for high-permeability rocks as well. The proposed method evaluates the permeability under unsteady-state flow and requires short time period to determine the flow capacity of the low-permeability rock.

## 7.4. *Sonic Velocity*

Sonic velocity, or seismic velocity, is a measure of a formation's capacity to transmit seismic waves. It varies with lithology and rock textures, most notably decreasing with an increasing effective porosity. This means that a sonic log can be used to calculate the porosity of a formation if the seismic velocity of the rock matrix and pore fluid are known, which is very useful for hydrocarbon exploration. The velocity is calculated by measuring the travel time from the transmitter to the receiver. There are many types of seismic waves. Two types of wave, primary waves (P-waves) and secondary waves (S-waves), are used to test the sonic velocity in rock in this study. P-waves are compressional waves that are longitudinal in nature. P waves are pressure waves that travel faster than S-waves through the rock. S-waves are shear waves that are transverse in nature. P-waves can travel through any materials. S waves can travel only through solids, as fluids (liquids and gases) do not support shear stresses. S waves are slower than P waves.

AutoLab 1500 is used to test the sonic velocity of core plug. The following is a step-by-step procedure for conducting the experiment.

- 1) Prepare the specimen.
- 2) Measure the dry bulk density of the specimen.
- 3) Measure the porosity of the specimen.
- 4) Jacket the specimen with copper foil. Insert the specimen into a pliable jacket. Seal the jacket to the end plugs with a section of rubber tubing the same diameter as the test specimen. The rubber jacket is secured to the end plugs at two points with several wraps of steel wire.
- 5). Secure the test specimen to the PS2 ultrasonic velocity transducer assembly after applying shear wave couplant to the face of the transducers. Secure the specimen at one end of the assembly using a section of elastomer jacket with the same inside diameter as the test specimen. The rubber jacket is attached to the transducer assembly at two points with several wraps of steel wire. Secure the other transducer to the specimen with a section of rubber tubing as described above. It is important that the vibration direction for the S1 and S2 components of the shear waves are aligned to obtain good shear wave data. The S1 component on each transducer is marked and indicated with a line ground into the transducer assembly.
- 6). Connect the PS2 ultrasonic velocity transducer output; make sure that the connections are in the correct position.
- 7) Insert the transducer assembly with the jacketed specimen into the pressure vessel.
- 8) Set the servo-controllers to panel mode. Turn the control knobs fully counterclockwise.
- 9) Turn on the hydraulic power supply.
- 10) Fill the pressure vessel with mineral oil.
- 11) Advance the axial piston inside the vessel approximately 5 mm and close the valve between the intensifier and the vessel.
- 12) Increase the confining pressure to desired level.
- 13) Initiate the AutoLab Software.
- 14) Select Acquire Data in the NER Laboratory Process Monitor.

15) Select the appropriate PS2 ultrasonic velocity transducer under the transducer selection. Set the gain and attenuation information for the pulse-receiver.

16) Check the waveforms for the compressional and shear wave velocities. Locate the oscilloscope panel and configure the scope to obtain a clear waveform for a P wave. Once you have obtained satisfactory waveforms for the compressional wave, subsequently check the S1 and S2 waveforms to make sure that there is sufficient amplitude near the first arrival of the shear wave to make accurate measurements of velocity. Select Accept Scope from the Commander window.

17) Set the Sampling Interval and click Collect a/d channels. axial strain as a function of differential stress.

18) In Commander, select Mode/Script.

19) A Scriptor window file will appear. Once the Scriptor window appears select File. A pop-down menu will appear. Select an existing file or choose Editable from the menu. A red box will appear in the window. Now you can generate a script file for the loading and data acquisition sequence. Save the file with a unique designation: the file will be reused for subsequent experiments, over the same loading path.

20) Make a final check of all of the servo-controls on the electronics console and the Analog Monitor. If all of the variables are within the appropriate range, select Run in the Scriptor window to initiate the experiment. The experiment begins immediately.

21) Terminate the data acquisition at the end of the experiment by clicking the Collect a/d channels button on the Commander window to stop A/D data collection.

22) Select Stop Data Acquisition in the Commander window. Select Process/Print Existing Data from the NER Laboratory Process Monitor.

23) When File Browser appears, highlight the file name of the experiment that you have just completed. Select Process Traces.

24) Select the wave type to be displayed by clicking the mouse on the p, s1, or s2 buttons in the upper right hand corner of the Arrival Picker. The selected waveforms for each wave type will appear as a waterfall plot.

25) Process the P waves. The compressional waves that you have recorded during the experiment will appear. Using the mouse click the mouse at the approximate point of the first arrival (the onset of compressional wave energy) for each trace. Once all of the first arrivals for all of the compressional waveforms have been selected, save the data by selecting Save at the bottom of the window.

26) Process the shear wave data. Select s1 at the top of the window. The button will appear red and the shear wave data for the S1 component will appear on the screen. Repeat the procedure described above for compressional waves. When the data is processed select Save at the bottom of the screen. Then repeat the process for the S2 shear waveforms. When you have completed picking all of the waveforms for the P and the S waves select Save Changes and Exit.

27) Print a velocity report.

In the AutoLab 1500, the pulser-receiver is used to excite the ultrasonic transducer assembly and amplify the received signal. When making measurements on a sample, we increase the confining pressure to the maximum value expected during the test in order to properly set the pulser-receiver. The settings should be adequate for both the compressional and shear waves if both types are to be recorded. Once the experiment has been completed, the data is edited and plotted. The first step is to display the waveforms and pick the first arrivals for each wave type: compressional or polarized shear wave. After the times of first arrival of P (Figure 7-12), S1 (Figure 7-13), S2 (Figure 7-14) are selected. An example of the compression and shear wave velocities of core plug are shown in Figure 7-15.

### 7.5. *Dynamic Moduli and Poisson's Ratio*

By definition, dynamic moduli and Poisson's ratio are those calculated from the elastic wave velocity and density. They are different from static dynamic moduli and Poisson's ratio moduli, which are directly measured in a deformational experiment. The static and dynamic moduli of the same rock may significantly differ from each other. The main reason is likely to be the difference in the deformation, or strain, amplitude between the dynamic and static experiments. In this study, dynamic Young's modulus and Poisson's ratio are calculated from the P-waves and S-waves velocities and density.

$$E_{dyn} = \rho v_s^2 \frac{3v_p^2 - 4v_s^2}{v_p^2 - v_s^2} \dots\dots\dots(7-26)$$

$$\nu_{dyn} = \frac{v_p^2 - 2v_s^2}{2(v_p^2 - v_s^2)} \dots\dots\dots(7-27)$$

where  $E_{dyn}$  is the dynamic elastic modulus,  $\nu_{dyn}$  is the dynamic Poisson's ratio,  $\rho$  is the density of rock sample,  $v_p$  is P-wave velocity, and  $v_s$  is S-wave velocity.

Dynamic Young's modulus and Poisson's ratio can be calculated from sonic velocity test. Figure 7-15 shows the dynamic properties calculated from sonic velocity measurement of a Bakken core plug.

## 7.6. Static Moduli and Poisson's Ratio (Non-Destructive Strength Test)

Young's modulus, also known as the tensile modulus or elastic modulus, is a measure of the stiffness of an elastic material and is a quantity used to characterize materials. It is defined as the ratio of the stress along an axis over the strain along that axis in the range of stress in which Hooke's law holds. Young's modulus,  $E$ , can be calculated by dividing the tensile stress by the tensile strain in the elastic (linear) portion of the stress-strain curve (Figure 7-16).

$$E = \frac{\sigma}{\varepsilon} \dots\dots\dots (7-28)$$

where

$E$  is the Young's modulus (modulus of elasticity)

$\sigma$  is the axial stress exerted on specimen

$\varepsilon$  is the strain of specimen in axial direction

Figure 7-16 Static Young's modulus calculated from stress-stain relation

Poisson's ratio,  $\nu$ , named after Siméon Poisson, is the negative ratio of transverse to axial strain. When a material is compressed in one direction, it usually tends to expand in the other two directions perpendicular to the direction of compression (Figure 7-17). This phenomenon is called the Poisson effect. The Poisson ratio is the ratio of the fraction of expansion divided by the fraction of compression, for small values of these changes.

$$\nu = \frac{\varepsilon_D}{\varepsilon_L} \dots\dots\dots (7-29)$$

where

$$\varepsilon_D = \frac{\Delta D}{D} \dots\dots\dots (7-30)$$

$$\varepsilon_L = \frac{\Delta L}{L} \dots\dots\dots (7-31)$$

$\varepsilon_D$  is the strain of specimen in radial direction

$\varepsilon_L$  is the strain of specimen in axial (or vertical) direction

If the material is stretched, it usually tends to contract in the directions transverse to the direction of stretching. The Poisson's ratio will be the ratio of relative contraction to relative stretching, and will have the same value as above. Due to the requirement that Young's modulus, the shear modulus and bulk modulus have positive values, Poisson's ratio can vary from initially 0 to about 0.5. Generally, "stiffer" materials will have lower Poisson's ratios than "softer" materials. If Poisson's ratios are larger than 0.5, it implies that the material was stressed to cracking, or caused by experimental error, etc.

Figure 7-17 Poisson's ratio from a deformed cylinder-shape specimen  
[http://classes.engr.oregonstate.edu/cce/winter2012/ce492/Modules/06\\_structural\\_design/poissons\\_ratio.htm](http://classes.engr.oregonstate.edu/cce/winter2012/ce492/Modules/06_structural_design/poissons_ratio.htm)

Static dynamic moduli and Poisson's ratio moduli are directly measured in a deformational experiment. In this work we measured the strain in the axial and radial directions of core plug. The compressional stresses in the axial and radial directions are also recorded. We used the following procedure to conduct a uniaxial stress experiment.

- 1) Prepare the specimen.
- 2) Measure the dry bulk density of the specimen.
- 3) Jacket the specimen with thick copper.
- 4) Seat the jacket to specimen.
- 5) Attach strain gages to the test specimen.
- 6) Secure the sample to the end caps. Place the sample assembly on the base plug of the pressurization system.
- 7) Connect strain gage leads in the base plug. Make sure that the leads for the radial and axial gages are soldered to the appropriate connectors.

- 8) Insert the sample assembly into the pressure vessel. Fill the pressure vessel with oil.
- 9) Initiate the AutoLab software.
- 10) Check the Analog Channel Monitor to ensure that the strain gages are on scale.
- 11) Now calibrate the strain gages.
- 12) Increase the differential stress and the confining pressure to the initial value for the uniaxial stress measurement. Activate the window for the Uniaxial Stress measurement.
- 13) Fill in the appropriate values in the Uniaxial Stress experiment command module. Select the loading rate and set the amplitude of the shear stress cycle, and set the number of loading cycles for the experiment.
- 14) Select the portion of the stress-strain data that will be processed after the capture.
- 15) Once all the data is satisfactorily entered into the Uniaxial Stress experiment user interface, apply the load to conduct test.
- 16) At the conclusion of the test sequence, the processed data are presented.
- 17) Examine the data and accept them if they are acceptable. The data are now permanently stored.
- 18) Increase the mean stress to the next value and repeat the cyclic-loading experiment described above.
- 19) Step wise increase the confining pressure as desired to determine the elastic constants as a function of confining pressure.
- 20) At the termination of the test sequence, terminate the data acquisition and end the experiment.
- 21) Process and review the data that has been collected, recalculate the moduli for different portions of the load/unload cycles, and print a final report.

Figure 7-18 shows an example of stress and strain in a non-destructive strength test in this study.

Figure 7-18 An example of stress and strain in a non-destructive strength test in this study

After the velocity test and non-destructive strength test, Young's modulus and Poisson's ratio from both test are compared.

## 7.7. Biot's Coefficient

Biot's coefficient is an important parameter used to determine the influence of pore pressure on rock deformation. Biot's coefficient defines the relationship among total stress, effective stress and pore fluid pressure (Biot and Willis, 1957; Geertsma, 1957). It describes how soon the matrix stress will respond when the pore fluid pressure is changed. It is more important to low permeability rocks, such as the Bakken Formation. This parameter is used in hydraulic fracturing treatment design and wellbore stability. Physical fracturing of these formations could enhance the overall

formation permeability and thus improve shale oil extraction. One of the outstanding issues in rock fracturing is to determine the magnitude of applied effective stress. The general effective-stress law is defined as

$$\sigma_{eff} = \sigma_c - \alpha \sigma_p \dots\dots\dots (7-32)$$

where

$\sigma_c$  is total confining stress,

$\sigma_p$  is fluid pore pressure,

$\sigma_{eff}$  is effective stress,

$\alpha$  is Biot's coefficient,

Each physical quantity of rock responds to total stress and pore pressure in a different way, and thus each quantity has its own unique Biot's effective-stress coefficient. The main objective of this study is to experimentally determine the Biot's coefficient for Bakken formation. According to Equation (7-32), Biot's coefficient can be estimated by measuring two sets of fluid pore pressure and confining pressure under constant effective stress, or constant strains, which is achievable in the experiment. Therefore, Biot's coefficient,  $\alpha$ , is the ratio between confining pressure difference and pore pressure difference under constant strains.

$$\alpha = \frac{\Delta \sigma}{\Delta p} \text{ at } \Delta \epsilon = 0 \text{ at both axial and radial directions } \dots\dots\dots (7-33)$$

The measurement consists of measuring the strains under a set of fluid pore pressure and confining pressure, and then fluid pore pressure is changed; meanwhile confining pressure is adjusted to keep the strains constant. Biot's coefficient can be obtained from these two set of pressures (Figure 7-19).

Figure 7-19 Biot's coefficient measurement using constant deformation under different confining pressure

The test procedure is similar to the stress-strain test. To obtain Biot's coefficient, several stress-strain tests are repeated by keeping the strains constant. Followings are steps for stress-strain test to calculate Biot's coefficient.

- 1) Prepare the specimen.
- 2) Measure the dry bulk density of the specimen.
- 3) Jacket the specimen with thick copper.
- 4) Seat the jacket to specimen.
- 5) Attach strain gages to the test specimen.

- 6) Secure the sample to the end caps. Place the sample assembly on the base plug of the pressurization system.
- 7) Connect strain gage leads in the base plug. Make sure that the leads for the radial and axial gages are soldered to the appropriate connectors.
- 8) Insert the sample assembly into the pressure vessel. Fill the pressure vessel with oil.
- 9) Initiate the AutoLab software.
- 10) Check the Analog Channel Monitor to ensure that the strain gages are on scale.
- 11) Now calibrate the strain gages.
- 12) Increase the differential stress and the confining pressure to the initial value for the uniaxial stress measurement. Activate the window for the Uniaxial Stress measurement.
- 13) Fill in the appropriate values in the Uniaxial Stress experiment command module.
- 14) Select the portion of the stress-strain data that will be processed after the capture.
- 15) Once all the data is satisfactorily entered into the Uniaxial Stress experiment user interface, apply the load to conduct test.
- 16) Record the strains and stresses.
- 17) Examine the data and accept them if they are acceptable. The data are now permanently stored.
- 18) Increase the pore pressure to the next value and adjust the confining pressure to keep strains constant. Record the strains and stresses.
- 19) Step wise increase the pore pressure and adjust confining pressure to keep strains constant.
- 20) At the termination of the test sequence, terminate the data acquisition and end the experiment.
- 21) Process and review the data that has been collected, calculate Biot's coefficient, and print a final report.

### ***7.8. Uniaxial/Triaxial Compressive Strength, Young's Modulus and Poisson's Ratio (Destructive)***

Uniaxial/triaxial compressive strength is measured together with Young's modulus and Poisson's ratio. Axial load, axial and lateral deformations are measured during the compression until failure of the specimen. Load-deformations curves are converted to stress-strain curves using the specimen's geometry, from which the Young's modulus and Poisson's ratio are obtained using the linear portion. Because the Williston Basin is very flat lying, we can assume that one of the three principal stresses will be parallel to the vertical direction. With this assumption, using the measured historic stresses in three different directions in the bedding plane would allow the determination of the two principal stresses in the bedding plane.

A detailed procedure for the experiment is given below. The recommended procedure for confined compression to failure experiments is as follows:

- 1) Prepare the specimens according to sample preparation.
- 2) Measure the dry bulk density of the specimen.

- 3) Jacket the specimen with 0.13 mm thick copper. The procedure is described as above.
  - 4) Seat the jacket to the specimen. Insert hardened steel end-plugs into the extensions of the foil jacket at each end of the specimen. Seal the jacket to the end plugs with a section of rubber tubing the same diameter as the test specimen. The rubber jacket is secured to the end plug at two points with several wraps of #19 steel wire. Insert the jacketed test specimen into the pressure vessel and increase the pressure to approximately 7 MPa (1,000 psi).
  - 5) Remove the jacketed test specimen from the pressure vessel and examine the surface of the copper jacket. There should be no punctures in the foil and the jacket should be tightly swaged to the specimen. If you observe small holes in the jacket, fill them with either epoxy or a spot of solder.
  - 6) Position the supporting ring for the axial displacement transducer (LVDT) barrels approximately one specimen radius below the upper end of the specimen. Carefully center the ring so that it is concentric with the specimen.
  - 7) Position the LVDT ring used to measure the radial displacement at the midpoint of the specimen. The supporting ring for the LVDT is positioned so that the line between the adjusting screw on the ring and the axis of the core barrel pass through the axis of the specimen and is perpendicular to the axis of the specimen.
  - 8) Position the lower support ring for the axial LVDT concentrically about the specimen approximately one specimen diameter below the upper ring. This ring supports the stainless steel extension rods for the LVDT cores. (Note: Always use non-magnetic stainless steel or brass extension rods to support the LVDT cores.) Be sure that the axis of the LVDT core barrels are aligned parallel with the axis of the specimen. The extension rods are supported with adjusting screws that are secured with locking nuts.
  - 9) Measure the center-to-center separation of the axial LVDT support rings with a caliper micrometer. Record this value in your notebook; this value will be used to compute the strain.
  - 10) Place the specimen assembly on the base plug of the load frame. Connect the two axial LVDTs and the radial LVDT to the electrical leads in the base plug.
  - 11) Make the final mechanical adjustments on the LVDT. Each LVDT is adjusted so that its initial amplified output is positive. All of the LVDTs are wired so that increasing the specimen diameter or shortening the specimen length results in an increasingly positive output voltage.
- For specimens tested in confined compression, there is an initial volume reduction. The output voltage of the radial displacement gage will decrease. The proper initial setting in this case will be strongly positive to account for the reduction in diameter due to hydrostatic compression. The axial LVDTs will become increasingly positive with pressurization. Consequently, a slightly negative voltage may be required to insure that the LVDTs have sufficient range at the appropriate sensitivity to measure the deformation of
- 12) Insert the sample assembly into the pressure vessel.
  - 13) Fill the pressure vessel with oil.
  - 14) Set the limit switches for the fail-safe module according to the properties of the specimen being tested.
  - 15) Turn the panel command knobs for the servo-controllers fully counterclockwise. Lock the differential pressure intensifier.
  - 16) Turn on the hydraulic power supply.
  - 17) Set the differential pressure intensifier to force feedback.
  - 18) Unlock the differential pressure intensifier.

- 19) Slowly increase the command signal for the axial force until the piston begins to slowly move down to contact the specimen. Make sure that the vent valve for the confining pressure system is open.
- 20) Back off the axial force after it touches the specimen. When the force on the specimen drops to zero, lock the differential load intensifier.
- 21) Balance the displacement transducer monitoring the position of the piston. It is important that the LVDT is set exactly at 0.00 and that the output voltage read on the computer is also 0.00.
- 22) Switch the mode control for the differential pressure intensifier from force to displacement feedback.
- 23) Unlock the differential load intensifier. The piston will remain close to the top of the specimen assembly but exert no load on the specimen.
- 24) Lock the differential intensifier.
- 25) Initiate the AutoLab Software.
- 26) Select Acquire Data in the NER Laboratory Process Monitor.
- 27) Choose Deformation (without Velocity, Resistivity, or Permeability or any of the other experiment types) in the Experiment Type Panel and click OK.
- 28) Fill in the Experimental Information Panel. Under Channel File Selection, select a channel file where displacement is the feedback signal for the differential pressure intensifier. Click Done.
- 29) Change the mode selection switches on the servo-controllers from panel to computer once the Commander window appears. The computer is now controlling the servo-hydraulic intensifiers.
- 30) Check the Analog Channel Monitor panel to ensure that the displacement transducers have not shifted during set-up.
- 31) Close the vent valve on the confining pressure system.
- 32) Unlock the Failsafe for the differential pressure intensifier.
- 33) Increase the slide bar to the desired confining pressure, in this case 10.0 MPa.
- 34) Select a Ramp Time of two minutes and using the mouse, Send the command to the servo-amplifiers. The confining pressure on the specimen will increase. There is no change in the axial force measured with the force cell or the position of the moveable piston in the pressure vessel.
- 35) Wait until the confining pressure reaches 10.0 MPa and check the output of the LVDTs. Are they on scale, (i.e. between 0 and 10 volts)? Adjust the output offset on the appropriate signal-conditioning card between 0.250 and 0.750 volts.
- 36) Estimate the strain at which the specimen will fail based on previous measurements. From this information, compute the approximate displacement that the specimen will experience during the loading process. Triple this value to account for elastic deformation in the system and to compensate for excessively strong specimens.
- 37) Set the displacement slide bar in Commander to the value computed in step 36. Choose a strain rate for the experiment. Typically, the minimum recommended strain rate for confined compression to failure experiments is  $10^{-5} \text{ s}^{-1}$ . Compute the time that will result in an appropriate strain rate for the specimen. After several experiments

with the system you will be able to estimate the strain rate in the specimen from the displacement rate of the system. Since the system will behave identically from experiment to experiment, a simple chart of displacement rate versus strain rate can be used to apply the same loading rate for an entire suite of experiments.

38) Select a Sampling Interval. Depending on the duration of the test the frequency of data acquisition is selected. For most experiments, collecting data every two to five seconds is adequate. However, after you become experienced with the system and with performing experiments an appropriate data acquisition rate will become apparent. Click Collect a/d data.

39) It is frequently useful to monitor the experiment. Select the axis on the graph that will provide you with the most information concerning the experiment.

40) Leave the confining pressure at its existing value of 10.0 MPa and click Send to initiate loading.

41) Continue the experiment until the specimen fails. Monitor the output voltages of the LVDTs throughout the experiment. In many cases it is useful to use a graphical representation of the experiment as deformation proceeds. In this case you may wish to initiate the xmgrace graphical program and to monitor individual channels that are of interest to you. Typically, the most important data are obtained by monitoring one of the axial LVDTs as a function of force and one of the axial LVDTs as a function of the change in diameter (the radial LVDT).

42) Continue the loading to examine the post failure behavior of the specimen, if it is important. Since the system is operating in displacement feedback, failure will be accompanied by a drop in the force on the specimen. Most likely the specimen will not be completely unloaded and the piston will not unload the total elastic energy stored in the system into the specimen. By continuing the experiment the post failure behavior of the specimen can be observed. As the specimen continues to deform, it will support a lower stress than prior to failure. If the axial LVDTs have not been misaligned during failure, the shortening of the specimen may be observed in the post failure regime.

43) Terminate the experiment by first stopping the collection of A/D data. Click Collect a/d channels to terminate the data acquisition. Set the slide bars for displacement and confining pressure to zero and choose a Ramp Time of two minutes. Click the Send button.

44) Select Stop Data Acquisition from the NER Laboratory Process Monitor window.

45) Drain the confining fluid from the pressure vessel using the procedure outlined in Chapter 2. Remove the specimen from the pressure vessel and examine the failure characteristics and note any pertinent information in your laboratory notebook.

46) Select Process/Print Existing Data from the NER Laboratory Process Monitor window.

47) Select the file that you wish to process from the File Browser. For this experiment we will be processing the A/D analog data from the confined compression experiment on Berea sandstone. In order to process the data, we write the data file to a spreadsheet. Choose the file for the experiment that has just been completed. Make sure that the end of the line in the File Browser for the file you have chosen contains the designation ending with "A/D: yes", indicating that this data file has an associated ".a2d" file.

48) Select A/D to Spreadsheet from the menu in the file browser. A pop-up panel will appear. This gives options for the configuration of the spreadsheet. Select the criteria that conform to the spread sheet you use. Select the directory that the data is to be stored in and click OK.

49) Transfer the data to a computer running your favorite spreadsheet program.

50) Open the file using your favorite spreadsheet program and process the data. The following data should be processed. The differential stress applied to the specimen is computed from the force data. Compute the cross-sectional area of the specimen and divide it by the force. Convert the stress to units of MPa or psi depending on your preference. For this experiment we selected MPa. Next, the strains are computed from the output voltages of the LVDTs. Computing the strains is straightforward. First, multiply the scale factors for the displacement transducer by the output voltage (after first correcting for the initial offset in the output voltage). This quantity is divided by the separation between the rings. For this experiment the separation between the rings was 50.08 mm (2.0 inches). The result of this calculation is the strain computed for one axial LVDT. Repeat the procedure for the other axial LVDT. To obtain the average axial strain, average the two strains. To compute the radial strain on the specimen, first calculate the change in the diameter of the specimen by multiplying the scale factor for the radial displacement transducer by the change in the output voltage of the device. This value is then divided by the diameter of the specimen to obtain the strain normal to the loading axis.

51) Plot the data from the experiment. Figure 7-20 graphically displays the data collected on a sample. Strain, in millistrain, is plotted as a function of stress difference. In this diagram we plot three strains: axial, radial, and volumetric. Volumetric strain for a cylindrical sample is computed by summing the axial strain plus twice the radial strain. (Remember that the radial strain has a different sign than the axial strain.) The data collected on Berea sandstone are typical of most sandstones. The sample compacts to approximately two-thirds of its failure stress and then begins to dilate. The dilation is most apparent in the radial and volumetric strain. If Young's modulus and Poisson's ratio are to be computed, they should be computed over a linear portion of the stress-strain curve over a stress interval of between approximately 10 to 50% of the stress difference.

Figure 7-20. Strain and stress data collected on a sample

## **7.9. Mohr's Circle, Angle of Internal Friction and Cohesive Strength**

With the decline in conventional oil and gas production worldwide, petroleum exploration and production from unconventional oil and gas resources have gained great momentum throughout the world to fill the gap between ever increasing demand of energy and decreasing production of conventional reservoirs. Knowledge of geomechanical properties of target reservoirs ensures producing hydrocarbons from unconventional resources safely, environmental friendly, and economically. Rock geomechanical properties are key parameters in designing oil and gas well drilling and completion, modeling fluids flow in reservoir, and forecasting well production. Direct measurement of rock strength parameters such as cohesive strength and angle of internal friction is accomplished through uniaxial or triaxial strength experiment (destructive test).

The Mohr Theory of Failure, also known as the Coulomb-Mohr criterion or internal-friction theory, is based on the famous Mohr's Circle. Mohr's theory is often used in predicting the failure of brittle materials, and is applied to cases of 2D stress. Mohr-Coulomb theory is a mathematical model describing the response of rock to shear stress as well as normal stress. Generally the theory applies to materials for which the compressive strength far exceeds the tensile strength. In geotechnical engineering it is used to define shear strength of soils and rocks at different effective stresses. In structural engineering it is used to determine failure load as well as the angle of fracture of a displacement fracture in concrete and similar materials. Coulomb's friction hypothesis is used to determine the combination of shear and normal stress that will cause a fracture of the material. Mohr's circle is used to determine which principal stresses that will produce this combination of shear and normal stress, and the angle of the plane in which this will occur. According to the principle of normality the stress introduced at failure will be perpendicular to the line describing the fracture condition. It can be shown that a material failing according to Coulomb's friction hypothesis will show the displacement introduced at failure forming an angle to the line of fracture equal to the angle of friction. This makes the strength of the material determinable by comparing the external mechanical work introduced by the displacement and the external load with the internal mechanical work introduced by the strain and stress at the line of failure. By conservation of energy the sum of these must be zero and this will make it possible to calculate the failure load.

Mohr's theory suggests that failure occurs when Mohr's Circle at a point in the body exceeds the envelope created by the two Mohr's circles for uniaxial tensile strength and uniaxial compression strength. This envelope is shown in the Figure 7-21.

Figure 7-21 Mohr envelop for Bakken formation, established by drawing the best fit tangent to experimentally determined failure stresses at a range of confining pressures and isothermal conditions

## 7.10. Uniaxial Tensile Strength

Tensile strength of rocks is one of the most important parameters for drilling excavation in rocks, because rocks are much weaker in tension than in compression. There are two methods for determining the tensile strength of rock: indirect method such as Brazil Test, and direct method (ISRM, 1978). Because the cored Bakken samples can't meet the requirements of indirect testing methods for tensile strength in terms of size and quantities, we developed a uniaxial tensile strength tester that allows us to test 1-in diameter by 2-in length and 2-in diameter by 4-in length cylindrical rock specimens. This report introduces the apparatus and the verification testing results..

To perform direct measurement, an in-house tensile strength test apparatus (Figure 7-22) is set up. This uniaxial tensile strength tester was designed and developed following the ISRM (1978) suggested methods with references to some earlier literature (Fairhurst, 1961; Vutukuri et al., 1974). It is composed of a movable frame, a jack, a lever, upper and lower chains with swivel adaptors, a transparent bucket, and a dynamometer. A dynamometer (Figure 7-23) on the top is used to record the force where the specimen is loaded. Two steel caps are used to grip the specimen by gluing on each end of the specimen. A jack is used to increase the force.

Figure 7-22. Tensile strength test apparatus

Figure 7-23. Dynamometer on top of tensile strength test apparatus

During the measurement, it is important to mount the specimen in tension grips. Cylindrical specimen and epoxy based cements are used. The rock specimen is glued onto two caps in advance (Figure 7-24). During sample installation, the two caps are connected onto the upper and lower adaptors (Figures 7-25 and 7-26). The installed specimen is inside the center of a transparent bucket. The bucket allows observation during testing, and provides protection to the specimen at failure.

Figure 7-24. Specimen glued to steel caps

Figure 7-25. Tensile test apparatus (with upper side of the specimen is fixed)

Figure 7-26. Tensile test apparatus (with both sides of the specimen was fixed)

After the specimen installation is completed, the lower chain, the specimen, the upper chain, and the loading point of the dynamometer are all on a vertical line, without any torque and resistance, and each is free to rotation, the load force will be increased slowly with the jack until the specimen was crashed (Figure 7-27). At the testing, the jack applies load to the lever which pulls the rock specimen along the upper and lower chains until failure. The tensional force is showing on the dynamometer. At failure, the peak force can be recorded by the dynamometer (Figure 7-28).

Figure 7-27. Specimen is crashed

Figure 7-28. Reaching peak force as the specimen is crashed

The key for direct tensile strength test is to provide direct tension onto the sample. The criterion to verify if the apparatus, and thus the test, is successful is that the rock sample would fail in pure tension. This can be checked from the broken specimen. From Figure 7-27, it is obvious that the rock specimen is failure under pure tension, because the failure plane is flat and rough. Therefore, it can be concluded that this Uniaxial Tensile Strength Tests provides the capability of measuring the direct tensile strength.

## 8. EXPERIMENTAL RESULTS

We have tested 240 core plugs to obtain porosity, permeability, sonic velocity, static Young's modulus, static Poisson's ratio, Biot's coefficient, rock strength (destructive test), cohesive strength, and angle of internal friction. Information of 8 wells providing core plugs for test are shown in Table 8-1. The location of these wells can be found in Figure 3-2.

Table 8-1. Wells providing core plugs for test in this study

## 8.2. Permeability

Permeabilities of core plugs from 8 wells have been tested. Test results are listed in Table 8-3. More detail can be found in Attachments.

## 8.4. Dynamic Young's Modulus and Poisson's Ratio

Dynamic Young's modulus and Poisson's ratio of core plugs calculated from sonic velocity are shown in Table 8-5. More detail can be found in Attachments.

Table 8-5. Dynamic Young's modulus and Poisson's ratio of core plugs calculated from sonic velocity

## 8.5. Static Young's Modulus and Poisson's Ratio

Static Young's modulus and Poisson's ratio of core plugs are measured through non-destructive strength test. The measurement results are shown in Table 8-6. More detail can be found in Attachments.

Table 8-6. Static Young's modulus and Poisson's ratio of core plugs measured by non-destructive strength test.

Well #	Depth	Formation	Static Young's Modulus	Static Poisson's Ratio	Well #	Depth	Formation	Static Young's Modulus	Static Poisson's Ratio	Well #	Depth	Formation	Static Young's Modulus	Static Poisson's Ratio

## 8.6. Biot's Coefficient

Biot's coefficients of core plugs from 8 wells have been tested. Test results are listed in Table 8-7. More detail can be found in Attachments.

Table 8-7. Biot's coefficients of core plugs tested in this study

## 8.8. Cohesive Strength and Angle of Internal Friction Calculate from Uni/Triaxial Destructive Test

Cohesive strength and angle of internal friction of rock can be calculated from peak stress and confining pressure in uni/triaxial destructive test. The calculated results are shown in Table 8-9. More detail can be found in Attachments.

Table 8-9. Cohesive strength and angle of internal friction calculated from uni/triaxial destructive test.

### 8.9. Uniaxial Tensile Strength Test

Uniaxial tensile strength test is conducted on Hinckley sandstone sample only. The specimen diameter is 24.8 mm. The recorded peak force is 530 N. Therefore, the calculated tensile strength of this Hinckley sandstone is 10.97 MPa.

One vertical Bakken core plug from Well#96 was tested. The specimen diameter is 24.8 mm with a length of 52.27 mm. The recorded peak force is 3610 N. Therefore, the calculated tensile strength of this Bakken core plug is 74.7 MPa. Figure 8-1 shows the preparation of core plug for tensile strength test. Figure 8-2 illustrates the installation of core plug on tensile strength test apparatus. Figure 8-3 depicts the destruction of core plug after tensile strength test.

Figure 8-1. The preparation of core plug for tensile strength test

Figure 8-2 The installation of core plug on tensile strength test apparatus.

Figure 8-3 Pictures of the destruction of core plug after tensile strength test.

## 9. APPLICATION GUIDELINES FOR HORIZONTAL DRILLING AND HYDRAULIC FRACTURING

Several procedures and technologies have been developed through this project. We believe these procedures can play as guidelines or references for future exploration, development, and production of unconventional oil and gas resource like Bakken formation and depositional basin similar to Williston Basin. The technologies we propose here will benefit the energy sector through increasing experiment efficiency, shortening experimental test time, lowering experimental cost, optimizing drilling and stimulation design, reducing drilling and completion costs, and improving exploration and production efficiencies.

### 9.1. *Guideline for Creating 3D RQD (or Other Geological Parameter) Model*

A three dimensional RQD (or other geological parameter) model is very useful in revealing the geological features of the formation from different directions, at different levels, or in different angles. These models can be built using standard well logs or from self-defined well logs. If standard well logs are available, and the features of interest are directly or indirectly calculable from the logs, then the 3D model can be created directly using industrial software packages, such as PETREL.

Most old well logs were in image record. In this case, they need to be digitized at first. When the features of interest cannot be directly derived from standard well logs, self-defined well logs need to be used. This will include collecting the data from the cores, extrapolating the discrete data to a continuous distribution along the well, and create a digital self-defined well log. After that, PETREL or other similar software packages can be used to create the 3D geological model. The following steps show how a self-defined, three dimensional RQD (or other geological parameter) model is built.

- 1) Collect data through well logging or core laboratory measurement,
- 2) Self-define a well log,
- 3) Create and digitize well logs or RQD,
- 4) Calculate geological parameter if building other geological parameter model
- 5) Scale up the well logs or geological parameter,
- 6) Project the logs or geological parameter onto well cells,
- 7) Populate the logs or geological parameter from well cells into 3D space,
- 8) Application of the 3D model.

### 9.2. *In-Situ Stress Analysis and Guideline for Horizontal Drilling*

#### 9.2.1 Orientation of the Principal Stresses

Because the Williston basin is a cratonic basin, and vertical and sub-vertical faulting occurred in the basement and extended to the sedimentary formations, the in-situ stress field in the basin is in normal faulting stress regime, meaning that the maximum principal stress,  $\sigma_1$ , is vertical or sub-vertical. Consequently, the intermediate and minimum principal stresses,  $\sigma_2$  and  $\sigma_3$ , are horizontal, corresponding to the maximum and minimum horizontal principal stresses,  $\sigma_H$  and  $\sigma_h$ . The existence of some continuous lineament structures in the NE-SW direction, and some discontinuous, interrupted lineaments in the NW-SE direction indicates that in most area, the maximum horizontal principal stress,  $\sigma_H$ , is in the NE-SW direction, and the minimum horizontal principal stress,  $\sigma_h$ , is in the NW-SE direction. In some areas, this might be different due to local heterogeneity.

Because of the difficulties of measuring the in-situ stress tensors directly, the alternative way is to observe on oriented cores or on well walls. Unfortunately, there are no available conditions to carry out such kind of investigation. Therefore, we screened all the well completion reports available in North Dakota Geological Survey, and found 15 wells that contain some useful data for in-situ stress analysis. These in-situ stress data mainly relied on induced fractures in oriented cores, anelastic strain recovery, acoustic velocity anisotropy, and induced fractures in well walls, and the dip sonic method. At the same time, we searched all the related literatures for the in-situ stress of

the Bakken formation in the Williston Basin. These wells are scattered all over the southeastern part of the Williston Basin, the western part of North Dakota. Figure 9-1 shows the exact locations of these data wells on a North Dakota map.

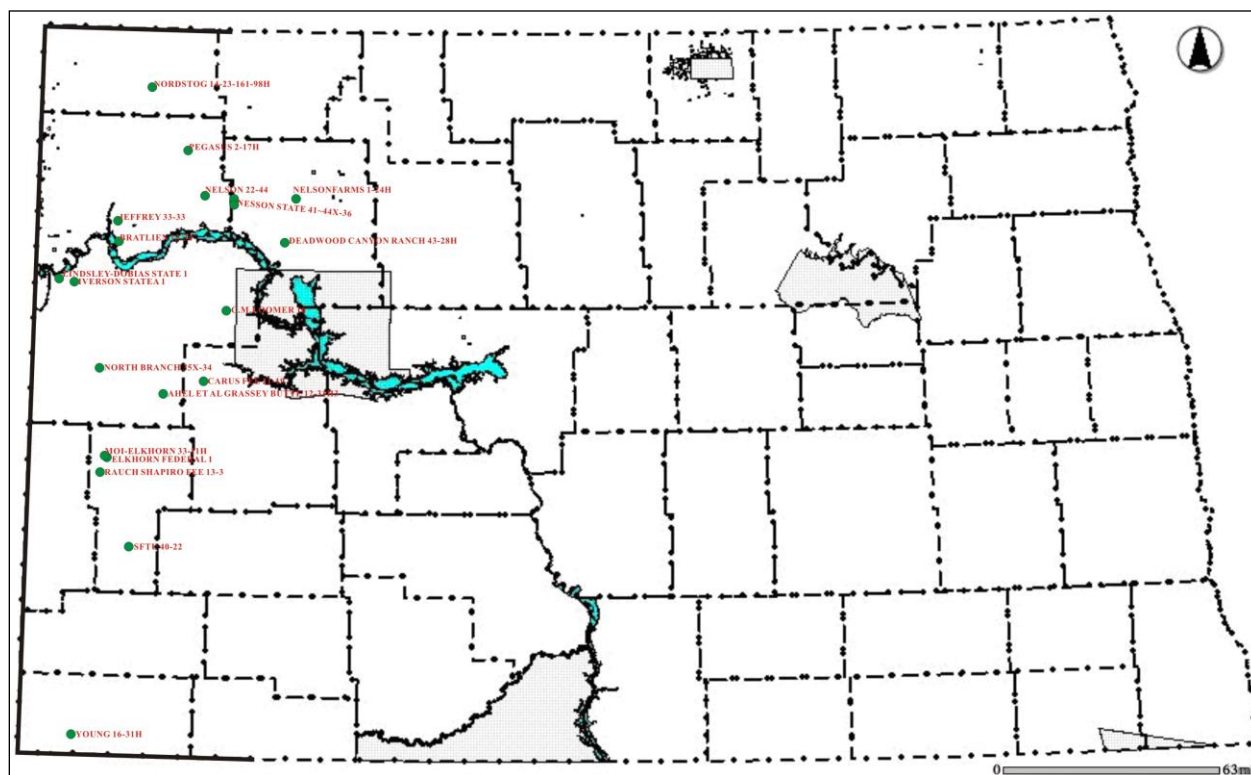

Figure 9-1. Distribution of data wells in North Dakota.

Table 9-1 shows all the collected data. Orientations of the maximum horizontal principal stress were plotted on a North Dakota map to show their change with geographic locations, as shown in Figure 9-2. From the data in Table 9-1 and Figure 9-2, we can conclude that the orientation of the maximum horizontal principal stress is between N30 E to N70 E, statistically.

Table 9-1 Summary of orientations of the maximum horizontal principal stresses in the Bakken formation

### 9.2.2 Stress Magnitude

In-situ stress magnitude can be determined through field test in the oil well, or in lab test on cores. These tests include micro hydraulic fracturing ( $\mu$ -HF) test, anelastic strain recovery (ASR), differential strain analysis (DSA), etc. Different methods can offer different data types, for example, the  $\mu$ -HF test can estimate stress magnitudes, but the ASR and DSA only can offer ratios among the three principal stresses. According to the previous section on the tectonics, the research area is under the dominant effect of normal faulting, with secondary strike-slip faulting. Based on the collected data, we have come to the uniform conclusion that the vertical principal stress is approximately equal to the overburden. Tables 9-2 and 9-3 summarize the data based on different methods and from different sources. According to these two tables, the stress gradients or magnitudes may differ a little bit with location and with formation. For the Bakken formation, the fracture gradient ranges from 0.75 to 0.85 psi/ft.

The ratios among three principal stresses, i.e., the vertical principal stress, the maximum horizontal principal stress and the minimum horizontal principal stress are 1:0.95-0.85:0.85-0.75, which means the stress conditions is favorable for normal faults and/or strike slip faults. Thus, the stress states should be  $\sigma_v > \sigma_H > \sigma_h$ .

For the orientation of the maximum horizontal principal stress, most data indicate a range between N30 E to N70 E; a few (four) data points show an orientation in NW. After examining these four data carefully, we found that three of the four data were based on the acoustic velocity anisotropy (AVA). According to Narr and Burruss (1984) (Figure 9-3) and Table 9-4, the secondary strike direction of natural fractures is NW. So for the three sets of data based on AVA, we intend to believe that the orientation very likely indicates the strike of micro natural fractures present in the oriented core, and represent a secondary orientation due to local heterogeneity. For the data serial No. 4, we checked the data quality and source carefully, and found that all these induced fractures in the oriented core are along with the orientation scribe line, so we think these fractures were created by the scribe groove.

We can get other evidence to support our estimated orientation of the maximum horizontal principal stress. The first reliable source comes from the World Stress Map (WSM) (Figure 9-4). According to the WSM, there are only a few data available in Williston basin, but the stress directions around this area is NE. The other source is the literatures. Several researchers (Haimson, 1978; Narr and Burruss, 1984) have compiled hydraulic fracturing in-situ stress measurement data onto a map (Figure 9-5), this map shows the stress orientation around this area is NE to NEE. In summary, the orientation of the maximum horizontal principal stress is mainly NE to NEE in the Bakken formation in the Williston Basin, North Dakota.

For the stress magnitudes, data shown in Tables 9-1 and 9-2 are rather scattered, which are reasonable. We can still extract some useful information from the above data sheets: i. e. the differences among three principal stresses are smaller than those calculated using Hooke's law; and the stress anisotropy is not remarkable. This is consistent with the analysis in the tectonics section in which the two slat layers neighboring the Bakken formation are considered responsible to this pseudo-lithostatic status.

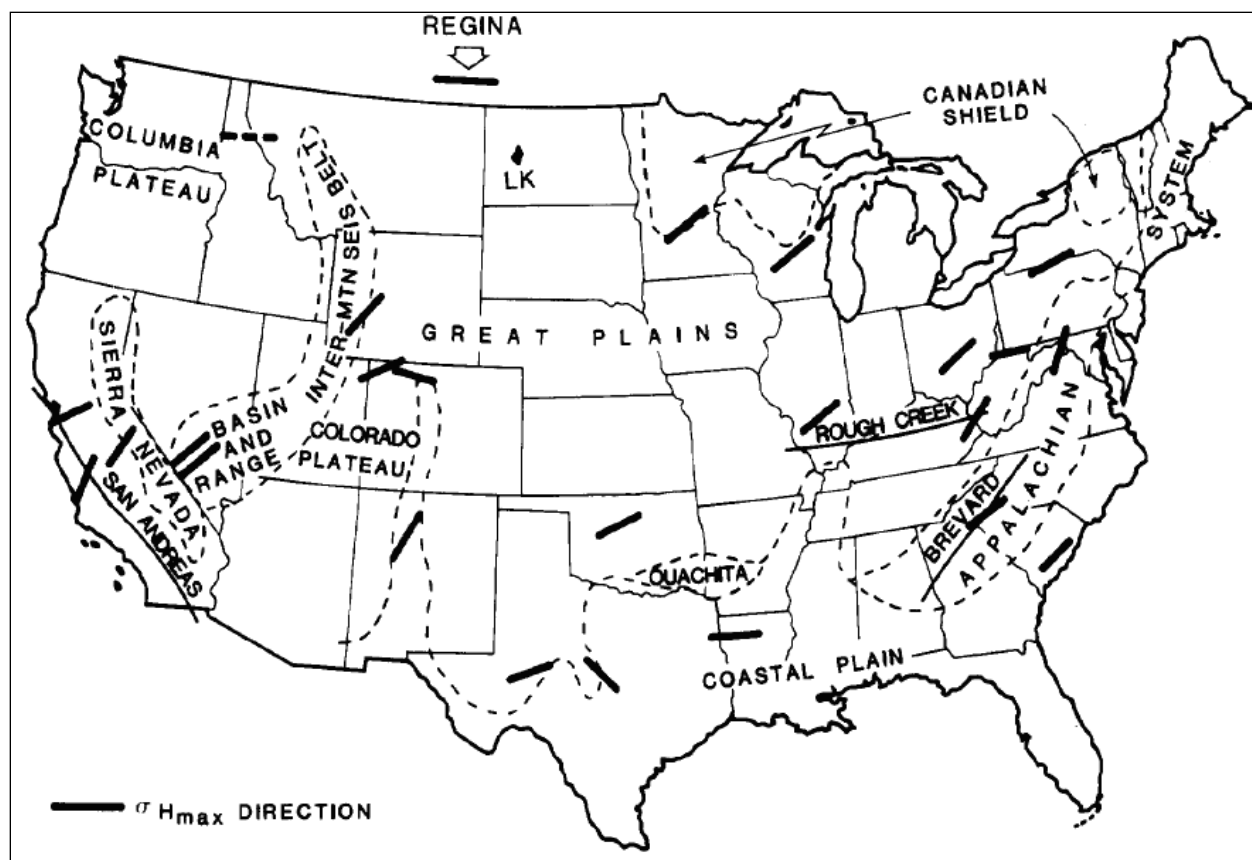

Figure 9-5 The maximum horizontal principal stress directions in continental United States based on the orientation of vertical hydrofractures (after Haimson, 1978; Narr and Burruss, 1984)

Such a conclusion can be proved by the structural characteristics of this region. Just as addressed above, in the Williston basin of North Dakota, most faults are normal faults, part are strike-slip faults, which means  $\sigma_v \geq \sigma_H > \sigma_h$ . However, according to the seismic investigation, there still exist some reverse faults, and the only possible explanation for this phenomenon is that the differential stress is very small, and such stress conditions can make all these things happen.

In summary, in the Bakken formation, the fracture gradient ranges from 0.75 to 0.85 psi/ft, and the ratios among three principal stresses, i.e. the vertical principal stress, the maximum horizontal principal stress, and the minimum horizontal principal stress are 1:0.95-0.85:0.85-0.75 (Table 9-4).

### 9.2.3. Numerical Modeling of Stress Distribution

The general technical route for numerical modeling is: (1) building the model to cover the target area, (2) obtaining data in some controlling points using direct measurement or other techniques, (3) determining the boundary conditions for the model; and (4) simulating the distribution of the properties in question in the whole area. Following these steps, we built a numerical model and simulated the in-situ stress field in the Bakken Formation using the data summarized in Tables 9-1 through 9-4.

#### *Building the numerical model*

The establishment of a numerical model includes determining the geometries and estimating physical parameters of the materials inside the model.

For the Bakken Formation, based on the figures of Fred (1978), we built the model as shown in Figures 9-6 and 9-7. Our objectives were to cover the maximum area with acceptable resolution in the depth direction. To achieve the objectives, we exaggerated the thickness and compress the lengths of the simulated block. The final numerical model was 217.1 miles long in the X-direction (SE-NW direction), 125.8 miles long in the Z-direction (SW-NE direction), and 270 ft in the Y-direction (vertical direction) which included the whole Bakken Formation (upper, middle and lower units), and part of Lodgepole formation on the top, and part of Three Forks formation at the bottom. The upper boundary was at the elevation of -10,000 feet, and the lower boundary plane is at the elevation plane of -10,270 feet. The six sides of this numerical model were rectangular planes. Figure 9-8 shows the geometry and the geological information in the depth direction.

The top layer of the model was the Lodgepole formation. It was limestone. The middle layer was Bakken formation, which include three parts: the upper Bakken, the middle Bakken, and the lower Bakken. The upper and lower Bakken are black shale; and the middle Bakken is sandstone, inter-bedded with siltstone, dolomite and limestone. The lower layer of the model is the Three Forks formation; it was dolomite. Because all these formations were at great depth, there is no mechanically significant fault and other discontinuities in the modeled area. Therefore, an

elastic and continuous model was assumed. Figures 9-8 and 9-9 show the numerical model; it contained 40,545 elements and 180,181 nodes. Element size was selected to reflect the deformation of the geological structural features.

### ***Boundary conditions and input parameters***

In finite element simulation, it is required to constrain the boundaries of a numerical model. Correct constraint conditions can help assure the reliability and rationality of the calculated results.

For this numerical modeling study, the bottom plane (i.e.  $Y = -10,270$  ft plane) was constrained rigidly in the  $Y$ -direction; the right  $X$ -plane (i.e.  $X = +217.1$  mile plane) was rigidly constrained in the  $X$ -direction, and the back  $Z$ -plane (i.e.  $Z = 0$  mile plane) was under the rigid constraints in the  $Z$ -direction. Evenly distributed planar vertical load (overburden) of 10,000 psi was applied to the upper boundary (i.e.  $Y = -10,000$  ft plane). The left  $X$ -plane (i.e.  $X = 0$  mile plane) and the front  $Z$ -plane (i.e.  $Z = +125.8$  mile plane) were loaded with linearly increased horizontal stresses, each at a stress gradient of 0.8 psi/ft and 0.9 psi/ft, respectively. Figure 9-10 shows the schematic boundary conditions.

Loads on the numerical model were classified into two categories. The first category included the gravitational load on the top plane, and the hydrostatic loads on the side planes due to the overburden pressure. The gravitational load was applied to the center of each element; the magnitude was determined by the weight of rock column above the element. The second category of the loads was the loads to be determined, which were applied onto the left  $X$  plane ( $X = 0$  mile plane) and the front  $Z$  plane ( $Z = +125.8$  mile plane), as indicated in Figure 9-10. During the back analysis process, the above-mentioned data in Table 9-4 were used as the stress constraint conditions. Using linear elasticity, the load magnitudes on the two side planes were determined. Finally, the loads on the entire numerical model were calculated.

Figure 9-10. Boundary conditions for the numerical model.

### Input parameters

Generally, lab tested strength parameters of rock specimens are different from that of real field rock-masses. How to apply the lab test results on intact rock specimens to represent reservoir rock-mass properties is one of the research topics in geomechanics. One of the widely accepted methods is the Hoek-Brown strength criterion. According to the physical and mechanical parameters summarized above, combined with the characteristics of this numerical model, the physical and mechanical properties of reservoir rock-masses in the research area were estimated with the new version of Hoek-Brown Criterion. All the input parameters are shown in Table 9-5.

Table 9-5 Input parameters for the numerical model

Formation	Rock type	$E_m$ ( $\times 10^6$ psi)	$\sigma_t$ (psi)	$C$ (psi)	$\phi$ ( $^\circ$ )	$\gamma$ (psi/ft)	Lateral loading coefficient X	Lateral loading coefficient Z
Lodgepole	Limestone	3.88	87.46	785.4	37.7	1	0.8	0.9
Upper Bakken	Shale	1.35	12.62	229.2	28.1	1	0.8	0.9
Middle Bakken	Sandstone	2.24	71.79	876.89	41.3	1	0.8	0.9

Three Forks	Dolomite	6.53	162.87	1307.5	38.2	1	0.8	0.9

### 9.2.4 Results and Discussion

Numerical modeling serves two major functions: (1) as a numerical tester to find (define) the proper boundary conditions with some known (controlling) values, and (2) as a calculator to find the distribution of some properties inside the middle of some known (controlling) points.

First, we conducted the numerical modeling according to the above-mentioned boundary conditions and stress constraints to estimate the unknown loads. Then we calculated the stress magnitudes on the two lateral planes. After multiple backward calculations and parameter adjustments, the unknown loads were determined. The final loads on the X-plane start from 8000 psi at  $Y = -10,000$  ft, and increase by 0.8 psi/ft downward to  $Y = -10,270$  ft; the direction of the load is parallel to the X-axis, compressive to the X-plane. Similarly, the final loads on the Z-plane start from 9000 psi at  $Y = -10,000$  ft, and increases by 0.9 psi/ft downward to  $Y = -10,270$  ft; the direction of the load is parallel to the Z-axis, compressive to the Z-plane. Based on these geometric, material and load conditions, we got an estimated stress distribution in the Bakken Formation.

According to the modeling results and the actual engineering needs, Figures 9-11 through 9-15 show the distribution of the maximum and minimum stresses in the Bakken Formation. In all the figures, the stresses are in psi, and negative values represent compressive stresses. The maximum and minimum principal stresses are defined by their absolute values.

Figure 9-11. Orientations of principal stresses.

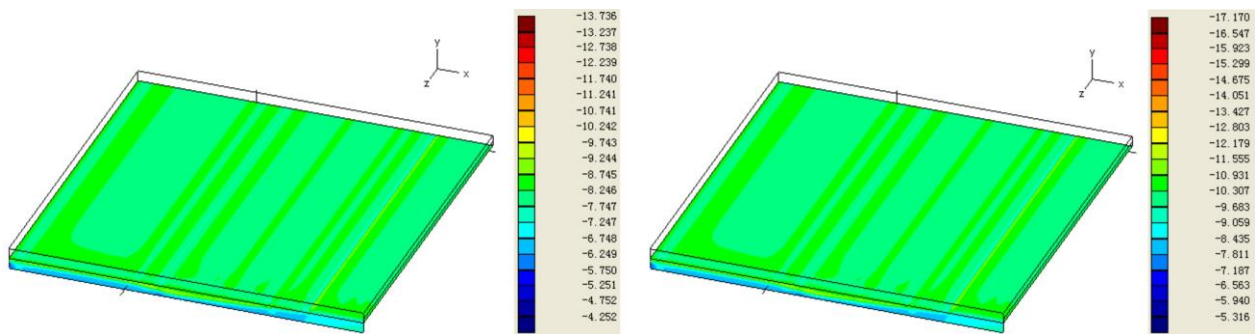

Figure 9-12. Distribution of minimum (left) and maximum (right) principal stresses in the Bakken Formation.

Figure 9-13. Distribution of minimum principal stress on the horizontal plane at Y = -10135ft.

Figure 9-14. Distribution of maximum principal stress on the horizontal plane at Y = -10135ft.

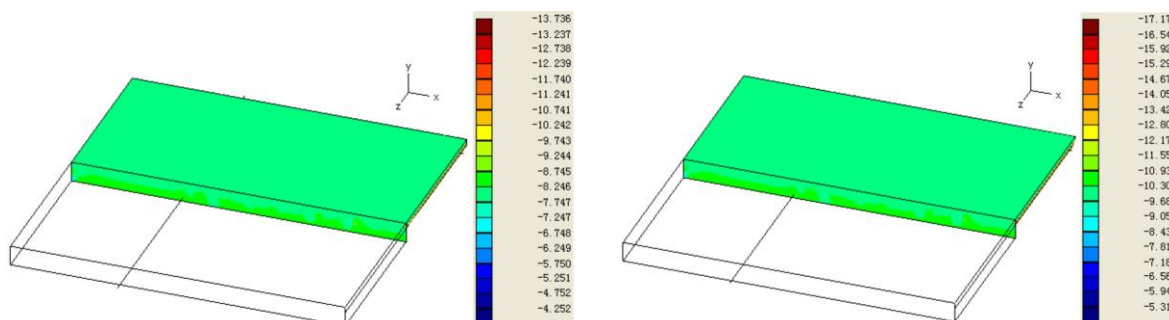

Figure 9-15. The min (left) and the max (right) principal stresses on the vertical plane at Z= 62.9 mile planes.

From the above numerical results, one can see that, under the assumed boundary conditions and material properties, the orientation of the principal stresses are stable and consistent across the simulated area (Figure 9-11). Change of the maximum and minimum principal stresses in the Bakken Formation is relatively homogeneous (Figures 9-12 to 9-14); their magnitudes are mainly influenced by the material properties of the rock-mass in these formations (Figure 9-15). In general, the principal stresses increase with the depth.

### 9.3. Guideline for Horizontal Drilling- Impacts of Stresses on the Stability of Horizontal Wells

#### 9.3.1 Impacts of Stresses on the Stability of Horizontal Wells

After we know the stress field in the Bakken Formation, we can further study how the stress regime affects the stability of horizontal wells. After screening on all the oil wells in Williston Basin, North Dakota, we found that most horizontal wells were parallel to the direction of the maximum horizontal principal stress ( $\sigma_H$ ), some were perpendicular to  $\sigma_H$ , and a few were in an acute angle with  $\sigma_H$ . According to these facts, we designed three cases to simulate the impact of the in-situ stresses on the stability of horizontal wells: (1) well axis is parallel to  $\sigma_H$ ; (2) well axis is perpendicular  $\sigma_H$ ; and (3) well axis is  $45^\circ$  to  $\sigma_H$ .

#### 9.3.2 Establishment of the Numerical Model

The establishment of a numerical model includes determining the boundary geometries and sizes of the interested area and estimating physical and mechanical parameters for the numerical model. To investigate the impact of in-

situ stresses on the stability of horizontal wells in the Bakken Formation, we built the models according to the well completion report, as shown in Figure 9-16. In order to get a better resolution at the current limitation of software and computational capacity, for Cases 1 and 2, we built a rectangular parallelepiped model of 36-inch X 36-inch X 100-inch, with a 6-inch diameter horizontal well through the center of the model. The six outer side surfaces of this model are flat, regular planes (Figure 9-17). For Case 3, we built a cubic model of 36-inch, with a 6-inch diameter horizontal well through, and counter-clockwise rotated  $45^\circ$  of the maximum and minimum horizontal principal stresses  $\sigma_H$  and  $\sigma_h$  with respect to the well axis, i.e., the Z-axis changed from SW-NE to S-N, and X-axis from SE-NW to E-W (Figure 9-18). Because the Middle Bakken Unit is currently the major production zone, our models focus on this unit. Again the model is simplified to be elastic and continuous.

Figure 9-16. Generalized depiction of an open-hole completion in the Middle Bakken Unit (based on NDDMR-OGD well file).

Figure 9-17. Model for the horizontal well parallel/perpendicular to the maximum horizontal principal stress,  $\sigma_H$ .

Figure 9-18. Model for a horizontal well at 45 °angle to the maximum horizontal principal stress,  $\sigma_H$ .

### 9.3.3 Boundary Conditions and Input Parameters

#### *Boundary conditions*

During the finite element simulation, it is required to constrain the boundaries of the model. For Cases 1 and 2, the bottom boundary is constrained rigidly in the Y-direction; the right X plane is rigidly constrained in the X direction; and the back Z plane is under the rigid constraints in Z direction. Due to the relatively small size, evenly distributed loads were applied to the upper Y, left X, and front Z boundary planes. The schematic boundary conditions for these two cases are shown in Figures 9-19 and 9-20. For Case 3, the loads were applied on top and the four extended lateral planes (because it is hard to apply strain constraints on to these planes); the bottom boundary is constrained rigidly in Y direction, as shown in Figure 9-21.

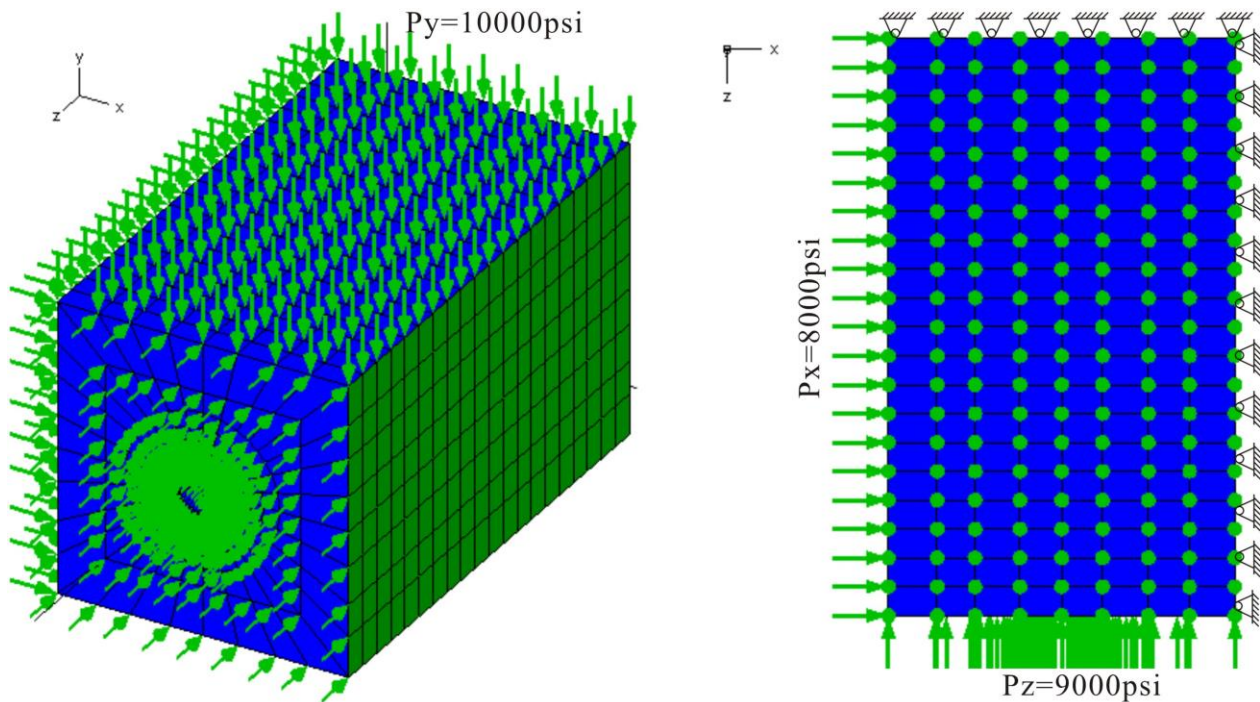

Figure 9-19. Boundary conditions for the Case 1, well axis parallel to  $\sigma_H$ .

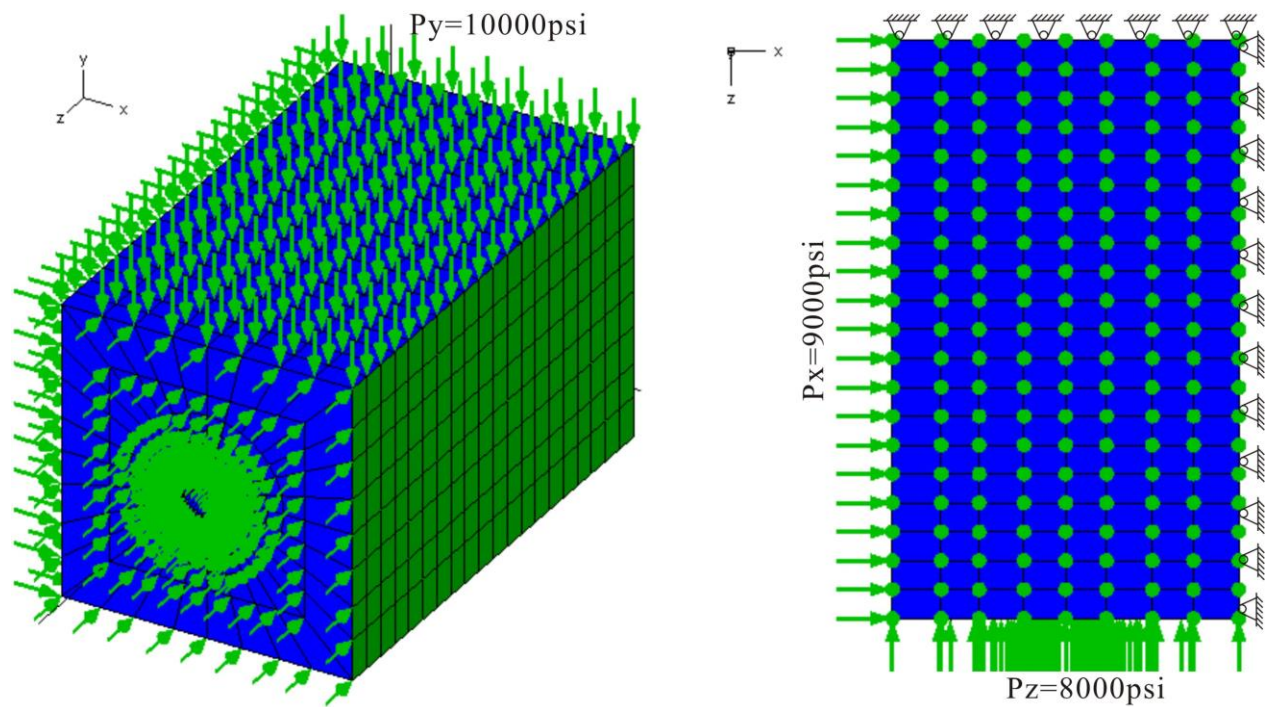

Figure 9-20. Boundary conditions for the Case 2, well axis perpendicular to  $\sigma_H$ .

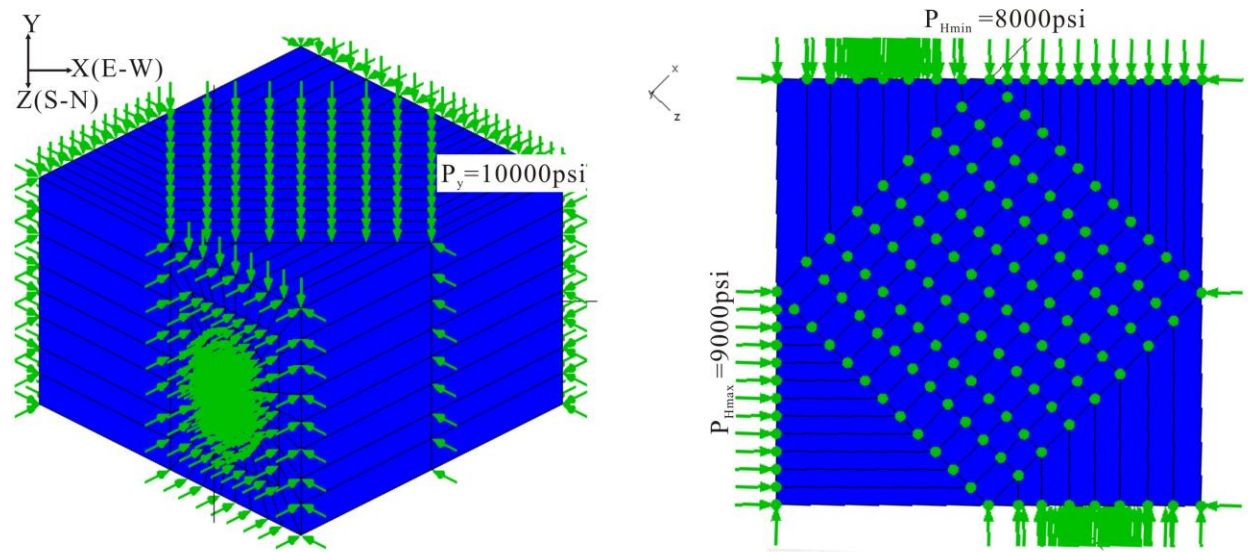

Figure 9-21. Boundary conditions for the Case 3, well axis is  $45^\circ$  to  $\sigma_H$ .

**Input parameters**

The procedures and rock properties used in the previous section were used here, as shown in Table 9-6.

Table 9-6. Input parameters for the Middle Bakken Unit numerical model

Formation	Rock type	$E_m$ ( $10^6 \text{ psi}$ )	$\sigma_t$ (psi)	$C$ (psi)	$\phi$ ( $^\circ$ )	$\gamma$ (psi/ft)	Lateral loading coefficient $X$	Lateral loading coefficient $Z$
Middle Bakken	Sandstone	2.24	71.79	876.89	41.3	1	0.8	0.9

9.3.4 Case 1- Well Axis Parallel to the Maximum Horizontal Principal Stress

Figures 9-22 and 9-23 show the distribution of maximum and minimum stresses around the well section. The maximum and minimum stresses along the well axis are shown in Figures 9-24 and 9-25. According to these results, the compressive stress concentration will occur at the two middle lateral spots of the well wall, and the tensile stress concentration will occur at the top and bottom arch spots of the well. The concentration coefficient of the maximum principal stress is larger than that of the minimum principal stress. As indicated in Figure 9-26, tensile failures may occur at the top and bottom arch spots of the well wall. These two spots may tend to fail during the construction and operation of the horizontal well. So special attention should be given to this stability problem.

Figure 9-22. Case 1: The maximum principal stress  $\sigma_1$  around the well bore section.

Figure 9-23. Case 1: The minimum principal stress  $\sigma_3$  around the well bore section.

Figure 9-24. Case 1: The maximum principal stress along the well axis.

Figure 9-25. Case 1: The minimum principal stress along the well axis.

Figure 9-26. Case 1: Safety coefficient for minimum principal stresses. Possible tensile failure on top and bottom of the well bore.

9.3.5 Case 2- Well Axis Perpendicular to the Maximum Horizontal Principal Stress

The following figures show the stress distribution around the well section (Figures 9-27 and 9-28) and along the well axis (Figures 9-29 and 9-30). The tensile stress concentration also occurred at the top and bottom of the well bore (Figure 9-31). According to these results, these results are similar to those mentioned above, but here the stress magnitudes (absolute values) are lower than those in Case 1.

Figure 9-27. Case 2: The maximum principal stress  $\sigma_1$  around the well bore section.

Figure 9-30. Case 2: The minimum principal stress along the well axis.

Figure 9-31. Case 2: Safety coefficient for minimum principal stresses. Possible tensile failure on top and bottom of the well bore.

### 9.3.6 Case 3- Well Axis 45-Degree to the Maximum Horizontal Principal Stress

The following figures show the stress distribution around the well section (Figures 9-32 and 9-33). The safety coefficient for Case 3 is shown in Figure 9-34. Comparing to the results in Cases 1 and 2, it is seen that the distribution of the maximum and minimum principal stresses are similar in all three cases, however, their magnitudes are different.

Figure 9-32. Case 3: The maximum principal stress  $\sigma_1$  around the well bore section.

Figure 9-33. Case 3: The minimum principal stress  $\sigma_3$  around the well bore section.

Figure 9-34. Case 3: Safety coefficient for minimum principal stresses. Possible tensile failure on top and bottom of the well bore.

9.3.7 Discussion

Actually, the above figures show the overall distribution of the maximum and minimum principal stresses for each of the studied each cases. However, to compare the differences among the three cases, we need to set up specific stress monitoring points around the well section to get the specific magnitudes of each case and compare them. From the above study, it is obvious that the top, bottom, and the middle spots of the well bore are the most stress-concentrated points, and need more attention on their detailed values (Figure 9-35).

Figure 9-35. Stress monitoring points around the well section.

Table 9-7 summarizes all the data from these four stress-concentrated points. According to the data shown in Table 9-7, there are small differences among these three research cases. However, we can also find out that case 2 is good to the stability the horizontal well, and case 3 is the worst design among the three.

Table 9-7 Summary of stress data at the four monitoring points

Cases	Monitoring point	Coordinates		$\sigma_1$ (1000 psi)	$\sigma_2$ (1000 psi)	$\sigma_3$ (1000 psi)
		X	Y			
Case1	A	240	300	-0.049	-0.055	-0.061
	B	300	240	-22.104	-24.867	-27.63
	C	240	180	-0.05	-0.056	-0.062
	D	180	240	-21.901	-24.639	-27.376
Case2	A	240	300	-0.068	-0.076	-0.085
	B	300	240	-21.096	-23.733	-26.37
	C	240	180	-0.068	-0.076	-0.085
	D	180	240	-20.867	-23.475	-26.084
Case3	A	240	300	0.726	0.654	0.581
	B	300	240	-17.812	-20.039	-22.265
	C	240	180	0.801	0.721	0.64
	D	180	240	-19.166	-21.561	-23.957

### 9.3.8 Conclusion on In-Situ Stress on Stability of Horizontal Wells

From screening and reviewing previous work by oil companies, the orientation of the maximum horizontal principal stress is NE to NEE in the Bakken Formation, Williston Basin, North Dakota. For the Bakken Formation, the fracture gradient ranges from 0.75 to 0.85 psi/ft, and the ratios among three principal stresses, i.e. the vertical principal stress, the maximum horizontal principal stress and the minimum horizontal principal stress are approximately 1:0.95-0.85:0.85-0.75. Based on a simplified numerical modeling, distribution of in-situ stresses in the Bakken Formation is relatively homogeneous. The stress orientations are stable and consistent across the study area; and the magnitudes may be affected by the mechanical properties of the rock-mass in the formations. In general, the stress magnitude increases with the depth, i.e. the stress magnitudes will increase at a certain stress gradient. Impact of in-situ stress on stability of horizontal wells were numerically studied. Compressive stress concentration appeared at the middle of the well-bore side walls, and tensile stress concentration appeared at the top and bottom of the well bore. The magnitude varied with the relative orientation of the horizontal well axis with respect to the maximum horizontal stress. From the stability point of view, the case of the well axis perpendicular to the maximum horizontal principal stress is the best; and the case of the well axis at 45° angle with the maximum horizontal principal stress is worst.

In this study, we collected and compiled existing geomechanical data from previous work by others. After screening all reports of 4000+ Bakken wells. We derived the orientation and magnitude of the in-situ stress field in the Bakken Formation, and numerically modeled the impact on stability of horizontal wells in different directions. As a summary, we obtained the following insights about the basin and the geomechanical properties of the Bakken Formation:

- 1) The Williston Basin is a cratonic basin. There have been no major tectonic activities since Paleozoic eon.
- 2) The tectonics of the basement controls the geology in the sedimentary formations. The anticlines and domes in the sedimentary formations represent the subsurface highs in the basement.
- 3) Vertical and sub-vertical faulting was the dominant fracturing process. Strike-slip faulting in the NE-SW and NE-SW directions were secondary and tertiary fracturing processes.
- 4) The Bakken formation is around 10,000 ft below the surface. There are two major salt formations above and below the neighborhood of the Bakken formation. The salt formations changed the overburden-induced horizontal stress magnitude from dominated by Hooke's law to Pascal's law.
- 5) In-situ stresses in the Bakken formation is controlled by the above features, and can be estimated as follows:
  - a. The maximum principle stress,  $\sigma_1$ , is in the vertical direction, and can be estimated with the overburden pressure,  $\sigma_v$ ;
  - b. The intermediate principle stress,  $\sigma_2$ , is in the horizontal direction. It is the maximum horizontal stress,  $\sigma_H$ . It is in the NE direction in general, but may vary due to local heterogeneity. The ratio of  $\sigma_H / \sigma_v$  is about 0.9, closer to the hydrostatic status than to the Hooke's status.

- c. The minimum principle stress,  $\sigma_3$ , is in the horizontal direction. It is the minimum horizontal stress,  $\sigma_h$ . It is in the NW direction in general, but may vary due to local heterogeneity. The ratio of  $\sigma_h / \sigma_v$  is about 0.8, closer to the hydrostatic status than to the Hooke's status.

Using the collected geomechanical data from previous work by others and this study, we conducted 3-dimensional numerical modeling to simulate the stress distribution inside the Bakken Formation and investigated the impact of in-situ stress orientation on wellbore stability. The results indicate that compressive and tensile stress concentration occurs around the wellbore at different points, and the magnitudes change with the orientation of the well with respect to the maximum horizontal stresses.

## 10. NEW METHODOLOGY FOR IN-SITU STRESSES AND FRACTURE TOUGHNESS

### 10.1. *Kaiser Effect Method for In-Situ Stresses*

In this study we have designed the Kaiser In-Situ Stress (KISS) system. The KISS system's goal is to determine in-situ stresses in rock formations by means of stress-induced acoustic emission (AE) and the Kaiser effect. The KISS system is a non-destructive approach of in-situ stress determination and has received much attention in the past. To fully understand AE, the Kaiser effect and how it is used to determine stress we present the necessary theoretical background, available experimentation and results from other investigators to investigate the plausibility of AE and the Kaiser effect for in-situ stress determination. The final goal of the design is to investigate the uniaxial compression induced AE and the Kaiser effect in rock to determine the fundamental process of the Kaiser effect. Once confirmation of the Kaiser effect from the uniaxial compression method is achieved, more sophisticated experimentation with triaxial compression-induced AE and the Kaiser effect, which simulates the in-situ conditions, can be analyzed (Blanksma, 2011).

Besides only proposing the KISS system as a theoretical design we also presents results from an initial design KISS system. In order to find out the plausibility of using AE and the Kaiser effect for in-situ stress determination, experiments have to be conducted using fundamental processes. Theoretical work on AE and the Kaiser effect has been investigated extensively and the only way to determine scientific plausibility is by empirical observation and analysis. The process investigates uniaxial compression induced AE to determine the presence of the Kaiser effect. By actually performing the experiments that quantify physical phenomena comparisons can be made to see if uniaxial compression induced AE can determine in-situ stresses and be developed further to determine true states of in-situ stress (Blanksma, 2011).

#### 10.1.1 Importance of Kaiser Effect Method

The in-situ stresses in rocks can be determined by means of compression induced acoustic emission (AE) and the Kaiser effect. AE is analogous to earthquakes. Earthquakes transmit energy by means of compression waves and shearing waves. Micro cracks transmit energy by means of compression waves in the form of acoustic emission. The Kaiser effect is an AE phenomenon defined as the absence of detectable acoustic emission until the previously applied stress level is exceeded (Norlund and Li). It is a measure of damage, specifically microcracks in a material subjected to loading. It is firstly investigated on metals by Joseph Kaiser (Kaiser, 1950).

#### 10.1.2 Kaiser Effect Method- Problem Definition

Current methods for determining rock in-situ stresses used today can be classified into two categories: destructive method and non-destructive method. Destructive methods disturb the in-situ rock conditions, i.e. inducing strain, deformations or crack openings. Non-destructive methods are based on observation of the rock behavior without major influence on the rock. We focus on non-destructive method by developing a method to determine in-situ stresses in rock that is inexpensive, non-evasive and relatively accurate, based on the fundamental idea of induced acoustic emission. The work contains two stages: 1) development of the KISS system, 2) testing and improving.

The goal of the first stage is to develop the KISS system based on the theoretical framework of acoustic emission and the Kaiser effect. Hardware is set up and software is designed at this stage. Another goal in this step is to become familiar with coding the data acquisition system for the KISS system. National Instruments *LabVIEW* will be utilized for data acquisition and data analysis. Since substantial knowledge is required to use *LabVIEW*, designing the data acquisition code offers the opportunity to learn and use a powerful program. In addition, knowing how to code programs using different software is a vital part of all engineering disciplines. Once the in-situ stresses are experimentally obtained by the KISS system, stress transformation equations are implemented to determine the principle stress tensor. The stress tensor contains the magnitude of the principal stresses and the direction cosines for each stress (Blanksma, 2011).

The second stage involves all the testing and calibration of the hardware and software. Different rock samples that represent different oil containing formations will be analyzed to compare one against the other. Because the system relies on analog to digital processing, large amounts of data will need to be stripped down to reveal the physical properties that are useful to this design.

### 10.1.3 Kaiser Effect Method- Theory

#### *Kaiser Effect in Rock*

The Kaiser effect is a physical phenomenon prevalent in many materials as well as rocks. The theoretical foundation of the Kaiser Effect can be demonstrated by many different physical phenomena including electromagnetic waves, seismic waves and important to this study, induced acoustic waves. AE (acoustic waves) is a property of wave mechanics and is the propagation of a lateral compression wave through a medium that is produced by an energetic event such as cracking or sudden deformation. The energy of the wave can range greatly. For example, large scale waves travelling through a rock mass are the source of what is commonly known as earthquakes. However, small scale waves are also produced by small strain. These small waves are nowhere near the magnitude of an earthquake, but the idea is logical that some induced AE waves represent “miniature” earthquakes travelling through a rock mass. Depending on the rate of change in the volume of a rock mass relative to its original volume, i.e. strain rate, energy may be transformed into a pressure wave travelling through the rock mass if cracking occurs. The propagating wave is identified as AE and it directly indicates an amount of damage in a rock specimen from the formation of a crack (Blanksma, 2011).

The Kaiser effect can be produced empirically numerous ways. One method for identifying damage in rock is to count acoustic events and look for any changes in time; changes of the number of AE in time represent an increase or decrease in crack growth. The empirical method that exploits the Kaiser effect takes place in rocks and materials subjected to cyclic loading/unloading. In the simplest case of cyclic, uniaxial loading with the cycles peak stress increasing from cycle to cycle, the acoustic emission is zero or close to the background level as long as the current stress remains below the largest previously reached stress value. As this peak stress value is attained, the AE activity increases dramatically (Lavrov, 2003). The change in AE activity at the point of previously applied maximum stress is the Kaiser Effect. A graph in Figure 10-1 of AE versus time for two cycles illustrates the concept (Blanksma, 2011).

Figure 10-1. Two loading cycles showing AE counts versus stress. The absence of AE in cycle 2 indicates the Kaiser Effect

The rate of AE is a function of stress on a rock and most importantly the time the rock has been under stress. Because of this relationship rock have the ability to “remember” the largest previous stress that had once acted upon it. The theory is that the first cycle of compression is actually the in-situ stress state of a rock in the subsurface and

by extracting a sample of the rock and reloading can be completed in a lab to determine the previously applied maximum stress. This maximum “memorized” stress is a direct consequence of the Kaiser effect and can be determined experimentally. By verifying that the memorized stress is in fact the maximum previously applied stress may allow for determination of the entire in-situ stress regime of the rock. Determining the “memorized” stress ( $\sigma_m$ ) requires mathematical analysis of the second cycle cumulative AE hits versus stress. The Kaiser effect can be recognized as an inflection point (change in slope) on the graph of cumulative AE versus stress (Lavrov, 2003). **Figures 10-2 and 10-3** show the location of  $\sigma_m$ . Finding the inflection point can be performed by bilinear regression, or by drawing tangents to the two parts of the curve and searching for their intersection (Lavrov, 2003).

**Figure 10-2.** A graph of the cumulative AE hits ( $\Sigma N$ ) versus stress ( $\sigma$ ) for two loading cycles subject to uniaxial compression.

**Figure 10-3.** Inflection in the cumulative AE hits ( $\Sigma N$ ) versus stress ( $\sigma$ ) graph indicates the previous maximum stress state.

Determining the inflection point as the peak memorized stress level requires high resolution equipment and therefore is not always evident when comparing cumulative AE hits versus stress. A technique developed by Yoshikawa and Mogi (1989) can be used by comparing the AE hit rate versus stress. **Figure 10-4** gives a graphical example of this method. This graph shows a better indication of where the Kaiser point is located. The Kaiser point will be indicated by the separation of the two lines corresponding to different loading cycles. In the first cycle AE hit rate increases as stress increases. In the second cycle AE hit rate will be the same as in cycle one. However, once the stress level in cycle two reaches the previous applied stress level in cycle one, AE hit rate will no longer be the same for both cycle one and two. The bifurcation point is the Kaiser point (Blanksma, 2011).

**Figure 10-4.** AE hit rate versus stress ( $\sigma$ ) reveals the Kaiser point at the bifurcation of the two different loading cycles.

### ***Physical Models for the Kaiser Effect***

Empirical evidence for the Kaiser effect clearly shows the physical phenomenon and has been extensively investigated prior to the 1980's. However an accepted physical model was not fully developed until much later and still receives changes to this day. The Kaiser effect was first investigated by Joseph Kaiser in the early 1950's. His initial experiments were conducted on metals, woods and sandstones (Kaiser, 1953). Since the work of Joseph Kaiser many physical models have been suggested to explain the Kaiser effect.

For practical purposes the physical model that best explains AE and the Kaiser effect is analogous to the mechanics of an earthquake. During an earthquake deformation of crustal material occurs rapidly and releases energy in the form of shearing (S-waves) and compression (P-waves) waves. In small rock mass, on the order of inches and feet, rapid deformation takes place when exposed to a force. The deformation exists in the form of microcracks. The microcracks can be related to earthquakes but have orders of magnitude less energy. **Figure 10-5** shows a schematic of the microcrack model (Blanksma, 2011). Many more sophisticated models have been investigated for AE and the Kaiser effect. Stevens and Holcomb (1980) presented a sliding crack model to account for stress memory in rock. Holcomb (1980) also suggested a reversible Griffith crack model to explain the Kaiser effect. Later suggested models by Lavrov (1997) used Fairhurst-Cook wing crack models to interpret the Kaiser effect in uniaxial compression (cycle 2) after true triaxial compression (cycle 1) (Blanksma, 2011).

Figure 10-5. The microcrack model for AE

## 10.2. Kaiser Effect Method –Experiment Setup and Procedure

### 10.2.1 Design Constraints

Obtaining a rock specimen that has been cored from a rock formation can be accomplished directly or indirectly. Direct coring of a rock formation, especially oil containing rock formation is expensive and problematic for the KISS system. For example core from the Bakken Formation in North Dakota is highly valuable and difficult to obtain. Also, obtaining core samples directly disturbs the in-situ stress on the rock and results in damage caused by tensile and shear stresses near the drill bit, thus complicating any Kaiser Effect observation on the sample core (Lavrov A. , 2003). An indirect approach can be considered by using rock with known characteristics that resemble oil containing rocks. Acquiring these rocks is usually inexpensive; however the accuracy of the results depends completely on the similarity of the rock being tested to oil bearing rock. In this study indirect measurement on various rock types will be implemented to ensure the system works properly, if oil containing core can be obtained it will be tested by the KISS system. Rock type has a profound effect on AE. Most Kaiser effect experiments were performed on brittle rocks because they produce more micro cracks upon compression and thus have a higher AE frequency compared to softer rocks. Results obtained by Filimonov et al. (2002) on rock salt, a very ductile rock, revealed a well pronounced Kaiser effect. Results by Dunning et al. (1989) revealed a clear Kaiser effect on sandstone if the sample was preloaded to about 60% of its peak strength and inclined at an angle to simulate a fault zone (Blanksma, 2011).

After obtaining a suitable core sample to test, time is of the essence. Like humans, the ability for a rock to retain its memorized stress history fades with time. Once the rock is removed from the rock mass, AE activity decays exponentially to the point where the Kaiser effect is indistinguishable (Lavrov , 2003). The reason for the crack “healing” has been an issue that needs further investigation. By receiving a core sample as soon as it is cored will result in a better analysis of the in-situ stresses in the rock formation. Another issue that must be addressed is the type of testing. When the Kaiser effect was first being investigated most lab measurements involved a uniaxial compression test on the sample. However, Holcomb (1993) showed that it is impossible to determine a rock’s stress

history by uniaxial compression when it was stressed in a triaxial environment. The only way a Uniaxial Load Method (ULM) will work effectively in determining stress history is if the primary principle stress ( $\sigma_1$ ) during reloading is parallel by no more than  $10^\circ$  to the primary principle stress during preloading (Lavrov, 2003). This requires an estimate of which direction  $\sigma_1$  acted on the rock sample while it was in-situ. In the case of the KISS system and in most lab methods  $\sigma_1$  is considered to be in the vertical direction, as a result of the overlying rock mass. If obtaining the preloaded  $\sigma_1$  stress direction is accomplished and the sample is reloaded by the ULM, the very best results are only a linear combination of the in-situ stress tensor of the rock in question (Lavrov, 2003).

After determining which method of compression is better suited for the experiment, determining how to conduct the experiment is crucial. During the cyclic loading test it is best to ensure that the preloading cycle does to reach the maximum strength of the rock. The closer the preloading stress to the ultimate strength of the rock, the less pronounced the Kaiser effect is during reloading (Kurita & Fujii, 1979). According to Lavrov, in order to obtain a well – pronounced Kaiser effect, the preload stress should be in a range from about 30% to about 80% of the ultimate strength (Lavrov, 2003). Experiments have shown that the longer the duration of loading on soft rocks in the first cycle creates a clearer Kaiser effect in the reloading cycle (Michihiro, Yoshioka, & Hata, 1989). On brittle rocks experiments have shown little influence of the duration of loading on the Kaiser effect (Yoshikawa & Mogi, 1989). However, a study on brittle rocks has found that if the loading rate in the first cycle is fast compared to that of the second cycle, then the Kaiser effect occurred at 67% of the peak stress of the first cycle. When the order was reversed (first cycle slow, second cycle fast) the Kaiser effect occurred at the peak stress of the first cycle. The dependency of the Kaiser Effect on the loading rate has not been determined for soft rocks and plastic rocks (Lavrov, 2001).

The KISS system is intended to provide a more cost effective rock in-situ stress testing method than its predecessors without sacrificing accuracy. For example, in the majority of rock testing methods used today an expensive piece of equipment has to be placed down the borehole into the rock formation and analyzed on site. These methods do work; however, the KISS system eliminates the need to send equipment into the borehole. The KISS system requires only obtaining core samples of the rock formation that can then be brought back to a lab for analysis (Blanksma, 2011).

### 10.2.2 Software

Software is a crucial component of the KISS system. While many programs exist for other rock testing systems the KISS system is unique in the way that it will need its own data acquisition program. Creating a program for the KISS system will require substantial knowledge about coding. In industry, a practical solution may be to hire a software engineer or computer scientist. However, in an industry that also hinges on technical application and economic practicality, being able to create your own code for projects that require customized data acquisition eliminates the need to hire a software engineer or computer scientist.

All programs in this system have been designed by the author. Proficiency in coding for data acquisition and correlation is necessary to create and understand programs that record reliably. The software used in the KISS system is National Instruments LabVIEW 8.2. Because of its superior data analysis and ease of coding using G-language, LabVIEW is excellent software for coding customizable programs. The three important programs for the KISS system include; 1 – The data acquisition program that will be used during experimentation, 2 – a waveform analysis program to determine AE and its corresponding times and, 3 – a correlating program to match force data with AE data to construct a cumulative AE versus stress/force graph (Blanksma, 2011).

### 10.2.3 Preliminary Design Options

The KISS system can be designed two ways: The first using the uniaxial load method (ULM), and the second using a triaxial load method. The ULM requires applying a load along the axis of the rock sample in a direction that is no more than 10 degrees different from the in-situ principal stress direction (Lavrov, 2003). The method relies on the estimation that the in-situ principal stress is directed along the vertical axis (Figure 10-6) of the rock sample. Upon loading, acoustic transducers will record analog signals of the AE activity and run the signal to a high-speed digitizer. The digital signals will be recorded and analyzed by signal analyzing software. At the same time the uniaxial compression system will also have force transducers to record the stress data along with the corresponding time of each stress level. By comparing the stress values and acoustic emission values with the corresponding times, the memorized stress level can be deduced on principles described in the Section 3. However, the limit of finding the

memorized stress level for the ULM is only a linear combination and the entire stress tensor can never be achieved using the ULM, as described in previous section. (Blanksma, 2011).

**Figure 10-6.** Rock sample showing direction of vertical stress and attachment of ART's (Acoustic Receiving Transducers)

The triaxial design option includes similar but much more sophisticated waveform analysis software, and very different hardware. A triaxial load method requires a compression machine that can achieve three degrees of pressure. In the case of a triaxial KISS system, axisymmetric ( $\sigma_1 > \sigma_2 = \sigma_3$ ) or true triaxial ( $\sigma_1 > \sigma_2 > \sigma_3$ ) compression is needed to exploit the Kaiser Effect. Operating a triaxial compression machine that can be either axisymmetric or triaxial requires a high degree of operating knowledge and maintenance. However, finding the complete stress tensor requires a device that can achieve true triaxial compression (Holcomb, 1993).

#### 10.2.4 Selected Design

The KISS system will use the Uniaxial Loading Method (see [Figure 10-7](#)). While using a triaxial compression machine is ideal, the fundamental concept of uniaxial compression and the Kaiser Effect needs to be experimentally evaluated before triaxial experimentation can continue. An MTS 816 Rock Mechanics Testing system will provide the uniaxial compression. This rock testing system was chosen because it provides servo-controlled loading for highly stabilized loading rates.

The components of the uniaxial rock testing system include a pump which controls the compression hydraulics, the uniaxial compression machine, two acoustic receiving transducers (ARTS), a pre-amplifier, a high-speed digitizer, and two computers; one to control the uniaxial compression machine and the other for the AE acquisition (Blanksma, 2011). A schematic of the entire MTS 816 Rock Testing System is shown below in [Figure 10-8](#).

Figure 10-7. A close-up picture of the Uniaxial Loading Method (816 Rock Test System)

Figure 10-8. A layout of the 816 Rock Test System (MTS). Other components include an amplifier and a high-resolution digitizer. This system uses a uniaxial loading method on the rock sample.

Another reason the ULM has been chosen is because one of the KISS system goals is to investigate the possibility of using the ULM in a new way. A way that may result in determining the entire in-situ stress tensor rather than just a linear combination of the principal in-situ stresses. The new method hinges on the idea that if the orientation of the maximum principal in-situ stress is known, the in-situ stress tensor can be determined from four different specimens cut at four different orientations from one another that are cut from a single core sample (Fa, et al., 2010). **Figure 10-9** shows how the sample would be cut. Mathematical techniques for determining the principal in-situ stresses are given in below. Equations for determining the principle stresses are given by Fa et al. (2010):

$$\sigma_v = \sigma_{v0} + \alpha p_p \dots\dots\dots (10-1)$$

$$\sigma_H = \frac{\sigma_{0^\circ} + \sigma_{90^\circ}}{2} + \frac{\sigma_{0^\circ} - \sigma_{90^\circ}}{2} (1 + \tan^2 2\theta)^{1/2} + \alpha p_p \dots\dots\dots (10-2)$$

$$\sigma_h = \frac{\sigma_{0^\circ} + \sigma_{90^\circ}}{2} - \frac{\sigma_{0^\circ} - \sigma_{90^\circ}}{2} (1 + \tan^2 2\theta)^{1/2} + \alpha p_p \dots\dots\dots (10-3)$$

$$\tan 2\theta = \frac{\sigma_{0^\circ} + \sigma_{90^\circ} - 2\sigma_{45^\circ}}{\sigma_{0^\circ} - \sigma_{90^\circ}} \dots\dots\dots (10-4)$$

$\sigma_v$  = vertical principal stress

$\sigma_H$  = maximum horizontal principal stress

$\sigma_h$  = minimum horizontal principal stress

$\alpha$  = effective stress coefficient

$p_p$  = pore pressure

$\sigma_{v0}$  = Kaiser stress in the vertical direction

$\sigma_{0^\circ}, \sigma_{45^\circ}, \sigma_{90^\circ}$  = Kaiser stress in the plugs orientated at directions 0, 45 and 90 respectively (**Figure 10-9**).

$\theta$  = angle between the  $0^\circ$  direction and the maximum horizontal principal stress direction

**Figure 10-9.** Kaiser stress in the plugs orientated at directions 0, 45 and 90, respectively.

The data acquisition portion of the KISS system includes Acoustic Receiving Transducers (ARTs) that will receive waveforms generated during AE activity that send analog signals to a wide band width AE Amplifier. After signal amplification a *National Instruments* high-speed Digitizer will convert all incoming analog signals into digital signals that the selected software can receive and analyze. The selected software will be *National Instruments LabVIEW* because of its ease of graphical coding and signal analysis capabilities.

The high-speed digitizer has a resolution of 16 bit to 24 bit. The advantage of having variable resolution allows a higher sampling rate at a lower resolution or a lower sampling rate at a higher resolution (Fa, et al., 2010). This becomes important when different kinds of rocks are tested. Previous section explained that brittle rocks have more frequent AE events than soft rocks. Therefore, the sampling rate can be lowered to allow for higher resolution for soft rocks that require higher resolution to detect any AE activity, and a higher sampling rate for brittle rocks that do not require such high resolution. A picture of the data acquisition components is given in [Figure 10-10](#).

**Figure 10-10.** Wide band width amplifier (left) and NI Chassis (right) with a high-resolution digitizer and interface card installed.

In the first stage of experimentation the KISS system tests Hinckley sandstone, obtained from Hinckley Minnesota. Some of the physical characteristics of Hinckley sandstone are shown in [Table 10-1](#).

**Table 10-1.** Physical properties of Hinckley sandstone

Porosity	10.57%
Degree of Saturation	3.85%
Point Load Strength	0.0386 (lbf/mm <sup>2</sup> )
Uniaxial Compressive Strength	2500 psi
Young's Modulus	6250000 (psi)
Cohesion Coefficient	722 psi
Internal Angle of Friction	31 °

The sandstone is a good representation for sandstone oil reservoirs and past experimentation has shown sandstone to have a well pronounced Kaiser point (Dunning, et al., 1989). Since the Hinckley sandstone has not been under any forces for a long period of time it will serve as a good control and calibration experiment for the KISS system to verify the ULM for AE and the Kaiser effect. By preloading the sandstone to a desired point below its ultimate strength the KISS system will attempt to replicate the previous known stress via the AE detection rates outlined in previous section. If the determined Kaiser stress in the second loading cycle correlates with the known stress in the first cycle, then the KISS system is functional and may be expanded further to triaxial testing (Blanksma, 2011).

## 10.2.5 KISS test procedure

Procedural guideline for the KISS system – uniaxial loading is as follows:

### *Sample Preparation*

- 1) Core out a right cylindrical sample. Coring is completed in the sample preparation lab. The diameter of the sample should be approximately 1.5 inches and the length of the sample approximately 3 inches. Record the length and diameter with calipers.

- 2) Ensure the ends of the samples are cut smoothly and equally as possible. Ideally within 0.005 mm of being parallel. Also, be sure there are no undesired joints or fractures that may create a plane of weakness when the sample is loaded.
- 3) Use a file or sand paper to create a small flattened surface on one side of the rock sample and 180 degrees on the other side of the sample. This is where the ART's (Acoustic Receiving Transducers) attach. Be sure not to sand off too much rock material as it may diminish the structural integrity of the rock sample. **Figure 10-6** shows a picture of a rock sample with an attached ART.

### Hardware Setup

- 1) Set up the digitizer and amplifier as illustrated in **Figures 10-11 and 10-12**.
- 2) One or two ART's need to be attached to the sample. Usually the ART's are attached with super glue located at the area's that have been slightly flattened. A rubber band is also a good way to attach the ART's to the rock sample.
- 3) If you are using a single ART attach the connector to the Preamplifier port on the AE amplifier. A second ART may be wired directly to the digitizer.
- 4) Once the setup in part c is complete turn on the NI Digitizer and amplifier followed by the computer with the *LabVIEW* data acquisition (DAQ) program.
- 5) See **Figures 10-7, 10-8, 10-11, and 10-12** for a full picture of the set up including the computer for detecting AE, the computer for controlling loading, digitizer, and amplifier.

**Figure 10-11.** Setup of pre-amplifier and digitizer

**Figure 10-12.** Picture of back side of pre-amplifier

### Test Preparation

#### 1) Acoustic Detection Program – *LabVIEW*

Open the folder labeled KISS on the desktop. Next, open the folder labeled *DAQ\_programs* and the *DAQ\_Kaiser\_effect.vi*:

- 2) Amplification – **Table 10-2** shows values of amplification for different triggering threshold voltages. These are only suggested values and determining the correct triggering and amplification depends on the level of noise during experimentation and the type of rock.

**Table 10-2.** Values of amplification for different triggering threshold voltages

GAIN (dB)	Threshold Voltage (mV)
20	-
35	20
40	90
55	120
61	150

#### 3) Running a Test

This is a two cycle test. The first cycle simply loads the rock specimen to a desired force level, but below its peak strength. The only necessary piece of information in the first cycle is obtaining the maximum force.

##### CYCLE 1

Step 1: Load the specimen to within 30% – 80 % of its peak strength. Determining the peak strength will require a failure test or knowledge of the rock properties of the specimen.

Step 2: All the uniaxial loading data will be saved and stored for later analysis. Once cycle 1 is complete unload the sample.

##### CYCLE 2

Step 1: Prepare the 816 Rock Test System (**Figures 10-7, 10-8, 10-11, and 10-12**) by moving the compression platen to the point where it just touches the rock sample. DO NOT apply a load at this point to the rock sample.

Step 2: Click the run icon on the Front Panel of the *DAQ\_Kaiser\_effect\_op1.vi* program. You will be asked to select or create a TDMS file to save your data to. Create the file and save it to the *waveform\_data* folder in the *Data* folder.

Step 3: Begin the procedure of loading the rock sample with the 816 MTS Rock Test System and press the START button on the front panel of the DAQ program. Once the start button is pressed the initial time dialogue box will show the time data acquisition began. Be sure to make a note of this time.

Step 4: Monitor the program as it is running. Once the second cycle of compression is completed, click STOP on the Front Panel of the *DAQ\_Kaiser\_effect\_op1.vi*.

Step 5: A window will appear asking if you would like to view your data in the TDMS viewer. Select cancel to end the test or OK to view your data in the *TDMSviewer.vi*.

#### 4) Analyzing the Data

##### 5) Correlating AE data and Force Data

Step 1: Open the file *data\_time\_finder.vi* in the *Analysis* folder. Select the box icon to the right of AE Time file and find the AE time data from the *ae\_time\_data* folder. Also select the MTS Force/Time file button and select the file from the 793.61 Rock Mechanics Software that contains all the displacement, force and time data from the experiment.

Step 2: These two sets of data contain both time data in seconds. The program searches the MTS Force/Time file for the equivalent time from the AE Time file and returns the force level for that particular acoustic event.

Step 3: Run the program – You will be asked to create a *Correlated Time file*. This file contains all the necessary information to construct a cumulative AE graph versus time. Save the file in the *correlated\_data* folder found in the *Data* folder.

Step 4: Since both the AE data and the force data are functions of time the cumulative number of acoustic events in cycle 2 can be plotted against the force data. The resulting graph is similar to **Figure 10-13**. The Kaiser stress is indicated as the inflection point. **Figure 10-14** shows a sample of cumulative AE versus force for a Hinckley Sandstone specimen loaded twice.

Figure 10-13. Inflection in the cumulative AE hits ( $\Sigma N$ ) versus stress ( $\sigma$ ) graph indicates the previous maximum stress state.

Figure 10-14. Sample graph of Cumulative AE counts versus Force for Hinckley Sandstone in the second cycle of compression

### 10.3. Kaiser Effect Method –Data Analysis

#### 10.3.1 Experiment on Hinckley Sandstone

The data presented in this section has been obtained to investigate the plausibility of the KISS system using the ULM. Figure 10-15 shows that Hinckley sandstone has identifiable Kaiser Effect point. Figures 10-16 through 10-19 show that at different stages of deformation, the induced acoustic emissions will have different waveforms, and different frequency features.

Figure 10-15 Kaiser point on the stress & cumulative AE vs. strain curves in Hinckley sandstone.

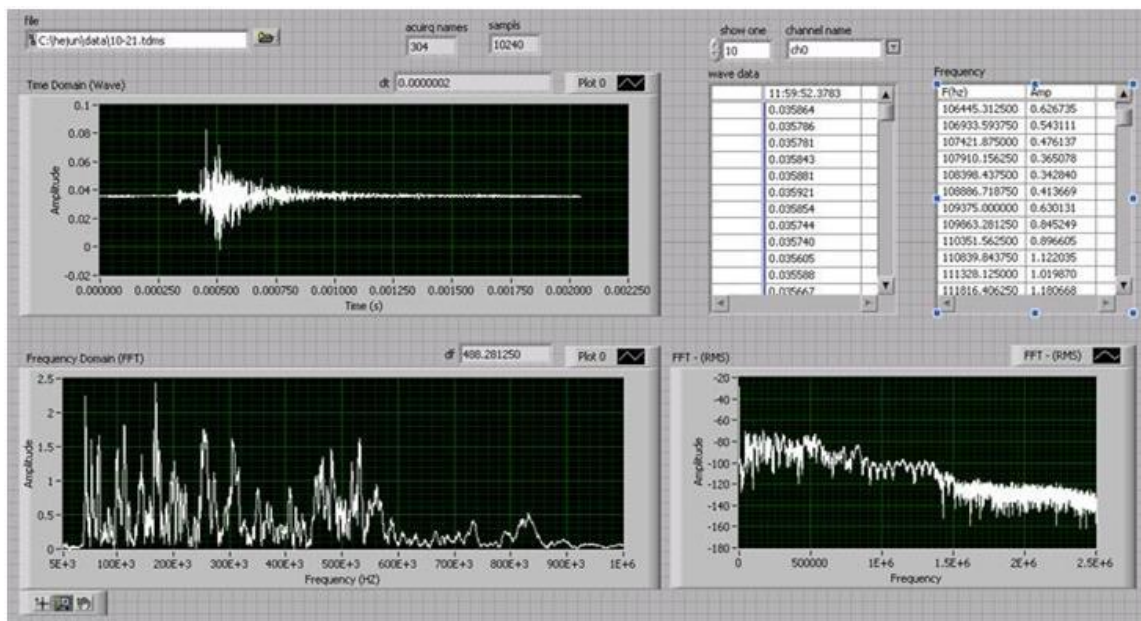

Figure 10-16. Full waveforms and frequency spectrum of AE events in Stage 1 of Figure 10-15.

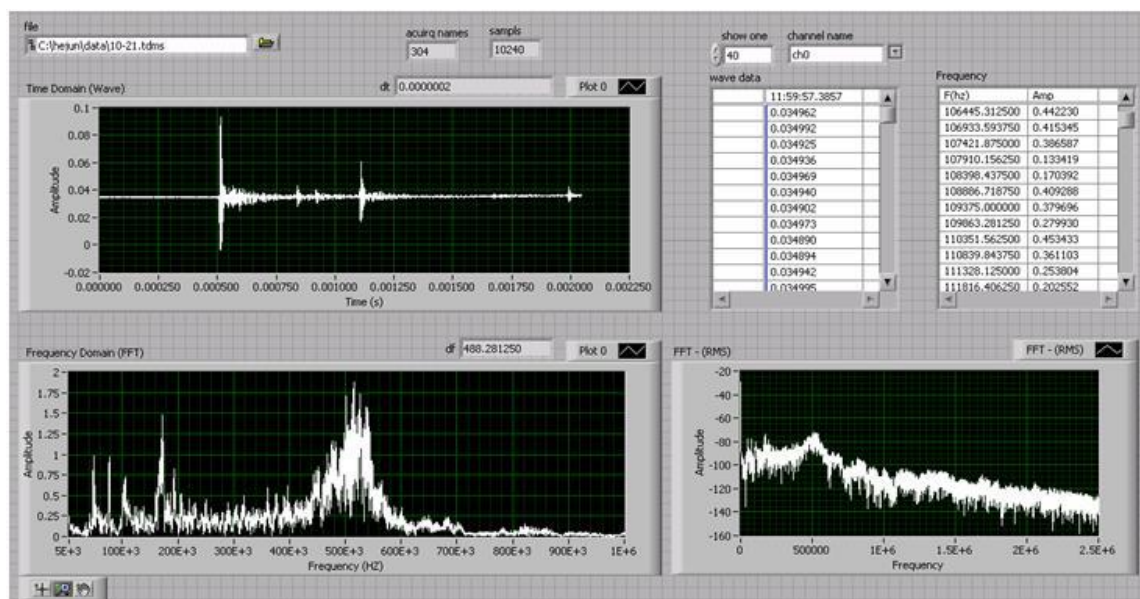

Figure 10-17. Full waveform and frequency spectrum of AE events in Stage 2 of Figure 10-15.

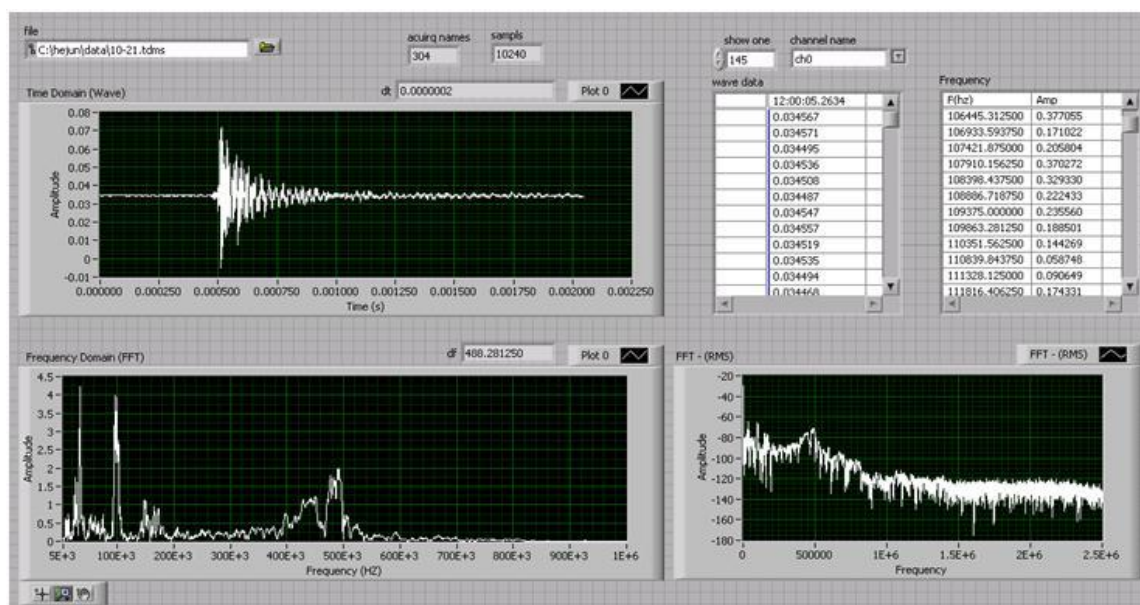

Figure 10-18 Full waveform and frequency spectrum of AE events in Stage 3 of Figure 10-15.

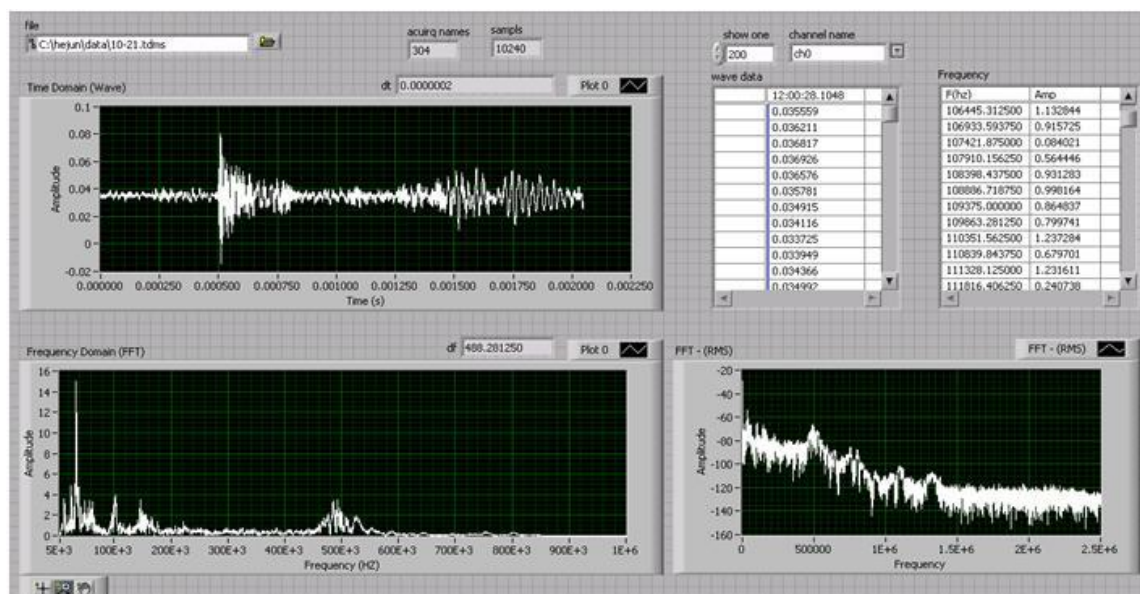

Figure 10-19. Full waveform and frequency spectrum of AE events in Stage 4 of Figure 10-15.

Figure 10-20 shows cumulative AE for 126 acoustic events gathered over a time of 22.78 minutes at a loading rate of 0.0003658 mm/s for channel 0. Figure 10-14 shows cumulative AE versus time considering over 1800 acoustic events. All acoustic events in Figure 10-14 were considered to have amplitudes of 0.001 v or more.

All programs to correlate time data with force data were created and used by the author. Error between correlating the MTS Force/Time data with the AE data is on the order of 0.001 seconds since that was the range for matching time data.

Figure 10-20. Cumulative AE for 126 acoustic events gathered over a time of 22.78 minutes in cycle 2

Figure 10-20 indicates that there is an inflection point at approximately 25.15 kN. This has about a 50% error since the true stress achieved in cycle one was 50 kN. The reason for this discrepancy may be acoustic events that are associated with frictional sliding rather than microcracking has been recorded in Figure 10-20. Another issue is that Figure 10-20 contains only 126 acoustic events. This is a product of the LabVIEW program that recorded the AE. In the program, triggers were considered as the AE event and data that recorded one second after each trigger was ignored. However, considering the boxed section in Figure 10-20 small inflection points in the range of approximately 45 kN to 60 kN are discernible.

In order to mitigate this lack of resolution the entire data set was reanalyzed for over 1800 acoustic events each of which was defined as having amplitude of 0.001 volts. Figure 10-14 shows the results of cycle 2 after analyzing over 1800 acoustic events. After close inspection it can be seen in Figure 10-14 that from 0 kN to approximately 50 kN the cumulative AE remains between 0 and 40. However, once the 50 kN point is reached, cumulative AE increase rapidly, especially at the 55 kN point and approximately the 62 kN point. The 50 kN point was the maximum stress level achieved in cycle 1 and thus in cycle 2 the Kaiser effect is observed.

### 10.3.2 Conclusion on KISS System

The KISS system offers the capabilities of determining in-situ stresses in rocks that are non-evasive, relatively cheap and capable of delivering accurate results. AE and the Kaiser effect have been extensively studied and analyzed to determine in-situ stresses in rocks. Many of these attempts to use AE and the Kaiser effect have fallen short due to the lack of sophisticated computing technology. However, the KISS system incorporates the use of high resolution digitizers, servo-controlled compression and a faster computing process to identify stress memory in rocks, where before, computing capabilities could not yield high enough resolution to distinguish stress memory.

Many fundamental problems must be addressed in order for this system to work, however by following the design proposal this system is the initial step to creating a system that can one day calculate the entire stress tensor. Using

the KISS system with the uniaxial compression method revealed the Kaiser effect on cyclically loaded Hinckley sandstone, as shown in section 6. The knowledge gained and methods used created a fundamental starting point for more sophisticated experimentation such as, triaxial compression. It is clear that the only way to recreate the entire stress state of a subsurface rock mass is to reload a rock specimen in a triaxial environment. Little work has been produced on this subject, however new ideas and methods are being developed and the first stage of development has been laid out in this project.

There is much promise for the KISS system. As far as improving the system better waveform filtering techniques such as Fourier transforms, Nyquist frequency and analysis in the frequency domain offers better noise reduction and identification of AE associated with microcracking. Also, better software development would help with time synchronization and data recording. All of these developments will help the KISS system find more accurate and better results.

#### 10.4. CDISK Method for Fracture Toughness-Background

Rock fracture toughness is a property which describes the ability of a rock containing a crack to resist fracture, and is one of the most important properties of rock for oil and gas well drilling and stimulation. To determine the fracture toughness of rocks, the International Society for Rock Mechanics (ISRM) recommended two methods with three types of core-based specimens: chevron bend and short rod specimens (Ouchterlony 1988), and cracked chevron notched Brazilian disc (CCNBD) specimen (Fowell, 1995). The cracked chevron notch Brazilian disc (CCNBD) method is one of the widely used techniques to characterize rock fracture toughness. The CCNBD is an ideal specimen for rock fracture toughness measurement. The good features are large failure load, simple loading fixture, convenient and flexible specimen preparation.

We developed the tools and method on sample preparation, and compared the test results of Indiana limestone and Pierre shale using 2-in and 1-in diameters. It seems that results of 1-in diameter samples are systematically lower than that from 2-in samples, but the difference is within 5%.

#### 10.5. CDISK Method-Fracture Toughness Measurement

##### 10.5.1 Fracture toughness measurement on Indiana limestone

Fracture toughness is the resistance offered by a material against preexisting crack's propagation. It is an important material property which describes the critical states of stresses or energy near the crack tip required for the initiation of fracturing (Krishnan et al., 1997; Ayatollahi and Aliha, 2008). The International Society for Rock Mechanics (ISRM) suggested method (ISRM, 1995), CCNBD is used to measure fracture toughness of Indiana limestone. This method uses a specimen with a chevron shaped notch cut along the core diameter, as shown in the following figure.

Figure 10-21. The cracked chevron notched Brazilian disc specimen (modified after ISRM, 1995)

The chevron notch causes crack propagation to start at the tip of the V alignment and to proceed outwards in a stable fashion. All the dimensions of the geometry should be converted into dimensionless parameters with respect to the specimen radius  $R$  as follows:

$$\alpha_0 = a_0/R; \quad \alpha_1 = a_1/R; \quad \alpha_B = B/R \quad (10-5)$$

The selected dimensions should satisfy the following restrictions:

$$\alpha_1 \geq 0.4; \quad \alpha_1 \geq \alpha_B/2; \quad \alpha_1 \geq 0.4$$

$$\alpha_B \leq 1.04; \quad \alpha_B \geq 1.1729 \cdot \alpha_1^{1.6666}; \quad \alpha_B \geq 0.44 \quad (10-6)$$

With the help from the Technology department of UND, a circular diamond saw mounted on a computer controlled lathe was used to cut the required notch, in which the flanks of the chevron notch was straight by a linear cutting motion. As programmed, the chevron notches were ensured to be exactly in the center of the disc and the geometrical dimensions conformed to the given tolerances, as shown in Figure 10-22.

Figure 10-22. CCNBD specimen preparation

After finishing the sample preparation, the MTS rock tester was used to compress the sample to develop a failure surface for further measurements, and at the same time, the force versus displacement curve was recorded, as shown in Figure 10-23.

Figure 10-23. Sample compressed by MTS rock tester and the fracture surface after failure

Figure 10-24. Load versus displacement of loading piston (sample T10L06).

The fracture toughness of the specimen is calculated by the following formula (ISRM, 1995):

$$K_{IC} = \frac{P_{max}}{B \cdot \sqrt{D}} \cdot Y_{min}^* ; \dots\dots\dots (10-7)$$

where  $Y_{min}^* = u \cdot e^{v \cdot \alpha_1}$

where  $P_{max}$  is the maximum load that breaks the sample, and  $Y_{min}^*$  is called the critical dimensionless stress intensity value, which is determined by the specimen geometry, and  $u$  and  $v$  are constants interpolated by  $\alpha_0$  and  $\alpha_B$  from Table 2 of ISRM (1995). It was noted that some minor modifications to this formula and the “ $u$ ”, “ $v$ ” values were suggested in the past few years (Zeng and Roegiers, 2000; Wang et al., 2004; Wang, 2010), however, before a formal standard is published by the ISRM, this formula is followed to keep the test results consistent. The test results are shown in the Table 10-3.

From the tests results, one can see that these results are insensitive to the sample sizes as fracture toughness is an intrinsic mechanical property of materials. However, the diameter of the sample should be related to the size of the largest grain in the rock by the ratio of at least 10:1 (ISRM, 1995); obviously, this criterion is believed to be sufficiently satisfied by considering the fine grain nature of limestone. All the tested samples were in the valid geometrical range as shown in Figure 10-24.

Some experimental studies support the assumption that fractures, once initiated, will propagate as long as the stress intensity at the crack tip exceeds the fracture toughness of the material (Warpinski et al., 1979).

### 10.5.2 Fracture toughness measurement on Pierre shale

Following similar method and procedure for the testing on Indiana limestone, we conducted fracture toughness test on Pierre shale. After a test, a typical load versus displacement curve based on loading piston is shown in Figure 10-26.

Table 10-3. Fracture toughness tests on Indiana limestone

Sample ID	Diameter D (mm)	Thickness B (mm)	$2a_1$ (mm)	$2a_0$ (mm)	$Y^*_{min}$	Pmax (kN)	$K_{IC}$ $MPa\sqrt{m}$
10F03	50.35	20.38	33.90	17.12	0.930878	1.463	0.298
10F04	50.18	16.81	30.06	9.08	0.772534	1.455	0.299
10F11	50.34	17.82	31.07	9.46	0.831154	0.942	0.196
10F07	50.48	19.56	36.69	19.48	1.019895	0.962	0.223
Average							0.261
Standard deviation							0.052
T10L03	24.73	11.82	17.60	0.00	0.890603	0.626	0.300
T10L04	24.45	11.26	17.89	2.43	0.900698	0.588	0.301
T10L05	24.78	11.70	18.29	4.27	0.930112	0.485	0.245
T10L06	24.80	12.14	17.97	2.78	0.889921	0.338	0.157
T10L07	24.78	11.38	18.41	3.83	0.936906	0.574	0.300
T10L08	24.52	12.02	17.28	2.76	0.860530	0.668	0.305
T10L09	24.50	11.28	18.09	4.36	0.935208	0.546	0.289
Average							0.271
Standard deviation							0.054

Figure 10-25. Both large and small samples (left) are in the valid geometrical range (right).

Figure 10-26. Load versus displacement of loading piston (sample T10S01).

Similarly, both large and small samples were tested, and it was found that the fracture surfaces were all very well developed (Figure 10-27). Thus the anisotropy of shale seems to be overcome by the induced fractures.

Figure 10-27. Both large and small samples show well defined fracture surfaces.

Also note all the shale samples tested were in the valid geometrical range as shown in the following figure.

Figure 10-28. Verification of sample geometry qualification.

The test results are shown in the Table 10-4.

Table 10-4. Fracture toughness tests on Pierre shale

Sample ID	Diameter D (mm)	Thickness B (mm)	2a1 (mm)	2a0 (mm)	Y*min	Pmax (kN)	KIC $MPa\sqrt{m}$
T10S01	25.84	9.65	17.05	2.42	0.826497	0.510	0.272

Average							0.262
Standard deviation							0.084

One can see that the fracture toughness of Pierre shale is smaller than that of Indiana limestone. Besides, its deviation is smaller. Figures 10-29 and 10-30 show the test and fractured surface of rock samples. Note due to the smaller sample size, a steel cylinder was added for the test. Figure 10-31 shows fractured surfaces after tests for the test samples.

### ***10.6. CDISK Method-Concluding Remarks on Fracture Toughness***

We have developed a set of procedure that allow us to prepare the fracture toughness sample for cracked Chevron notched Brazilian disc (CCNBD) in any direction at samples as small as 1-in diameter.

Comparison test on Indiana limestone and Pierre shale of both 2-in and 1-in disc samples indicated that tested fracture toughness of larger samples is systematically higher than those from small samples. However, the difference is only about 5%. In addition, fracture toughness of Indiana limestone is higher than that of Pierre shale, which is reasonable.

## 11. TECHNOLOGY TRANSFER

The technologies developed in this project have been transferred to the public through journal papers, conference papers, and technical presentations. We have developed a website database for public access.

## 12. CONCLUSIONS

By finishing this project, we have trained locally sustainable technical team in petroleum geomechanics and petrophysics. We have built local capability in lab testing in related areas. We also have made progresses in understanding Bakken geomechanics, which includes

- 1) built a 3D Bakken geological model using thickness data.
- 2) developed a method that can help build 3D Bakken model of any petrophysical and geomechanical properties as long as adequate amount data is available from lab testing and field correlation, with the possibility of improving model using updated data.
- 3) developed a conceptual model that allows integration of plug-scale lab-testing data, core-scale data and field scale data.
- 4) set up the foundation of testing various of petrophysical and geomechanical properties, and have completed test of middle, upper, and middle Bakken core plugs from 8 wells.
- 5) published 29 technical papers and presented more than 50 presentations to transfer technology.
