## KEY POINTS:

Stratospheric C-14 is governed by cosmogenic production, transport, and stratosphere-troposphere exchange.

Global annual mean C-14 production rate and net flux to the troposphere are determined empirically.

C-14 is a sensitive tracer of stratospheric transport and residence times.

## Abstract:

Measurements of the  $^{14}\text{C}$  content of carbon dioxide in air collected by high-altitude balloon flights in 2003, 2004, and 2005 reveal the contemporary radiocarbon distribution in the northern midlatitude stratosphere, four decades after the Limited Test Ban Treaty restricted atmospheric testing of nuclear weapons. Comparisons with results from a 3D chemical-transport model show that the  $^{14}\text{CO}_2$  distribution is now largely governed by the altitude/latitude dependence of the natural cosmogenic production rate, stratospheric transport, and propagation into the stratosphere of the decreasing radiocarbon trend in tropospheric  $\text{CO}_2$  due to fossil fuel combustion. From the observed correlation of  $^{14}\text{CO}_2$  with  $\text{N}_2\text{O}$  mixing ratios, an annual global mean net flux of  $^{14}\text{CO}_2$  to the troposphere of  $1.6(\pm 0.4) \times 10^{17} \text{‰ mol CO}_2 \text{ yr}^{-1}$  and a global production rate of  $2.2(\pm 0.6) \times 10^{26} \text{ atoms } ^{14}\text{C yr}^{-1}$  are empirically derived. The results also indicate that contemporary  $^{14}\text{CO}_2$  observations provide highly sensitive diagnostics for stratospheric transport and residence times in models.

## 1. Introduction

Carbon-14 is produced in the stratosphere and upper troposphere by nuclear reactions of atmospheric nitrogen with thermal neutrons produced naturally by cosmic rays and by atmospheric nuclear weapons testing primarily in the 1950s and 60s. The radiocarbon atoms are then rapidly ( $<3$  months) oxidized to CO and then  $\text{CO}_2$ , an inert gas which circulates throughout the stratosphere and troposphere; at Earth's surface  $^{14}\text{CO}_2$  can enter the oceanic and terrestrial carbon reservoirs. Because its production and redistribution in the Earth system are unlike any other gas,  $^{14}\text{CO}_2$  is a unique geophysical and biogeochemical tracer. For example, measurements of the decay of the bomb radiocarbon signal yielded insight into the stratospheric circulation that is independent of chemistry occurring there [e.g., *Hall and Waugh*, 2000; *Jackman et al.*, 1991; *Johnston*, 1989; *Kinnison et al.*, 1994; *Park et al.*, 1999; *Prather and Remsberg*, 1993], unlike most other tracers. Likewise, its partitioning between the atmosphere, oceans, soils, plants and other carbon reservoirs, as well as its absence in fossil fuel-derived  $\text{CO}_2$  [*Suess*, 1955], has been used to quantify the inventories, residence times, and gross fluxes of carbon in and between these reservoirs [e.g., *Braziunas et al.*, 1995; *Broecker and Peng*, 1994; *Caldeira et al.*, 1998;

*Guilderson et al.*, 2000; *Levin et al.*, 2003; *Randerson et al.*, 2002; *Trumbore*, 2000]. However, only 14 measurements of stratospheric  $^{14}\text{CO}_2$  [*Nakamura et al.*, 1994] have been made since 1974 – that is, since the atmospheric circulation has purged the stratosphere of the large amounts of  $^{14}\text{C}$  originally deposited there by nuclear weapons testing. Moreover, no stratospheric radiocarbon datasets have yet included simultaneous measurements of other long-lived tracers, which has hampered interpretation and comparison with global-scale models by exploiting the correlations between long-lived tracers [e.g., *Boering et al.*, 1996; *Plumb*, 2007; *Plumb and Ko*, 1992]. Despite the promise outlined by, e.g., *Johnston* [1989] and *Levin and Hesshaimer* [2000], this lack of data (and unwarranted lack of confidence in the stratospheric bomb era  $^{14}\text{CO}_2$  data [*Hesshaimer and Levin*, 2000]) has limited the use of  $^{14}\text{CO}_2$  as a stratospheric tracer, as well as for assessment of models of the cosmogenic  $^{14}\text{C}$  production rate and transport to the troposphere needed for carbon cycle studies. The latter assessments are particularly needed now that the natural cosmogenic production rate, and the rates and details of radiocarbon transport to the troposphere, are playing an increasingly important role relative to the bomb radiocarbon input in studies of surface radiocarbon and its redistribution there [e.g., *Graven et al.*, 2012a; *Levin et al.*, 2010; *Randerson et al.*, 2002] and the use of atmospheric observations to infer regional anthropogenic emissions [e.g., *Graven et al.*, 2012b; *Levin et al.*, 2010; *Randerson et al.*, 2002; *Riley et al.*, 2008].

Here, we present measurements of stratospheric  $^{14}\text{CO}_2$  from whole air samples collected by high-altitude balloon flights in 2003, 2004, and 2005 for which measurements of other long-lived tracers were also made, including nitrous oxide ( $\text{N}_2\text{O}$ ). We use these new measurements and comparisons with a 3D global chemical transport model to (1) show current levels of  $^{14}\text{CO}_2$  in the middle and lower stratosphere and the dominant processes controlling its distribution and variations, (2) empirically estimate the annual global mean net flux of stratospheric radiocarbon to the troposphere and the global radiocarbon production rate, and (3) demonstrate that  $^{14}\text{CO}_2$  observations can be used as a sensitive diagnostic for stratospheric transport and residence times in models.

## 2. Methods

A cryogenic whole air sampler (CWAS) [*Froidevaux et al.*, 2006; *Lueb et al.*, 1975] was flown by high altitude balloons launched from Ft. Sumner, New Mexico (34.47°N, 104.24°W) on

5 October 2003, 29 September 2004, and 1 October 2005. The CWAS consists of a manifold of 26 electropolished, 800mL stainless steel canisters, which are immersed in liquid neon to serve as a cryopump when each motor-driven canister valve is actuated. Airflow into the canisters was monitored by pressure changes in the manifold, and the canisters were filled to pressures of 245-310 psi. Samples were collected between 15.3 and 33.3 km altitude. The mixing ratios (mole fractions) of a number of trace gases in the canisters were then measured at the University of Miami or NCAR, including N<sub>2</sub>O and CH<sub>4</sub> using an HP5890 II+ series GC and NIST-traceable standards to precisions of 0.1% and 0.3%, respectively. Aliquots of a total of 59 samples from these 3 flights were transferred to 1.6L electropolished stainless steel canisters and shipped to UC Berkeley, where the CO<sub>2</sub> in the samples was cryogenically collected and purified using a series of 5 traps immersed in LN<sub>2</sub> and/or LN<sub>2</sub>/ethanol slushes at -95°C, and then flame-sealed in glass ampoules. Samples were subsequently split into 2 or 3 aliquots of 20 to 30 micromoles of CO<sub>2</sub> each for separate analyses of radiocarbon and, for some samples,  $\delta^{13}\text{C}$ ,  $\delta^{17}\text{O}$ , and  $\delta^{18}\text{O}$ . For the  $^{14}\text{C}$  analyses, using methods similar to Graven *et al.* [2012a], the CO<sub>2</sub> samples were graphitized and then analyzed by accelerator mass spectrometry. Measurements are reported as  $\Delta^{14}\text{C}$  for geochemical samples [Stuiver and Polach, 1977] (corrected assuming  $\delta^{13}\text{C}$  of -8‰ V-PBD) with a precision of 2‰ (1 $\sigma$ ) or better.

To gain a global perspective on the measurements,  $^{14}\text{CO}_2$  and N<sub>2</sub>O were simulated using the Lawrence Livermore National Laboratory's (LLNL) 3D global chemical-transport model IMPACT (Integrated Massively Parallel Atmospheric Chemical Transport). IMPACT is based on an operator-split method of emissions, advection, diffusion, deposition, convection, gravitational settling, photolysis, and chemistry, and can be run using either input meteorological fields from a general circulation model (GCM) or assimilated data [Rotman *et al.*, 2004]. Unless otherwise noted, all the model results reported here were generated using (1) meteorological data from the MACCM3 climate model at 4x5 degree latitude-longitude horizontal resolution, with 52 levels in the vertical from the ground to 0.006 mbar; meteorological data for the period 1 January to 31 December 1997 were used for every model year [Rotman *et al.*, 2004]; (2) cosmogenic radiocarbon production rates as a function of latitude, longitude, and altitude from the formulation of Koch and Rind [1998], based in turn on Lal and Peters [1967] and Lingenfelter [1963], interpolated bilinearly onto the IMPACT grid; and (3) prescribed surface boundary conditions for  $\Delta^{14}\text{C}$  of CO<sub>2</sub> from a linear fit to observations at La Jolla, CA (32.87°N,

117.25°W) from June 1992 to February 2007 [Graven *et al.*, 2012a], for CO<sub>2</sub> mixing ratios from an average [Boering *et al.*, 1996] of observations at Mauna Loa and American Samoa from July 1976 to March 2010 from the Global Monitoring Division of NOAA's Earth System Research Laboratory (<http://www.esrl.noaa.gov/gmd/ccgg/>) and for N<sub>2</sub>O mixing ratios from mean surface observations from 20°S to 20°N from 1977 to 2007 from the World Data Center for Greenhouse Gases (<http://ds.data.jma.go.jp/gmd/wdcgg/>). For simulating stratospheric N<sub>2</sub>O, three reactions were included: N<sub>2</sub>O+hν→N<sub>2</sub>+O(<sup>1</sup>D), N<sub>2</sub>O+O(<sup>1</sup>D)→N<sub>2</sub>+O<sub>2</sub>, and N<sub>2</sub>O+O(<sup>1</sup>D)→2NO. The model was run from 1962 to 2012, which includes 20 years of spinup needed for the model atmosphere to lose memory of the initial model conditions chosen.

To test the sensitivity of modeled Δ<sup>14</sup>C of CO<sub>2</sub> to solar cycle variations in the <sup>14</sup>C production rate, an upper limit was estimated here by assuming that the largest local variation in the solar-cycle-dependent <sup>14</sup>C production rate of 10% [Jockel *et al.*, 1999] is applicable globally and then modulating the 3D production rates with a sinusoid of amplitude 10% and periodicity of 11 years. Finally, to test the sensitivity of Δ<sup>14</sup>C of CO<sub>2</sub> to meteorology, we also used meteorological fields from the FVCCM (Finite Volume Community Climate Model) and FVDAS (Finite Volume Data Assimilation System) at 4x5 horizontal resolution with 28 levels in the vertical from the ground to 0.656 mbar for 1 July 1999-30 June 2000 [e.g., Schoeberl *et al.*, 2003] in separate model runs. The MACCM3, FVCCM, and FVDAS meteorologies used here are known to have significant differences in their residual circulations and, hence, result in significant differences in stratospheric mean ages of air [e.g., Schoeberl *et al.*, 2003].

### 3. Results and Discussion

Vertical profiles of Δ<sup>14</sup>C of CO<sub>2</sub> and of N<sub>2</sub>O are shown in Figure 1a and b. In general, values for Δ<sup>14</sup>C increase with altitude, as expected for a long-lived tracer with a stratospheric source and tropospheric sink, with a leveling off at ~ 24 km and above. The main excursions away from this trend with altitude observed at 34°N for any given balloon flight are consistent with filaments of air from higher or lower latitudes moving into the balloon flight path. For example, in 2003, older, photochemically-aged air from higher latitudes with much lower values of N<sub>2</sub>O was sampled between 19 and 22 km, with correspondingly higher values of Δ<sup>14</sup>C. This interpretation is consistent with the model results, which show large variations in Δ<sup>14</sup>C with latitude for a given altitude, with older air at higher latitudes having significantly larger Δ<sup>14</sup>C values (Fig. 1a).

Similarly, in 2004, the profiles are influenced by higher latitude air with higher  $\Delta^{14}\text{C}$ /lower  $\text{N}_2\text{O}$  values up to  $\sim 22$  km and then again above 28 km; and in 2005, higher  $\Delta^{14}\text{C}$ /lower  $\text{N}_2\text{O}$  air from higher latitudes is apparent at  $\sim 24$  km, while lower  $\Delta^{14}\text{C}$ /higher  $\text{N}_2\text{O}$  air from lower latitudes is apparent above  $\sim 28$  km. Indeed, the variability due to these filaments is largely smoothed out by plotting  $\Delta^{14}\text{C}$  versus  $\text{N}_2\text{O}$  (Figure 1c) in which the data follow a tighter relationship, as expected when two tracers that are long-lived with respect to quasi-horizontal transport and mixing are plotted against each other [e.g., *Plumb*, 2007; *Plumb and Ko*, 1992]. In these  $\Delta^{14}\text{C}:\text{N}_2\text{O}$  scatterplots,  $\Delta^{14}\text{C}$  increases as  $\text{N}_2\text{O}$  decreases down to  $\sim 200$  ppb (nmol/mol) and then levels off for  $\text{N}_2\text{O} < 200$  ppb. In other words,  $\Delta^{14}\text{C}$  increases with increasing mean age up to a mean age of roughly 4 years [*Boering et al.*, 1996] and then levels off. The model results predict a small decrease in  $\Delta^{14}\text{C}$  ( $< 5\%$ ) for this higher altitude extratropical air, although the filaments of air influencing the balloon profiles make it difficult to test this particular model prediction.

After considering the impact of filaments of air from higher or lower latitudes, the next identifiable influence on the stratospheric  $^{14}\text{CO}_2$  profiles and their correlation with  $\text{N}_2\text{O}$  from year to year is the propagation of the trend in  $\Delta^{14}\text{C}$  of tropospheric  $\text{CO}_2$  into the stratosphere.  $\Delta^{14}\text{C}$  of tropospheric  $\text{CO}_2$  is decreasing by 7 to  $12\%$   $\text{yr}^{-1}$  [e.g., *Graven et al.*, 2012a; *Levin et al.*, 2010], due solely since 1990 to the burning of fossil fuel [*Levin et al.*, 2010], which, because of its age, has no  $^{14}\text{C}$  [*Suess*, 1955]. Thus, in general,  $\Delta^{14}\text{C}$  of stratospheric  $\text{CO}_2$  is lower in 2004 than 2003 and lower in 2005 than 2004. Although the filaments of older or younger air from higher or lower latitudes, respectively, make a precise determination of the difference from year to year due to the tropospheric trend difficult, the decreases of  $\sim 10\%$  and  $7\%$  between 2003 and 2004 and between 2004 and 2005, respectively (calculated as the differences between linear fits to the 2003, 2004, and 2005 data for  $\text{N}_2\text{O}$  between 120 and 200 ppb) are consistent with observed tropospheric trends and with model predictions of a  $5\%$  decrease at  $34^\circ\text{N}$ . Decreases of  $\sim 5$  to  $7\%$  between 2004 and 2005 are also apparent in Figure 2, which shows  $\Delta^{14}\text{C}$  versus  $\text{N}_2\text{O}$  for  $250 < \text{N}_2\text{O} < 320$  ppb, and are similar to IMPACT model predictions of  $5\%$  decreases at these lower altitudes. Comparison of these measurements with  $^{14}\text{CO}_2$  measured on 14 samples collected by balloon over Japan in September 1989 and July 1990 [*Nakamura et al.*, 1994; 1992] show that these trends also extend to longer timescales, with average decreases of  $\sim 8$  to  $10\%$   $\text{yr}^{-1}$  between 1989/90 and 2003, 2004, and 2005 for all samples collected above 21 km.

In addition to the propagation of the decreasing tropospheric trend and to differences due to regional and relatively small-scale filaments of air encountered in the balloon flights, it is also possible that variations in  $\Delta^{14}\text{C}$  for the 2003, 2004, and 2005 datasets could arise from the time-dependence of the radiocarbon production rates due to modulation of the cosmic ray flux by the 11-year cycle in solar activity [e.g., *Jockel et al.*, 2000]. Inputting an estimated upper limit to the solar cycle modulation (see Methods) into the model, however, resulted in much smaller variations in  $\Delta^{14}\text{C}$  than either of the other two effects above – less than 2‰ for  $250 < \text{N}_2\text{O} < 320$  ppb (not shown). While more realistic variations can be input into global models [e.g., *Jockel et al.*, 2000], we expect the year-to-year variation due to the solar cycle between 2003 and 2005 to be only a small fraction of that due to propagation of the tropospheric trend and, to first order, can be neglected.

Importantly, the correlation of  $\Delta^{14}\text{C}$  with  $\text{N}_2\text{O}$  also allows empirical estimates of (1) the global net isoflux between the stratosphere and troposphere and (2) the global  $\Delta^{14}\text{C}$  production rate to be made. Plumb & Ko [1992] showed that the slope of the compact relationship between two tracers that are in slope-equilibrium (that is, are long-lived with respect to vertical and quasi-horizontal transport) is equal to the ratio of their net vertical fluxes. Since  $\text{N}_2\text{O}$  is destroyed only in the stratosphere, the global net vertical flux of  $\text{N}_2\text{O}$  is simply the global  $\text{N}_2\text{O}$  loss rate, known independently to be  $4.50 \times 10^{11} (\pm 25\%) \text{ mol N}_2\text{O yr}^{-1}$  [*Minschwaner et al.*, 1993; *Prather and Ehhalt*, 2001]. Thus, the global net vertical flux for other species of interest can be estimated from the value of the slope of their correlations with  $\text{N}_2\text{O}$ , an approach used previously to estimate global cross-tropopause fluxes of  $\text{O}_3$  [*McLinden et al.*, 2000; *Murphy and Fahey*, 1994], nitrogen oxides [*Murphy and Fahey*, 1994; *Olsen et al.*, 2001], meteoritic material [*Cziczo et al.*, 2001], and  $\text{N}_2\text{O}$  and  $\text{CO}_2$  isotopologues [*Luz et al.*, 1999; *Park et al.*, 2004]; since air is returning to the troposphere from the lower stratosphere, observations for  $\text{N}_2\text{O}$  mixing ratios  $> 250$  ppb are generally used. Indeed, model results in Fig 1c show that we expect that the  $\Delta^{14}\text{C}:\text{N}_2\text{O}$  relationship is quite compact and nearly global for  $\text{N}_2\text{O} > 250$  ppb (except for the deep tropics) and hence that the *Plumb and Ko* approach for  $\text{N}_2\text{O} > 250$  ppb is likely to provide a reasonable approximation for the stratospheric radiocarbon production rate. From the data in Figure 2, we can estimate a global net vertical  $\Delta^{14}\text{C}$  flux between the stratosphere and troposphere using Equation (1), based on *Luz et al.* [1999] and *Park et al.* [2004]:

$$Global\ Net\ \Delta^{14}C\ flux = MF_{air}[CO_2]_{strat} \left[ m \cdot \left( -\frac{(L + G_{strat})}{MF_{air}} \right) + \Delta^{14}C_{trop} \right] - MF_{air}[CO_2]_{trop} [\Delta^{14}C_{trop}] \quad (1)$$

where  $MF_{air}$  is the air mass flux between the stratosphere and troposphere in mol air  $yr^{-1}$ ;  $[CO_2]_{trop}$  and  $[CO_2]_{strat}$  are the  $CO_2$  mixing ratios for air entering and leaving the stratosphere, respectively;  $m$  is the slope of the stratospheric  $\Delta^{14}C$ :  $N_2O$  correlation for  $N_2O > 250$  ppb,  $L$  is the global loss and  $G_{strat}$  is the net stratospheric growth rate of  $N_2O$  ( $4.5 \times 10^{11}$  and  $1.10 \times 10^{10}$  mol  $N_2O\ yr^{-1}$ , respectively), and  $\Delta^{14}C_{trop}$  is the tropospheric  $\Delta^{14}C$  value in ‰. Furthermore, since  $[CO_2]_{strat} = [CO_2]_{trop}$  to within 1%, Equation 1 simplifies to Equation (2).

$$Global\ Net\ \Delta^{14}C\ flux = [CO_2](m[-(L + G_{strat})]) \quad (2)$$

Using air mass fluxes from Appenzeller [1996] or Holton [1990] and corresponding  $CO_2$  mixing ratios in Equation (1) or simply using Equation (2) yields a global net  $\Delta^{14}C$  flux of  $1.6 \times 10^{17}$  ‰ mol  $CO_2\ yr^{-1}$  ( $\pm 30\%$ ,  $1\sigma$ ); see Table S1 in supporting information. (Note that large differences in assumed air mass fluxes largely cancel out in isotope flux calculations [e.g., Luz *et al.*, 1999].)

Next, we note that the annually-averaged global net vertical  $\Delta^{14}C$  flux from Equations (1) or (2) is equivalent to the annually-averaged stratospheric  $^{14}C$  production rate. Assuming a stratospheric-to-total  $^{14}C$  production ratio of 0.5 [Masarik and Beer, 1999] and multiplying by Avogadro's number, the Modern Standard ratio of mass-14 to mass-12 abundances of carbon ( $1.176 \times 10^{-12}$ ), and 0.001 to convert from ‰ to  $^{14}C$  atoms yields a global  $^{14}C$  production rate of  $2.2 \pm 0.6 \times 10^{26}$  atoms  $^{14}C\ yr^{-1}$ . This is the first completely empirical estimate of the global annual mean  $^{14}C$  production rate that does not rely on estimates of reservoir sizes and exchange rates. It falls at the low end of the range in estimates from previous studies (Table 1), independently continuing the general downward trend of all the estimates. It is also lower than recent calculations by Kovaltsov *et al.* [2012] using updated galactic cosmic ray energy spectra for  $\alpha$ -particles and heavier nuclei which they assert explains the reduction relative to the many earlier calculations. Our stated  $1\sigma$  uncertainty of 30% includes summing the uncertainties in the  $N_2O$  loss rate (25%) and the Williamson-York iterative bivariate fit [Cantrell, 2008] to the  $^{14}CO_2:N_2O$  correlation ( $\sim 5\%$ ), as well as considering small differences between using the 2004, 2005, or the combined dataset (Table S1), or using a lower cut-off of 250 vs. 280 ppb  $N_2O$ . Not included are possible systematic errors that could result from assuming that (1) the Plumb and Ko method is

globally applicable based on midlatitude measurements, (2) the stratospheric-to-total  $^{14}\text{C}$  production ratio is 0.5, and (3) the loss of stratospheric  $^{14}\text{CO}$  to the troposphere before oxidation to  $^{14}\text{CO}_2$  is small. For (1), we believe that the *Plumb and Ko* method is reasonably sound since the global production rate in the IMPACT model can be retrieved using the modeled  $^{14}\text{CO}_2:\text{N}_2\text{O}$  correlations (but with some uncertainty due to sparse model points for  $\text{N}_2\text{O}>250$  ppb); see Table 1. For (2), if the true stratospheric-to-total production ratio is as high as 0.65 [Masarik and Beer, 1999], our estimated global  $^{14}\text{C}$  production rate would be even lower by 20%. For (3), we used  $^{14}\text{CO}$  observations from 1993 [Brenninkmeijer et al., 1995] to estimate a conservative upper bound for a low bias in our global  $^{14}\text{C}$  production rate due to  $^{14}\text{CO}$  loss to the troposphere of  $<5\%$ . In addition, we note that sunspot number was a maximum in 2001 and a minimum in 2008 [Gray et al., 2010]; thus the 2004 and 2005 data likely represent mid-solar cycle  $^{14}\text{C}$  production rates, integrated over the midlatitude stratospheric age spectrum for  $\text{N}_2\text{O}>250$  ppb (with a mean age  $\leq 2$  years [Andrews et al., 2001]). Our simplified solar cycle model results suggest an upper limit less than  $\sim 10\%$  higher and a lower limit  $\sim 5\%$  lower than the production rate estimated from the 2004/2005 observations (Table 1). Given that the uncertainty in the  $\text{N}_2\text{O}$  loss rate is a constant systematic rather than random error, such a solar cycle variation may be detectable from additional  $^{14}\text{C}$  and  $\text{N}_2\text{O}$  measurements that span a solar cycle, while reduction in the  $\text{N}_2\text{O}$  loss rate uncertainty could narrow the overall uncertainty in the absolute global  $^{14}\text{C}$  production rate.

Finally, Figure 1d shows that using different meteorological inputs in the same model yields very large differences in predicted  $^{14}\text{CO}_2$  levels. The model results using MACCM3 meteorology simulate the  $\Delta^{14}\text{C}$  observations well, and this meteorology is known to produce mean ages that are in generally good agreement with observations [e.g., Strahan et al., 2011]. In contrast, the FVCCM and FVDAS meteorologies used here are known [Schoeberl et al., 2003] to produce larger and smaller mean ages, respectively. The predicted  $^{14}\text{CO}_2$  levels using these met fields also follow this order: too high for a residual circulation that is likely too slow and too low for a residual circulation that is too fast. These results demonstrate that contemporary radiocarbon measurements and their modeling provide important new constraints on stratospheric transport into, within, and out of the stratosphere and can serve as a sensitive new model diagnostic. Such constraints are greatly needed to accurately predict the timing of the recovery of the ozone layer as climate changes and to determine whether the stratospheric circulation is speeding up as the climate is warming. For example, a combination of mean age estimates from earlier tracer

observations [Engel et al., 2009; Stiller et al., 2012] suggests that there has been no change in mean age over the past 30 years (at least at altitudes of 25-30 km at midlatitudes and to within the uncertainties), while models suggest it should have decreased significantly due to both ozone depletion and radiative forcing [e.g., Butchart et al., 2010; Li et al., 2012] and there appear to have been significant increases in tropical upwelling [Kawatani and Hamilton, 2013; Randel et al., 2006]. If tropical upwelling has increased but mean ages have not, then to reconcile both there must be a faster circulation in the lower stratosphere than in the middle stratosphere (and/or more air recirculating back into the tropics via the lower stratosphere or the upper troposphere) [e.g., Bonisch et al., 2011]. Stratospheric radiocarbon, which is expected to be a tracer of stratospheric residence times [e.g., Hall and Waugh, 2000], may best test these features of the stratospheric circulation and how they may be changing over time and whether models are capturing the most important circulation features (and their sensitivity to climate) or not. Validation of stratospheric  $\Delta^{14}\text{C}$  levels and reliable fluxes of  $\Delta^{14}\text{C}$  to the troposphere in models will also reduce uncertainties in carbon cycle studies that aim to partition radiocarbon signals at the surface between the atmosphere, oceans, terrestrial biosphere and human influences such as fossil fuel burning for which a higher time and spatial resolution of flux to the troposphere is needed beyond the annual mean estimate we provide here.

#### 4. Conclusions

Measurements of radiocarbon ( $\Delta^{14}\text{C}$  of  $\text{CO}_2$ ) and  $\text{N}_2\text{O}$  mixing ratios from 59 whole air samples collected in 2003, 2004, and 2005 between 15 and 33 km at  $\sim 34^\circ\text{N}$ , and their comparison with model simulations using a 3D CTM, show that contemporary stratospheric radiocarbon levels are governed by cosmogenic production and stratospheric transport, as well as by propagation of the decreasing  $\Delta^{14}\text{C}$  trend in tropospheric  $\text{CO}_2$ . From the correlation of  $\Delta^{14}\text{C}$  of  $\text{CO}_2$  with  $\text{N}_2\text{O}$ , coupled with independent knowledge of the  $\text{N}_2\text{O}$  loss rate, the global net vertical  $^{14}\text{C}$  isoflux to the troposphere and the global production rate were empirically estimated for 2004-2005, with the global production rate falling at the low end of estimates and calculations from previous studies. In addition to the entirely empirical net isoflux and global production rate for  $^{14}\text{C}$  useful for carbon cycle studies, our work indicates that stratospheric  $^{14}\text{CO}_2$  can provide new diagnostics for mean ages and residence times in stratospheric models.

## Acknowledgements

We thank Rich Lueb and Roger Hendershot for development and deployment of the Cryosampler and X. Zhu and L. Pope for laboratory assistance. We gratefully acknowledge support from NASA UARP (NNX13AH10G and NNX09AJ95G to KAB and NNX13AH20G and NNX12AH02G to ELA); UC Lab Fees LF-09-118804 to KAB and PCS; UC IGPP/LLNL 07-GS-019 to KAB and TG; NOAA Climate Program Office (NA05OAR4311166 to TG), and to the Lawrence Scholar's Program for AK; portions of this work were performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory (W-7405-Eng-48 and DE-AC52-07NA27344 by AK, TG, PC, and DB). All measurements are available online in supporting information.

**Table 1: Comparison of Global  $^{14}\text{C}$  Production Rates**

Global Mean $^{14}\text{C}$ Production Rate ( $10^{26}$ atoms $^{14}\text{C}$ yr $^{-1}$ )	Time Period	Solar Max, Solar Min Production Rate ( $10^{26}$ atoms $^{14}\text{C}$ yr $^{-1}$ )	Study
2.2 ( $\pm 0.6$ )	~2002-2005 (mid-Solar Cycle 23)	--	<b>This work</b> (Empirically-derived from $^{14}\text{C}:\text{N}_2\text{O}$ observations) <sup>a</sup>
1.8-2.4 <sup>b</sup>	--	2.1, 2.4 <sup>c</sup>	<b>This work</b> (Derived from IMPACT model results for $^{14}\text{C}$ and $\text{N}_2\text{O}$ ) <sup>a</sup>
2.33	--	--	<b>This work</b> (Global mean production rate in the IMPACT model) <sup>d</sup>
4.0( $\pm 0.8$ )	1867-1963	3.3, 4.2	Lingenfelter [1963] (calculated)
2.9			Suess [1965] ( $^{14}\text{C}$ inventory)
3.7( $\pm 0.4$ )	1964-1976	3.1, 4.2	Light <i>et al.</i> [1973] (calculated)
3.2			Damon <i>et al.</i> [1978] ( $^{14}\text{C}$ inventory)
2.9		2.6, 3.1	O' Brien [1979] (calculated)
3.3( $\pm 0.3$ )	1953-1995	2.7-3.9	Masarik and Beer [1999] (calculated)
2.96 or 3.68 <sup>e</sup>	1989-2001	~2.2, 3.5 or 2.4, 4.3	Lowe and Allen [2002] (calculated)
2.1			Levin <i>et al.</i> [2010] ( $^{14}\text{C}$ inventory)
2.64	1951-2010	1.8, 3.5	Kovaltsov <i>et al.</i> [2012] (calculated)

<sup>a</sup> Using the relationship between  $^{14}\text{C}$  and  $\text{N}_2\text{O}$  in the lower stratosphere (see text).

<sup>b</sup> Including model results for  $34^\circ$  and  $50^\circ\text{N}$ .

<sup>c</sup> Estimate of upper (2.2+10%) and lower limit (2.2–5%) to Plumb & Ko-based method using IMPACT model results with a 10% solar cycle variation in  $^{14}\text{C}$  production rate everywhere extrapolating from the empirical production rate from 2004/2005.

<sup>d</sup> Total  $^{14}\text{C}$  content in the atmosphere in the IMPACT model after one year with the planetary boundary layer sink turned off, using the Koch and Rind [1998] implementation of  $^{14}\text{C}$  rates from Lal and Peters [1967].

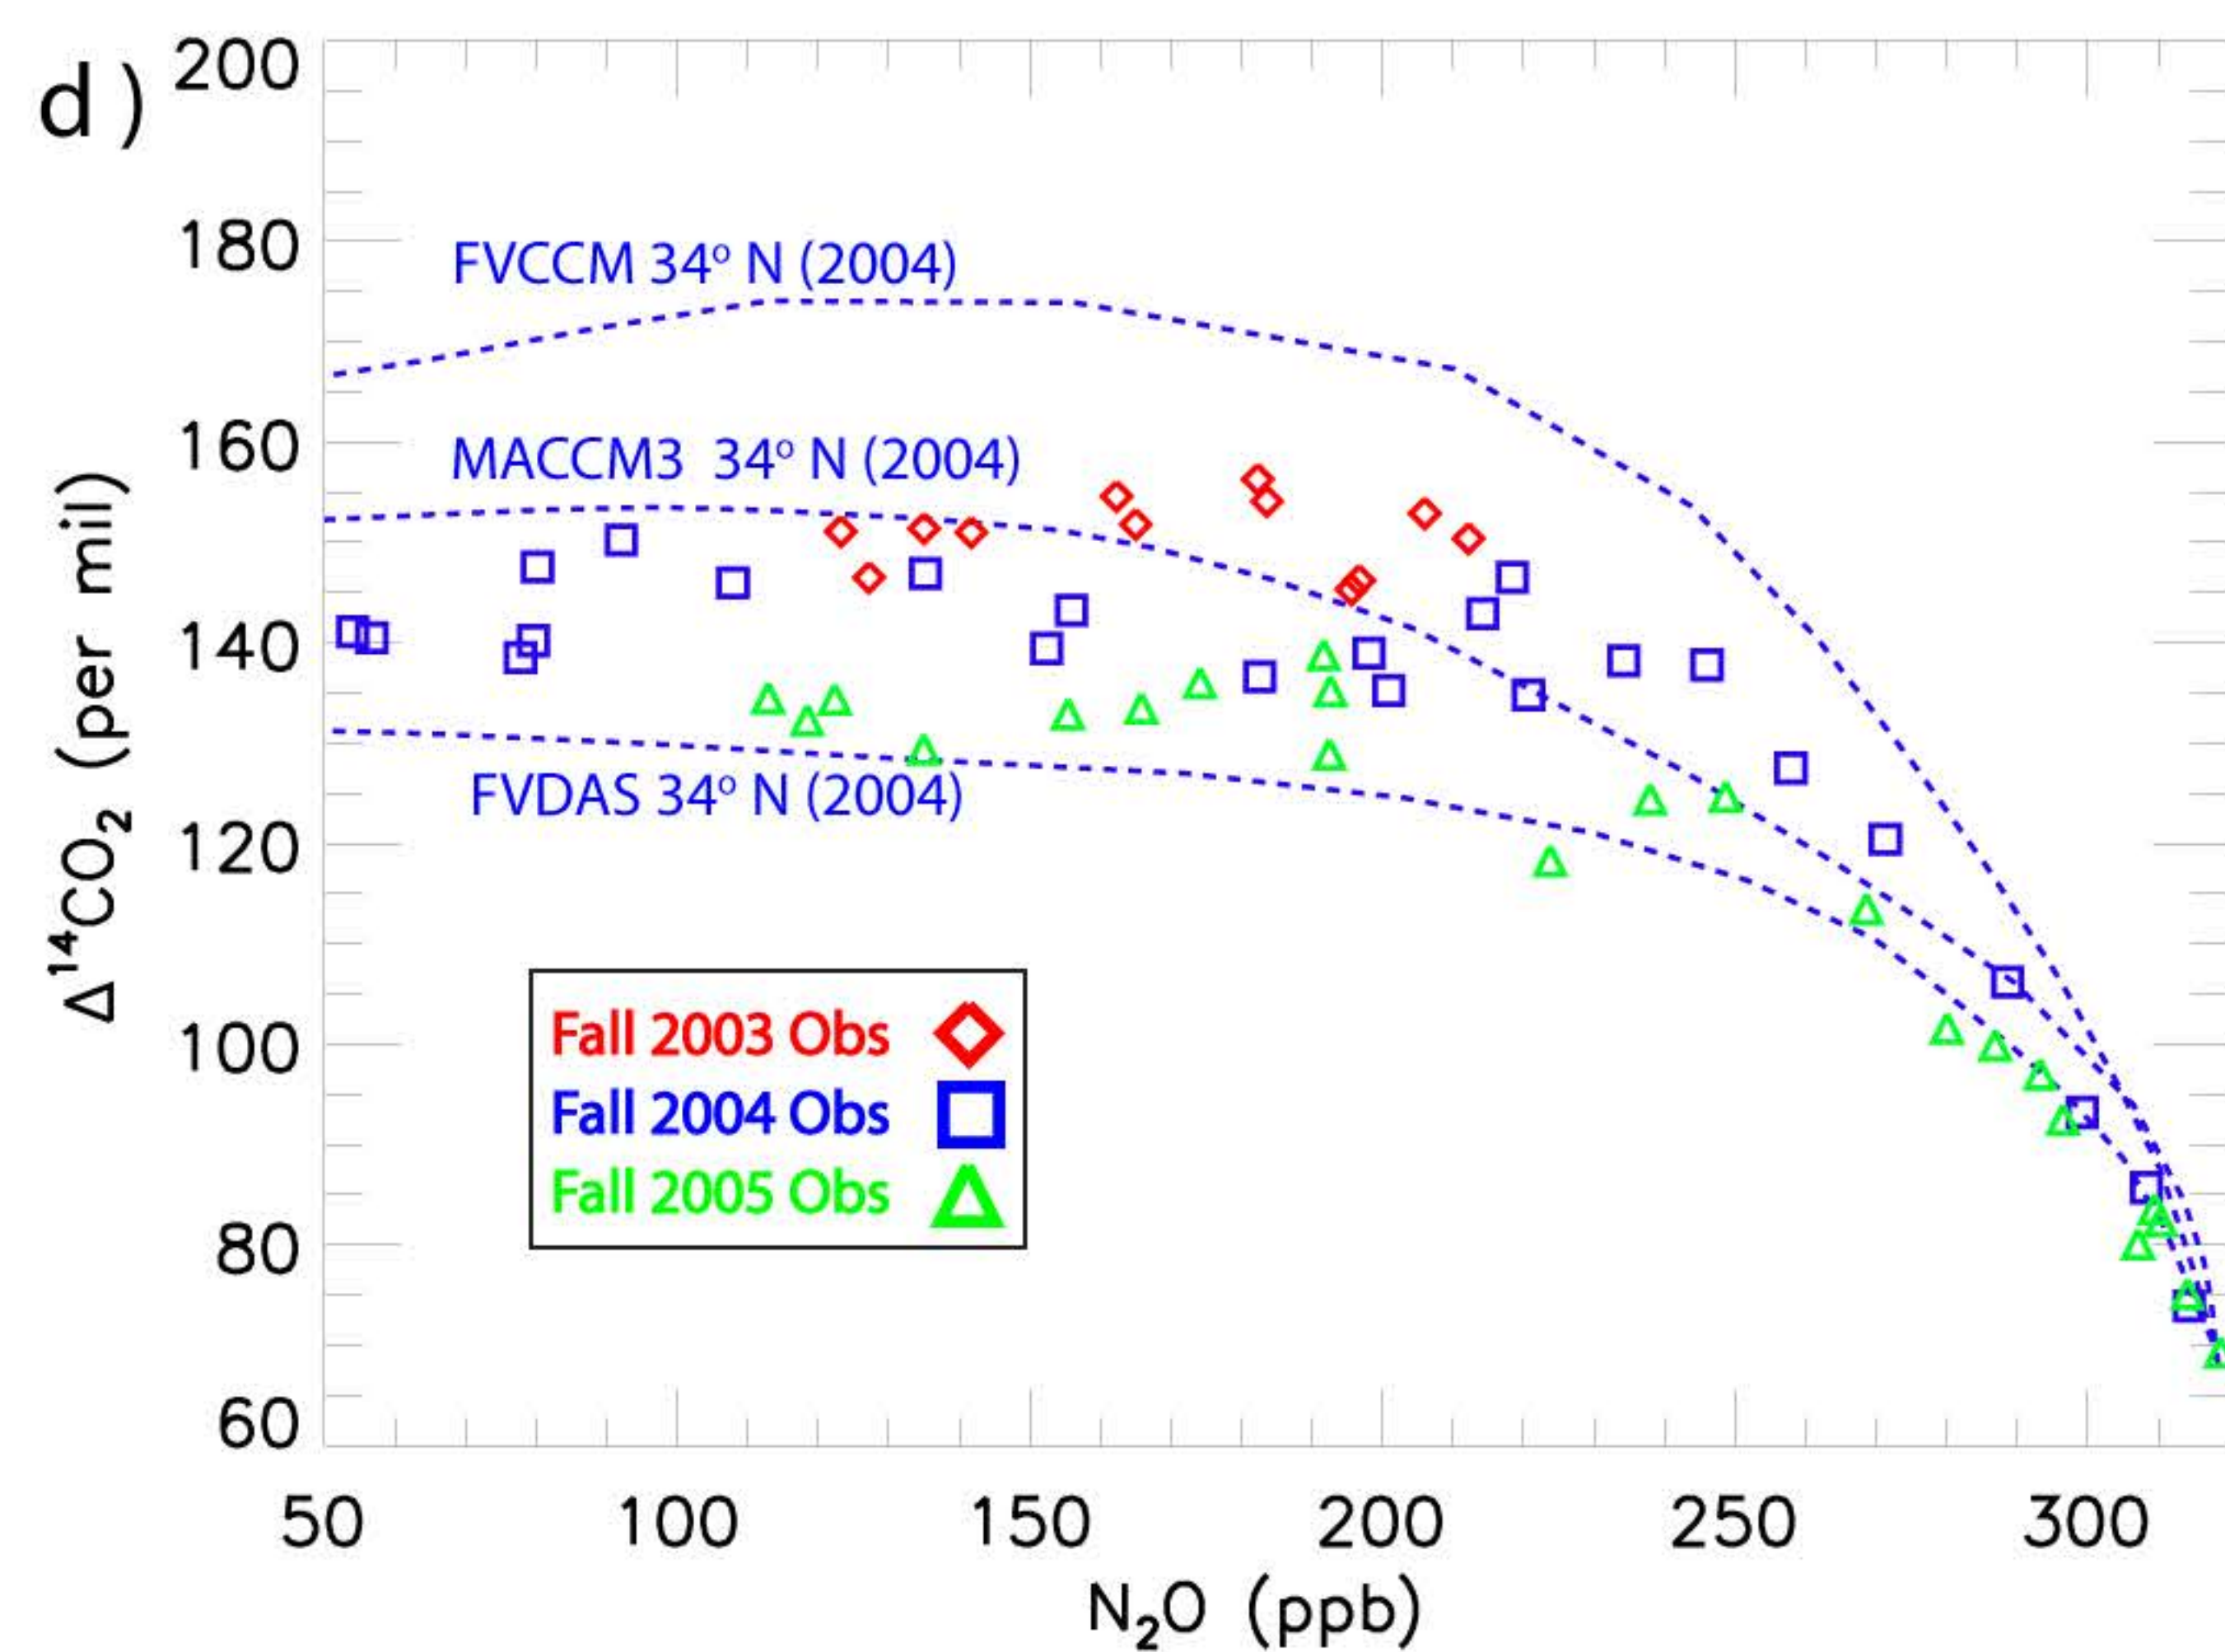

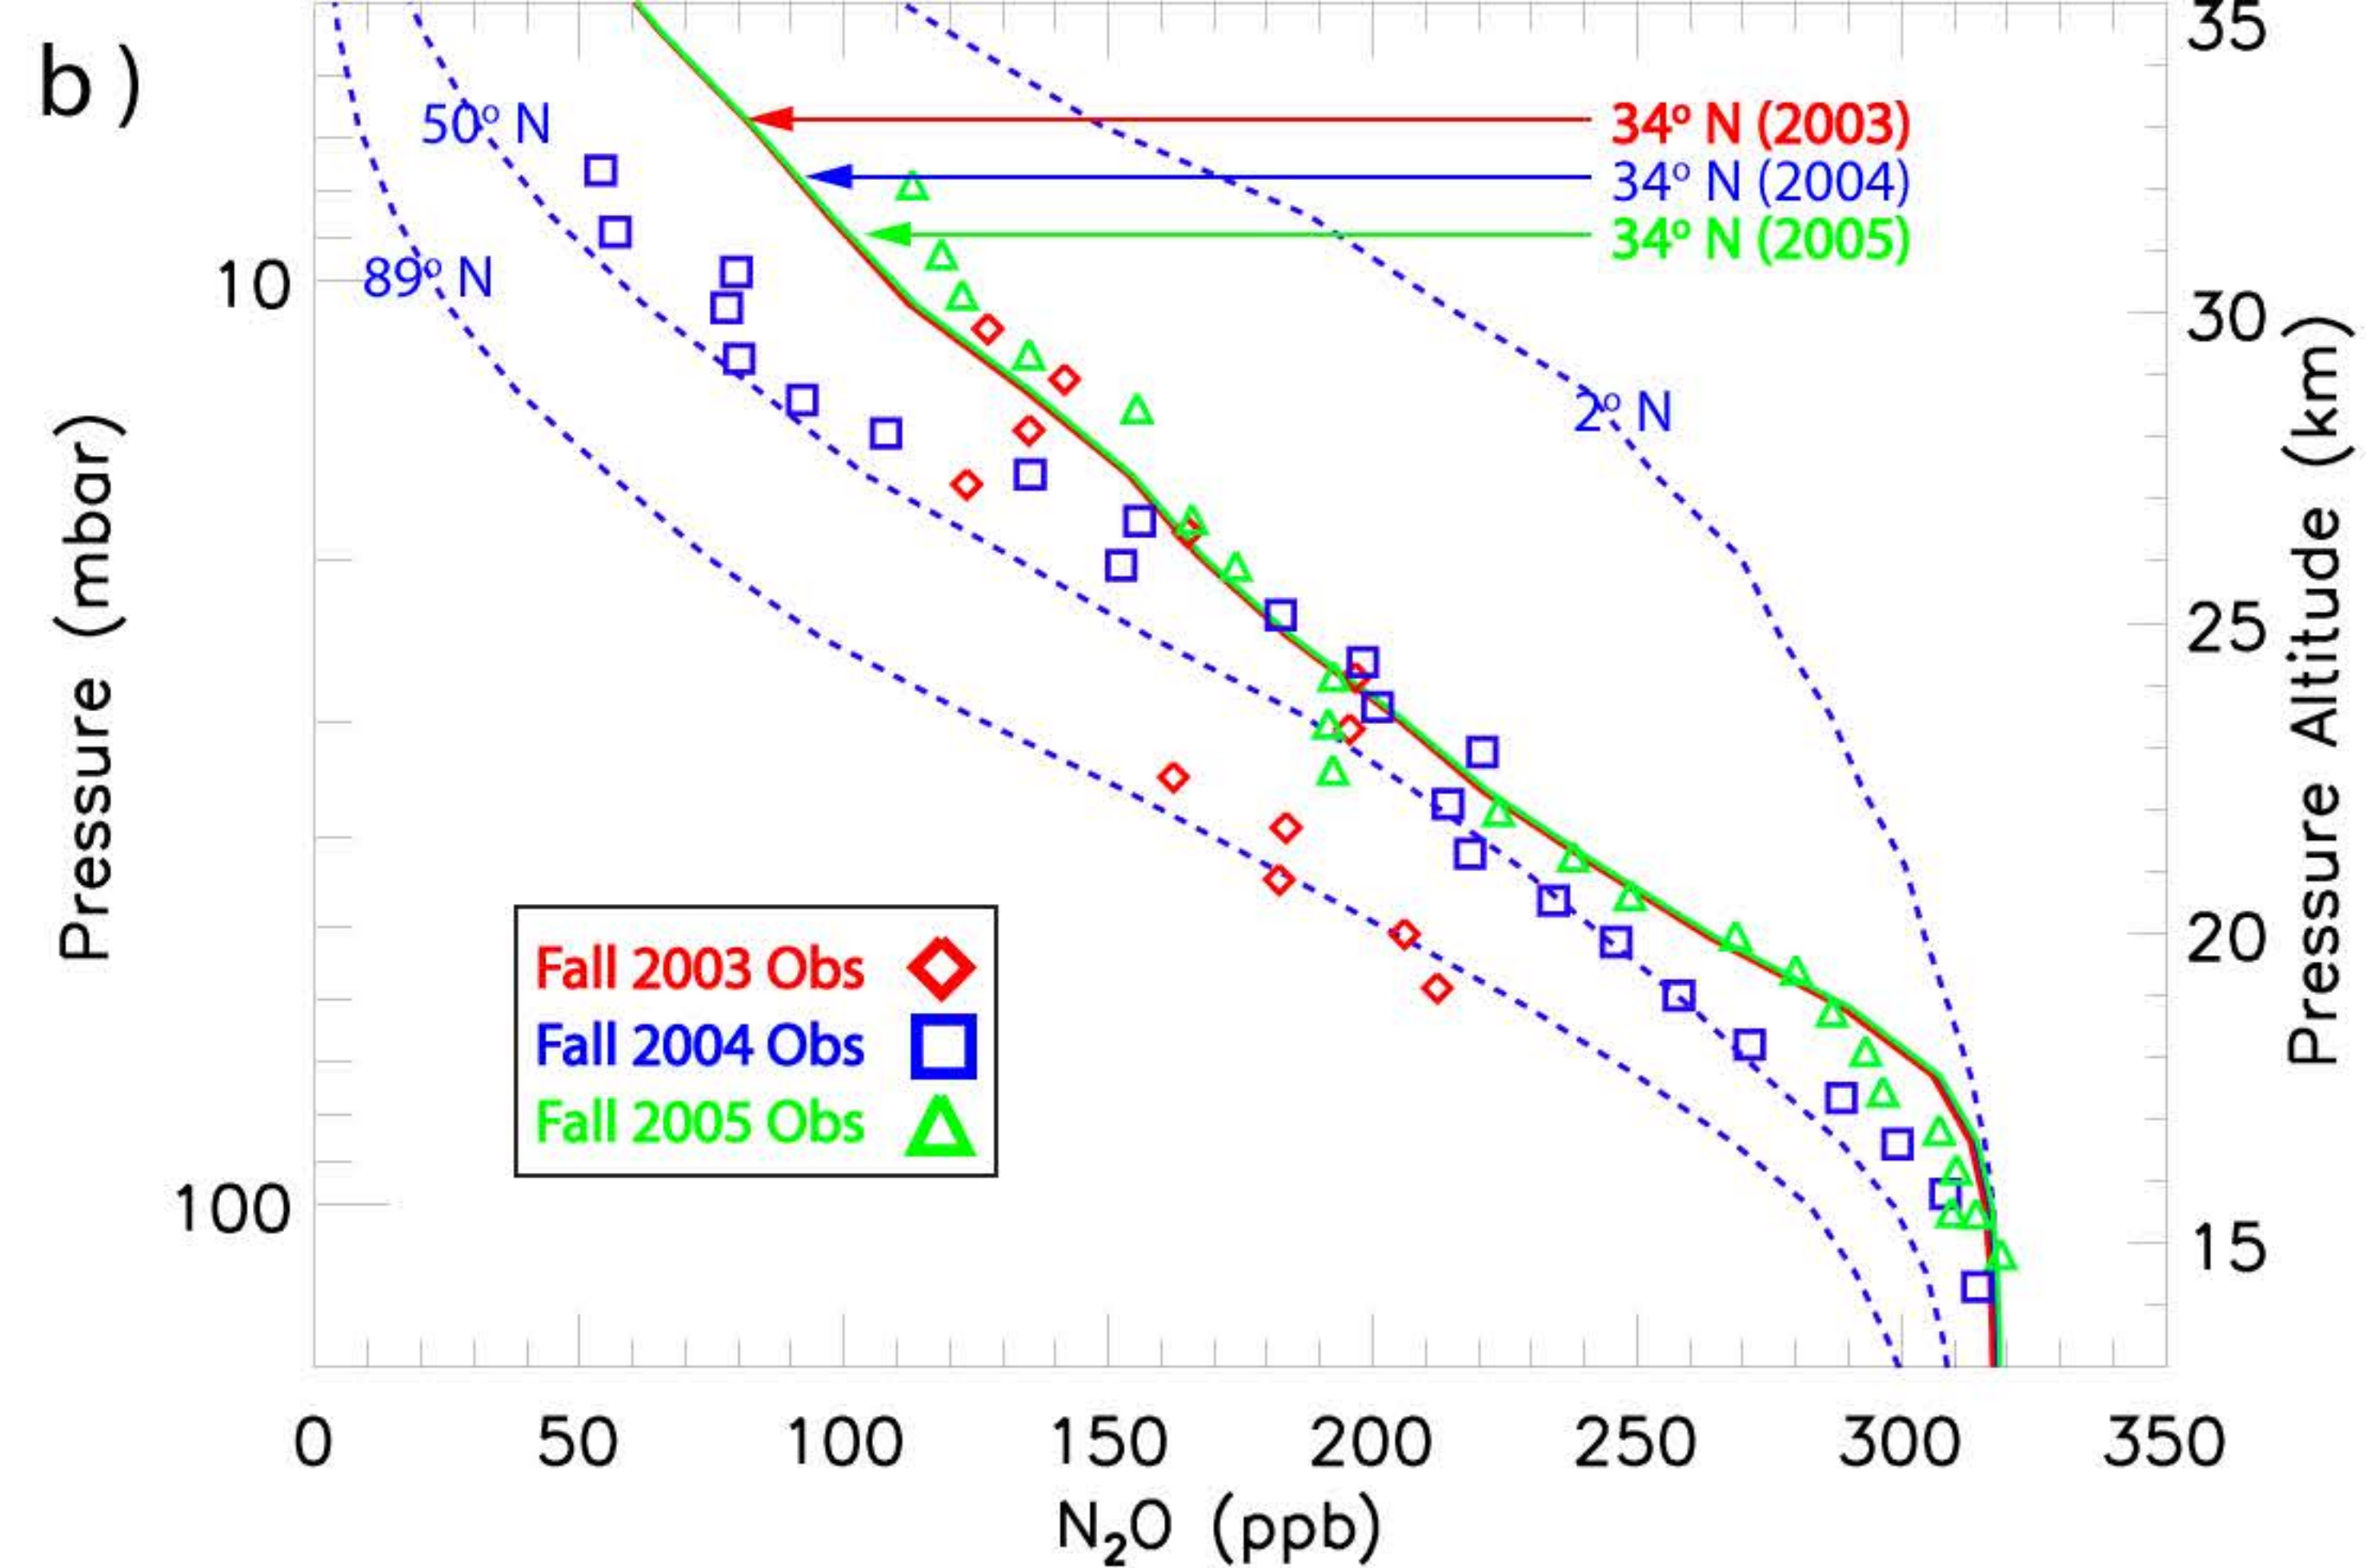

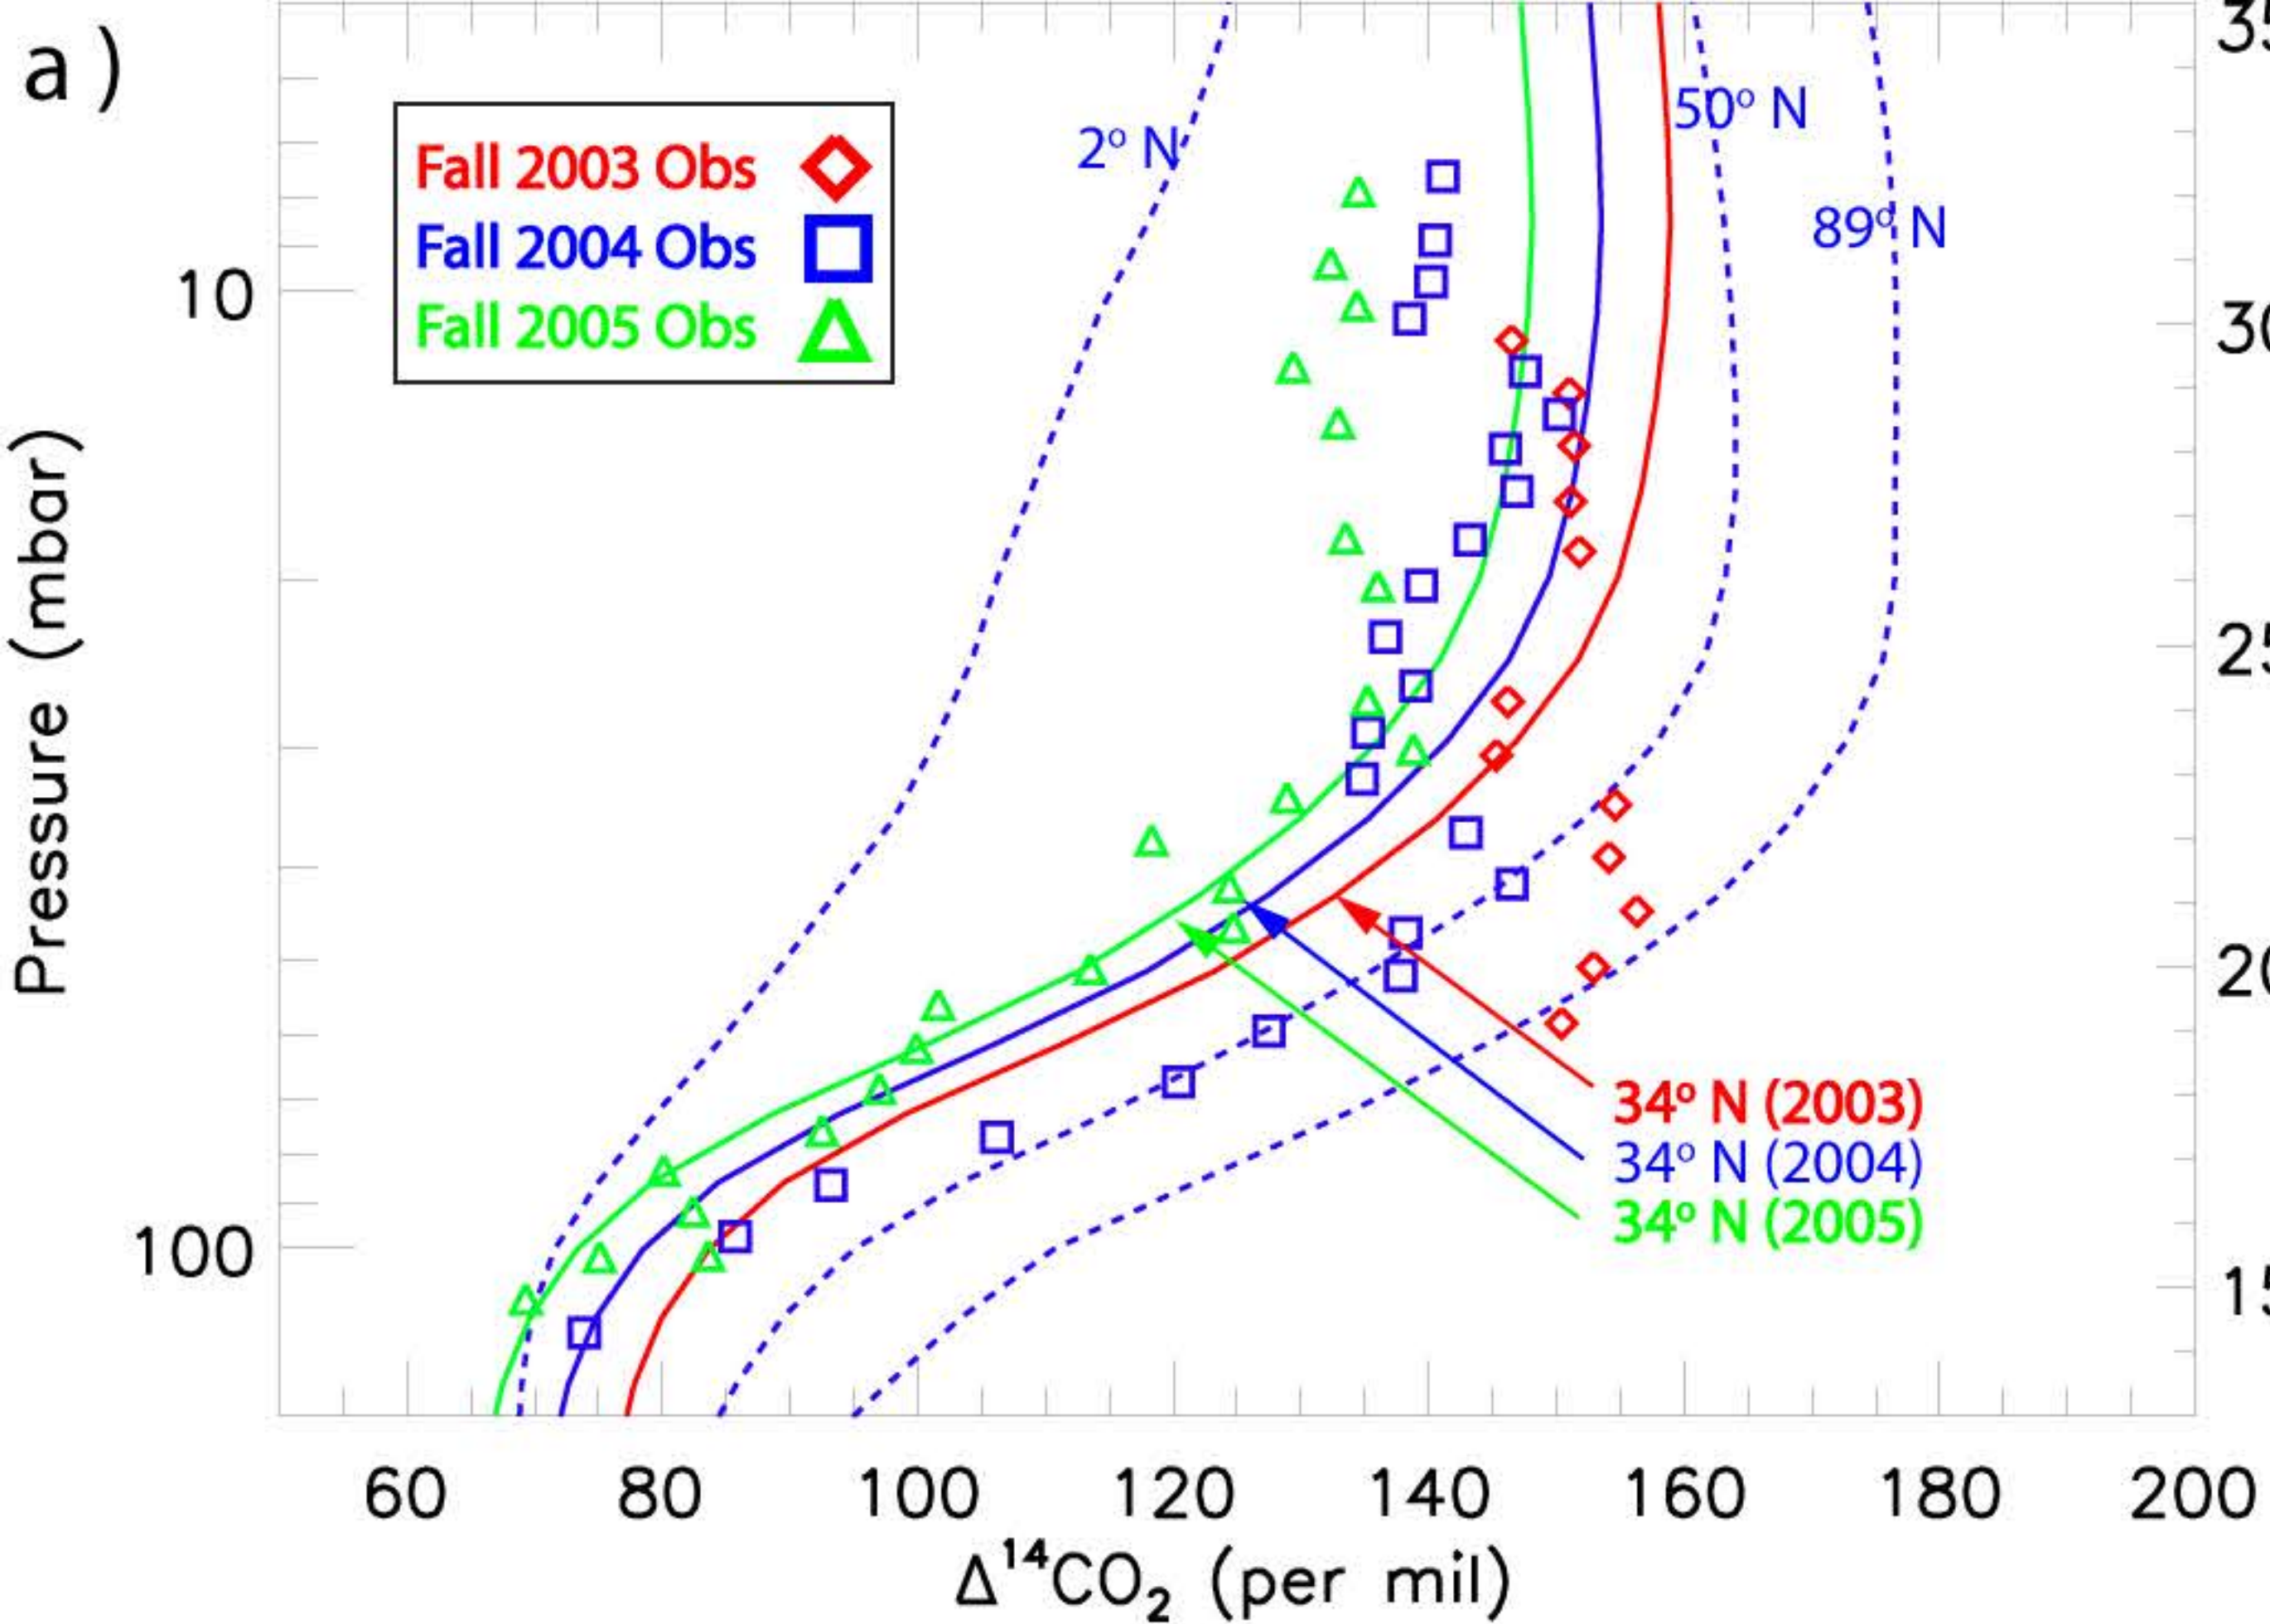

<sup>e</sup> Value depends on the functional form of the relationship between the solar modulation parameter,  $\Phi$ , and the  $^{14}\text{C}$  yield.

## Figure Captions

**Figure 1:** (a)  $\Delta^{14}\text{C}$  of  $\text{CO}_2$  and (b)  $\text{N}_2\text{O}$  versus pressure (mbar) and pressure altitude (km) for samples collected from the Cryogenic Whole Air Sampler (CWAS) at  $34^\circ\text{N}$  over Fort Sumner, NM (symbols) for single flights in 2003, 2004, and 2005, along with IMPACT model results using meteorological fields from MACCM3 for  $34^\circ\text{N}$  (solid lines, color-coded by year) and at the additional latitudes indicated for 2004 (dashed lines). (c) and (d):  $\Delta^{14}\text{C}$  of  $\text{CO}_2$  versus  $\text{N}_2\text{O}$  from the CWAS samples (symbols) along with model results for different latitudes using MACCM3 (in c) and using the FVDAS, MACCM3, FVCCM meteorologies at  $34^\circ\text{N}$  (in d).

**Figure 2:**  $\Delta^{14}\text{C}$  vs  $\text{N}_2\text{O}$  for  $\text{N}_2\text{O} > 250$  ppb (nmol/mol) for the data in Fig. 1; also shown are the Williamson-York bivariate fits [Cantrell, 2008] for 2004 (blue line;  $m = -0.93 \pm 0.07$ ), 2005 (green line;  $m = -0.82 \pm 0.06$ ), and the combined 2004/2005 dataset (black line;  $m = -0.90 \pm 0.05$ ), yielding a global  $^{14}\text{C}$  production rate of 2.30, 2.04, and  $2.24 \times 10^{26}$  atoms  $\text{yr}^{-1}$ , respectively, with uncertainties of  $\pm 30\%$  ( $1\sigma$ ), using Equation 2.

Tables S1 to S2

**Table S1: Empirically Derived Global Net Isoflux and Global Mean Production Rate of  $^{14}\text{C}$**

<b>Net Isoflux</b> ( $\text{‰ mol CO}_2 \text{ yr}^{-1}$ )	<b>2004<sup>a</sup></b>	<b>2005<sup>a</sup></b>	<b>2004 &amp; 2005<sup>a</sup></b>
Equation (1) with the Appenzeller <i>et al.</i> [1996] Air Mass Flux $2.35 \times 10^{19} \text{ mol air yr}^{-1}$ (across the 380 K surface)	$1.61 \times 10^{17}$ $\text{CO}_2 \text{ strat} = 376.9$ $\text{CO}_2 \text{ trop} = 377.7$	$1.43 \times 10^{17}$ $\text{CO}_2 \text{ strat} = 378.8$ $\text{CO}_2 \text{ trop} = 379.6$	$1.56 \times 10^{17}$ $\text{CO}_2 \text{ strat} = 377.9$ $\text{CO}_2 \text{ trop} = 378.6$
Equation (1) with the Holton [1990] Air Mass Flux $6.91 \times 10^{18} \text{ mol air yr}^{-1}$ (across the 100 mbar surface)	$1.58 \times 10^{17}$ $\text{CO}_2 \text{ strat} = 373.3$ $\text{CO}_2 \text{ trop} = 377.7$	$1.41 \times 10^{17}$ $\text{CO}_2 \text{ strat} = 375.2$ $\text{CO}_2 \text{ trop} = 379.6$	$1.54 \times 10^{17}$ $\text{CO}_2 \text{ strat} = 374.2$ $\text{CO}_2 \text{ trop} = 378.6$
Equation (2) assuming $[\text{CO}_2]_{\text{strat}} = [\text{CO}_2]_{\text{trop}}$ (independent of air mass flux)	$1.62 \times 10^{17}$ $[\text{CO}_2] = 377.7$	$1.44 \times 10^{17}$ $[\text{CO}_2] = 379.6$	$1.58 \times 10^{17}$ $[\text{CO}_2] = 378.6$
<b>Best Estimate: <math>1.6(\pm 0.4) \times 10^{17} \text{ ‰ mol CO}_2 \text{ yr}^{-1}</math></b>			
<b>Global Mean Production Rate</b> (atoms $^{14}\text{C yr}^{-1}$ ) <sup>b</sup>			
<i>Appenzeller</i> Flux	$2.28 \times 10^{26}$	$2.02 \times 10^{26}$	$2.22 \times 10^{26}$
<i>Holton</i> Flux	$2.24 \times 10^{26}$	$1.99 \times 10^{26}$	$2.18 \times 10^{26}$
$\text{CO}_2(\text{strat}) = \text{CO}_2(\text{trop})$	$2.30 \times 10^{26}$	$2.04 \times 10^{26}$	$2.24 \times 10^{26}$
<b>Best Estimate: <math>2.2(\pm 0.6) \times 10^{26} \text{ atoms } ^{14}\text{C yr}^{-1}</math></b>			

<sup>a</sup> Results are shown for  $\text{N}_2\text{O} > 250 \text{ ppbv}$ . The  $1\sigma$  uncertainties from summing errors in  $\text{N}_2\text{O}$  global loss rate (25%,  $1\sigma$ ) and the Williamson-York bivariate fit to the  $\Delta^{14}\text{C}:\text{N}_2\text{O}$  relationship (5%,  $1\sigma$ ) are  $\pm 30\%$ .

<sup>b</sup>  $[\text{CO}_2]_{\text{strat}}$  in air returning to the troposphere was estimated from the time-dependent deseasonalized boundary condition for  $[\text{CO}_2]_{\text{trop}}$  used in the model (see text) using the stratospheric turnover time for the Appenzeller or the Holton air mass fluxes as the time delay

between the current tropospheric boundary condition at time,  $t$ , so that  $[\text{CO}_2]_{\text{trop}} = [\text{CO}_2]_{\text{trop},t}$  and  $[\text{CO}_2]_{\text{strat},t} = [\text{CO}_2]_{\text{trop},(t-\text{stratospheric turnover time})}$ .

<sup>c</sup> Assuming a ratio of stratospheric-to-total  $^{14}\text{C}$  production of 0.50.
