Title: Methane and nitrous oxide porewater concentrations and surface fluxes of a regulated river

Article Type: Research Paper

Keywords: hyporheic zone
methane conductance
porewater
methane flux
nitrous oxide flux

Abstract: Greenhouse gas (GHG) emissions from rivers are a critical missing component of current global GHG models. Their exclusion is mainly due to a lack of in-situ measurements and a poor understanding of the spatiotemporal dynamics of GHG production and emissions, which prevents optimal model parametrization. We combined simultaneous observations of porewater concentrations along different beach positions and depths, and surface fluxes of methane and nitrous oxide at a plot scale in a large regulated river during three water stages: rising, falling, and low. Our goal was to gain insights into the interactions between hydrological exchanges and GHG emissions and elucidate possible hypotheses that could guide future research on the mechanisms of GHG production, consumption, and transport in the hyporheic zone (HZ). Results indicate that the site functioned as a net source of methane. Surface fluxes of methane during river water stages at three beach positions (shallow, intermediate and deep) correlated with porewater concentrations of methane. However, fluxes were significantly higher in the intermediate position during the low water stage, suggesting that low residence time increased methane emissions. Vertical profiles of methane peaked at different depths, indicating an influence of the magnitude and direction of the hyporheic mixing during the different river water stages on methane production and consumption. The site acted as either a sink or a source of nitrous oxide depending on the elevation of the water column. Nitrous oxide porewater concentrations peaked at the upper layers of the sediment throughout the different water stages. River hydrological stages significantly influenced porewater concentrations and fluxes of GHG, probably by influencing heterotrophic respiration (production and consumption processes) and transport to and from the HZ. Our results highlight the importance of including dynamic hydrological exchanges when studying and modeling GHG production and consumption in the HZ of large rivers.

Response to Reviewers: Dear editor,

Thanks for your time and consideration of our paper. We have addressed all comments and suggested revisions from the reviewers. We conducted a thorough grammatical revision of the manuscript that included the reviewer's suggestions.

Below, we list our response to all review comments, with our response in italic font, following each comment.

Reviewers/Editor comments:

Reviewer #1:
Summary
Villa et al. present results of a measurement campaign of porewater concentrations and water-atmosphere fluxes of CH4 and N2O from depth transects along the Columbia River during the three river stages of 2018. The results, although presenting only a snapshot, are interesting and merit publication. I recommend that some minor additional discussion and, if possible, references to complementary data be added (as listed under the comments section below) to enhance the background understanding of the site characteristics and put the results into better context.

Response: Thanks for your detailed review of the manuscript. The comments were of great help to improve the quality of the content and the text. We addressed all your comments and suggestions in this revised version. Please see below.

Comments
R1-1 Were the chambers attached or anchored to the peepers or peeper locations in any way? How did you corroborate the location of the peepers when submerged for the chamber placement?

Response: "We used standard 4-inch PCV conduit anchored to the river sediments above the peeper location with rebar to house the peeper tubing, allowing for easy sampling even when water levels were high, and marking the peeper location.". We now explain our approach in L153-155 and L207-211. For your reference please see the figure in attached file.

R1-2 What was the flow rate of the water/river during the chamber flux measurements? Surely, if the water is turbulent, there will be more oxygenation and hence loss of methane in the water column, or can this be assumed to be negligible? I see you discuss the impacts of this later in the results.

Response: Although we did not measure the flow rate directly at the experimental site, we consider the effect of the flow negligible. We intentionally placed our sampling plot in a small cove that isolated the site from the flow of the main channel (white frame in Figure 1A in the manuscript). We are clarifying this point in the manuscript. L119-120.

R1-3 Do you have dissolved oxygen measurements of the water?

Response: Unfortunately, we did not measure dissolved oxygen in the water. However, although we did not measure systematically dissolved oxygen in the sediment-water interface and the water column during our samplings, we conducted a series of surveys before sampling that

indicated that both were consistently supersaturated. We included the clarification in the revised version of the manuscript. L354-359.

R1-4 Looking at the porewater CH4 concentrations there seems to be a difference in the relative location of the peak of the profile depending on whether the depth level is within the fluctuating water level or permanently inundated, i.e. the peak in the profile is relative to the sediment surface if it is within the fluctuating water level zone, vs. the peak being at the same absolute depth if below the permanent water line (or minimum position of the whole season).

Response: We included this explanation in section 3.3. L426-430.

R1-5 Is there any information on the organic carbon content of the sediments? In Section 3.3. you discuss the effect of organic soils on methane production, but these soils seem to be mostly sand (mentioned in the site introduction).

Response: We did not measure directly organic carbon content in the sediments, but we are supporting our discussion in findings from previous studies conducted in the Handford Reach in nearby sites with similar conditions. We are stressing the location of the referenced studies in the text for a better contextualization L407, L433-434.

R1-6 Comparisons of the porewater analysis with dissolved CH4 and CO2 in the river water would be interesting to see what the lateral transport and background values are relative to the sediment porewater. This could help determining the upwelling versus downwelling relationships. It would also be interesting to see what the groundwater CH4 levels are and how much methane is stored in deep sediment porewater of saturated soils. The same can be said for N2O. Is there lateral transport (or of nitrate, etc.) during the rising phase? Would this explain the decoupling of porewater CO2 with N2O concentrations?

Response: We agree with the reviewer. Unfortunately, we did not measure dissolved CH4, N2O or CO2 in the river water. We include the relevance of these measurements for future studies, including a supporting reference for N2O transport in groundwater as a possible explanation of the decoupling of N2O and CO2 (i.e, Clough et al., 2006). L368-370, L536-537.

R1-7 I would welcome some discussion of the role of water flow rate and residence time in relation to the oxygenation and stratification, which you mention to be important for CH4 concentrations, but also for the N2O discussion (Section 3.4).

Response: Lower flow rates are associated with low oxygen concentrations, which may enhance N2O consumption. We rephrase some sentences in Section 3.4 to explain the connection between low flow and N2O consumption. L495-498.

Minor comments:

R1-8 Line 12: add comma between "shallow, intermediate …"

Response: We added the comma. L12.

R1-9 Line 51: either replace previous full stop with a semi colon or add a verb to the sentence, such as "In other words, this is equivalent to …"

Response: We revised accordingly. L51.

R1-10 Line 58: remove comma before "and"

Response: We removed the comma. L58.

R1-11 Line 60: "…processes that lead to …"

Response: We revised accordingly. L60.

R1-12 Line 63: "… a 100-year horizon,"

Response: We revised accordingly. L63.

R1-13 Line 68: no comma after "and"

Response: We removed the comma. L68.

R1-14 Line 84: "the main production pathway"

Response: We revised accordingly. L87.

R1-15 Line 96: "to more robustly represent biogeochemical …" and remove second "aquatic"

Response: We revised accordingly. L99.

R1-16 Line 112: capitalize "Reach"

Response: We revised accordingly here and in other instances of the document. L114, L123, L407, L434, L445, L507.

R1-17 Line 120: rephrase first sentence segment, such as "We sampled on three occasions between 25th April and 25th August in 2018 consisting of (1) …"

Response: We revised accordingly. L123.

R1-18 Section 2.2: possibly use "level" instead of "elevation" when referring to the height of the river and groundwater.

Response: We re-defined “elevation” as “level” and replace it here (L128), and where appropriate throughout the document, including Figure 1.

R1-19 Figure 1: Is there any meaning of the transect marked in red?

Response: Yes, thank you for noticing our omission. The transect marked in red denotes the transect where sediment temperatures were measured. We included this explanation in L142-143 and the legend of figure 1.

R1-20 Lines 139-140: "in the proximal shore their direction," it's unclear what is meant.

Response: We clarified to “To determine the strength of groundwater flow toward the river, we calculated the hydraulic gradient (HG, m m-1) between the river water and groundwater-well level as…” . L137-138.

R1-21 Line 201: "24-minute periods"

Response: We revised accordingly. L202.

R1-22 Line 271: "fit models for flux calculations, and "

Response: We revised accordingly. L282.

R1-23 Line 292: "after the spring thaw"

Response: We revised accordingly. L303.

R1-24 Line 295: "and remained low during the …"

Response: We revised accordingly. L306.

R1-25 Line 312: "each sampling stage" and "… of each sampling period."

Response: We meant the sampling conducted during each river stage. We are clarifying now in the Figure 2 legend.

R1-26 Line 316: again "At each sampling stage"

Response: We meant the sampling conducted during each river stage. We are clarifying now in the Figure 2 legend.

R1-27 Line 318: "(which are labeled in (B) for clarification)."

Response: We revised accordingly. Figure 2 legend.

R1-28 Line 345-346: "low concentrations throughout the sediment"

Response: We revised accordingly. L343.

R1-29 Lines 362-366: rephrase or shorten sentence for clarification.

Response: We rephrased the sentence. L363-370.

R1-30 Figure 4 caption: add what the thick brown line represents.

Response: We included what the thick brown represents in the legends of Figure 4 and Figure 8.

R1-31 Line 439: capitalize "Hanford Reach" and again on lines 472, 551

Response: We revised accordingly here and in other instances of the document. L114, L123, L407, L434, L445, L507.

R1-32 Line 492: "when the water level drops"

Response: We revised accordingly. L456.

R1-33 Line 499: "with a shift from"

Response: We revised accordingly. L463.

R1-34 Line 528: "benthic zone water column" and possibly you mean either "system gains size" or "system grain size"?

Response: We rephrase the sentence for more clarity. L483-484.

R1-35 Line 533: remove comma before "and" and again on line 538

Response: We revised accordingly.

R1-36 Line 547: "dynamics" and again on 553

Response: We revised accordingly. L503, L509.

R1-37 Line 550: add "the" to "the nitrification and denitrification functional potential" and again on line 554 "the N-cycling functional potential"

Response: We revised accordingly. L506, L510.

R1-38 Line 557: either "concentrations peak" or "concentration peaks"

Response: It is “concentration peak”. We revised accordingly. L513.

R1-39 Line 563: "predominantly released gas"

Response: We revised accordingly. L519.

R1-40 Lines 581-582: rephrase sentence "This would explain the negative … porewater concentrations, which were also seen in observations of other riverine settings …"

Response: We revised accordingly. L530-532.

R1-41 Line 585: "water elevation transitions"

Response: We revised as “water level transitions. L536.

R1-42 Line 586: "N-cycling populations vary"

Response: We revised accordingly. L535.

R1-43 Lines 588-592: Replace "different" with explaining what the relationship is and how it changes (positive/negative, becomes stronger/weaker etc.)

Response: We revised accordingly. L540.

R1-44 Line 625: "the influence of river regulation"

Response: This sentence was removed.

R1-45 Line 629: "will therefore be"

Response: We revised accordingly. L589-590.

Reviewer #2:
General Comments:

A very interesting study that has produced a lot of relevant data on the mechanisms that control the greenhouse gas emissions from rivers. This is clearly a research area that needs more focus and this study feels like it could be just the start of larger scale experiments. The authors make several hypotheses on the nature of some mechanisms which will be important in guiding further research to test them. My main criticism would be that some of the figures are very dense with information and could use some improvements with their formatting to improve their clarity. Overall though this study was certainly a worthwhile endeavor that opens up many new lines of questioning and should be accepted with minor revisions.

I think the text overall is a bit dense to read but that is likely just due to the relative complexity of the hyporheic zone dynamics the authors are describing. I would recommend the authors ensure they are organizing some of their more complex sentences in the clearest way possible. I have highlighted some of these instances in my more specific comments below. I have also included below some other specific suggestions on edits to the text and figures. I would also recommend the authors review the text with an eye for grammatical errors as I have found a few, some I have called out below, but I do not intend to correct them all.

Response: Thank you for the positive comments. We have addressed all your comments and suggestions, included a thorough grammatical revision of the document.

More Specific Suggestions/Edits:
R2-1 Page 3 Line 67: "MicClain" should be "McClain", small edit but will cause proofing headaches if left in.

Response: We revised accordingly. L67.

R2-2 Page 5 Line 100-101: "links between fluxes with lateral groundwater fluxes", this statement is unclear, maybe need to add 'GHG' before the first 'fluxes' or change 'groundwater fluxes' to 'groundwater flows' if that makes sense in this context (are we talking about just water flow or also gasses that may be in that water?).

Response: To clarify, we revised to “field studies of GHG fluxes in rivers rarely address small-scale spatial variability across the bank, and temporal variation in relation to the hydrological dynamics between the groundwater and river.” L101-103.

R2-3 Page 7 Line 139-140: "To determine the strength of groundwater flows at a given time in the proximal shore their direction,.." It is not clear to me what this sentence is saying, I would consider rewording.

Response: We clarified to “To determine the strength of groundwater flow toward the river, we calculated the hydraulic gradient (HG, m m-1) between the river water and groundwater-well level as…” . L137-138.

R2-4 Page 8 Line 162-165: In this methods paragraph, I would consider briefly explaining why the container is filled with N2 to avoid oxygen intrusion, and also why the 10-ml containers were pre-acidified.

Response:” The sampling consisted of extracting 10-ml of water from the cells through one of the cell tubings while keeping the other connected to a container filled with N2 to avoid oxygen intrusion that could

disturb the anaerobic environment within and around the cells. After the extraction, the cell was refilled with deionized water degassed with N2. Samples were placed in 10-ml containers pre-acidified with 0.2 ml HCl 2M to ensure pH levels below 2.0, which prevent the post-sampling biological transformation of the gases dissolved in the sample.“ Lines 159-166.

R2-5 Page 8 Lines 173-174: This sentence is a bit unclear, I would reword it to say "Helium (25 ml min-1) was used as a carrier gas for methane and CO2 analysis, while ultra-pure N2 (10 ml min-1) was used as a carrier for N2O analysis.

Response: We revised accordingly. L174-176.

R2-6 Page 10 Line 204: check "same quality use control to measure" I think this should read "same quality control used to measure"

Response: We revised accordingly. L205.

R2-7 Page 11 Line 235: again the use of a list and "respectively" in this manner is difficult to parse, I would reword this to be clearer (e.g. 28 for methane and 29 for N2O).

Response: We revised accordingly. L244-246.

R2-8 Page 17 Lines 356-360: very complex sentence, would recommend breaking this up with periods or semicolons at least,

Response: We rewrote the sentence. L359-363.

R2-9 Page 21 Lines 424-425: weird punctuation here, consider revising.

Response: We revised the sentence. L400-402.

R2-10 Page 33 Line 617: what process is using nitrous oxide as a terminal electron acceptor? May be worth mentioning.

Response: We rephrased the sentences expanding on the explanation of the processes and included an additional supporting reference (i.e., Khalil et al., 2004). L560-564.

R2-11 Figure 2: I would add in a legend for the dark blue and light blue lines of graphs B, C, and D. Only having these definitions in the (very long) caption seems less than ideal. The axes labels are color coded to their corresponding line colors, but I am not sure if this is clear enough. I would also recommend repeating the River Elevation axis title on the left side, it might be slightly more cluttered, but would add some clarity. Finally, the last sentence in the caption says 'horizontal gray bars' but should say 'vertical gray bars' an important distinction.

Response: We included the legends for dark and light blue in Figure 2C. We duplicated the left y-label titles as suggested and additionally changed “River elevation” for “River level” in attention to the comment 18 from reviewer 1. We corrected vertical gray bars in the legend as well.

R2-12 Figure 4: I like that the spatial structure of these plots corresponds to real world elevations, but the actual data is largely overlapping and difficult to discern. I am not sure how to best fix this,

but urge the authors try to make the results a bit easier to parse (thinner lines or lines of varying thickness for each color maybe?). There are also the thick colored gradient lines which are only defined in the caption, I would somehow label them in figure if there is room (perhaps up with the legend in the upper left). Finally, in the last sentence of the caption, "Tick" should be "Thick".

Response: We improved the clarity of the figure by reducing the width of the lines and filling the markers of the data for the samplings during the falling and water stages. We included labels for the gradients in the figure and also provided descriptions in the text (L426-430).

R2-13 Figure 8: See the first two sentences of my comments for Figure 4, they also apply to this figure.

Response: We improved the clarity of Figure 8 in the same way as we did for Figure 4.

Reviewer # 3
Thanks for the opportunity to review your very interesting manuscript.

Big Picture comments:
The authors present a unique set of GHG concentration (porewater) and chamber flux
measurements at a range of elevations and river stages and comment on potential mechanisms of
the patterns observed. The motivation for the work – that dynamic river GHG fluxes are largely missing from models, is valid, although the paper is not able to proscribe specific modeling frameworks that should be implemented – other than pointing out how dynamic and variable river GHG are at various river stages and elevations – which is an important first step.
As discussed, net flux or concentration measurements are the product of consumption and
production of CH_4 or N_2O; the methods used here are able only to speculate about the reasons for the small scale spatio-temporal variability (e.g. Line 398, Line 575). The authors are up front with this limitation (repeatedly mention that they don't measure oxidation or reduction directly,
or different CH_4 or N_2O-producing pathways).

Despite these limitations, the measurement 'snapshots' (Line 621) are novel and the dataset is
worthy of this standalone reporting. While the discussion/conclusions are well written, the paper may benefit from:

Response: Thank you for the positive comment. We addressed all of your comments and incorporated your suggestions. Please see below.

R3-1 Clearer descriptions of how the findings of this paper could lead to improved
biogeochemical river submodels (Line 95). It would be useful in the conclusion or late
discussion to revisit this intention, and describe what parameters or mechanisms would
be most important to model to get GHG fluxes from river sediment right.

Response: We included specific mentions in the conclusion section regarding the processes that could help improve model representation of GHG fluxes in the Hyporheic Zone. L555-557, L566-569.

R3-2 More discussion of how the management of the river impacts the GHG flux. This issue is
eluded to in line 635 ('…assess the influence river regulation on GHG production and
consumption processes…'). You also mention a 'regulated river' in the title. It would be
interesting for the reader to understand how a managed river compares to an unmanaged
river… I wonder if the authors could speculate as to how an unregulated river would
compare, to draw out the human impact on this system of management?

Response: We rephrased and expanded the second paragraph of the conclusions to include a clearer picture of river regulation in GHG dynamics, including a contrast with non-regulated systems. L570-585.

R3-3 A more general recognition that GHG production and consumption is a result of a
constellation of aspects: microbial population, temperature, nutrient content, and redox
conditions. The paper seems to mostly emphasize the redox controls, but the production
and consumption is driven by all of these aspects – which would need to be dealt with in
a modeling framework.

Response: We have included explicit allusions to these aspects in the introduction (L68-70) and in the conclusions (L580-581).

Overall, the paper is well-written and clear, with good figures and a novel dataset. I recommend
acceptance with minor revisions.

Response: Thank you for recognizing the novelty character of our dataset.

Detailed comments:

R3-4 Line 60: 'lead' not 'leads'

Response: We revised accordingly. L60.

R3-5 Line 79: 'mediated' not 'meditated'

Response: We revised accordingly. L82.

R3-6 Line 96: 'aquatic' doubled

Response: We removed the additional 'aquatic'. L99.

R3-7 Line 139: please revise 'in the proximal shore their direction' for clarity

Response: We clarified to “To determine the strength of groundwater flow toward the river, we calculated the hydraulic gradient (HG, m m-1) between the river water and groundwater-well level as…” . L137-138.

R3-8 Line 236: please say more about the decision to remove r2<0.8. How was this cutoff established? What is the impact of keeping this data?

Response: We expanded the explanation regarding the cutoff on the r2 of the linear and non-linear regressions (L241-246). The use of the r2 threshold to determine the goodness of fit in linear and non-linear regressions is a common practice in the measurement of greenhouse gas fluxes using static chambers. There is not a standard procedure or an established criterion to determine the cutoff value (Hüppi et al., 2018). Usually, r2 values are set by researchers between 0.7 (e.g. Pihlatie et al., 2007) and 0.9 (e.g. Veber et al., 2018) based on expert knowledge. After reviewing our chamber runs, we opted for the 0.8 value as an acceptable compromise between the number of points measured and the uncertainty in the assumptions of the linear (N2O) and non-linear regressions (CH4) (Pedersen et al., 2010; Hüppi et al., 2018). We further decided to use the same cutoff for methane and N2O chambers for consistency. We deemed measurements with r2 values below the threshold (r2<0.8) as measurements of poor quality and excluded them from the analyses to avoid error.

R3-9 Line 246: The first five concentrations – is this deemed to be before the chamber space is
influenced by soil and water efflux? Please explain.

Response: This is correct. We re-wrote the sentence explaining what the first five measurements represent. L256-260.

R3-7 Line 256: Is this a theoretically valid assumption? Are there citations that support this?

Response: We rephrased and provided a reference: “We followed the approach by Bastviken et al., (2004) to independently determine the conductance to methane in the water column K_w for each flux chamber, by solving the following equation”. L267-268.

Science of the Total Environment

We wish to submit the research article entitled *"Methane and nitrous oxide porewater concentration and surface fluxes of a regulated river"* for consideration by Science of the Total Environment.

In this paper, we investigated the interaction between hydrological exchanges and greenhouse gas emissions in a large regulated river. We aimed to understand the spatio-temporal heterogeneity of greenhouse gas emissions of a river beach section and elucidate possible hypotheses that could guide future research of greenhouse gas production, consumption, and transport in the hyporheic zone. Our measurements of greenhouse gases, conducted in the sediment porewater and water/air interface, and hydrological measurements of river and groundwater elevations of a dam-regulated river lay on the intersection of the biosphere, atmosphere, hydrosphere, and anthroposphere.

Our manuscript features results of methane, nitrous oxide, and carbon dioxide porewater concentrations in horizontal and vertical resolutions along an elevation gradient, coupled with co-located methane and nitrous oxide chamber measurements during three river stages characteristic of the hydrological dynamic of the Columbia River. Results indicate that the beach section we evaluated acted as a net sink of methane and as either a sink or source of nitrous oxide depending on the elevation of the water column. The difference in the hydrological mixing during the three different river stages drove different methane and nitrous oxide porewater concentrations, their distribution in the vertical profile, and their correlation with the carbon dioxide porewater concentrations. Altogether, results indicate the relative importance of river downwelling and groundwater upwelling in the conditions leading to methane and nitrous oxide production and consumption and provide evidence supporting previous studies in the same river reach highlighting changes in microbial processes driven by hydrological mixing.

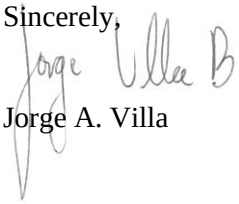
In this first submission, we have placed the figures accompanying the text to facilitate the work of the reviewers. For the revised version, we will place the figures at the end of the manuscript.

We confirm that this manuscript has not been published elsewhere and is not under consideration by another journal. All authors have approved the manuscript and agreed with its submission Science of the Total Environment, and we have no conflicts of interest to declare.

Please address all correspondence concerning this manuscript to me at villa-betancur.1@osu.edu.

Thank you for your consideration of this manuscript.

Sincerely,



Jorge A. Villa

Methane and nitrous oxide porewater concentrations and surface fluxes of a regulated river

Dear editor,

Thanks for your time and consideration of our paper. We have addressed all comments and suggested revisions from the reviewers. We conducted a thorough grammatical revision of the manuscript that included the reviewer's suggestions.

Below, we list our response to all review comments, with our response in italic font, following each comment.

Reviewers/Editor comments:

Reviewer #1:
Summary
Villa et al. present results of a measurement campaign of porewater concentrations and water-atmosphere fluxes of CH_4 and N_2O from depth transects along the Columbia River during the three river stages of 2018. The results, although presenting only a snapshot, are interesting and merit publication. I recommend that some minor additional discussion and, if possible, references to complementary data be added (as listed under the comments section below) to enhance the background understanding of the site characteristics and put the results into better context.

Response: Thanks for your detailed review of the manuscript. The comments were of great help to improve the quality of the content and the text. We addressed all your comments and suggestions in this revised version. Please see below.

Comments
R1-1 Were the chambers attached or anchored to the peepers or peeper locations in any way? How did you corroborate the location of the peepers when submerged for the chamber placement?

Response: "We used standard 4-inch PCV conduit anchored to the river sediments above the peeper location with rebar to house the peeper tubing, allowing for easy sampling even when water levels were high, and marking the peeper location.". We now explain our approach in L153-155 and L207-211. For your reference please see the figure below.

Figure 1. Chamber positioning approach. (A) installed peeper (below ground) with white PVC conduit extending above the peeper location held up by 3 rebar rods (inside the conduit, not visible in picture). The PVC conduit houses the sampling tubing (in the picture, the tubing is extended to full length beyond the top end of the PVC tube and held by Dr. Villa's hand). (B) positioning and securing of the methane sampling chamber above the peeper location as marked by the PVC conduit. (C) positioning and anchoring of the N_2O *sampling chambers, surrounding the PVC conduit around the peeper location.*

R1-2 What was the flow rate of the water/river during the chamber flux measurements? Surely, if the water is turbulent, there will be more oxygenation and hence loss of methane in the water column, or can this be assumed to be negligible? I see you discuss the impacts of this later in the results.

Response: Although we did not measure the flow rate directly at the experimental site, we consider the effect of the flow negligible. We intentionally placed our sampling plot in a small cove that isolated the site from the flow of the main channel (white frame in Figure 1A in the manuscript). We are clarifying this point in the manuscript. L119-120.

R1-3 Do you have dissolved oxygen measurements of the water?

Response: Unfortunately, we did not measure dissolved oxygen in the water. However, although we did not measure systematically dissolved oxygen in the sediment-water interface and the water column during our samplings, we conducted a series of surveys before sampling that indicated that both were consistently supersaturated. We included the clarification in the revised version of the manuscript. L354-359.

R1-4 Looking at the porewater CH_4 concentrations there seems to be a difference in the relative location of the peak of the profile depending on whether the depth level is within the fluctuating water level or permanently inundated, i.e. the peak in the profile is relative to the sediment surface if it is within the fluctuating water level zone, vs. the peak being at the same absolute depth if below the permanent water line (or minimum position of the whole season).

Response: We included this explanation in section 3.3. L426-430.

R1-5 Is there any information on the organic carbon content of the sediments? In Section 3.3. you discuss the effect of organic soils on methane production, but these soils seem to be mostly

sand (mentioned in the site introduction).

Response: We did not measure directly organic carbon content in the sediments, but we are supporting our discussion in findings from previous studies conducted in the Handford Reach in nearby sites with similar conditions. We are stressing the location of the referenced studies in the text for a better contextualization L407, L433-434.

R1-6 Comparisons of the porewater analysis with dissolved CH_4 and CO_2 in the river water would be interesting to see what the lateral transport and background values are relative to the sediment porewater. This could help determining the upwelling versus downwelling relationships. It would also be interesting to see what the groundwater CH_4 levels are and how much methane is stored in deep sediment porewater of saturated soils. The same can be said for N_2O. Is there lateral transport (or of nitrate, etc.) during the rising phase? Would this explain the decoupling of porewater CO_2 with N_2O concentrations?

Response: We agree with the reviewer. Unfortunately, we did not measure dissolved CH_4, N_2O *or* CO_2 *in the river water. We include the relevance of these measurements for future studies, including a supporting reference for* N_2O *transport in groundwater as a possible explanation of the decoupling of* N_2O *and* CO_2 *(i.e, Clough et al., 2006). L368-370, L536-537.*

R1-7 I would welcome some discussion of the role of water flow rate and residence time in relation to the oxygenation and stratification, which you mention to be important for CH_4 concentrations, but also for the N_2O discussion (Section 3.4).

Response: Lower flow rates are associated with low oxygen concentrations, which may enhance N_2O *consumption. We rephrase some sentences in Section 3.4 to explain the connection between low flow and* N_2O *consumption. L495-498.*

Minor comments:

R1-8 Line 12: add comma between "shallow, intermediate …"

Response: We added the comma. L12.

R1-9 Line 51: either replace previous full stop with a semi colon or add a verb to the sentence, such as "In other words, this is equivalent to …"

Response: We revised accordingly. L51.

R1-10 Line 58: remove comma before "and"

Response: We removed the comma. L58.

R1-11 Line 60: "…processes that lead to …"

Response: We revised accordingly. L60.

R1-12 Line 63: "… a 100-year horizon,"

Response: We revised accordingly. L63.

R1-13 Line 68: no comma after "and"

Response: We removed the comma. L68.

R1-14 Line 84: "the main production pathway"

Response: We revised accordingly. L87.

R1-15 Line 96: "to more robustly represent biogeochemical …" and remove second "aquatic"

Response: We revised accordingly. L99.

R1-16 Line 112: capitalize "Reach"

Response: We revised accordingly here and in other instances of the document. L114, L123, L407, L434, L445, L507.

R1-17 Line 120: rephrase first sentence segment, such as "We sampled on three occasions between 25th April and 25th August in 2018 consisting of (1) …"

Response: We revised accordingly. L123.

R1-18 Section 2.2: possibly use "level" instead of "elevation" when referring to the height of the river and groundwater.

Response: We re-defined "elevation" as "level" and replace it here (L128), and where appropriate throughout the document, including Figure 1.

R1-19 Figure 1: Is there any meaning of the transect marked in red?

Response: Yes, thank you for noticing our omission. The transect marked in red denotes the transect where sediment temperatures were measured. We included this explanation in L142-143 and the legend of figure 1.

R1-20 Lines 139-140: "in the proximal shore their direction," it's unclear what is meant.

Response: We clarified to "To determine the strength of groundwater flow toward the river, we calculated the hydraulic gradient (HG, m m^{-1}) between the river water and groundwater-well level as…" . L137-138.

R1-21 Line 201: "24-minute periods"

Response: We revised accordingly. L202.

R1-22 Line 271: "fit models for flux calculations, and "

Response: We revised accordingly. L282.

R1-23 Line 292: "after the spring thaw"

Response: We revised accordingly. L303.

R1-24 Line 295: "and remained low during the …"

Response: We revised accordingly. L306.

R1-25 Line 312: "each sampling stage" and "… of each sampling period."

Response: We meant the sampling conducted during each river stage. We are clarifying now in the Figure 2 legend.

R1-26 Line 316: again "At each sampling stage"

Response: We meant the sampling conducted during each river stage. We are clarifying now in the Figure 2 legend.

R1-27 Line 318: "(which are labeled in (B) for clarification)."

Response: We revised accordingly. Figure 2 legend.

R1-28 Line 345-346: "low concentrations throughout the sediment"

Response: We revised accordingly. L343.

R1-29 Lines 362-366: rephrase or shorten sentence for clarification.

Response: We rephrased the sentence. L363-370.

R1-30 Figure 4 caption: add what the thick brown line represents.

Response: We included what the thick brown represents in the legends of Figure 4 and Figure 8.

R1-31 Line 439: capitalize "Hanford Reach" and again on lines 472, 551

Response: We revised accordingly here and in other instances of the document. L114, L123, L407, L434, L445, L507.

R1-32 Line 492: "when the water level drops"

Response: We revised accordingly. L456.

R1-33 Line 499: "with a shift from"

Response: We revised accordingly. L463.

R1-34 Line 528: "benthic zone water column" and possibly you mean either "system gains size" or "system grain size"?

Response: We rephrase the sentence for more clarity. L483-484.

R1-35 Line 533: remove comma before "and" and again on line 538

Response: We revised accordingly.

R1-36 Line 547: "dynamics" and again on 553

Response: We revised accordingly. L503, L509.

R1-37 Line 550: add "the" to "the nitrification and denitrification functional potential" and again on line 554 "the N-cycling functional potential"

Response: We revised accordingly. L506, L510.

R1-38 Line 557: either "concentrations peak" or "concentration peaks"

Response: It is "concentration peak". We revised accordingly. L513.

R1-39 Line 563: "predominantly released gas"

Response: We revised accordingly. L519.

R1-40 Lines 581-582: rephrase sentence "This would explain the negative … porewater concentrations, which were also seen in observations of other riverine settings …"

Response: We revised accordingly. L530-532.

R1-41 Line 585: "water elevation transitions"

Response: We revised as "water level transitions. L536.

R1-42 Line 586: "N-cycling populations vary"

Response: We revised accordingly. L535.

R1-43 Lines 588-592: Replace "different" with explaining what the relationship is and how it changes (positive/negative, becomes stronger/weaker etc.)

Response: We revised accordingly. L540.

R1-44 Line 625: "the influence of river regulation"

Response: This sentence was removed.

R1-45 Line 629: "will therefore be"

Response: We revised accordingly. L589-590.

Reviewer #2:
General Comments:
A very interesting study that has produced a lot of relevant data on the mechanisms that control the greenhouse gas emissions from rivers. This is clearly a research area that needs more focus and this study feels like it could be just the start of larger scale experiments. The authors make several hypotheses on the nature of some mechanisms which will be important in guiding further research to test them. My main criticism would be that some of the figures are very dense with information and could use some improvements with their formatting to improve their clarity. Overall though this study was certainly a worthwhile endeavor that opens up many new lines of questioning and should be accepted with minor revisions.

I think the text overall is a bit dense to read but that is likely just due to the relative complexity of the hyporheic zone dynamics the authors are describing. I would recommend the authors ensure they are organizing some of their more complex sentences in the clearest way possible. I have highlighted some of these instances in my more specific comments below. I have also included below some other specific suggestions on edits to the text and figures. I would also recommend the authors review the text with an eye for grammatical errors as I have found a few, some I have called out below, but I do not intend to correct them all.

Response: Thank you for the positive comments. We have addressed all your comments and suggestions, included a thorough grammatical revision of the document.

More Specific Suggestions/Edits:
R2-1 Page 3 Line 67: "MicClain" should be "McClain", small edit but will cause proofing headaches if left in.

Response: We revised accordingly. L67.

R2-2 Page 5 Line 100-101: "links between fluxes with lateral groundwater fluxes", this statement is unclear, maybe need to add 'GHG' before the first 'fluxes' or change 'groundwater

fluxes' to 'groundwater flows' if that makes sense in this context (are we talking about just water flow or also gasses that may be in that water?).

Response: To clarify, we revised to "field studies of GHG fluxes in rivers rarely address small-scale spatial variability across the bank, and temporal variation in relation to the hydrological dynamics between the groundwater and river." L101-103.

R2-3 Page 7 Line 139-140: "To determine the strength of groundwater flows at a given time in the proximal shore their direction,.." It is not clear to me what this sentence is saying, I would consider rewording.

Response: We clarified to "To determine the strength of groundwater flow toward the river, we calculated the hydraulic gradient (HG, m m^{-1}) between the river water and groundwater-well level as…" . L137-138.

R2-4 Page 8 Line 162-165: In this methods paragraph, I would consider briefly explaining why the container is filled with N2 to avoid oxygen intrusion, and also why the 10-ml containers were pre-acidified.

Response:" The sampling consisted of extracting 10-ml of water from the cells through one of the cell tubings while keeping the other connected to a container filled with N2 to avoid oxygen intrusion that could disturb the anaerobic environment within and around the cells. After the extraction, the cell was refilled with deionized water degassed with N2. Samples were placed in 10-ml containers pre-acidified with 0.2 ml HCl 2M to ensure pH levels below 2.0, which prevent the post-sampling biological transformation of the gases dissolved in the sample." Lines 159-166.

R2-5 Page 8 Lines 173-174: This sentence is a bit unclear, I would reword it to say "Helium (25 ml min-1) was used as a carrier gas for methane and CO_2 analysis, while ultra-pure N2 (10 ml min-1) was used as a carrier for N_2O analysis.

Response: We revised accordingly. L174-176.

R2-6 Page 10 Line 204: check "same quality use control to measure" I think this should read "same quality control used to measure"

Response: We revised accordingly. L205.

R2-7 Page 11 Line 235: again the use of a list and "respectively" in this manner is difficult to parse, I would reword this to be clearer (e.g. 28 for methane and 29 for N_2O).

Response: We revised accordingly. L244-246.

R2-8 Page 17 Lines 356-360: very complex sentence, would recommend breaking this up with periods or semicolons at least,

Response: We rewrote the sentence. L359-363.

R2-9 Page 21 Lines 424-425: weird punctuation here, consider revising.

Response: We revised the sentence. L400-402.

R2-10 Page 33 Line 617: what process is using nitrous oxide as a terminal electron acceptor? May be worth mentioning.

Response: We rephrased the sentences expanding on the explanation of the processes and included an additional supporting reference (i.e., Khalil et al., 2004). L560-564.

R2-11 Figure 2: I would add in a legend for the dark blue and light blue lines of graphs B, C, and D. Only having these definitions in the (very long) caption seems less than ideal. The axes labels are color coded to their corresponding line colors, but I am not sure if this is clear enough. I would also recommend repeating the River Elevation axis title on the left side, it might be slightly more cluttered, but would add some clarity. Finally, the last sentence in the caption says 'horizontal gray bars' but should say 'vertical gray bars' an important distinction.

Response: We included the legends for dark and light blue in Figure 2C. We duplicated the left y-label titles as suggested and additionally changed "River elevation" for "River level" in attention to the comment 18 from reviewer 1. We corrected vertical gray bars in the legend as well.

R2-12 Figure 4: I like that the spatial structure of these plots corresponds to real world elevations, but the actual data is largely overlapping and difficult to discern. I am not sure how to best fix this, but urge the authors try to make the results a bit easier to parse (thinner lines or lines of varying thickness for each color maybe?). There are also the thick colored gradient lines which are only defined in the caption, I would somehow label them in figure if there is room (perhaps up with the legend in the upper left). Finally, in the last sentence of the caption, "Tick" should be "Thick".

Response: We improved the clarity of the figure by reducing the width of the lines and filling the markers of the data for the samplings during the falling and water stages. We included labels for the gradients in the figure and also provided descriptions in the text (L426-430).

R2-13 Figure 8: See the first two sentences of my comments for Figure 4, they also apply to this figure.

Response: We improved the clarity of Figure 8 in the same way as we did for Figure 4.

Reviewer # 3

Thanks for the opportunity to review your very interesting manuscript.

Big Picture comments:

The authors present a unique set of GHG concentration (porewater) and chamber flux

measurements at a range of elevations and river stages and comment on potential mechanisms of the patterns observed. The motivation for the work – that dynamic river GHG fluxes are largely missing from models, is valid, although the paper is not able to proscribe specific modeling frameworks that should be implemented – other than pointing out how dynamic and variable river GHG are at various river stages and elevations – which is an important first step.
As discussed, net flux or concentration measurements are the product of consumption and production of CH_4 or N_2O; the methods used here are able only to speculate about the reasons for the small scale spatio-temporal variability (e.g. Line 398, Line 575). The authors are up front with this limitation (repeatedly mention that they don't measure oxidation or reduction directly, or different CH_4 or N_2O-producing pathways).

Despite these limitations, the measurement 'snapshots' (Line 621) are novel and the dataset is worthy of this standalone reporting. While the discussion/conclusions are well written, the paper may benefit from:

Response: Thank you for the positive comment. We addressed all of your comments and incorporated your suggestions. Please see below.

R3-1 Clearer descriptions of how the findings of this paper could lead to improved biogeochemical river submodels (Line 95). It would be useful in the conclusion or late discussion to revisit this intention, and describe what parameters or mechanisms would be most important to model to get GHG fluxes from river sediment right.

Response: We included specific mentions in the conclusion section regarding the processes that could help improve model representation of GHG fluxes in the Hyporheic Zone. L555-557, L566-569.

R3-2 More discussion of how the management of the river impacts the GHG flux. This issue is eluded to in line 635 ('…assess the influence river regulation on GHG production and consumption processes…'). You also mention a 'regulated river' in the title. It would be interesting for the reader to understand how a managed river compares to an unmanaged river… I wonder if the authors could speculate as to how an unregulated river would compare, to draw out the human impact on this system of management?

Response: We rephrased and expanded the second paragraph of the conclusions to include a clearer picture of river regulation in GHG dynamics, including a contrast with non-regulated systems. L570-585.

R3-3 A more general recognition that GHG production and consumption is a result of a constellation of aspects: microbial population, temperature, nutrient content, and redox conditions. The paper seems to mostly emphasize the redox controls, but the production and consumption is driven by all of these aspects – which would need to be dealt with in a modeling framework.

Response: We have included explicit allusions to these aspects in the introduction (L68-70) and in the conclusions (L580-581).

Overall, the paper is well-written and clear, with good figures and a novel dataset. I recommend acceptance with minor revisions.

Response: Thank you for recognizing the novelty character of our dataset.

Detailed comments:

R3-4 Line 60: 'lead' not 'leads'

Response: We revised accordingly. L60.

R3-5 Line 79: 'mediated' not 'meditated'

Response: We revised accordingly. L82.

R3-6 Line 96: 'aquatic' doubled

Response: We removed the additional 'aquatic'. L99.

R3-7 Line 139: please revise 'in the proximal shore their direction' for clarity

Response: We clarified to "To determine the strength of groundwater flow toward the river, we calculated the hydraulic gradient (HG, m m^{-1}) between the river water and groundwater-well level as…" . L137-138.

R3-8 Line 236: please say more about the decision to remove r^2<0.8. How was this cutoff established? What is the impact of keeping this data?

Response: We expanded the explanation regarding the cutoff on the r^2 of the linear and non-linear regressions (L241-246). The use of the r^2 threshold to determine the goodness of fit in linear and non-linear regressions is a common practice in the measurement of greenhouse gas fluxes using static chambers. There is not a standard procedure or an established criterion to determine the cutoff value (Hüppi et al., 2018). Usually, r^2 values are set by researchers between 0.7 (e.g. Pihlatie et al., 2007) and 0.9 (e.g. Veber et al., 2018) based on expert knowledge. After reviewing our chamber runs, we opted for the 0.8 value as an acceptable compromise between the number of points measured and the uncertainty in the assumptions of the linear (N_2O) and non-linear regressions (CH_4) (Pedersen et al., 2010; Hüppi et al., 2018). We further decided to use the same cutoff for methane and N_2O chambers for consistency. We deemed measurements with r^2 values below the threshold (r^2<0.8) as measurements of poor quality and excluded them from the analyses to avoid error.

R3-9 Line 246: The first five concentrations – is this deemed to be before the chamber space is influenced by soil and water efflux? Please explain.

Response: This is correct. We re-wrote the sentence explaining what the first five measurements represent. L256-260.

R3-7 Line 256: Is this a theoretically valid assumption? Are there citations that support this?

Response: We rephrased and provided a reference: "We followed the approach by Bastviken et al., (2004) to independently determine the conductance to methane in the water column K_w for each flux chamber, by solving the following equation". L267-268.

Abstract

Greenhouse gas (GHG) emissions from rivers are a critical missing component of current global GHG models. Their exclusion is mainly due to a lack of in-situ measurements and a poor understanding of the spatiotemporal dynamics of GHG production and emissions, which prevents optimal model parametrization. We combined simultaneous observations of porewater concentrations along different beach positions and depths, and surface fluxes of methane and nitrous oxide at a plot scale in a large regulated river during three water stages: rising, falling, and low. Our goal was to gain insights into the interactions between hydrological exchanges and GHG emissions and elucidate possible hypotheses that could guide future research on the mechanisms of GHG production, consumption, and transport in the hyporheic zone (HZ). Results indicate that the site functioned as a net source of methane. Surface fluxes of methane during river water stages at three beach positions (shallow, intermediate and deep) correlated with porewater concentrations of methane. However, fluxes were significantly higher in the intermediate position during the low water stage, suggesting that low residence time increased methane emissions. Vertical profiles of methane peaked at different depths, indicating an influence of the magnitude and direction of the hyporheic mixing during the different river water stages on methane production and consumption. The site acted as either a sink or a source of nitrous oxide depending on the elevation of the water column. Nitrous oxide porewater concentrations peaked at the upper layers of the sediment throughout the different water stages. River hydrological stages significantly influenced porewater concentrations and fluxes of GHG, probably by influencing heterotrophic respiration (production and consumption processes) and transport to and from the HZ. Our results highlight the importance of including dynamic

hydrological exchanges when studying and modeling GHG production and consumption in the HZ of large rivers.

Keywords: hyporheic zone, methane conductance, porewater, methane flux, nitrous oxide flux

1. Introduction

Rivers and streams cover a relatively small area of the planet's terrestrial phase (0.47%). Nonetheless, they play a pivotal role in greenhouse gas (GHG) emissions (Raymond et al., 2013). It is estimated that they emit annually 6.6 Pg of carbon dioxide (CO_2) (Raymond et al., 2013), 26.8 Tg of methane (CH_4) (Stanley et al., 2016) and 1.1 Tg of nitrous oxide (N_2O) (Beaulieu et al., 2011). In other words, this is the equivalent to ~12% of CO_2 emissions from fossil fuels and industry (Jackson et al., 2017), and ~5% and ~10% of global methane and N_2O emissions, respectively (Beaulieu et al., 2011; Saunois et al., 2016). The disproportionate contributions from rivers to GHG budgets have challenged the early assumption of rivers as "passive" or "neutral" pipes in global and regional GHG budgets (Cole et al., 2007; Aufdenkampe et al., 2011), placing them as active hotspots for GHG exchange.

Whereas the biogeochemical processes that lead to CO_2 emissions from rivers have traditionally received more attention (Raymond et al., 2013; Hotchkiss et al., 2015) and are relatively better represented in current models (e.g., E3SM, Golaz et al., 2019), the processes that lead to methane and N_2O emissions remain poorly constrained in space and time (Bridgham et al., 2013; Quick et al., 2019). Methane and N_2O emissions are low compared with those of CO_2, yet on an equal mass basis, they have 45 and 270 times the potential of CO_2 to warm the atmosphere over a 100-year horizon, respectively (Neubauer and Megonigal, 2015). Most of the biogeochemical activity that leads to methane and N_2O production and consequent emission in rivers occurs within the hyporheic zone (HZ), a transition zone in the saturated sediments adjacent to the streamflow where surface water and subsurface waters are permanently mixing (McClain et al., 2003; Krause et al., 2011). The mixing of downwelling oxidized surface water, and upwelling of reduced subsurface water provides a unique environment of enhanced nutrient

and light availability, gradients of temperature and redox potentials, pH, organic matter content, and microbial numbers and activity (Woessner, 2017). This environment represent biogeochemical hotspots for microbial activity where aerobic and anaerobic microbial metabolisms co-occur (Boulton et al., 1998). In general, the HZ is a net source of methane and N_2O (Reeder et al., 2018).

Hydrologic exchange strongly affects the flow of organic dissolved carbon, an essential microbial substrate for GHG production processes, as well as the transport of GHG themselves. Methane can be produced in the anaerobic environment within the HZ from CO_2 and H_2 or acetate during the degradation of organic matter (Lyu et al., 2018). Methane may also be transported from the surrounding upland areas dissolved in groundwater (Jones and Mulholland, 1998). Once in the HZ, methane can be oxidized and transformed back into CO_2 with sufficient electron acceptors, particularly oxygen, by methanotrophic microorganisms (Chistoserdova et al., 2009). The remaining portion of methane that is not oxidized can be emitted via diffusion, ebullition, or plant-mediated transport (Bridgham et al., 2013).

N_2O production in the HZ is mainly the result of four distinct processes: (1) denitrification or reduction of nitrate or nitrite to dinitrogen with nitrous oxide as an intermediate, (2) by-products of oxidation of ammonia to nitrate or nitrite, (3) dissimilatory reduction of nitrate to ammonia, and (4) chemo-denitrification involving the abiotic reaction of nitrite with iron(II) (Quick et al. 2019), of which denitrification is thought as the main production pathway in lotic systems (Baulch et al., 2011a; Beaulieu et al., 2011). N_2O transport from the HZ to the atmosphere occurs primarily via diffusion (Baulch et al., 2011a).

A better understanding of the dynamics and interactions of different processes throughout the HZ is needed in order to resolve the role of rivers in global GHG emissions correctly. There is a

need for an improved mechanistic understanding of the biogeochemical processes involved in the production, consumption, and transformation of carbon and nitrogen species leading to riverine GHG emissions. However, river systems are spatially complex and temporally dynamic, making predictions of GHG emissions, especially challenging. The lack of observations for evaluating specific parameters that describe each process often leads to simplistic representation in models, and consequently, high sensitivity and uncertainty in the model results. The inclusion of sub-models that can resolve transient hydrological exchanges in land-surface models is paramount to more robustly represent biogeochemical processes in the terrestrial-aquatic interphases (Buchkowski et al., 2017; Graham et al., 2019). With very few exceptions (e.g., Rulík et al., 2000; Bednařík et al., 2015; Comer-Warner et al., 2018), field studies of GHG fluxes in rivers rarely address small-scale spatial variability across the bank, and temporal variation in relation to the hydrological dynamics between the groundwater and river. In addition, very few have considered simultaneously methane and N_2O and how they may be linked at the site scale.

Here we present results from methane and N_2O porewater concentrations and chamber flux measurements conducted at different river stages at a plot of the Columbia River, a large regulated river. Our goal was to assess the spatio-temporal variability in porewater concentrations and surface fluxes. We further utilize the results to identify the relationships between HZ hydrological processes and the sources or sinks of methane and N_2O.

2. Methods

2.1 Study site and sampling approach

This study was conducted in the experimental 'Genome to Greenhouse Gas (3G) observatory' at the Columbia River on the Hanford Reach (Hanford 300 Area), Washington State, USA

(Figure 1). The observatory consists of an array of 3 triplicate porewater samplers (peepers) deployed at a sandy beach on bank-to-river transects (6 m long) along a microtopographic gradient representing three nominal beach positions: shallow, intermediate and deep (Figure 1B). The sampling array encompasses a small, 11 m-long plot. The plot is located in a small cove that isolates the site from the flow influences of the main river channel. Concurrent measurements of methane, CO_2 and N_2O porewater concentrations and surface fluxes of methane and N_2O were conducted during three distinct river stages representing the main phases of a typical hydrological year at the study site, ~80 km downstream of the Priest Rapids Dam at the Hanford Reach. We sampled on three occasions between 25th April and 25th August in 2018 consisting of (1) a rising water stage during spring snowmelt, (2) a falling water stage during summer after the annual peak in early June, and (3) a highly regulated low water stage starting late in the summer that typically extends to the onset of the next spring snowmelt.

2.2 River levels and hydraulic gradient

River water and groundwater levels were recorded using pressure transducers. We conducted river water measurements at the 3G observatory during August 2018 (5 min resolution) and river water and groundwater measurements in a transect perpendicular to the river, 410 m downstream of the 3G observatory during 2018 (15 min resolution) (Figure 1A). We generated a time series for the 3G observatory during 2018 using water levels from the point of measurement downstream (r^2 = 0.99, p < 0,001, 27 days in August), and a known discrete level at the 3G site. We used as a zero-reference location for the water level the sediment surface of the shallow position (Figure 1C).

To determine the strength of groundwater flow toward the river, we calculated the hydraulic gradient (HG, m m^{-1}) between the river water and groundwater-well level as:

$$HG = \Delta h \, L^{-1} \quad (1)$$

Where Δh is the head difference between the river water level (m) and the groundwater level of the well (m) at a given time, and L is the distance between their two points of measurement (114 m). Sediment temperatures (at 10 cm sediment depth) were measured at each position along one transect during the study period using thermistors (marked in red in Figure 1A).

2.3 Porewater sampling and processing

Vertical profiles of methane, N_2O, and CO_2 concentration of sediment porewater were determined at each gradient's position using the peepers described by MacDonald et al. (2013). The peepers allowed for non-destructive consecutive sampling of the sediment profile at the same depth and beach positions. The peepers feature 20 stacked cells (61.4 ml) at a 2.8 cm vertical resolution. Each cell has 22.5 cm^2 windows covered with a 0.22-µm pore size polyethersulfon membrane that allows water inside the cell to equilibrate with dissolved gas concentrations in the sediments. Cells were fitted with two sampling ports consisting of plastic tubing that allowed water extraction and refill. We used standard 4-inch PCV conduit anchored to the river sediments above the peeper location with rebar to house the peeper tubing, allowing for easy sampling even when water levels were high, and marking the peeper location. Peepers were deployed two months before our first sampling to ensure equilibration, which usually could take between 4 days and up to three weeks (MacDonald et al. 2013).

We sampled ten cells, starting at the top cell (at zero sediment depth) and every other after that, until reaching the bottom-most cell at 50-cm sediment depth. The sampling consisted of

extracting 10-ml of water from the cells through one of the cell tubings while keeping the other connected to a container filled with N_2 to avoid oxygen intrusion that could disturb the anaerobic environment within and around the cells. After the extraction, the cell was refilled with deionized water degassed with N_2. Samples were placed in 10-ml containers pre-acidified with 0.2 ml HCl 2M to ensure pH levels below 2.0, which prevent the post-sampling biological transformation of the gases dissolved in the sample. Then, samples were refrigerated and transported to the laboratory for further processing.

2.4 Porewater concentrations

Gas concentrations in porewater were determined using the gas chromatograph headspace equilibration technique described by (Kampbell et al., 1989). We used a 5-ml subsample of each vial to equilibrate with a 15-ml N_2 headspace. Upon equilibration, we injected 10 ml of headspace into 10-ml pre-evacuated vials and analyzed them in a gas chromatograph equipped with a flame ionization detector fitted with a 1.8 Poropack Q column and an electron capture Ni-63 detector (Shimadzu GC-2014, Shimadzu Scientific Instruments, Kyoto, Japan). Helium (25 ml min^{-1}) was used as the carrier gas for methane and CO_2 analysis and ultra-pure N_2 (10 ml min^{-1}) was used as the carrier gas for N_2O analysis. We included methane, CO_2, and N_2O check standards every 20 samples to ensure that the chromatograph maintained the calibration throughout the analysis. If the deviation between the measured value and the value of the check standard was greater than 10%, we recalibrated the chromatograph and re-ran the samples.

Molar concentrations of methane, CO_2, and N_2O (C_{molar_pore}) were calculated from the measured gas concentrations as:

$$C_{molar\_pore} = \frac{\frac{p_i}{RT} Vh + \frac{p_i}{H^{cp}} Vl}{Vl} \quad (2)$$

183 Where p_i is the partial pressure of methane, CO_2 or N_2O, R is the universal gas constant (m^3 Pa
184 mol^{-1} K^{-1}), T is the room temperature (K), Vh is the volume of the headspace (ml), H^{cp} is
185 Henry's volatility constant (m^3 Pa mol^{-1}) for methane, CO_2, and N_2O, respectively, and Vl the
186 volume of the liquid subsample used to create the headspace (ml).
187
188 **2.5 Surface flux measurements**
189 Flux measurements were conducted using non-steady-state chambers. At each sampling, we
190 conducted triplicate chamber measurements at the water surface right above the peepers when
191 they were submerged or around it when the water table was below the sediments, and the peepers
192 were surfacing. We used transparent polypropylene dome-shaped chambers (7.3×10^{-2} m^2
193 surface area, 7.7×10^{-3} m^3 volume), equipped with a digital thermometer to record inner
194 temperatures and a 12v fan to mix air within the chamber and polyethylene foam in the bottom
195 rim for flotation. For methane flux measurements, we used a single chamber connected to a
196 cavity ring-down spectroscopy methane analyzer (Gas Scouter G4301, Picarro, Santa Clara, CA)
197 that recirculated the air at a rate of 1L min^{-1}. The analyzer recorded methane concentrations in
198 the chamber at a 1-Hz frequency. Each chamber deployment lasted for three minutes, and
199 measurements were consecutive at each peeper location.
200 For N_2O flux measurements, the chambers included a 30-cm long, 1.6 mm ID tube for pressure
201 relief and a gray butyl rubber stopper as a sampling port as well. At each sampling, we deployed
202 three chambers simultaneously for 24-minute periods at each peeper location. Six 10-ml samples
203 were collected at 4-min frequency during each deployment, placed in pre-evacuated vials and
204 transported for chromatography analysis in the laboratory. The concentrations of the gas samples

were analyzed in the same chromatograph, and under the same quality control used to measure N_2O concentrations in porewater.

Methane and N_2O chambers positioning during sampling followed an equilateral triangular arrangement with two chambers positioned parallel to the shore. For methane sampling, we ensured the position of the single manually during the sampling period. For the N_2O sampling, we attached the cambers with polyethylene foam and then the chamber array was anchored above the peeper location by surrounding the PVC conduit used to house the peeper tubbing.

2.6 Surface flux calculations

For each methane chamber measurement, we fitted a 2 minute, 1-Hz time series of methane concentrations, C_{HM} (µmol mol^{-1}), to the non-linear Hutchinson and Moiser one-dimension diffusion model (Hutchinson and Mosier, 1981; Kutzbach et al., 2007; Pedersen et al., 2010):

$$C_{HM} = C_s + (C_0 - C_s)\, e^{-kt} \quad (3)$$

Where C_0 is the pre-deployment concentration of methane (µmol mol^{-1}), C_s is the constant source or sink concentration (µmol mol^{-1}), and k is a curve shape parameter (h^{-1}). C_0, C_s, and k are parameters determined by fitting the observed gas concentrations in the chamber over time, t (h). We then calculated the flux of methane (F_CH_4, µmol m^{-2} h^{-1}) at the water or sediment surface as:

$$F\_CH_4 = k\,(C_0 - C_s)\,\frac{P\,V}{R\,T\,A}, \quad (4)$$

where P (Pa) is the atmospheric pressure, measured with a digital barometer at the site; V the volume of the chamber (m^3), R the universal gas constant (m^3 Pa mol^{-1} K^{-1}), T the temperature inside the chamber (K), and A the surface area of the chamber (m^2).

For N_2O chamber measurements, we calculated the molar concentrations of N_2O (C_{molar_Ch}, µmol m^{-3}), in each sample using a modified gas law, following the procedure described by (Holland et al., 1999):

$$C_{molar\_Ch} = \frac{Cv\ P}{R\ T} \quad (5)$$

where Cv is the concentration (nmol mol^{-1}) of N_2O in the sample, P is atmospheric pressure (Pa), R is the universal gas constant (m^3 Pa mol^{-1} K^{-1}), and T is the air temperature (K) of the chamber. Then, the accumulation rate, C_{rate} (nmol m^{-3} h^{-1}), was determined using the slope of the linear regression fitted to the time points (t, h) collected for each chamber after rejecting outliers in the regressions following the procedure described by (Rey-Sanchez et al., 2018):

$$C_{molar\_Ch}(t) = C_{molar\_Ch}(0) + C_{rate} \times t \quad (6)$$

and with the C_{rate}, we calculated the flux rate (F_N_2O, nmol m^{-2} h^{-1}) as:

$$F\_N_2O = \frac{V\ C_{rate}}{A}\ , \quad (7)$$

where V is the volume of the chamber (m^3), and A the area of the water/sediment surface covered by the chamber (m^2).

We used the coefficient of determination (r^2) of the fit between the model (linear in the case of N2O or non-linear in the case of CH4) and concentration observations in the chamber and a quality control criterion. Flux measurements with $r^2 < 0.8$ were considered of poor quality and were discarded from our analyses to avoid error. Out of the 81 flux measurements for methane and N_2O, 28 for methane and 29 for N_2O, were discarded due to this criterion of poor observation quality.

2.7 Methane conductance and conductivity

We used the following general expression to solve for the bulk transfer velocity of methane, or methane conductance (K), at the different beach positions and river water stages assuming that methane is not being produced in the water column:

$$F\_CH_{4d} = K\,(C_{sed} - C_{air}\,P\,H^{cp}) \quad , for\ F > 0 \qquad (8)$$

where F_CH_{4d} is methane the flux measured at each flux chamber but in units of µmol m^{-2} d^{-1} to correspond with the unit convention of conductance. C_{sed} (µmol m^{-3}) is the concentration of methane in the sediments porewater at a given depth and C_{air} (µmol m^{-3}) is the aqueous equivalent of the concentration of methane in the air, calculated as the product of the initial concentration in the chamber (µmol mol^{-1}), P the atmospheric pressure at the moment of sampling (Pa), and H^{cp} the Henry's solubility constant for methane (mol Pa^{-1} m^{-3}). The initial concentration in the chamber, representing the concentration before enclosure, was calculated as the average of the first five measurements of each chamber run.

We assume that the overall conductance, K, is the combined result of two transport processes – K_w, the conductance to methane transport in the water from the soil surface to the air, and K_s, the conductance for methane diffusion/transport in the soil from the peak concentration depth to the soil surface. Adding the resistance to methane flux in a sequential process, we obtain the term for the combined conductance K:

$$K = \frac{K_w\,K_s}{K_w + K_s} \qquad (9)$$

We followed the approach by Bastviken et al., (2004) to independently determine the conductance to methane in the water column K_w for each flux chamber, by solving the equation:

$$F\_CH_4 = K_w\,(C_{ss} - C_{air}) \qquad (10)$$

where C_{ss} (µmol m^{-3}) is the concentration of methane at the surface of the sediments assumed as the concentration in the first peeper cell.

Substituting eq 9 into eq 8, and using the porewater concentration at the depth of peak concentration in the soil, C_{ps} we obtain an equation for K_s:

$$F\_CH_{4d} = \frac{K_w K_s}{K_w + K_s} (C_{ps} - C_{air}) \quad (11)$$

Equation 11 can be solved using the value we obtained for K_w, from equation (10).

Then we calculated the conductivity (i.e., conductance per unit length) to methane transport/diffusion in the soil (k_s) as:

$$k_s = \frac{K_s}{D_p} \quad (12)$$

Where D_p (m) is the depth at which concentration peaks in the sediment profile.

2.8 Data analysis

We processed data, fit models for flux calculations, and conducted regression tests of porewater concentrations using MATLAB ® 2018b. We used JMP Pro 14.0.0 for all other statistical tests. All the statistical tests were conducted at a 0.05 significance level.

We used Spearman rank correlation to infer the significance of the relationship between average porewater concentrations in the sediment profile and fluxes. We tested the significance of the difference of fluxes and porewater concentrations between water stages for each beach position using paired nonparametric comparisons with the Wilcoxon method. For testing the significance of the differences of water and sediment conductance and sediment conductivity between water stages and within beach positions, we used an ordinal logistic model with the conductances or the conductivity as the response variable, position as a fixed effect and water stage nested by position.

2.9 Data availability

All porewater concentrations and fluxes data will be made available through ESS-DiVE (https://ess-dive.lbl.gov/), DOI pending. Additional ancillary data for the Hanford site is available through the Phoenix – PNNL Environmental Information Exchange (https://www.hanford.gov/page.cfm/PHOENIX).

3. Results and discussion

3.1 Water level and sediment temperature

The water level at the shallow bank position was low (near the sediment surface) during the first part of the year until April when water levels started rising after the spring thaw (Figure 2A). The maximum water levels (> 3 m above the reference elevation, set at the shallow peeper position) were observed in mid-May and were followed by a steadily falling water stage until the beginning of July and remained low during the rest of the year. A brief rising limb in the second half of June was driven by dam water release during the falling stage and coincided with the moment we conducted our sampling. Water levels below the reference elevation were observed during the low stages before the rising stage and after the falling stage. The water level during the low water stage was more variable than during previous stages. The operation of the dam upstream can cause up to 0.5 m variations in water levels within a daily period (Zhou et al., 2018).

Positive hydraulic gradients (downwelling) occurred through the hydrological year, including the time during the rising and falling water stages (Figure 2B, C). However, reversals to the negative hydraulic gradient (upwelling) were frequent during the low water stage. Hydraulic gradient reversal represents groundwater upwelling or moments when the river receives water

from the aquifer. Reversals were also frequent on the days preceding the low water stage sampling (Figure 2D).

Sediment temperature increased throughout the sampling period. In general, mean positions' temperatures had a 10 °C increase between the beginning of the study during the rising water stage in April and the study end in August (Figure 2). Temperatures were similar throughout the different beach positions during the rising and falling stages but differed and were more variable at the low water stage when the water level dropped below the soil surface at the reference level.

3.2 Methane porewater concentration and fluxes respond similarly to river stage variation

Methane flux to the atmosphere is the result of a balance between methane production and consumption and is influenced by the relative importance of the transport pathways, including diffusion, bubbling, and plant transport (Bridgham et al. 2013). At our site, we regard diffusion as the main transport pathway. We did not observe evidence of bubbling in our peeper chamber measurements (i.e., sudden spikes in methane concentration in the time series during chamber deployments). We also neglected the influence of plant transport because macrophyte vegetation was not present near the sampling locations, although a negligible fraction could have been transported from the shallow bank position through the vascular system of some shrubs present on the riverbank. Methane porewater concentrations and fluxes at the 3G site were negligible during the rising water stage when the sediment temperatures were low (~10 ^{o}C, Figure 3A), which is not surprising given the high sensitivity of methane production to temperature (Yvon-Durocher et al., 2014). Methane flux was low at the shallow position during the low water stage as well, when the water level was below the sediment surface (Table 1). Despite relatively higher concentrations in the sediment profile (Figure 3B), the water level dropdown during the low

water stage may have resulted in unsaturated or oxygenated sediments and as a result, a predominantly aerobic environment that would have increased methane oxidation above the water table in the sediment column (Segers, 1998). Indeed, the porewater concentration profile at the shallow position during the low water stage showed very low concentrations throughout the sediment above the water table (Figure 4), consistent with increased methane oxidation coupled to aerobic respiration (Conrad and Rothfuss, 1991) or low methane production due to thermodynamic exclusion (Bethke et al., 2011).

Both methane production and consumption can co-occur in sediments (Le Mer and Roger, 2001) since methanogenic and methanotrophic bacteria can be correlated in terms of population in sediments subject to flooding (Joulian et al., 1997) and the ratio between methanogens to methanotrophs is correlated to methane transfer velocity (Rey-Sanchez et al., 2019). Bednařík et al. (2015) demonstrated that benthic methane fluxes are correlated with porewater concentrations, suggesting that differences between porewater concentrations and surface methane fluxes might be due to the activity of methane-oxidizing bacteria in the upper sediment layers (Oremland and Culbertson, 1992) or the water column (Matoušů et al., 2017). Although we did not systematically measure dissolved oxygen in the sediment-water interface and the water column during our samplings, we conducted a series of surveys for dissolved oxygen levels before sampling. These indicated that both the water column and the porewater at the water-sediment interface were consistently supersaturated, offering optimal conditions for biological methane oxidation. In deeper systems, such as estuaries and reservoirs, methane fluxes are greater at low water levels because of reduced storage turnover times, which is the time methane remains in the water column after being produced in the sediments (Valentine et al., 2001; Zhu et al., 2010; Lei et al., 2019). Lessened turnover times, reduce the time for

potential oxidation while methane diffuses through the water column. Methane oxidation rate in the water column of rivers has been correlated with the concentration of dissolved methane in the water and with water temperature (Matoušů et al., 2018), which are proxies for the substrate and the enzymatic activity of methanotrophic microorganisms. Therefore, we hypothesize that the effect of storage-turnover time on methane oxidation will be effective in rivers, including near-bank shallow waters as well. Future studies coupling methane fluxes, and oxidation rates with simultaneous measurements of methane concentrations in the sediment and water column could help test this hypothesis.

During the falling and low water stages when sediment temperatures were more favorable for methane production, river level had a dissimilar effect on porewater concentrations and fluxes across positions, although in general, methane fluxes were correlated (Spearman's $\rho = 0.62$, $p < 0.001$) and followed the dynamics of the integrated sediment-profile porewater concentrations. Methane porewater concentration and fluxes decreased at the shallow position after the water level transition from the falling to the low water stage, while porewater concentration and fluxes remained similar at the deep position. In contrast, at the intermediate position, methane fluxes increased at the low stage, when the water levels were also low, while the median porewater concentration increased as well, though not at a significant level.

Low or near-zero fluxes accompanied by decreasing methane concentrations towards the surface of the sediments in the shallow position strongly indicate the activity of methanotrophs actively reducing methane emissions to the atmosphere in the upper region of the sediment profile in the shallow position during the low water stage (Figure 4). However, the activity of methanotrophs in the upper layers of the soil profile was not evident at the intermediate or deep positions (that maintained water above the sediment surface). Even during the low water stage of

386 the intermediate position, the peak in methane concentrations occurred well below the sediment
387 elevation. It is possible that reduced downwelling of electron acceptors and oxygen during low
388 water stages not only stimulated heterotrophic production of methanogenic substrates but also
389 limited dissolved oxygen that is toxic to methanogens and reduced aerobic methanotrophic
390 respiration. However, without specific measurements of oxidation rates at our site, it is hard to
391 pinpoint the specific cause of the variability of methane fluxes across the different beach
392 positions and river water stages.

393 Different apparent conductance to methane transport through the water column between falling
394 and low water stages suggests that methane oxidation may occur at different rates depending on
395 the water levels (Figure 5A). Because we did not account for oxidation during transport in the
396 water column, our observations of higher apparent conductance to methane transport may be the
397 outcome of lower oxidation. Differences in conductance to methane transport through the water
398 column were evident in the intermediate position, with larger conductance during the low water
399 stage. In the sediment profile, conductance to methane was not different between falling and low
400 water stages. Nonetheless, there were differences in the apparent conductance to methane in the
401 sediments among beach positions (Figure 5B), suggesting that there may be a significant spatial
402 variation in oxidation rates at the plot scale.

403

404 **3.3 Methane concentrations in porewater peak along an elevation gradient**

405 Similar to surface fluxes, methane concentrations in the sediment profile are the result of a
406 balance between methane production, consumption, and transport to and from the sediment zone.
407 Previous studies at the Hanford Reach in similar sites to ours have shown that hydrological
408 mixing stimulates heterotrophic respiration and organic carbon turnover (Stegen et al., 2016).

409 Under anaerobic conditions, heterotrophic respiration at the HZ of organic matter would
410 stimulate methane production by producing favored substrates and depleting electron acceptors
411 (Schindler, 1998; Romeijn et al., 2019), whereas under aerobic conditions methane oxidation
412 would be favored (Conrad and Rothfuss, 1991). Complementarily, methane may be imported in
413 the upwelling groundwater as well. Inputs of methane dissolved in groundwater have been
414 observed at low order streams in peat-dominated watersheds (Hope et al. 2001), headwater
415 streams (Jones and Mulholland, 1998), streams in agricultural dominated landscapes (Comer-
416 Warner et al., 2019) and other riverine settings including the Willamette River, the main
417 tributary of the Columbia River (Anthony et al., 2012).
418 The observed methane porewater concentrations profile in the sediment showed distinct peaks
419 that varied among bank positions following the sediment surface elevation gradient during the
420 falling and low water stages (Figure 4). During the falling water stage, concentrations at the
421 shallow positions peaked at the lower sediment layers (relative sediment depth – RSD: -25 to -40
422 cm), while at the intermediate position, concentrations peaked at the upper sediment layers (top
423 20 cm from the sediment surface, RSD: -50 to -70 cm). During the low water stage,
424 concentrations peaked at the lowest depths at the shallow position (around RSD: -50 cm), mid-
425 to-lower depths from the sediment surface at intermediate position (RSD: -80 to -105 cm), and
426 upper sediment layers at the deep position (RSD: -100 to -110 cm). Overall the peaks in methane
427 concentration were observed at upper sediment layers during the falling water stage when the site
428 remained permanently inundated (thick blue line in Figure 4), and at lower sediment layers
429 during the low water stage when the water level was fluctuating around the reference elevation
430 (thick orange line in Figure 4).

The peaks may have resulted from a combination of heterotrophic respiration and imports through groundwater into the HZ from the nearby upland area. Methane and CO_2 porewater concentrations were significantly correlated (Figure 6). Based on the low concentrations of acetate measured in similar sites along the Handford Reach, with only 1/50 samples being above the detection limit (>78 µM), and uncertainty of methyl compound identity and potential utilization (Hou et al., 2017), we infer that the prevailing mode of methanogenesis was hydrogenotrophic, requiring hydrogen and CO_2. However, we acknowledge that this correlation is a function of overall microbial activity, rather than the result of the direct use of CO_2 for methanogenesis alone (Moore and Dalva, 1997; Comer-Warner et al., 2019). Interestingly, we found that the slope of the regression between methane and CO_2 porewater concentrations varied during the three water stages and was larger during the falling water stage when the river downwelling was stronger than during the low water stage when downwelling diminished and groundwater upwelling was more frequent (Figure 6). The difference in the strength of microbial activity between falling water and low water stages support findings by previous studies at adjacent sites along the Hanford Reach that showed a shift in microbial communities as labile organic carbon stimulates heterotrophic respiration during river downwelling periods (Stegen et al. 2016). As water drops and the influence of groundwater upwelling increases, heterotrophic processes of carbon cycling and decomposition succumb to autotrophic processes (Graham et al., 2017).

On the other hand, as groundwater upwelling becomes more frequent during the low water stage and heterotrophic respiration recede (and presumably the production of methane), imports of dissolved methane in the groundwater increase, maintaining similar porewater concentrations than during the falling water stage. This hypothesis is supported by the increase in conductivity

of methane in the sediments we observed at the deep position (Figure 5C), which indicates that during groundwater upwelling, methane transport is faster. We hypothesize that while microbial methane production is reduced when the water level drops and groundwater upwelling is increased, methane concentrations and fluxes are maintained because allochthonous methane is "pushed out" from the surrounding upland soils and river sediments.

We propose that the observed peaks in methane concentration through the sediment profile during the falling water stage occurred at predominantly anaerobic zones, where hydrological mixing of downwelling surface water from the river and upwelling groundwater from the aquifer is enhanced. The predominant zone of methane production moved vertically downward within the HZ as the river transitioned from falling to low water stage, coinciding with a shift from river water dominated to groundwater-dominated mixing ratios.

3.4 Nitrous oxide porewater concentrations and fluxes have different dynamics across river water stages

Unlike methane, N_2O porewater concentrations in the sediment profile and fluxes to the atmosphere did not follow similar patterns throughout the river water stages (Spearman's ρ = 0.29, p = 0.14). N_2O porewater concentrations were higher during the rising water stage than during the falling water stage in all the three beach positions and during the low water stage at the intermediate position (Figure 7A). Instead, N_2O fluxes increased from the rising to the low water stage at the shallow position, while remained similar at the intermediate and deep positions during the three water stages (Figure 7B).

The decoupling between the observed N_2O porewater concentrations in the sediments and the fluxes is not surprising. N_2O production in large rivers might occur primarily at the water column

in microsites within suspended particles. There is significant evidence of substantial N_2O production via denitrification in pelagic zones of estuaries (Barnes and Owens, 1999; de Wilde and de Bie, 2000). Beaulieu et al. (2010) presented evidence of a similar pattern at a large river, with N_2O production rates in the water column doubling that of the sediments, which could help explain the lack of correlation between the porewater concentrations and fluxes. Marzadri et al. (2014) and Marzadri et al. (2017) explained that in lotic systems there is a shift in the predominant zones of N_2O production from the hyporheic-benthic zone in streams to the benthic-water column zone in rivers as the system gains size, due mainly to the increase in suspended particle loads.

Notably, we observed negative fluxes throughout the different river water stages and in all positions, which is consistent with high rates of N_2O consumption at either the sediments or the water column. Our plot acted primarily as a sink at the shallow position while the sediments were fully saturated, and the water level was above the sediment surface and on the intermediate position during the low water stage when the water level at this position was low as well (Figure 7A). N_2O is often produced as an intermediate species of microbially mediated denitrification, or a byproduct of nitrification or reduction of ammonia to nitrate (Quick et al., 2019). Dissolved organic carbon in the HZ plays a critical role in fueling nitrification under aerobic conditions (Graham et al., 2016; Graham et al., 2017) and in addition, may lead to low oxygen and nitrate conditions that ultimately favor N_2O consumption (Soued et al., 2015). Low oxygen conditions may result from the low flow as well (Baulch et al., 2011b), which prevailed in the 3G observatory, especially at lower water levels, explaining the dominant sinking functioning of the shallow and intermediate positions partially. It may also be possible that atmospheric nitrous oxide consumption occurred in the water column in the absence of other denitrification

processes, which has been demonstrated only for a few model microorganisms and ecosystems (Jones et al., 2014; Yoon et al., 2016).

A more robust understanding of the nexus (or lack thereof) of the spatial heterogeneity and dynamics of N_2O porewater concentrations and fluxes must build upon the synergistic effects of the seasonal hydrological exchanges, inorganic nitrogen availability, and the activity of the microbial community involved in cycling nitrous oxide at the HZ and the water column. For instance, the nitrification and denitrification functional potential of microbial communities in the HZ of the Hanford Reach (and possibly many other lotic systems) are linked with the ratio of groundwater to surface water, likely due to the input of N in the groundwater (Nelson et al., 2019). However, it is still not clear if or how the dynamics of groundwater N or other environmental drivers are affecting the N-cycling functional potential in the water column and overall how N_2O is produced and consumed in the sediment-water column continuum.

3.5 Nitrous oxide concentrations peak at the sediment/water table interface

Mathematical and conceptual models propose that N_2O production at the HZ is maximized along flowlines representing intermediate travel times of downwelling surface water, which are usually few cm below the sediment surface (Reeder et al., 2018; Quick et al., 2016). At shallower depths, at the surface of the sediments (i.e., shortest travel times), nitrate is not transformed, whereas at deeper depths (i.e., longest travel times), denitrification is completed and N_2 is the predominantly released gas. The N_2O porewater concentrations we observed at the 3G are consistent with the modeling predictions, showing increased concentrations at the proximity of the sediment/water table interface (~ up to 15 cm) (Figure 8).

522 We found significant negative correlations between N_2O and CO_2 porewater concentrations for
523 pooled data from the three water stages and the shallow and intermediate beach positions (Figure
524 9). We cannot discern whether the correlation is the result of N_2O production or consumption.
525 Partial denitrification, nitrate reduction to N_2O, is coupled to carbon oxidation to CO_2 and
526 therefore, we would expect a positive correlation (Tsuruta et al., 1997). Therefore, N_2O
527 production appeared decoupled from denitrification and more closely tied to other processes. The
528 negative correlations could be explained by the release of N_2O during nitrification coupled to
529 CO_2 assimilation or heterotrophic microorganisms utilizing N_2O as a terminal electron acceptor
530 (Hink et al., 2017; Lycus et al., 2018). This may help explain the negative correlation between
531 N_2O and CO_2 porewater concentrations, which were also seen in observations of other riverine
532 settings (Richey et al., 1988; Teodoru et al., 2015). However, we do not rule out that
533 simultaneous processes of production and consumption are co-occurring and that their relative
534 importance change as the river water level transitions and substrates, environmental conditions,
535 and the relative diversity and abundance of N-Cycling populations vary (Nelson et al., 2019).
536 The decoupling between N_2O and CO_2 may be explained as well at some degree by lateral
537 transport of N_2O dissolved in groundwater (Clough et al., 2006).
538 It is noteworthy that the strength of the correlation between N_2O and CO_2 porewater was
539 dictated by beach positions, indicating that different processes are occurring between locations.
540 Weaker negative correlations at the shallow position may be explained by contributions of both
541 nitrification byproducts and denitrification, N_2O consumption as an electron acceptor in the
542 absence of other denitrification processes, and labile carbon oxidation, or the increased
543 contributions from heterotrophic denitrifications. Coupling inorganic nitrogen concentrations and

544 organic carbon concentration measurements should help unveil the prevalence of these processes
545 and their influence in the observed variability between beach positions.
546
547 **4. Conclusions and outlook**
548 Hyporheic zones of rivers and streams are important hotspots of greenhouse gas emissions. The
549 interaction of river stage and biogeochemical processes govern the production, consumption, and
550 flux dynamics. This interaction of the governing factors results in high heterogeneity at the small
551 scale (m to cm) in horizontal and vertical planes. At the plot scale, methane porewater
552 concentrations have a marked vertical temporal dynamic with concentrations peaking at different
553 depths depending on the influence of the magnitude and direction of hyporheic mixing. Methane
554 fluxes followed the dynamics of porewater concentrations throughout the river water stages but
555 highlighted the potential influence of oxidation in the resulting fluxes. Hence the need for sub-
556 models capable of representing the potential effects of hydrological exchanges on methane
557 oxidation in the HZ. The effect was pronounced for the intermediate position where methane
558 fluxes increased (and the conductance to methane in the water column) from the falling water
559 stage to the low water stage. In turn, N_2O porewater concentrations rely more on the permanent
560 mixing at the HZ and occur at the upper layers just below the sediment surface. Contrary to
561 methane, fluxes of N_2O were not correlated to porewater concentrations and were reduced at low
562 water elevations, possibly because of the release of N_2O as a byproduct of aerobic nitrification or
563 the use of N_2O as an alternative terminal electron acceptor to oxygen for microbial respiration at
564 the sediment-water interface (Khalil et al., 2004; Jones et al., 2014). Overall results indicated that
565 the plot functioned as a net source of methane and could function as either a sink or source for
566 N_2O depending on both the season and position within the riparian zone. Therefore, identifying

the potential nexus between N_2O production and consumption and concurrency at the HZ represents a critical challenge for better representation of the N_2O dynamic in biogeochemical models.

Here we presented snapshots of detailed vertical profiles and surface fluxes of methane and N_2O porewater concentrations through the different typical hydrological stages of a large-regulated river. As our results indicate, river stages and consequent groundwater mixing, drive the dynamics of porewater concentrations and fluxes of methane and N_2O on a seasonal scale. However, coupling hydrological dynamics with methane and N_2O concentrations and fluxes at small scales and parametrizing the governing processes will require longer-term and more frequent assessments, especially the inclusion of measurements at a small temporal scale (days-hours). Such a scale is of particular interest to assess the effects of large intra-daily water level oscillations, which are characteristic of regulated rivers, on the GHG production and consumption processes. This daily/sub-daily measurement scale could help to elucidate the effects of preceding environmental conditions set by previous water levels (including microbial populations, temperature, nutrient availability and transformations, and redox conditions) on the production and consumption of GHGs. In non-regulated rivers, we would expect a similar control of seasonal groundwater mixing than the one we observe here. However, in contrast to regulated rivers, the shorter-term effects of preceding environmental conditions would likely be less dramatic given the lower water intra-daily fluctuations.

Finally, as our results indicate, GHG concentration and fluxes can be significantly different across small horizontal (6 m W × 11 m L) and vertical (0.5 m) spatial scales. Moreover, water level fluctuation has a significant effect on the functioning of the HZ as a sink or source of methane and N_2O. The coupling of hydrology and GHGs emissions at small scales will,

590 therefore, be essential to help parametrize and calibrate predictive models in large rivers like the
591 Columbia River and other rivers and streams as well. More importantly, it is a necessary task to
592 test hypotheses discerning the microbial processes explaining the spatiotemporal heterogeneity
593 of methane and N_2O at the HZ.

Tables

Table 1. Mean water levels (m) along three beach positions at the Columbia River during samplings of porewater concentrations and fluxes of methane (CH_4) and N_2O under three different river water stages.

Sampling	Position		
	Shallow	Intermediate	Deep
Rising water stage (porewater & fluxes)	0.46	1.00	1.44
CH_4 fluxes	0.50	1.04	1.48
N_2O fluxes	0.61	1.15	1.60
Falling water stage (porewater & fluxes)	0.78	1.32	1.76
CH_4 fluxes	0.83	1.37	1.82
N_2O fluxes	0.50	1.04	1.49
Low water stage (porewater & fluxes)	-0.28	0.26	0.70
CH_4 fluxes	0.83	1.37	1.82
N_2O fluxes	-0.81	-0.27	0.18

List of figures

Figure 1. Experimental design. (A) Peeper array at the 3G observatory and river and groundwater monitoring at the 300 Area, Hanford reach, Washington State. (B) Diagram depicting the general sampling design and (C) the conventions used throughout the manuscript. The transect marked in red in (A) denotes the transect where sediment temperatures were measured.

Figure 2. Hydrological conditions during the study period (4/24 to 8/25 2018). (A) River water levels (dark blue), sediment temperature (red lines), and sampling periods (vertical bars with different colors). (B – D) River water levels (dark blue) and hydraulic gradient (light blue) during each river stage sampling, including the five preceding days of each sampling. The horizontal dashed line indicates the reference elevation (sediment surface at the shallow position – left axis) and the zero hydraulic gradient (right axis). Water levels above the horizontal line represent water above the sediment surface. Hydraulic gradients above that line represent river dowelling, whereas values below the line represent groundwater upwelling. At each river stage sampling, we sampled peepers first (2 days), then methane (few hours during the next day) and N_2O (few hours during the following day), as indicated by vertical gray bars (which are labeled in (B) for clarification).

Figure 3. (A) Integrated sediment-profile methane porewater concentrations and (B) methane fluxes along a beach transect (plot scale) at the 3G observatory during three river water stages. Boxes represent the 25^{th} and 75^{th} percentiles, the horizontal black line the median, circles mark outliers, defined as observations that are 1.5 greater than the upper interquartile range.

Whiskers extend to the furthest observation not considered an outlier. Letters represent statistical differences calculated with non-parametric Wilcoxon paired tests for each position (α = 0.05).

Figure 4. Methane porewater concentrations on the sediment profile at shallow (left), intermediate (middle), and deep (right) positions of a beach transect (plot scale) at the Columbia River during three river water stages. Data points (circles) represent the mean concentration, and the error bars the standard error (n=3). Horizontal blue areas indicate the water level range during the different water stages. Thick transparent color lines indicate an elevation gradient in the peaks of methane concentrations during the rising water stage (blue) and the low water stage (orange). The thick brown line represents the beach elevation along the gradient.

Figure 5. Methane conductance in the water column and sediments (A and B), and methane conductivity (i.e., conductance per depth) in the sediments (C) along a beach transect (plot scale) at the Columbia River during falling and low river water stages (during the rising water stage fluxes and porewater concentrations were negligible). Boxes represent the 25^{th} and 75^{th} percentiles, the horizontal black line the median and circles outliers defined as observations that are 1.5 greater than the upper interquartile range. Whiskers extend to the furthest observation not considered an outlier. Capital letters indicate differences between beach positions and lowercase letters, differences between river water stages with positions.

Figure 6. Correlations between methane and CO_2 porewater concentrations on sediment profiles of a beach transect (plot scale) at the Columbia River during three river water stages. Dotted

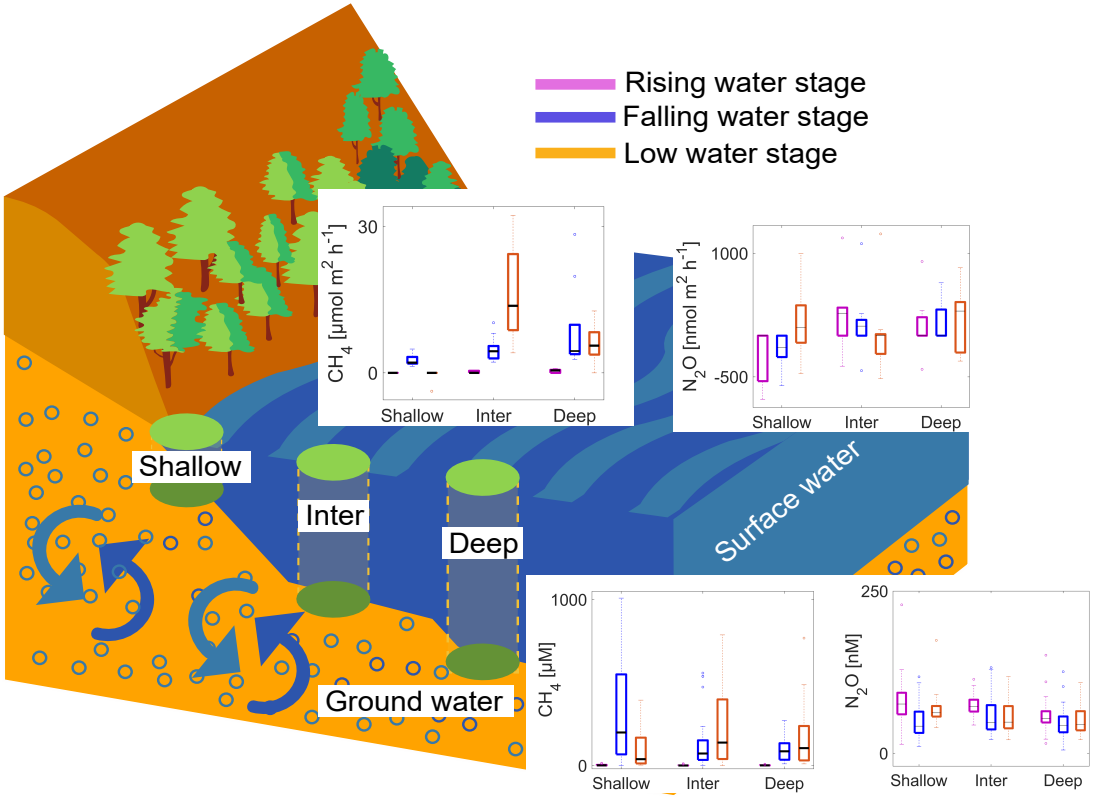
lines accompanying the regression lines represent the 95% confidence intervals. The correlation is stronger during the falling water stage.

Figure 7. (A) Integrated sediment-profile methane porewater concentrations and (B) N_2O fluxes along a beach transect (plot scale) at the Columbia River during three river water stages. Boxes represent the 25^{th} and 75^{th} percentiles, the horizontal black line the median and circles outliers defined as observations that are 1.5 greater than the upper interquartile range. Whiskers extend to the furthest observation not considered an outlier. Letters represent statistical differences calculated with non-parametric Wilcoxon paired tests for each position ($\alpha = 0.05$).

Figure 8. N_2O porewater concentrations along the sediment profile at shallow (left), intermediate (middle), and deep (right) positions of a beach transect (plot scale) at the Columbia River during three river water stages. Data points (circles) represent the mean concentration, and the error bars the standard error (n=3). Horizontal blue areas indicate the water level range during the different water stages. The thick brown line represents the beach elevation along the gradient.

Figure 9. Correlations between N_2O and CO_2 porewater concentrations along sediment profiles of a beach transect (plot scale) at the Columbia River during three river water stages. Dotted lines accompanying the regression lines represent the 95% confidence intervals. Note that the correlation is not significant for the deep position (gray markers). The overall correlation for data of all positions (not shown) is also significant (slope = -2.97, $r^2 = 0.065$, $p < 0.01$).

***Graphical Abstract**



Highlights:

A better understanding of methane and nitrous oxide emissions from rivers is needed

Porewater concentrations and fluxes were measured at three different hydrological stages

We used co-located peepers and static chambers at a beach transect in three elevations

River stage forced different gas dynamics in vertical and horizontal planes

Small-scale hydro-biogeochemical exchanges are crucial for better predictions

Abstract

Greenhouse gas (GHG) emissions from rivers are a critical missing component of current global GHG models. Their exclusion is mainly due to a lack of in-situ measurements and a poor understanding of the spatiotemporal dynamics of GHG production and emissions, which prevents optimal model parametrization. We combined simultaneous observations of porewater concentrations along different beach positions and depths, and surface fluxes of methane and nitrous oxide at a plot scale in a large regulated river during three water stages: rising, falling, and low. Our goal was to gain insights into the interactions between hydrological exchanges and GHG emissions and elucidate possible hypotheses that could guide future research on the mechanisms of GHG production, consumption, and transport in the hyporheic zone (HZ). Results indicate that the site functioned as a net source of methane. Surface fluxes of methane during river water stages at three beach positions (shallow, intermediate and deep) correlated with porewater concentrations of methane. However, fluxes were significantly higher in the intermediate position during the low water stage, suggesting that low residence time increased methane emissions. Vertical profiles of methane peaked at different depths, indicating an influence of the magnitude and direction of the hyporheic mixing during the different river water stages on methane production and consumption. The site acted as either a sink or a source of nitrous oxide depending on the elevation of the water column. Nitrous oxide porewater concentrations peaked at the upper layers of the sediment throughout the different water stages. River hydrological stages significantly influenced porewater concentrations and fluxes of GHG, probably by influencing heterotrophic respiration (production and consumption processes) and transport to and from the HZ. Our results highlight the importance of including dynamic

hydrological exchanges when studying and modeling GHG production and consumption in the HZ of large rivers.

Keywords: hyporheic zone, methane conductance, porewater, methane flux, nitrous oxide flux

1. Introduction

Rivers and streams cover a relatively small area of the planet's terrestrial phase (0.47%). Nonetheless, they play a pivotal role in greenhouse gas (GHG) emissions (Raymond et al., 2013). It is estimated that they emit annually 6.6 Pg of carbon dioxide (CO_2) (Raymond et al., 2013), 26.8 Tg of methane (CH_4) (Stanley et al., 2016) and 1.1 Tg of nitrous oxide (N_2O) (Beaulieu et al., 2011). In other words, this is the equivalent to ~12% of CO_2 emissions from fossil fuels and industry (Jackson et al., 2017), and ~5% and ~10% of global methane and N_2O emissions, respectively (Beaulieu et al., 2011; Saunois et al., 2016). The disproportionate contributions from rivers to GHG budgets have challenged the early assumption of rivers as "passive" or "neutral" pipes in global and regional GHG budgets (Cole et al., 2007; Aufdenkampe et al., 2011), placing them as active hotspots for GHG exchange.

Whereas the biogeochemical processes that lead to CO_2 emissions from rivers have traditionally received more attention (Raymond et al., 2013; Hotchkiss et al., 2015) and are relatively better represented in current models (e.g., E3SM, Golaz et al., 2019), the processes that lead to methane and N_2O emissions remain poorly constrained in space and time (Bridgham et al., 2013; Quick et al., 2019). Methane and N_2O emissions are low compared with those of CO_2, yet on an equal mass basis, they have 45 and 270 times the potential of CO_2 to warm the atmosphere over a 100-year horizon, respectively (Neubauer and Megonigal, 2015). Most of the biogeochemical activity that leads to methane and N_2O production and consequent emission in rivers occurs within the hyporheic zone (HZ), a transition zone in the saturated sediments adjacent to the streamflow where surface water and subsurface waters are permanently mixing (McClain et al., 2003; Krause et al., 2011). The mixing of downwelling oxidized surface water, and upwelling of reduced subsurface water provides a unique environment of enhanced nutrient

and light availability, gradients of temperature and redox potentials, pH, organic matter content, and microbial numbers and activity (Woessner, 2017). This environment represent biogeochemical hotspots for microbial activity where aerobic and anaerobic microbial metabolisms co-occur (Boulton et al., 1998). In general, the HZ is a net source of methane and N_2O (Reeder et al., 2018).

Hydrologic exchange strongly affects the flow of organic dissolved carbon, an essential microbial substrate for GHG production processes, as well as the transport of GHG themselves. Methane can be produced in the anaerobic environment within the HZ from CO_2 and H_2 or acetate during the degradation of organic matter (Lyu et al., 2018). Methane may also be transported from the surrounding upland areas dissolved in groundwater (Jones and Mulholland, 1998). Once in the HZ, methane can be oxidized and transformed back into CO_2 with sufficient electron acceptors, particularly oxygen, by methanotrophic microorganisms (Chistoserdova et al., 2009). The remaining portion of methane that is not oxidized can be emitted via diffusion, ebullition, or plant-mediated transport (Bridgham et al., 2013).

N_2O production in the HZ is mainly the result of four distinct processes: (1) denitrification or reduction of nitrate or nitrite to dinitrogen with nitrous oxide as an intermediate, (2) by-products of oxidation of ammonia to nitrate or nitrite, (3) dissimilatory reduction of nitrate to ammonia, and (4) chemo-denitrification involving the abiotic reaction of nitrite with iron(II) (Quick et al. 2019), of which denitrification is thought as the main production pathway in lotic systems (Baulch et al., 2011a; Beaulieu et al., 2011). N_2O transport from the HZ to the atmosphere occurs primarily via diffusion (Baulch et al., 2011a).

A better understanding of the dynamics and interactions of different processes throughout the HZ is needed in order to resolve the role of rivers in global GHG emissions correctly. There is a

need for an improved mechanistic understanding of the biogeochemical processes involved in the production, consumption, and transformation of carbon and nitrogen species leading to riverine GHG emissions. However, river systems are spatially complex and temporally dynamic, making predictions of GHG emissions, especially challenging. The lack of observations for evaluating specific parameters that describe each process often leads to simplistic representation in models, and consequently, high sensitivity and uncertainty in the model results. The inclusion of sub-models that can resolve transient hydrological exchanges in land-surface models is paramount to more robustly represent biogeochemical processes in the terrestrial-aquatic interphases (Buchkowski et al., 2017; Graham et al., 2019). With very few exceptions (e.g., Rulík et al., 2000; Bednařík et al., 2015; Comer-Warner et al., 2018), field studies of GHG fluxes in rivers rarely address small-scale spatial variability across the bank, and temporal variation in relation to the hydrological dynamics between the groundwater and river. In addition, very few have considered simultaneously methane and N_2O and how they may be linked at the site scale.

Here we present results from methane and N_2O porewater concentrations and chamber flux measurements conducted at different river stages at a plot of the Columbia River, a large regulated river. Our goal was to assess the spatio-temporal variability in porewater concentrations and surface fluxes. We further utilize the results to identify the relationships between HZ hydrological processes and the sources or sinks of methane and N_2O.

2. Methods

2.1 Study site and sampling approach

This study was conducted in the experimental 'Genome to Greenhouse Gas (3G) observatory' at the Columbia River on the Hanford Reach (Hanford 300 Area), Washington State, USA

(Figure 1). The observatory consists of an array of 3 triplicate porewater samplers (peepers) deployed at a sandy beach on bank-to-river transects (6 m long) along a microtopographic gradient representing three nominal beach positions: shallow, intermediate and deep (Figure 1B). The sampling array encompasses a small, 11 m-long plot. The plot is located in a small cove that isolates the site from the flow influences of the main river channel. Concurrent measurements of methane, CO_2 and N_2O porewater concentrations and surface fluxes of methane and N_2O were conducted during three distinct river stages representing the main phases of a typical hydrological year at the study site, ~80 km downstream of the Priest Rapids Dam at the Hanford Reach. We sampled on three occasions between 25th April and 25th August in 2018 consisting of (1) a rising water stage during spring snowmelt, (2) a falling water stage during summer after the annual peak in early June, and (3) a highly regulated low water stage starting late in the summer that typically extends to the onset of the next spring snowmelt.

2.2 River levels and hydraulic gradient

River water and groundwater levels were recorded using pressure transducers. We conducted river water measurements at the 3G observatory during August 2018 (5 min resolution) and river water and groundwater measurements in a transect perpendicular to the river, 410 m downstream of the 3G observatory during 2018 (15 min resolution) (Figure 1A). We generated a time series for the 3G observatory during 2018 using water levels from the point of measurement downstream (r^2 = 0.99, p < 0,001, 27 days in August), and a known discrete level at the 3G site. We used as a zero-reference location for the water level the sediment surface of the shallow position (Figure 1C).

To determine the strength of groundwater flow toward the river, we calculated the hydraulic gradient (HG, m m^{-1}) between the river water and groundwater-well level as:

$$HG = \Delta h \, L^{-1} \quad (1)$$

Where Δh is the head difference between the river water level (m) and the groundwater level of the well (m) at a given time, and L is the distance between their two points of measurement (114 m). Sediment temperatures (at 10 cm sediment depth) were measured at each position along one transect during the study period using thermistors (marked in red in Figure 1A).

2.3 Porewater sampling and processing

Vertical profiles of methane, N_2O, and CO_2 concentration of sediment porewater were determined at each gradient's position using the peepers described by MacDonald et al. (2013). The peepers allowed for non-destructive consecutive sampling of the sediment profile at the same depth and beach positions. The peepers feature 20 stacked cells (61.4 ml) at a 2.8 cm vertical resolution. Each cell has 22.5 cm^2 windows covered with a 0.22-µm pore size polyethersulfon membrane that allows water inside the cell to equilibrate with dissolved gas concentrations in the sediments. Cells were fitted with two sampling ports consisting of plastic tubing that allowed water extraction and refill. We used standard 4-inch PCV conduit anchored to the river sediments above the peeper location with rebar to house the peeper tubing, allowing for easy sampling even when water levels were high, and marking the peeper location. Peepers were deployed two months before our first sampling to ensure equilibration, which usually could take between 4 days and up to three weeks (MacDonald et al. 2013).

We sampled ten cells, starting at the top cell (at zero sediment depth) and every other after that, until reaching the bottom-most cell at 50-cm sediment depth. The sampling consisted of

extracting 10-ml of water from the cells through one of the cell tubings while keeping the other connected to a container filled with N_2 to avoid oxygen intrusion that could disturb the anaerobic environment within and around the cells. After the extraction, the cell was refilled with deionized water degassed with N_2. Samples were placed in 10-ml containers pre-acidified with 0.2 ml HCl 2M to ensure pH levels below 2.0, which prevent the post-sampling biological transformation of the gases dissolved in the sample. Then, samples were refrigerated and transported to the laboratory for further processing.

2.4 Porewater concentrations

Gas concentrations in porewater were determined using the gas chromatograph headspace equilibration technique described by (Kampbell et al., 1989). We used a 5-ml subsample of each vial to equilibrate with a 15-ml N_2 headspace. Upon equilibration, we injected 10 ml of headspace into 10-ml pre-evacuated vials and analyzed them in a gas chromatograph equipped with a flame ionization detector fitted with a 1.8 Poropack Q column and an electron capture Ni-63 detector (Shimadzu GC-2014, Shimadzu Scientific Instruments, Kyoto, Japan). Helium (25 ml min^{-1}) was used as the carrier gas for methane and CO_2 analysis and ultra-pure N_2 (10 ml min^{-1}) was used as the carrier gas for N_2O analysis. We included methane, CO_2, and N_2O check standards every 20 samples to ensure that the chromatograph maintained the calibration throughout the analysis. If the deviation between the measured value and the value of the check standard was greater than 10%, we recalibrated the chromatograph and re-ran the samples.

Molar concentrations of methane, CO_2, and N_2O (C_{molar_pore}) were calculated from the measured gas concentrations as:

$$C_{molar\_pore} = \frac{\frac{p_i}{RT} Vh + \frac{p_i}{H^{cp}} Vl}{Vl} \quad (2)$$

Where p_i is the partial pressure of methane, CO_2 or N_2O, R is the universal gas constant (m^3 Pa mol^{-1} K^{-1}), T is the room temperature (K), Vh is the volume of the headspace (ml), H^{cp} is Henry's volatility constant (m^3 Pa mol^{-1}) for methane, CO_2, and N_2O, respectively, and Vl the volume of the liquid subsample used to create the headspace (ml).

2.5 Surface flux measurements

Flux measurements were conducted using non-steady-state chambers. At each sampling, we conducted triplicate chamber measurements at the water surface right above the peepers when they were submerged or around it when the water table was below the sediments, and the peepers were surfacing. We used transparent polypropylene dome-shaped chambers (7.3×10^{-2} m^2 surface area, 7.7×10^{-3} m^3 volume), equipped with a digital thermometer to record inner temperatures and a 12v fan to mix air within the chamber and polyethylene foam in the bottom rim for flotation. For methane flux measurements, we used a single chamber connected to a cavity ring-down spectroscopy methane analyzer (Gas Scouter G4301, Picarro, Santa Clara, CA) that recirculated the air at a rate of 1L min^{-1}. The analyzer recorded methane concentrations in the chamber at a 1-Hz frequency. Each chamber deployment lasted for three minutes, and measurements were consecutive at each peeper location.

For N_2O flux measurements, the chambers included a 30-cm long, 1.6 mm ID tube for pressure relief and a gray butyl rubber stopper as a sampling port as well. At each sampling, we deployed three chambers simultaneously for 24-minute periods at each peeper location. Six 10-ml samples were collected at 4-min frequency during each deployment, placed in pre-evacuated vials and transported for chromatography analysis in the laboratory. The concentrations of the gas samples

were analyzed in the same chromatograph, and under the same quality control used to measure N_2O concentrations in porewater.

Methane and N_2O chambers positioning during sampling followed an equilateral triangular arrangement with two chambers positioned parallel to the shore. For methane sampling, we ensured the position of the single manually during the sampling period. For the N_2O sampling, we attached the cambers with polyethylene foam and then the chamber array was anchored above the peeper location by surrounding the PVC conduit used to house the peeper tubbing.

2.6 Surface flux calculations

For each methane chamber measurement, we fitted a 2 minute, 1-Hz time series of methane concentrations, C_{HM} (µmol mol^{-1}), to the non-linear Hutchinson and Moiser one-dimension diffusion model (Hutchinson and Mosier, 1981; Kutzbach et al., 2007; Pedersen et al., 2010):

$$C_{HM} = C_s + (C_0 - C_s)\, e^{-kt} \quad (3)$$

Where C_0 is the pre-deployment concentration of methane (µmol mol^{-1}), C_s is the constant source or sink concentration (µmol mol^{-1}), and k is a curve shape parameter (h^{-1}). C_0, C_s, and k are parameters determined by fitting the observed gas concentrations in the chamber over time, t (h). We then calculated the flux of methane (F_CH_4, µmol m^{-2} h^{-1}) at the water or sediment surface as:

$$F\_CH_4 = k\,(C_0 - C_s)\,\frac{P\,V}{R\,T\,A}, \quad (4)$$

where P (Pa) is the atmospheric pressure, measured with a digital barometer at the site; V the volume of the chamber (m^3), R the universal gas constant (m^3 Pa mol^{-1} K^{-1}), T the temperature inside the chamber (K), and A the surface area of the chamber (m^2).

For N_2O chamber measurements, we calculated the molar concentrations of N_2O (C_{molar_Ch}, µmol m^{-3}), in each sample using a modified gas law, following the procedure described by (Holland et al., 1999):

$$C_{molar\_Ch} = \frac{Cv\ P}{R\ T} \quad (5)$$

where Cv is the concentration (nmol mol^{-1}) of N_2O in the sample, P is atmospheric pressure (Pa), R is the universal gas constant (m^3 Pa mol^{-1} K^{-1}), and T is the air temperature (K) of the chamber. Then, the accumulation rate, C_{rate} (nmol m^{-3} h^{-1}), was determined using the slope of the linear regression fitted to the time points (t, h) collected for each chamber after rejecting outliers in the regressions following the procedure described by (Rey-Sanchez et al., 2018):

$$C_{molar\_Ch}(t) = C_{molar\_Ch}(0) + C_{rate} \times t \quad (6)$$

and with the C_{rate}, we calculated the flux rate (F_N_2O, nmol m^{-2} h^{-1}) as:

$$F\_N_2O = \frac{V\ C_{rate}}{A}\ , \quad (7)$$

where V is the volume of the chamber (m^3), and A the area of the water/sediment surface covered by the chamber (m^2).

We used the coefficient of determination (r^2) of the fit between the model (linear in the case of N2O or non-linear in the case of CH4) and concentration observations in the chamber and a quality control criterion. Flux measurements with $r^2 < 0.8$ were considered of poor quality and were discarded from our analyses to avoid error. Out of the 81 flux measurements for methane and N_2O, 28 for methane and 29 for N_2O, were discarded due to this criterion of poor observation quality.

2.7 Methane conductance and conductivity

249 We used the following general expression to solve for the bulk transfer velocity of methane, or
250 methane conductance (K), at the different beach positions and river water stages assuming that
251 methane is not being produced in the water column:

252 $$F\_CH_{4d} = K\,(C_{sed} - C_{air}\,P\,H^{cp}) \qquad ,for\ F > 0 \qquad (8)$$

253 where F_CH_{4d} is methane the flux measured at each flux chamber but in units of μmol m^{-2} d^{-1} to
254 correspond with the unit convention of conductance. C_{sed} (μmol m^{-3}) is the concentration of
255 methane in the sediments porewater at a given depth and C_{air} (μmol m^{-3}) is the aqueous
256 equivalent of the concentration of methane in the air, calculated as the product of the initial
257 concentration in the chamber (μmol mol^{-1}), P the atmospheric pressure at the moment of
258 sampling (Pa), and H^{cp} the Henry's solubility constant for methane (mol Pa^{-1} m^{-3}). The initial
259 concentration in the chamber, representing the concentration before enclosure, was calculated as
260 the average of the first five measurements of each chamber run.

261 We assume that the overall conductance, K, is the combined result of two transport processes –
262 K_w, the conductance to methane transport in the water from the soil surface to the air, and K_s, the
263 conductance for methane diffusion/transport in the soil from the peak concentration depth to the
264 soil surface. Adding the resistance to methane flux in a sequential process, we obtain the term
265 for the combined conductance K:

266 $$K = \frac{K_w\,K_s}{K_w + K_s} \qquad (9)$$

267 We followed the approach by Bastviken et al., (2004) to independently determine the
268 conductance to methane in the water column K_w for each flux chamber, by solving the equation:

269 $$F\_CH_4 = K_w\,(C_{ss} - C_{air}) \qquad (10)$$

270 where C_{ss} (μmol m^{-3}) is the concentration of methane at the surface of the sediments assumed
271 as the concentration in the first peeper cell.

Substituting eq 9 into eq 8, and using the porewater concentration at the depth of peak concentration in the soil, C_{ps} we obtain an equation for K_s:

$$F\_CH_{4d} = \frac{K_w K_s}{K_w + K_s} (C_{ps} - C_{air}) \quad (11)$$

Equation 11 can be solved using the value we obtained for K_w, from equation (10).

Then we calculated the conductivity (i.e., conductance per unit length) to methane transport/diffusion in the soil (k_s) as:

$$k_s = \frac{K_s}{D_p} \quad (12)$$

Where D_p (m) is the depth at which concentration peaks in the sediment profile.

2.8 Data analysis

We processed data, fit models for flux calculations, and conducted regression tests of porewater concentrations using MATLAB ® 2018b. We used JMP Pro 14.0.0 for all other statistical tests. All the statistical tests were conducted at a 0.05 significance level.

We used Spearman rank correlation to infer the significance of the relationship between average porewater concentrations in the sediment profile and fluxes. We tested the significance of the difference of fluxes and porewater concentrations between water stages for each beach position using paired nonparametric comparisons with the Wilcoxon method. For testing the significance of the differences of water and sediment conductance and sediment conductivity between water stages and within beach positions, we used an ordinal logistic model with the conductances or the conductivity as the response variable, position as a fixed effect and water stage nested by position.

2.9 Data availability

All porewater concentrations and fluxes data will be made available through ESS-DiVE (https://ess-dive.lbl.gov/), DOI pending. Additional ancillary data for the Hanford site is available through the Phoenix – PNNL Environmental Information Exchange (https://www.hanford.gov/page.cfm/PHOENIX).

3. Results and discussion

3.1 Water level and sediment temperature

The water level at the shallow bank position was low (near the sediment surface) during the first part of the year until April when water levels started rising after the spring thaw (Figure 2A). The maximum water levels (> 3 m above the reference elevation, set at the shallow peeper position) were observed in mid-May and were followed by a steadily falling water stage until the beginning of July and remained low during the rest of the year. A brief rising limb in the second half of June was driven by dam water release during the falling stage and coincided with the moment we conducted our sampling. Water levels below the reference elevation were observed during the low stages before the rising stage and after the falling stage. The water level during the low water stage was more variable than during previous stages. The operation of the dam upstream can cause up to 0.5 m variations in water levels within a daily period (Zhou et al., 2018).

Positive hydraulic gradients (downwelling) occurred through the hydrological year, including the time during the rising and falling water stages (Figure 2B, C). However, reversals to the negative hydraulic gradient (upwelling) were frequent during the low water stage. Hydraulic gradient reversal represents groundwater upwelling or moments when the river receives water

from the aquifer. Reversals were also frequent on the days preceding the low water stage sampling (Figure 2D).

Sediment temperature increased throughout the sampling period. In general, mean positions' temperatures had a 10 °C increase between the beginning of the study during the rising water stage in April and the study end in August (Figure 2). Temperatures were similar throughout the different beach positions during the rising and falling stages but differed and were more variable at the low water stage when the water level dropped below the soil surface at the reference level.

3.2 Methane porewater concentration and fluxes respond similarly to river stage variation

Methane flux to the atmosphere is the result of a balance between methane production and consumption and is influenced by the relative importance of the transport pathways, including diffusion, bubbling, and plant transport (Bridgham et al. 2013). At our site, we regard diffusion as the main transport pathway. We did not observe evidence of bubbling in our peeper chamber measurements (i.e., sudden spikes in methane concentration in the time series during chamber deployments). We also neglected the influence of plant transport because macrophyte vegetation was not present near the sampling locations, although a negligible fraction could have been transported from the shallow bank position through the vascular system of some shrubs present on the riverbank. Methane porewater concentrations and fluxes at the 3G site were negligible during the rising water stage when the sediment temperatures were low (~10 ^{o}C, Figure 3A), which is not surprising given the high sensitivity of methane production to temperature (Yvon-Durocher et al., 2014). Methane flux was low at the shallow position during the low water stage as well, when the water level was below the sediment surface (Table 1). Despite relatively higher concentrations in the sediment profile (Figure 3B), the water level dropdown during the low

water stage may have resulted in unsaturated or oxygenated sediments and as a result, a predominantly aerobic environment that would have increased methane oxidation above the water table in the sediment column (Segers, 1998). Indeed, the porewater concentration profile at the shallow position during the low water stage showed very low concentrations throughout the sediment above the water table (Figure 4), consistent with increased methane oxidation coupled to aerobic respiration (Conrad and Rothfuss, 1991) or low methane production due to thermodynamic exclusion (Bethke et al., 2011).

Both methane production and consumption can co-occur in sediments (Le Mer and Roger, 2001) since methanogenic and methanotrophic bacteria can be correlated in terms of population in sediments subject to flooding (Joulian et al., 1997) and the ratio between methanogens to methanotrophs is correlated to methane transfer velocity (Rey-Sanchez et al., 2019). Bednařík et al. (2015) demonstrated that benthic methane fluxes are correlated with porewater concentrations, suggesting that differences between porewater concentrations and surface methane fluxes might be due to the activity of methane-oxidizing bacteria in the upper sediment layers (Oremland and Culbertson, 1992) or the water column (Matoušů et al., 2017). Although we did not systematically measure dissolved oxygen in the sediment-water interface and the water column during our samplings, we conducted a series of surveys for dissolved oxygen levels before sampling. These indicated that both the water column and the porewater at the water-sediment interface were consistently supersaturated, offering optimal conditions for biological methane oxidation. In deeper systems, such as estuaries and reservoirs, methane fluxes are greater at low water levels because of reduced storage turnover times, which is the time methane remains in the water column after being produced in the sediments (Valentine et al., 2001; Zhu et al., 2010; Lei et al., 2019). Lessened turnover times, reduce the time for

potential oxidation while methane diffuses through the water column. Methane oxidation rate in the water column of rivers has been correlated with the concentration of dissolved methane in the water and with water temperature (Matoušů et al., 2018), which are proxies for the substrate and the enzymatic activity of methanotrophic microorganisms. Therefore, we hypothesize that the effect of storage-turnover time on methane oxidation will be effective in rivers, including near-bank shallow waters as well. Future studies coupling methane fluxes, and oxidation rates with simultaneous measurements of methane concentrations in the sediment and water column could help test this hypothesis.

During the falling and low water stages when sediment temperatures were more favorable for methane production, river level had a dissimilar effect on porewater concentrations and fluxes across positions, although in general, methane fluxes were correlated (Spearman's $\rho = 0.62$, $p < 0.001$) and followed the dynamics of the integrated sediment-profile porewater concentrations. Methane porewater concentration and fluxes decreased at the shallow position after the water level transition from the falling to the low water stage, while porewater concentration and fluxes remained similar at the deep position. In contrast, at the intermediate position, methane fluxes increased at the low stage, when the water levels were also low, while the median porewater concentration increased as well, though not at a significant level.

Low or near-zero fluxes accompanied by decreasing methane concentrations towards the surface of the sediments in the shallow position strongly indicate the activity of methanotrophs actively reducing methane emissions to the atmosphere in the upper region of the sediment profile in the shallow position during the low water stage (Figure 4). However, the activity of methanotrophs in the upper layers of the soil profile was not evident at the intermediate or deep positions (that maintained water above the sediment surface). Even during the low water stage of

386 the intermediate position, the peak in methane concentrations occurred well below the sediment
387 elevation. It is possible that reduced downwelling of electron acceptors and oxygen during low
388 water stages not only stimulated heterotrophic production of methanogenic substrates but also
389 limited dissolved oxygen that is toxic to methanogens and reduced aerobic methanotrophic
390 respiration. However, without specific measurements of oxidation rates at our site, it is hard to
391 pinpoint the specific cause of the variability of methane fluxes across the different beach
392 positions and river water stages.

393 Different apparent conductance to methane transport through the water column between falling
394 and low water stages suggests that methane oxidation may occur at different rates depending on
395 the water levels (Figure 5A). Because we did not account for oxidation during transport in the
396 water column, our observations of higher apparent conductance to methane transport may be the
397 outcome of lower oxidation. Differences in conductance to methane transport through the water
398 column were evident in the intermediate position, with larger conductance during the low water
399 stage. In the sediment profile, conductance to methane was not different between falling and low
400 water stages. Nonetheless, there were differences in the apparent conductance to methane in the
401 sediments among beach positions (Figure 5B), suggesting that there may be a significant spatial
402 variation in oxidation rates at the plot scale.

403

404 **3.3 Methane concentrations in porewater peak along an elevation gradient**

405 Similar to surface fluxes, methane concentrations in the sediment profile are the result of a
406 balance between methane production, consumption, and transport to and from the sediment zone.
407 Previous studies at the Hanford Reach in similar sites to ours have shown that hydrological
408 mixing stimulates heterotrophic respiration and organic carbon turnover (Stegen et al., 2016).

Under anaerobic conditions, heterotrophic respiration at the HZ of organic matter would stimulate methane production by producing favored substrates and depleting electron acceptors (Schindler, 1998; Romeijn et al., 2019), whereas under aerobic conditions methane oxidation would be favored (Conrad and Rothfuss, 1991). Complementarily, methane may be imported in the upwelling groundwater as well. Inputs of methane dissolved in groundwater have been observed at low order streams in peat-dominated watersheds (Hope et al. 2001), headwater streams (Jones and Mulholland, 1998), streams in agricultural dominated landscapes (Comer-Warner et al., 2019) and other riverine settings including the Willamette River, the main tributary of the Columbia River (Anthony et al., 2012).

The observed methane porewater concentrations profile in the sediment showed distinct peaks that varied among bank positions following the sediment surface elevation gradient during the falling and low water stages (Figure 4). During the falling water stage, concentrations at the shallow positions peaked at the lower sediment layers (relative sediment depth – RSD: -25 to -40 cm), while at the intermediate position, concentrations peaked at the upper sediment layers (top 20 cm from the sediment surface, RSD: -50 to -70 cm). During the low water stage, concentrations peaked at the lowest depths at the shallow position (around RSD: -50 cm), mid-to-lower depths from the sediment surface at intermediate position (RSD: -80 to -105 cm), and upper sediment layers at the deep position (RSD: -100 to -110 cm). Overall the peaks in methane concentration were observed at upper sediment layers during the falling water stage when the site remained permanently inundated (thick blue line in Figure 4), and at lower sediment layers during the low water stage when the water level was fluctuating around the reference elevation (thick orange line in Figure 4).

The peaks may have resulted from a combination of heterotrophic respiration and imports through groundwater into the HZ from the nearby upland area. Methane and CO_2 porewater concentrations were significantly correlated (Figure 6). Based on the low concentrations of acetate measured in similar sites along the Handford Reach, with only 1/50 samples being above the detection limit (>78 μM), and uncertainty of methyl compound identity and potential utilization (Hou et al., 2017), we infer that the prevailing mode of methanogenesis was hydrogenotrophic, requiring hydrogen and CO_2. However, we acknowledge that this correlation is a function of overall microbial activity, rather than the result of the direct use of CO_2 for methanogenesis alone (Moore and Dalva, 1997; Comer-Warner et al., 2019). Interestingly, we found that the slope of the regression between methane and CO_2 porewater concentrations varied during the three water stages and was larger during the falling water stage when the river downwelling was stronger than during the low water stage when downwelling diminished and groundwater upwelling was more frequent (Figure 6). The difference in the strength of microbial activity between falling water and low water stages support findings by previous studies at adjacent sites along the Hanford Reach that showed a shift in microbial communities as labile organic carbon stimulates heterotrophic respiration during river downwelling periods (Stegen et al. 2016). As water drops and the influence of groundwater upwelling increases, heterotrophic processes of carbon cycling and decomposition succumb to autotrophic processes (Graham et al., 2017).

On the other hand, as groundwater upwelling becomes more frequent during the low water stage and heterotrophic respiration recede (and presumably the production of methane), imports of dissolved methane in the groundwater increase, maintaining similar porewater concentrations than during the falling water stage. This hypothesis is supported by the increase in conductivity

of methane in the sediments we observed at the deep position (Figure 5C), which indicates that during groundwater upwelling, methane transport is faster. We hypothesize that while microbial methane production is reduced when the water level drops and groundwater upwelling is increased, methane concentrations and fluxes are maintained because allochthonous methane is "pushed out" from the surrounding upland soils and river sediments.

We propose that the observed peaks in methane concentration through the sediment profile during the falling water stage occurred at predominantly anaerobic zones, where hydrological mixing of downwelling surface water from the river and upwelling groundwater from the aquifer is enhanced. The predominant zone of methane production moved vertically downward within the HZ as the river transitioned from falling to low water stage, coinciding with a shift from river water dominated to groundwater-dominated mixing ratios.

3.4 Nitrous oxide porewater concentrations and fluxes have different dynamics across river water stages

Unlike methane, N_2O porewater concentrations in the sediment profile and fluxes to the atmosphere did not follow similar patterns throughout the river water stages (Spearman's ρ = 0.29, p = 0.14). N_2O porewater concentrations were higher during the rising water stage than during the falling water stage in all the three beach positions and during the low water stage at the intermediate position (Figure 7A). Instead, N_2O fluxes increased from the rising to the low water stage at the shallow position, while remained similar at the intermediate and deep positions during the three water stages (Figure 7B).

The decoupling between the observed N_2O porewater concentrations in the sediments and the fluxes is not surprising. N_2O production in large rivers might occur primarily at the water column

in microsites within suspended particles. There is significant evidence of substantial N_2O production via denitrification in pelagic zones of estuaries (Barnes and Owens, 1999; de Wilde and de Bie, 2000). Beaulieu et al. (2010) presented evidence of a similar pattern at a large river, with N_2O production rates in the water column doubling that of the sediments, which could help explain the lack of correlation between the porewater concentrations and fluxes. Marzadri et al. (2014) and Marzadri et al. (2017) explained that in lotic systems there is a shift in the predominant zones of N_2O production from the hyporheic-benthic zone in streams to the benthic-water column zone in rivers as the system gains size, due mainly to the increase in suspended particle loads.

Notably, we observed negative fluxes throughout the different river water stages and in all positions, which is consistent with high rates of N_2O consumption at either the sediments or the water column. Our plot acted primarily as a sink at the shallow position while the sediments were fully saturated, and the water level was above the sediment surface and on the intermediate position during the low water stage when the water level at this position was low as well (Figure 7A). N_2O is often produced as an intermediate species of microbially mediated denitrification, or a byproduct of nitrification or reduction of ammonia to nitrate (Quick et al., 2019). Dissolved organic carbon in the HZ plays a critical role in fueling nitrification under aerobic conditions (Graham et al., 2016; Graham et al., 2017) and in addition, may lead to low oxygen and nitrate conditions that ultimately favor N_2O consumption (Soued et al., 2015). Low oxygen conditions may result from the low flow as well (Baulch et al., 2011b), which prevailed in the 3G observatory, especially at lower water levels, explaining the dominant sinking functioning of the shallow and intermediate positions partially. It may also be possible that atmospheric nitrous oxide consumption occurred in the water column in the absence of other denitrification

processes, which has been demonstrated only for a few model microorganisms and ecosystems (Jones et al., 2014; Yoon et al., 2016).

A more robust understanding of the nexus (or lack thereof) of the spatial heterogeneity and dynamics of N_2O porewater concentrations and fluxes must build upon the synergistic effects of the seasonal hydrological exchanges, inorganic nitrogen availability, and the activity of the microbial community involved in cycling nitrous oxide at the HZ and the water column. For instance, the nitrification and denitrification functional potential of microbial communities in the HZ of the Hanford Reach (and possibly many other lotic systems) are linked with the ratio of groundwater to surface water, likely due to the input of N in the groundwater (Nelson et al., 2019). However, it is still not clear if or how the dynamics of groundwater N or other environmental drivers are affecting the N-cycling functional potential in the water column and overall how N_2O is produced and consumed in the sediment-water column continuum.

3.5 Nitrous oxide concentrations peak at the sediment/water table interface

Mathematical and conceptual models propose that N_2O production at the HZ is maximized along flowlines representing intermediate travel times of downwelling surface water, which are usually few cm below the sediment surface (Reeder et al., 2018; Quick et al., 2016). At shallower depths, at the surface of the sediments (i.e., shortest travel times), nitrate is not transformed, whereas at deeper depths (i.e., longest travel times), denitrification is completed and N_2 is the predominantly released gas. The N_2O porewater concentrations we observed at the 3G are consistent with the modeling predictions, showing increased concentrations at the proximity of the sediment/water table interface (~ up to 15 cm) (Figure 8).

We found significant negative correlations between N_2O and CO_2 porewater concentrations for pooled data from the three water stages and the shallow and intermediate beach positions (Figure 9). We cannot discern whether the correlation is the result of N_2O production or consumption. Partial denitrification, nitrate reduction to N_2O, is coupled to carbon oxidation to CO_2 and therefore, we would expect a positive correlation (Tsuruta et al., 1997). Therefore, N_2O production appeared decoupled from denitrification and more closely tied to other processes. The negative correlations could be explained by the release of N_2O during nitrification coupled to CO_2 assimilation or heterotrophic microorganisms utilizing N_2O as a terminal electron acceptor (Hink et al., 2017; Lycus et al., 2018). This may help explain the negative correlation between N_2O and CO_2 porewater concentrations, which were also seen in observations of other riverine settings (Richey et al., 1988; Teodoru et al., 2015). However, we do not rule out that simultaneous processes of production and consumption are co-occurring and that their relative importance change as the river water level transitions and substrates, environmental conditions, and the relative diversity and abundance of N-Cycling populations vary (Nelson et al., 2019). The decoupling between N_2O and CO_2 may be explained as well at some degree by lateral transport of N_2O dissolved in groundwater (Clough et al., 2006).

It is noteworthy that the strength of the correlation between N_2O and CO_2 porewater was dictated by beach positions, indicating that different processes are occurring between locations. Weaker negative correlations at the shallow position may be explained by contributions of both nitrification byproducts and denitrification, N_2O consumption as an electron acceptor in the absence of other denitrification processes, and labile carbon oxidation, or the increased contributions from heterotrophic denitrifications. Coupling inorganic nitrogen concentrations and

organic carbon concentration measurements should help unveil the prevalence of these processes and their influence in the observed variability between beach positions.

4. Conclusions and outlook

Hyporheic zones of rivers and streams are important hotspots of greenhouse gas emissions. The interaction of river stage and biogeochemical processes govern the production, consumption, and flux dynamics. This interaction of the governing factors results in high heterogeneity at the small scale (m to cm) in horizontal and vertical planes. At the plot scale, methane porewater concentrations have a marked vertical temporal dynamic with concentrations peaking at different depths depending on the influence of the magnitude and direction of hyporheic mixing. Methane fluxes followed the dynamics of porewater concentrations throughout the river water stages but highlighted the potential influence of oxidation in the resulting fluxes. Hence the need for sub-models capable of representing the potential effects of hydrological exchanges on methane oxidation in the HZ. The effect was pronounced for the intermediate position where methane fluxes increased (and the conductance to methane in the water column) from the falling water stage to the low water stage. In turn, N_2O porewater concentrations rely more on the permanent mixing at the HZ and occur at the upper layers just below the sediment surface. Contrary to methane, fluxes of N_2O were not correlated to porewater concentrations and were reduced at low water elevations, possibly because of the release of N_2O as a byproduct of aerobic nitrification or the use of N_2O as an alternative terminal electron acceptor to oxygen for microbial respiration at the sediment-water interface (Khalil et al., 2004; Jones et al., 2014). Overall results indicated that the plot functioned as a net source of methane and could function as either a sink or source for N_2O depending on both the season and position within the riparian zone. Therefore, identifying

567 the potential nexus between N_2O production and consumption and concurrency at the HZ
568 represents a critical challenge for better representation of the N_2O dynamic in biogeochemical
569 models.
570 Here we presented snapshots of detailed vertical profiles and surface fluxes of methane and
571 N_2O porewater concentrations through the different typical hydrological stages of a large-
572 regulated river. As our results indicate, river stages and consequent groundwater mixing, drive
573 the dynamics of porewater concentrations and fluxes of methane and N_2O on a seasonal scale.
574 However, coupling hydrological dynamics with methane and N_2O concentrations and fluxes at
575 small scales and parametrizing the governing processes will require longer-term and more
576 frequent assessments, especially the inclusion of measurements at a small temporal scale (days-
577 hours). Such a scale is of particular interest to assess the effects of large intra-daily water level
578 oscillations, which are characteristic of regulated rivers, on the GHG production and
579 consumption processes. This daily/sub-daily measurement scale could help to elucidate the
580 effects of preceding environmental conditions set by previous water levels (including microbial
581 populations, temperature, nutrient availability and transformations, and redox conditions) on the
582 production and consumption of GHGs. In non-regulated rivers, we would expect a similar
583 control of seasonal groundwater mixing than the one we observe here. However, in contrast to
584 regulated rivers, the shorter-term effects of preceding environmental conditions would likely be
585 less dramatic given the lower water intra-daily fluctuations.
586 Finally, as our results indicate, GHG concentration and fluxes can be significantly different
587 across small horizontal (6 m W × 11 m L) and vertical (0.5 m) spatial scales. Moreover, water
588 level fluctuation has a significant effect on the functioning of the HZ as a sink or source of
589 methane and N_2O. The coupling of hydrology and GHGs emissions at small scales will,

therefore, be essential to help parametrize and calibrate predictive models in large rivers like the Columbia River and other rivers and streams as well. More importantly, it is a necessary task to test hypotheses discerning the microbial processes explaining the spatiotemporal heterogeneity of methane and N_2O at the HZ.

Tables

Table 1. Mean water levels (m) along three beach positions at the Columbia River during samplings of porewater concentrations and fluxes of methane (CH_4) and N_2O under three different river water stages.

Sampling	Position		
	Shallow	Intermediate	Deep
Rising water stage (porewater & fluxes)	0.46	1.00	1.44
CH_4 fluxes	0.50	1.04	1.48
N_2O fluxes	0.61	1.15	1.60
Falling water stage (porewater & fluxes)	0.78	1.32	1.76
CH_4 fluxes	0.83	1.37	1.82
N_2O fluxes	0.50	1.04	1.49
Low water stage (porewater & fluxes)	-0.28	0.26	0.70
CH_4 fluxes	0.83	1.37	1.82
N_2O fluxes	-0.81	-0.27	0.18

List of figures

Figure 1. Experimental design. (A) Peeper array at the 3G observatory and river and groundwater monitoring at the 300 Area, Hanford reach, Washington State. (B) Diagram depicting the general sampling design and (C) the conventions used throughout the manuscript. The transect marked in red in (A) denotes the transect where sediment temperatures were measured.

Figure 2. Hydrological conditions during the study period (4/24 to 8/25 2018). (A) River water levels (dark blue), sediment temperature (red lines), and sampling periods (vertical bars with different colors). (B – D) River water levels (dark blue) and hydraulic gradient (light blue) during each river stage sampling, including the five preceding days of each sampling. The horizontal dashed line indicates the reference elevation (sediment surface at the shallow position – left axis) and the zero hydraulic gradient (right axis). Water levels above the horizontal line represent water above the sediment surface. Hydraulic gradients above that line represent river dowelling, whereas values below the line represent groundwater upwelling. At each river stage sampling, we sampled peepers first (2 days), then methane (few hours during the next day) and N_2O (few hours during the following day), as indicated by vertical gray bars (which are labeled in (B) for clarification).

Figure 3. (A) Integrated sediment-profile methane porewater concentrations and (B) methane fluxes along a beach transect (plot scale) at the 3G observatory during three river water stages. Boxes represent the 25^{th} and 75^{th} percentiles, the horizontal black line the median, circles mark outliers, defined as observations that are 1.5 greater than the upper interquartile range.

Whiskers extend to the furthest observation not considered an outlier. Letters represent statistical differences calculated with non-parametric Wilcoxon paired tests for each position (α = 0.05).

Figure 4. Methane porewater concentrations on the sediment profile at shallow (left), intermediate (middle), and deep (right) positions of a beach transect (plot scale) at the Columbia River during three river water stages. Data points (circles) represent the mean concentration, and the error bars the standard error (n=3). Horizontal blue areas indicate the water level range during the different water stages. Thick transparent color lines indicate an elevation gradient in the peaks of methane concentrations during the rising water stage (blue) and the low water stage (orange). The thick brown line represents the beach elevation along the gradient.

Figure 5. Methane conductance in the water column and sediments (A and B), and methane conductivity (i.e., conductance per depth) in the sediments (C) along a beach transect (plot scale) at the Columbia River during falling and low river water stages (during the rising water stage fluxes and porewater concentrations were negligible). Boxes represent the 25^{th} and 75^{th} percentiles, the horizontal black line the median and circles outliers defined as observations that are 1.5 greater than the upper interquartile range. Whiskers extend to the furthest observation not considered an outlier. Capital letters indicate differences between beach positions and lowercase letters, differences between river water stages with positions.

Figure 6. Correlations between methane and CO_2 porewater concentrations on sediment profiles of a beach transect (plot scale) at the Columbia River during three river water stages. Dotted

lines accompanying the regression lines represent the 95% confidence intervals. The correlation is stronger during the falling water stage.

Figure 7. (A) Integrated sediment-profile methane porewater concentrations and (B) N_2O fluxes along a beach transect (plot scale) at the Columbia River during three river water stages. Boxes represent the 25^{th} and 75^{th} percentiles, the horizontal black line the median and circles outliers defined as observations that are 1.5 greater than the upper interquartile range. Whiskers extend to the furthest observation not considered an outlier. Letters represent statistical differences calculated with non-parametric Wilcoxon paired tests for each position ($\alpha = 0.05$).

Figure 8. N_2O porewater concentrations along the sediment profile at shallow (left), intermediate (middle), and deep (right) positions of a beach transect (plot scale) at the Columbia River during three river water stages. Data points (circles) represent the mean concentration, and the error bars the standard error (n=3). Horizontal blue areas indicate the water level range during the different water stages. The thick brown line represents the beach elevation along the gradient.

Figure 9. Correlations between N_2O and CO_2 porewater concentrations along sediment profiles of a beach transect (plot scale) at the Columbia River during three river water stages. Dotted lines accompanying the regression lines represent the 95% confidence intervals. Note that the correlation is not significant for the deep position (gray markers). The overall correlation for data of all positions (not shown) is also significant (slope = -2.97, $r^2 = 0.065$, $p < 0.01$).

Table 1. Mean water levels (m) along three beach positions at the Columbia River during samplings of porewater concentrations and fluxes of methane (CH_4) and N_2O under three different river water stages.

Sampling	Position		
	Shallow	Intermediate	Deep
Rising water stage (porewater & fluxes)	0.46	1.00	1.44
CH_4 fluxes	0.50	1.04	1.48
N_2O fluxes	0.61	1.15	1.60
Falling water stage (porewater & fluxes)	0.78	1.32	1.76
CH_4 fluxes	0.83	1.37	1.82
N_2O fluxes	0.50	1.04	1.49
Low water stage (porewater & fluxes)	-0.28	0.26	0.70
CH_4 fluxes	0.83	1.37	1.82
N_2O fluxes	-0.81	-0.27	0.18
