Abstract

Background: Residential natural gas cooking burners (NGCBs) can emit substantial quantities of pollutants and they are typically used without venting.

Objective: Quantify pollutant concentrations and occupant exposures resulting from NGCB use in California homes.

Methods: A mass balance model was applied to estimate time-dependent pollutant concentrations throughout homes and the "exposure concentrations" experienced by individual occupants. The model was applied to estimate nitrogen dioxide (NO₂), carbon monoxide (CO), and formaldehyde (HCHO) concentrations for one week each in summer and winter for a representative sample of Southern California homes. The model simulated pollutant emissions from NGCBs, NO₂ and CO entry from outdoors, dilution throughout the home, and removal by ventilation and deposition. Residence characteristics and outdoor concentrations of CO and NO₂ were obtained from available databases. Ventilation rates, occupancy patterns, and burner use were inferred from household characteristics. Proximity to the burner(s) and the benefits of using venting range hoods were also explored. Replicate model executions using independently generated sets of stochastic variable values yielded estimated pollutant concentration distributions with geometric means varying less than 10%.

Results: The simulation model estimates that in homes using NGCBs without coincident use of venting range hoods, 62%, 9%, and 53% of occupants are routinely exposed to NO₂, CO, and HCHO levels that exceed acute health-based standards and guidelines. NGCB use increased the sample median of the highest simulated 1-hr indoor concentrations by 100, 3000, and 20 ppb for NO₂, CO, and HCHO, respectively.

Conclusions: Reducing pollutant exposures from NGCBs should be a public health priority. Simulation results suggest that regular use of even moderately effective venting range hoods would dramatically reduce the percentage of homes in which concentrations exceed health-based standards.

Introduction

Natural gas cooking appliances are present in about half of the roughly twelve million housing units in California (CEC 2004). Nationally, 34% of households report using natural gas as their primary cooking fuel (US EIA 2005). Gas cooking burners emit air pollutants that can affect residential indoor air quality and increase health risks. Emitted pollutants include nitrogen dioxide (NO₂), carbon monoxide (CO), and formaldehyde (HCHO).

At elevated ambient concentrations, NO₂ has been associated with exacerbation of asthma (Hajat et al. 1999) and an increase in daily deaths (Touloumi et al. 1997). At higher concentrations, NO₂ has been associated with increased sensitivity to allergens in asthmatic patients (Tunnicliffe et al. 1994). Increased indoor NO₂ concentrations from gas cooking have been associated with adverse health effects such as wheezing and decreased respiratory function (Jarvis et al. 1998).

Many studies have examined gas appliance-related concentrations of NO₂ (Spengler et al. 1994; Yang et al. 2004) and CO (Akland et al. 1985; Fortmann et al. 2001) in homes. Measurement-based studies are imperative for understanding the physical properties that govern concentrations and exposures in homes; however, the costs and logistics of large scale monitoring are barriers to using this method to quantify population-wide impacts.

The goal of this study was to estimate the impact of cooking with natural gas burners on in-home exposures to NO₂, CO, and HCHO across a representative sample of Southern California homes. Particulate matter mass (PM) emissions, especially ultrafine particles (diameter <100 nm), are also a source of health concerns from natural gas burners, however PM was not addressed in this study.

To accomplish this analysis, we developed and utilized a population impact assessment modeling (PIAM) approach. The PIAM approach applies physics-based simulation model(s) to estimate one or more environmental or energy performance parameters for each home in a sample cohort selected or developed to represent a population. A key feature of the approach is that sample cohorts are developed from representative databases such as the Residential Energy Conservation Survey or the American Housing Survey (AHS) at the U.S. national level, or the Residential Appliance Saturation Survey (RASS) in California. Home and occupant characteristics that are needed for the model but not available in these datasets are assigned based on independently determined relationships between these unspecified characteristics and data that are included in the databases, or from other available data sources. Estimates for the individual homes are compiled to estimate population impacts. The approach can be applied at varying temporal or spatial scales; a recent application examined the impact of air sealing and ventilation on annual energy use for homes across the U.S. (Logue et al. 2013).

The PIAM approach was applied to estimate in-home pollutant concentrations and exposures for Southern California households that have and use natural gas cooking burners. A mass-balance model was used to estimate time-dependent pollutant concentrations within each home for typical weeks in summer and winter. Age-based occupancy patterns and factors accounting for proximity to the cooking burners were used to estimate exposure concentrations over selected time durations for each occupant of each home. Time durations were selected to align with acute health-based standards (1-h and 8-h) and over each simulated 1-week period as an indicator of chronic exposures. Results across all simulated homes were aggregated to estimate distributions for the population. The potential impact of routine use of venting range hoods also was assessed.

Methods

Indoor Air Model

The core component of the PIAM approach used for this analysis was a single-zone mass balance model that simulates the emissions, dilution, deposition to surfaces, and removal by air exchange of air pollutants produced by residential cooking burners. The indoor air model uses the following governing mass-balance equation:

$$V(dC_{in,i}/dt) = E_i - k_iVC_{in,i} - aVC_{in,i} + aVP_iC_{out,i} \quad [1]$$

In this equation, written for pollutant species i , V is residence volume (m^3), $C_{in,i}$ is the indoor concentration ($\mu g/m^3$), E_i is the emission rate ($\mu g/h$), k_i is the first-order deposition rate constant (per hour), a is the air exchange rate (per hour), P_i is penetration efficiency – the fraction of pollutant retained as air enters from outdoors, t is time (hours), and $C_{out,i}$ is the outdoor concentration ($\mu g/m^3$). E_i was selected from emission factors (ng/J) measured in a recent study of U.S. cooking ranges (Singer et al. 2009). Fuel use for cooktop burners was set at 1.23×10^5 J/min (7 kBtu/h) as an estimated time-averaged mean. An oven-specific fuel use algorithm was developed based on measurements of actual oven firing patterns as described below. P was assumed to be 1 for all pollutants modeled in this study.

Deposition was assumed to be negligible for CO and HCHO but not NO₂. Though formaldehyde is known to reversibly sorb to indoor materials, the overall rate coefficients for adsorption and desorption in furnished homes appear to be much slower than air exchange for all but the lowest ventilation rates considered in this study (Xu and Zhang 2003; Sherman and Hult 2013). The NO₂ first order deposition rate varies with humidity and surface characteristics, and reported values of the first order rate constant for furnished homes vary from 0.11 to 1.4/h (Nazaroff et al. 1993; Spengler et al. 1994; Spicer et al. 1994; Yang et al. 2004). Yang et al estimated a representative deposition rate of 1.05/h for western countries. This estimate is on the higher end of the range of values in the literature. Simulations were run with k_i values of 1.05/h and 0.5/h to encompass what we assess to be the upper and lower bounds on the median value across California homes.

Equation 1 was adapted into Equations 2a and 2b to separately track indoor pollutants originating from indoor emissions ($C_{in_I,i}$) and indoor pollutants from outdoor sources ($C_{in_O,i}$) with total concentrations calculated as the summed contributions from the two sources.

$$d(C_{in_I,i})/dt + (k_i + a)C_{in_I,i} - E_i/V = 0 \quad [2a]$$

$$d(C_{in_O,i})/dt + (k_i + a)C_{in_O,i} - aC_{out,i} = 0 \quad [2b]$$

$$C_{in,i} = C_{in_I,i}(t) + C_{in_O,i}(t) \quad [3]$$

Equations 2a and 2b can each be solved recursively for $C_{in_I,i}$ and $C_{in_O,i}$, respectively, with any of the parameters held constant within a given time step and allowed to vary from one time step to another. Equation 4a presents the recursive solution for the indoor concentration resulting from gas burner emissions:

$$C_{in_I,i}(t) = [C_{in_I,i}(t-1)\exp^{-(a(t)+k_i)\Delta t}] + \{[E_i(t)(1 - \exp^{-(a(t)+k_i)\Delta t})] / [(a(t) + k_i)V]\} \quad [4a]$$

In this equation, $C_{in_I,i}$ is the indoor concentration of pollutant i generated from appliance use at time t and at the previous time step ($t-1$), Δt is the time interval (set at 1 minute), and E and V are the emission rate and residence volume, as defined above. Equation 4b is the solution for the indoor concentration of pollutant i originating from outdoors:

$$C_{in_O,i}(t) = [C_{in_O,i}(t-1)\exp^{-(a(t)+k_i)\Delta t}] + C_{out,i}(t)\{[a(t)(1 - \exp^{-(a(t)+k_i)\Delta t})] / [a(t) + k_i]\} \quad [4b]$$

The recursive model was implemented and solved with code written in the R programming environment (R Core Team 2012). The primary outputs were indoor concentrations of NO₂, CO, and HCHO for typical summer and winter weeks, at 1-minute resolution. We estimated time-averaged indoor and exposure concentrations (concentrations experienced by individual occupants) over durations corresponding to acute health based standards (1-h and 8-h) and over each 1-week simulation. Exposure concentrations were estimated for each occupant considering only their pollutant intake in the home. For example, if in a given simulation an occupant remained at home for just 30 min after cooking was started and the time-averaged concentration of CO over those 30 min was 20 ppm, the 1-h exposure concentration was calculated as 10 ppm. Figure 1 provides example plots of NO₂ in-home concentrations and exposure concentrations for three occupants of one home during a simulated week in winter.

Model Implementation

We applied the PIAM approach to study a cohort of Southern California (SoCal) homes that included representative variations in the characteristics that impact pollutant emissions from cooking burners and the associated occupant exposures. We simulated two weeks of activity—one in summer and one in winter—for each residence in our sample. Only emissions from natural gas combustion, not emissions from cooking food, were included. The following six counties comprise the SoCal Region: Los Angeles, San Bernardino, Riverside, San Diego, Orange, and Ventura. We obtained distributional information about homes in this area from the publicly available 2003 RASS database, which contains anonymous data for almost 22,000 households throughout California (CEC 2004). The SoCal cohort taken from the 2003 RASS consists of 6,634 households containing 19,464 individual residents. The RASS dataset reflects the variability in home sizes and types seen in California. The RASS provides a weighting for each home in the database to construct a statistically representative sample of the population served by the four largest California utilities. Applying these weightings, the modeled SoCal cohort represents 3,560,000 homes and 11,680,000 occupants. The population estimates presented in this study reflect these weighting values. The RASS has information about building type, age, volume, location, household demographics, cooktop type, and the frequency of cooking with the cooktop or oven. We used the 2003 RASS dataset (collected in 2002-3) because it includes meal-specific cooking frequencies that were not collected in the 2009 RASS (CEC 2004). Our study sample included residences that reported using a gas cooktop or oven (excluding homes that used bottled gas to cook) at least once during the course of a typical week. In the SoCal region, 56% of homes reported using natural gas (this excludes the 2% who reported using bottled gas).

Required activity factors were assigned to each sample home based on household specific data available in the RASS and data from other published surveys and reports. Cooking frequency was taken directly from the RASS. Meal specific cooking durations and burner selections were calculated from a web-based cooking survey (Klug et al. 2011). The survey included responses from 372 people predominately in California and included questions relating to home, household and cooking appliance characteristics, and weekly patterns of meals cooked. This survey provided meal-specific data on the frequency of oven use, the number of cooktop burners used, and the duration of burner use. Based on the cooking survey, the model assumes one cooktop burner for breakfast or lunch and two cooktop burners for dinner, and includes oven use for all dinners cooked in half of the homes. The duration of each discrete cooking event was assigned by sampling from lognormal distributions of cooktop and oven use duration for the specific meal (breakfast, lunch, dinner), based on data collected in the cooking survey (Klug et al. 2011); the distribution summary statistics are provided in Supplemental Material, Table S1. We used the median reported data from the National Human Activity Patterns Survey (NHAPS) (Klepeis et al. 2001) to establish meal times and to establish archetypal home occupancy patterns based on age (0-5, 6-17, 18-64, 65+) and weekend or weekday; specific assignments are provided in Supplemental Material, Table S2. Cooking burner emission factors for NO₂, CO, and HCHO were based on measurements reported by Singer et al. (2009) for twelve ranges, each including a

cooktop and oven. Each home was randomly assigned the emission factors from one cooktop and one oven from the data set and those emission factors were used for all modeling of the home.

Air Exchange Rate. Distributions of empirical air exchange rates (AERs) were developed from studies reporting AER measurements in Southern California homes (Wilson et al. 1993; Wilson et al. 2003; Offerman 2009; AER 2010). Distributions were developed for winter and non-winter seasons for three home age ranges (pre-1980, 1981-1995, and post-1995). We randomly sampled from these distributions to select a winter AER and a summer AER for each home based on home age. Summer AERs were higher, likely due to more window opening. Higher summer AERs result in lower modeled concentration estimates in summer compared to winter. Relative to the 2003 RASS database, the current (ca. 2013) California housing stock includes newer homes with lower AERs. Lower AER translates to less dilution and higher concentrations of pollutants from indoor sources.

Outdoor Air Pollutants. Typical outdoor NO₂ and CO profiles were developed for each county for a winter week and a summer week based on concentrations measured at ambient air quality monitoring sites. Data were downloaded from the U.S. EPA AIRDATA website (US EPA 2012). A representative monitoring site was selected for each county and all homes in that county were assumed to have the same outdoor concentrations. If more than one monitoring site existed in a county, we selected the site that reported the median annual average concentration from among the available sites reporting data from the county. Hourly outdoor profiles for each site were developed by calculating the average concentrations from all available data from 2008-2009 by hour and by day of the week. Whereas CO and NO₂ indoor concentrations can be dominated by contributions from outdoor air and unvented indoor combustion sources, indoor formaldehyde typically depends on a wider variety of sources including material emissions, chemical reactions, outdoor sources, and indoor combustion (Zhang et al. 1994; Salthammer et al. 2010). We did not incorporate formaldehyde from other indoor or outdoor sources into the analysis; therefore, our estimates of indoor formaldehyde concentrations reflect only the incremental contribution of NGCB exhaust.

Estimated pollutant concentrations were linked to archetypal patterns of home occupancy according to age group (0-5, 6-18, 19-64, 65+) for each individual residing in each modeled home (Klepeis et al. 2001); this was done to explore the impact of age-based activity patterns on individual-level exposures. When occupants were not home based on occupancy profiles, their exposure concentrations were assumed to be zero.

Proximity Factors. The model accounts for elevated concentrations of NGCB pollutants in the kitchen relative to other parts of the home (Palmes et al. 1977; Palmes et al. 1979; Hoek et al. 1984; Noy and Lebreton 1986; Berwick et al. 1989) and assumes that anyone in the kitchen during cooking will be exposed to these higher concentrations. We account for this proximity effect by assigning one adult cook for each cooking event and by assuming that any young children (aged 0–5 years) present in the home during cooking are nearby. Exposures are calculated by

multiplying the estimated indoor generated pollutant concentration by proximity factors (F_{prox}) of 2.0 for the cook and 1.5 for children 0-5 years of age, then adding the contribution from outdoor sources, which was assumed uniform throughout the home. Proximity factors were determined by reviewing published data on burner-related pollutant concentration in kitchens and other areas of the home and determining ratios of concentrations measured in kitchens compared to other rooms (Hoek et al. 1984; Berwick et al. 1989; Garrett et al. 1999; Zota et al. 2005) and near source compared to away from source (McBride et al. 1999).

Sensitivity and Uncertainty Analysis. As described above, the model assigns values for key characteristics that are not specified in the RASS. Parameters that are assigned as non-varying for the week are the air exchange rate, cooktop and oven pollutant emission rates, whether the oven was used, specific days of week during which meals were prepared, the number of cooktop burners used for each meal, the start time of each meal on weekend days and weekdays, and which adult was the cook. The RASS database includes the self-reported frequency of breakfast, lunch, and dinner cooked during each week for each home. We randomly assigned days for those meals to be cooked during the week. The burner duration was assigned anew for each meal as described previously.

To evaluate the sensitivity of model results to these assigned values, we executed the model 15 times to simulate a winter week for the entire sample cohort, using the higher NO_2 first order deposition rate constant ($k_i = 1.05/\text{h}$) and with all parameters assigned anew for each model execution. We evaluated the consistency of results across model executions by calculating the variation in the geometric mean, geometric standard deviation, and summary statistics (5th, 25th, 50th, 75th, and 95th percentiles) of the calculated distributions of in-home and exposure concentrations.

To assess the impact of proximity factors, we also estimated exposures assuming that all occupants are exposed only to the time-dependent concentrations calculated for the home ($F_{\text{prox}}=1$ for all occupants) for the winter week, using the higher NO_2 first order deposition rate constant ($k_i = 1.05/\text{h}$). This assumes that being in the same room or adjacent to cooking has no impact on exposure.

Range Hood Pollutant Mitigation Analysis. We conducted an additional analysis to assess the potential benefits of widespread and routine use of vented range hoods. Use of a vented range hood can dramatically reduce concentrations of pollutants from cooking burners (Delp and Singer 2012). While the majority of California homes appear to have a range hood installed, it is unknown what fraction of these are vented as opposed to recirculating (Klug et al. 2011), and available data suggest that a minority of households routinely use range hoods during all cooking (Klug et al. 2011; Mullen et al. 2012). We simulated vented hood use by reducing all pollutant emission rates by 55%; this value reflects the mean capture efficiency reported in a measurement-based study of range hoods installed in California homes (Singer et al. 2012).

Pollutant Standards

We used ambient air quality standards set by the U.S. Environmental Protection Agency (EPA) and California EPA, and guidelines established by California's Office of Environmental Health Hazard Assessment (OEHHA) as benchmarks to set benchmarks for undesirable levels of indoor air pollutants (Table 1). Acute standards have averaging times of 1-h for NO₂, CO, and HCHO, and 8-h for CO and HCHO. Chronic (annual average) concentration limits are available for NO₂ and HCHO. We define an exceedance as occurring when the indoor household concentration, or an individual occupant's exposure, exceeds one of the benchmark levels noted in Table 1. We note, however, that outdoor standards can be strictly exceeded only when outdoor concentrations exceed those standards.

Scenarios

The simulation model was executed to estimate distributions of in-home concentrations and exposures for the population of Southern California (SoCal) homes that use line-distributed natural gas cooking burners at least once per week. Results are presented for simulated cooking over one week according to five scenarios:

Scenario 1: Winter, proximity effect included ($F_{\text{prox}} = 2.0$ for cook, 1.5 for 0-5 year olds), no range hood use;

Scenario 2: Summer, proximity effect included, no range hood use;

Scenario 3: Winter, no proximity effect ($F_{\text{prox}} = 1.0$ for all), no range hood use; and

Scenario 4: Winter, proximity effect included, all homes use range hoods with 55% capture efficiency.

Scenario 5: Summer, proximity effect included, all homes use range hoods with 55% capture efficiency.

Summary statistics for Scenario 1 with $k_i = 1.05 \text{ h}^{-1}$ for NO₂ are presented as a mean $\pm$ range to indicate the variation across the fifteen replicate runs that resulted from reassigning parameter values. The range is the difference between the mean value and the run with the largest difference, higher or lower, from the mean value. All uses of the $\pm$ notation throughout the remainder of the text are presenting the range of values for the 15 replicate runs for Scenario 1.

Results

Figure 2 shows the estimated distributions of one-week average household pollutant concentrations and exposure concentrations to formaldehyde from gas cooking burners. Figure 2 also shows distributions for NO₂ and CO concentrations and exposure concentrations from gas burners plus infiltration of outdoor pollutants. Estimated distributions are shown for typical winter and summer weeks for scenarios in which venting range hoods were not used (i.e., for Scenarios 1 and 2). The data used to construct Figure 2 are provided in Supplemental Material,

Table S3. Estimated exposure concentrations differ from the household concentrations because they account for proximity factors for cooks and small children, and also account for some people not being home during all periods when indoor concentrations are elevated. Since most occupants were assumed out of the home for 9 hours on weekdays and 2 hours on weekends, occupancy patterns reduced the weekly exposure concentrations relative to the household concentrations.

Indoor concentrations of NO₂ from either indoor or outdoor sources depend strongly on the rate constant of indoor deposition, the specified k_i values for NO₂. A higher k_i value assumes faster removal by deposition resulting in lower indoor concentrations. The median estimated weekly average indoor NO₂ concentration for the sample of home simulations was lower than the outdoor concentration predominately due to deposition losses indoors.

The simulation model calculated the contribution of NGCBs to the total weekly average concentration estimated for each modeled home. Across the various scenarios, the simulation model estimates that NGCBs had average contributions of 25% (summer, $k_i=1.05/h$), 33% (summer, $k_i=0.5/h$), 35±1% (winter, $k_i=1.05/h$), and 39% (winter, $k_i=0.5/h$) to the week-averaged indoor NO₂ concentrations. Cooking burners contributed on average 30% and 21±1% of the estimated indoor week-averaged concentrations of CO in the cohort in summer and winter respectively. Cooking burner contributions to indoor concentrations were smaller in the summer due to higher air exchange rates. The simulation model estimated that cooking burners would not yield indoor concentrations above chronic standards for NO₂ or CO for the scenarios evaluated (Figure 2). Modeled homes had an estimated median increase in week-average formaldehyde concentrations due to NGCBs on the order of 1 ppb. This is an order of magnitude lower than concentrations measured over multiple-day periods in homes. Logue et al (2011) aggregated multiple studies that reported measured formaldehyde concentrations in homes and reported a median measured concentration of 19 ppb. This is consistent with expectations that the contribution of emissions from burners to chronic formaldehyde in most homes is small compared with emissions from building materials and furnishings. Nonetheless, for the scenarios evaluated, the model estimates that formaldehyde emissions from NGCBs alone, in the absence of other formaldehyde sources, would lead to exposures exceeding at least one chronic standard for 3-10% of occupants and in 3-9% of homes depending on season (Figure 2). The lower bounds of these ranges are for summer; the upper bounds are for winter weeks. Distributions are presented in Figure 2 for winter (Scenario 1) and summer (Scenario 2).

Simulation model results suggest that acute air pollutant concentration standards are commonly exceeded in homes that use NGCBs without venting range hoods. Figure 3 shows distributions of the estimated maximum hourly concentration for the homes simulated in this study and estimated maximum hourly exposure concentrations for the occupants simulated in this study. The estimated contributions of outdoor pollutants to peak 1-hr indoor concentrations were negligible compared with model estimates of maximum 1-hour concentrations, indicating the importance of indoor sources to acute exposures (Figure 3). The simulation model estimates that

in homes that cook with unvented NGCBs, a large proportion of residences are exposed to concentrations that exceed the 1-hr standard for NO₂. The estimated fraction of residents exposed to a concentration exceeding the 1-h standard varies by season and with the assumed NO₂ deposition rate constant (k_i value), with estimates ranging from 41% to 70% (Table 2). The model produced a similar range of estimates (27-54%) for the number of occupants exposed to formaldehyde levels exceeding an acute standard and a smaller but sizeable fraction (4-9%) exposed to CO concentrations that exceed acute CO standards. Model estimates suggest that the majority of exceedences of the 1-h standard are due to indoor emissions from NGCBs (Table 2). The model estimated that the mean number of acute exceedences per week among homes in which exceedences occurred ranged from 2.4 for summer to 3.6 for winter scenarios without range hood use, depending on the pollutant and season (Table 2).

Table 3 presents estimated personal exposure exceedences for acute health-based standards by age group and for the assigned cooks for the simulated week during the winter. Table 3 includes estimated distributions from a simulation model execution that did not account for differences in exposure according to proximity to the kitchen (Scenario 3) and for a model execution that accounted for differences in proximity but assumed the home had a range hood operating during all cooking events (Scenario 4). Independent of the age group and cook status, if the model indicated that someone experienced an exceedance, on average they experienced 2-3 exceedences over the modeled week. When the proximity factors were applied, the sub-groups with the greatest likelihood to experience acute exceedences were cooks followed by 0-5 year olds. Cooks also had the largest difference between the percentage of individuals estimated to experience an exceedence when proximity factors were applied (Table 3, winter, differences by proximity) and when proximity was assumed to have no effect (Table 3, winter, no differences by proximity). The age group of 6-18 year-olds had the lowest percentage of people exceeding the standard since they were assumed to not cook or be in the kitchen at the time of cooking events. Variations in modeled concentrations between runs with and without proximity factors for non-cooks and those who are not 0-5 years of age are due to differences in initial parameters selected for each model run.

We performed 15 separate simulations for Scenario 1 to evaluate the influence of parameter selection on model-estimated distributions of concentrations in homes. The 15 separate simulations produced consistent results as indicated by the statistics of calculated in-home and exposure concentration distributions; results are presented in the Supplemental Material, Table S3. Geometric means, 25th, 50th, and 75th percentile values varied by less than 10%. Statistics at the tails (5th and 95th percentiles) varied by less than 20%. The repeated simulations produced ranges of estimates that were relatively narrow in relation to the median values across the simulations. Results are shown in Tables 2-3 for the winter week when no hood was used (using $k_i = 1.05/\text{h}$ for NO₂ deposition and accounting for differences in proximity). Although we did not evaluate the magnitude of uncertainty for other scenarios, we assume that it would be comparable to that observed for Scenario 1 (with $k = 1.05/\text{h}$ for NO₂ deposition). The only sampled distribution that varies between runs is the sample AER for summer vs. winter. While

the geometric means of these distributions are different, the geometric standard deviations are similar for each home age group and will result in similar uncertainties.

The results presented so far were for homes that did not use a venting range hood when cooking. We explored the benefit of all homes having and using venting range hoods for all cooking events by reducing mass emission rates by 55%, an estimate of mean effectiveness (Singer et al. 2012). The impact of universal use of moderately effective range hoods on the estimated maximum 1-hr in-home and exposure concentrations is shown in Figure 3 and Table 2. Table 2 shows that the estimated percentages of homes exceeding the most conservative 1-hr acute standard decreased from 55% to 18% for NO₂ with $k_i = 1.05 \text{ h}^{-1}$, from 70% to 30% for NO₂ with $k_i = 0.5 \text{ h}^{-1}$, from 7% to 2% for CO, and from 24% to 11 % for HCHO, compared to homes that did not use range hoods in winter. In summer simulations, the estimated percentage of homes exceeding the most conservative 1-hr acute standard decreased from 21% to 10% for NO₂ with $k_i = 1.05 \text{ h}^{-1}$, from 51% to 17% for NO₂ with $k_i = 0.5 \text{ h}^{-1}$, from 4% to 0.4% for CO, and from 15% to 4% for HCHO, compared to homes that did not use range hoods. Table 3 presents analogous results showing substantial reductions in the estimated frequencies of individual occupant exposure concentrations exceeding standards.

Discussion

There are many reports of residential NO₂ measurements in California and other U.S. locations (Spengler et al. 1983; Ryan et al. 1988; Spengler et al. 1994; Lee et al. 2002), yet few of these can be used to directly assess whether the simulation results of this study are consistent with current concentrations in homes. Many of the studies are decades old and outdoor concentrations were typically higher than those used in this simulation study. The older studies sampled in homes with appliances that were different and may have had different emission factors than cooking appliances currently in use. We thus compare our results to a recent measurement study of concentrations in California homes (Mullen et al. 2012) when possible, and refer to other literature reports as necessary and warranted.

During November 2011 through March 2012, pollutant levels were measured over 6-day periods in 155 homes, mostly in Northern California (Mullen et al. 2012). Measured concentrations were on par with simulated concentrations in this study. Among 117 homes that reported cooking with a gas appliance at least once during sampling, the time-integrated measurements had a fitted NO₂ GM (GSD) of 12 ppb (2.2) in the bedroom and 15 ppb (2.3) in the kitchen. Time-integrated outdoor NO₂ levels in the measurement study had a GM (GSD) of 14.1 ppb (1.8). The repeated winter simulations in the present study had a GM (GSD) of 10.1 ± 0.13 ppb (0.8 ± 0.02) when the higher first order rate constant for deposition ($k_i = 1.05/\text{h}$) was used and 16.2 ppb (1.6) for the single winter simulation with the lower NO₂ deposition value ($k_i = 0.5/\text{h}$). The outdoor NO₂ for the simulated homes had a fitted GM (GSD) of 21.2 ppb (1.3). Valid time-resolved CO data were available for 116 of the homes in the measurement study. The GM (GSD) of the highest 1-hour CO was 3.1 ppm (4.2) for these data. Highest 1-h CO levels in the simulation homes in the

repeated winter simulations had a GM (GSD) of 4.2 ± 0.16 ppm (2.7 ± 0.11) and highest 1-h CO due only to the gas burner emissions had a GM (GSD) of 2.6 ± 0.14 ppm (4.2 ± 0.23).

Wilson et al. (1995) measured CO concentrations in 277 California homes and reported median values for 1-hr and 48-hr averages of 3.0 and 1.2 ppm respectively. These are comparable to our median estimates for highest 1-hr and one-week average CO concentrations in SoCal homes in winter of 4.2 ± 0.3 ppm and 0.9 ± 0.02 ppm respectively. As shown in Figure 3 for the $k=1.05/h$ scenarios, the model estimated a median value of highest 1-hr indoor NO₂ concentrations across the sample cohort of 85 ppb for summer and 110 ± 3 ppb for winter. Estimated 5th and 95th percentile values were 27 ppb and 288 ppb for summer and 36 ± 2 ppb and 364 ± 31 ppb for winter. The only US study reporting peak NO₂ concentrations that we could find in the literature (Fortmann et al. 2001) reported peak NO₂ during cooking that ranged from 40 to 150 ppb based on a single cooktop. Taken as a group, these comparisons suggest that the estimates from our modeling study are reasonable and generally consistent with available monitoring data.

The model did not include homogeneous or heterogeneous chemical reactions, such as the reaction of NO and ozone to produce NO₂. These reactions would increase the effective NO₂ emission rate of the cooktop, particularly in summer, which underscores that our estimates for NO₂ concentrations in summer are conservative and that the health impact of NGCB is likely even larger than modeled here. The possible magnitude of this effect is discussed in the Supplemental Material.

Conclusions

Results of this modeling study suggest that in homes using natural gas cooking burners without venting range hoods, a substantial proportion of occupants experience pollutant concentrations that exceed health-based standards and guidelines. Through simulations of Southern California households cooking at least once per week, we estimate that pollutant levels exceed ambient air quality standards for CO and NO₂ in 7-8% and 55-70% of homes during a typical week in winter (see Table 2). As previously stated, about half of homes in California and 34% of homes nationally have natural gas cooking burners. Assuming that the critical parameters of pollutant emission rates from appliances, homes sizes and cooking patterns have similar distributions throughout the state as occur in the Southern California cohort, we estimate through extrapolation that approximately 1.7 million and 12 million Californians routinely could be exposed to CO and NO₂ levels exceeding ambient air standards in a typical week in winter. Additional work is needed to estimate the frequencies at which air quality benchmarks are exceeded in the tens of millions of U.S. homes that have natural gas cooking burners.

The US EPA and California outdoor health standards, NAAQS and CAAQS respectively, are legally enforceable regulations. If outdoor concentrations exceed these standards in specific areas they are referred to as "non-attainment" areas. The health impacts of being in non-attainment are thought to be significant enough to warrant a wide array of fiscal and regulatory penalties to achieve compliance. Our model-based estimates suggest that during the winter in Southern

California, 55-70% of homes that have and use natural gas burners without venting have indoor air pollution levels consistent with ambient outdoor levels in non-attainment areas.

The hazard posed by natural gas cooking burners can be mitigated substantially through the use of venting range hoods that capture cooking burner pollutants – as well as pollutants generated from cooking activities – at the point of emissions and exhaust them to the outdoors. The range hood modeled in this study was assumed to have the average capture efficiency measured by Singer et al. (2012) in homes. Our estimates suggest that improving range hood effectiveness through changes in occupant behavior or by installing hoods that are quieter (and thus more likely to be used), or by improving their capture efficiency (Delp and Singer 2012), would greatly reduce the number of people that may be exposed to indoor air pollutants at levels that exceed ambient air quality standards.

¹Summary statistics for Scenario 1 (only for $k=1.05 \text{ h}^{-1}$ for NO_2) are presented as a mean $\pm$ range to indicate the variation across the fifteen replicate runs that resulted from reassigning parameter values. The range is the difference between the mean value and the run with the largest difference, higher or lower, than the mean value.

² Mean exceedences per home exceeding indicates the mean number of times a home that exceeded the specified standard at least once exceeded that standard during the simulated week.

Table 3. Model-based estimates of the percentage of occupants that would be exposed to a time-averaged concentration exceeding an acute health-based pollutant standard during a typical winter week. First two groups of results assume no range hood use. Middle group assumes no proximity effect.

		NO ₂ ($k=1.05\text{ h}^{-1}$)	NO ₂ ($k=0.5\text{ h}^{-1}$)	CO		HCHO

¹Summary statistics for Scenario 1 (only for $k=1.05 \text{ h}^{-1}$ for NO_2) are presented as a mean $\pm$ range to indicate the variation across the fifteen replicate runs that resulted from reassigning parameter values. The range is the difference between the mean value and the run with the largest difference, higher or lower, than the mean value.

²First two groups of results assume no range hood use. Middle group assumes no proximity effect.

Figure 1. Example results: simulated time-resolved NO_2 concentrations in a 36 year-old, 1125 ft^2 home with 4 occupants (1 aged 0-5, 1 aged 6-18, and 2 aged 35-54) for one week in winter. Top panel: Indoor concentration of NO_2 originating from indoor and outdoor sources. Middle panel: Simulated "exposure concentration" experienced by the two occupants assumed to not be nearby to the cooking activity ($F_{\text{prox}}=1$). Bottom panel: Simulated exposure concentration for the cook ($F_{\text{prox}}=2$) and a small child assumed to be nearby to the cooking ($F_{\text{prox}}=1.5$).

Figure 2. One-week time-averaged indoor pollutant concentrations estimated by simulation modeling for weighted sample of 6634 homes in Southern California. Both summer (Scenario 2) and winter (Scenario 1) results presented in this figure assume no range hood use and apply near-source proximity factors to estimate exposure concentrations. Boxes show 25th (bottom), 50th (line across center), and 75th (top) percentiles; whiskers show 5th and 95th percentiles. Dashed horizontal lines are standards from Table 2 that are within ranges shown on

graphs. Results presented for Scenario 1 are the mean values from 15 model executions. Results are tabulated in Supplemental Material, Table S3.

Figure 3. Highest 1-h time-averaged indoor pollutant concentrations estimated by simulation modeling of the weighted sample of 6634 Southern California homes and exposure concentrations for the weighted sample of 19,464 individual occupants. Estimated indoor concentrations presented for Scenario 1 (winter) and Scenario 2 (summer), both of which assume no range hood use. Estimated exposure concentrations presented in this figure all apply

near-source proximity factors, with one pair of scenarios assuming no range hood use and the second pair of scenarios assuming use of a range hood with 55% capture efficiency during every cooking event. Boxes show 25th (bottom), 50th (line across center), and 75th (top) percentiles; whiskers show 5th and 95th percentiles. Dashed horizontal lines are standards from Table 2 that are within ranges shown on graphs. Results presented for Scenario 1 are the mean values from 15 model executions. Results are tabulated in Supplemental Material, Table S3.
