22

23 Abstract

24 The distribution of Rare Earth elements (REE) in coal-derived fly ashes can have  
25 distinctive patterns when fly ashes are produced from different coals within or between basins,  
26 such as the Pennsylvanian Class F fly ashes from the Illinois and Central Appalachian basins.  
27 Both the Fire Clay coal and a blend of a number of eastern Kentucky coals show strong Gd peaks  
28 and an H-type distribution in the Upper Continental Crust-corrected plots. The Fire Clay coal-  
29 derived ash has a higher heavy REE concentration than the blended coal-derived ash. The  
30 Illinois Basin-derived fly ash has an overall lower REE concentration than the latter ashes. Class  
31 C fly ash derived from Powder River Basin coals has, with the exception of an Eu peak, a flatter  
32 distribution of REE and an overall L-type or indistinct H- versus L-type distribution. The  
33 signatures of the REE in fly ashes may be useful in predicting their behavior in the extraction of  
34 the REE; simple extrapolations from the basic concentrations and the predicted extraction  
35 percentages for ashes from different basins are not necessarily indicative of the actual  
36 distribution of the extracted REE.

37

38 Keywords: lanthanides; heavy rare earth elements; fly ash beneficiation; rare earth processing

39  
40

## 1. Introduction

41 Rare earth elements (REE) are vital in the production of electronics, magnets, catalysts,  
42 optics, ceramics, and other products necessary for the functioning of modern society.<sup>1-7</sup> Albeit a  
43 moving target, based on a combination of their utilization needs versus their overall abundance,  
44 certain REE can be more critical (versus “excessive”). Coal combustion products, including, but  
45 not restricted to fly ash, are among the resources considered to be potential sources of  
46 lanthanides, Sc, and Y.<sup>8-12</sup> With over 29 Mt of fly ash (out of more than 78 Mt of coal  
47 combustion products) produced in the US in 2019,<sup>13</sup> plus the landfilled and ponded ashes from  
48 previous years, the resource potential is large. While there is potential to beneficiate fly ash to a  
49 relatively uniform material for the acid extraction of REE,<sup>14-31</sup> beneficiation alone does not  
50 resolve issues related to the basic elemental concentrations of the original ash, much less the  
51 natural variation in the relative concentrations of the elements.

52 In this investigation, selected case studies of fly ashes derived from Central Appalachian  
53 and Powder River Basin coal sources are examined from the standpoint of the distribution of the  
54 REE within the ashes. Illinois Basin coal sources were covered by Hower et al.<sup>32</sup> and will be  
55 briefly noted here. The discussion of the other basins expands upon the work of Taggart et al.<sup>33</sup>  
56 (first full paragraph on p. 5923 and Fig. S5 in the Supplementary Information). Specifically,  
57 with a focus on the shift in the Central Appalachian coal supply in one plant and a broader view  
58 of the entire suite of major oxides and minor elements in the sources from both basins, a greater  
59 understanding of the REE distributions can be achieved.

60

## 2. Methods

61

### 2.1 Nomenclature surrounding Rare Earth Element distributions

62 In this study, the lanthanide elements are referenced as REE and the addition of Y and Sc to  
 63 the REE is designated as REY and REYSc, respectively. REE nomenclature can vary between  
 64 users; for this study, light rare earth elements (LREE) include La through Sm and the heavy rare  
 65 earth elements (HREE) include Eu to Lu.<sup>34-37</sup> The Upper Continental Crust (UCC) corrections, a  
 66 means of normalizing the REE distributions, after McLennan and Taylor<sup>38</sup> are:

- 67 • L-type ( $La_N/Lu_N > 1$ ;  $_N$  indicates a value corrected against a standard distribution,  
 68 such, in this study, as the Upper Continental Crust),
- 69 • M-type ( $La_N/Sm_N < 1$ ,  $Gd_N/Lu_N > 1$ ), and
- 70 • H-type ( $La_N/Lu_N < 1$ ) enrichment patterns.

71 The following ratios, all based on the UCC corrections, decouple Ce, Eu, and Gd from the other  
 72 REE in the distribution patterns<sup>37, 39-41</sup>:

$$73 \quad Eu_N/Eu_N^* = Eu_N / (0.67Sm_N + 0.33Tb_N) \quad (1)$$

$$74 \quad Ce_N/Ce_N^* = Ce_N / (0.5La_N + 0.5Pr_N) \quad (2)$$

$$75 \quad Gd_N/Gd_N^* = Gd_N / (0.33Sm_N + 0.67Tb_N) \quad (3).$$

76

## 77 2.2. Sample and Data Collection

78 Every five years from 1992 to 2012, the University of Kentucky Center for Applied  
 79 Energy Research (CAER) sampled the feed coal (in most cases, the pulverized feed coal),  
 80 pulverizer rejects, fly ash, bottom ash, and flue-gas desulfurization products at all of the utility-

81 based power plants in Kentucky. Up to 22 utility-based coal-fired power plants with 61 units  
82 were in operation in the state, although not all were operating at the same time. More limited  
83 collections were made in the off years for various research projects. For all post-2000  
84 collections, fly ash was obtained from multiple rows (including cyclone (mechanical),  
85 baghouse/fabric filter (FF), and electrostatic precipitator (ESP) systems) and from multiple ash-  
86 collection hoppers in each row; an effort was made to sample the same hoppers every time. The  
87 2007 and 2012 results are discussed by Hower et al.<sup>42-43</sup> and the partitioning of select elements  
88 between the pulverized feed coal and the fly ash is discussed in Hower et al.<sup>44</sup> Rather than  
89 identify power plants in publications, a letter code system was developed in 1992 at the start of  
90 the collection efforts.

91 The samples investigated here represent select units burning Appalachian, Illinois Basin,  
92 and Powder River Basin (PRB) coals, with an emphasis on Kentucky power plants. Power  
93 plants from Georgia, Texas, and Missouri were added in order to broaden the coverage of PRB-  
94 derived fly ashes. The complete data set for the Appalachian and PRB samples is in the  
95 Supplementary Information and the Illinois Basin data is in the Supplementary Information  
96 associated with Hower et al.<sup>32</sup>

97 The proximate, heating value, and sulfur forms analyses of the feed coals and the ultimate  
98 analysis and major oxides and select minor elements, both done by X-ray fluorescence,  
99 determinations were performed at the CAER following the ASTM standards for the various  
100 techniques. The details of the HF-digestion REE analysis are presented in detail in Taggart et  
101 al.<sup>33</sup> The analyses were conducted by via inductively coupled plasma mass spectrometry (ICP-  
102 MS, Agilent 7700x) at Duke University.

### 103 3. Results and discussion

104 The concentration of REE varies between coal seams<sup>45-48</sup> and between coal-bearing  
105 basins. At a finer scale, as demonstrated by the latter authors, REE varies between locations  
106 across the extent of a coal deposit and, potentially, even more between lithotypes of the same  
107 coal. Owing to the relative impact of the multiple modes of emplacement and redistribution of  
108 REE, the relative concentrations of the REE may vary at all of the noted scales. There is no  
109 reason to expect that a discrete depositional event would have impacted any more than one coal.  
110 For example, the deposition of the REE-rich volcanic ash within the Central Appalachian Fire  
111 Clay coal did not influence any other Central Appalachian coal and, indeed, like any wind-blown  
112 deposit, the thickness and nature of the ash fall varies across the extent of the Fire Clay coal and  
113 the influence of the ash-fall event is not seen throughout the entire coal at any of the sites  
114 studied.<sup>36, 45-46</sup>

#### 115 3.1 Illinois Basin-coal-derived fly ashes

116 Hower et al.<sup>32</sup> discussed fly ashes from the combustion of high-S, high volatile C through  
117 high volatile A bituminous Illinois Basin coals. They emphasized the variation among the fly  
118 ashes from the power plants in their study, demonstrating that variations in the coal source  
119 certainly account for the variations between the plants and the collection times and that coals  
120 from different parts of the basin or even different proportions of the same coals could lead to  
121 different patterns. Despite the differences in the relative concentrations, all the patterns showed  
122 a general similarity, including high Gd concentrations and the overall H-type distributions.  
123 Relatively high Gd concentrations have been seen in several fly ashes, for example, the Fire Clay  
124 coal-derived fly ash discussed in section 3.2 and fly ashes beneficiated for chemical extraction.<sup>27,</sup>

125 <sup>47</sup> The latter two studies demonstrated that the magnetic fraction of the fly ash is particularly  
126 enriched in Gd. In that context, high Gd concentrations in fly ashes from medium- to high-S  
127 coals, with relatively high contributions of pyrite in the mix of minerals, are logical since  
128 magnetite and other Fe-rich spinels are formed in the breakdown of pyrite at the 1400-1500°C  
129 boiler temperatures.

### 130 3.2 Different Central Appalachian coals combusted at the same plant

131 Plant I, a two-unit southeastern Kentucky power plant, was sampled many times over the  
132 course of the University of Kentucky CAER's studies. In normal operations, a blend of  
133 southeastern Kentucky and northern Tennessee low- to medium-S, high volatile A bituminous  
134 coals is burned in both units. Sakulpitakphon et al.<sup>49-50</sup> arranged a single-seam, single-mine run  
135 of the Manchester coal, Mardon and Hower<sup>36</sup> arranged a similar run of the Dean coal (a Fire  
136 Clay correlative), and Hood et al.<sup>51</sup> sampled the fly ash from an exclusive run of the Fire Clay  
137 coal. Using the UCC-corrected values for the fly ashes, the latter 2014 sampling from unit 1 is  
138 compared with the 2007 sampling of blended-coal-derived fly ashes (Figure 1; after Hower et  
139 al.<sup>32</sup>). The average total REE is 430 ppm for the blended coal-derived fly ashes and 622 ppm for  
140 the Fire Clay-derived ashes. Mardon and Hower<sup>36</sup> reported an approximately 1000-1400-ppm  
141 range for Fire Clay-derived fly ashes from unit 1 at the same power plant.<sup>footnote 1</sup> In contrast to  
142 the fly ash from the combustion of the blended coals, the fly ash from the combustion of the Fire  
143 Clay coal has a negative  $Eu_N$  anomaly and a sharp positive  $Gd_N$  peak.

144 The contrast between the two runs is further emphasized in the plots of the  $Gd_N/Gd_N^*$  vs.  
145  $Eu_N/Eu_N^*$  (Figure 2),  $Ce_N/Ce_N^*$  vs.  $Eu_N/Eu_N^*$  (Figure 3), and  $Nd_N/Sm_N$  vs.  $Gd_N/Sm_N$  (Figure 4; all

---

<sup>1</sup> By the time of the 2014 sampling,<sup>51</sup> the configuration of unit 2 had changed and it was no longer possible to sample fly ash from that unit.

146 data in Supplementary files); in both cases the two sets of fly ash are shown to be distinctly  
147 different, confirming the distributions seen on Figure 1. The  $Gd_N/Gd_N^*$  vs.  $Eu_N/Eu_N^*$  and  
148  $Ce_N/Ce_N^*$  vs.  $Eu_N/Eu_N^*$  plots were used previously in geologic evaluation of coals.<sup>42</sup> The  
149  $Gd_N/Gd_N^*$  seen in this study compares favorably with the distribution seen in the latter study, the  
150  $Ce_N/Ce_N^*$  range is limited to the low end of their range, while the  $Eu_N/Eu_N^*$  values correspond to  
151 the high end of their distribution, although it is noted that Hower et al.<sup>46</sup> were examining  
152 specific coal and rock lithologies, not the entire coal bed and not fly ash derived from the coal.  
153 While the  $Gd_N/Gd_N^*$ ,  $Ce_N/Ce_N^*$ , and  $Eu_N/Eu_N^*$  are not strictly unique to a certain coal source, they  
154 do convey information about the coals.

155 The  $Nd_N/Sm_N$  vs.  $Gd_N/Sm_N$  convention has been used in an evaluation of the partitioning  
156 of REE in the beneficiation<sup>27</sup> and subsequent chemical processing of fly ashes.<sup>52</sup> Because, at  
157 least in the pilot study, the Sm concentration was relatively unchanged between the feed ash, the  
158  $HNO_3$ -extracted ash, and the spent ash, Sm was used to normalize the concentrations of Nd and  
159 Gd, two of the REE exhibiting greater variations. The plotted points (Figure 4) represent the  
160 baseline for a contrast of a feed ash (these samples) against the REE concentrate extracted from  
161 the ash and the spent ash following the chemical REE extraction (note, the latter material is not a  
162 “waste” or “refuse” since every product stream has the potential to be the feedstock for further  
163 processing or a direct input stream for utilization).

164 Both sets of fly ashes exhibit H-type REE distributions, although the Fire Clay-derived  
165 fly ash has a relatively higher concentration of heavy REE vs. light REE than the fly ash from  
166 the blended coals. Aside from the  $Eu_N$  and  $Gd_N$  anomalies, the REE distribution patterns from La  
167 through Sm and Tb through Lu are basically parallel.

### 168 3.3 Powder River Basin subbituminous coal sources

169 Particularly in the time before flue-gas desulfurization was required for power plants (the  
170 Cross-State Air Pollution Rule (CSAPR))<sup>53</sup>, power plants in several midwestern states, but also  
171 including Kentucky and Texas, began to burn low-S PRB coals in order to meet the SO<sub>2</sub>-  
172 emission standards. So, despite the abundant coal resources in those states, subbituminous PRB  
173 coal are utilized and the resultant fly ashes continue to be accumulated in these regions.

174 Dai et al.<sup>37</sup> noted that the analysis signal for <sup>153</sup>Eu via inductively coupled plasma mass  
175 spectrometry overlaps with the signals for barium oxide polyatomic species  
176 (<sup>137</sup>Ba<sup>16</sup>O, <sup>136</sup>Ba<sup>17</sup>O, <sup>135</sup>Ba<sup>18</sup>O, and <sup>134</sup>Ba<sup>18</sup>OH). If samples with Ba/Eu > 1000 (mass basis),  
177 slightly more than 3X the world average for Ba/Eu,<sup>54</sup> are flagged as unreliable for the  
178 interpretation of Eu anomalies,<sup>37, 55</sup> most of the PRB-derived fly ashes in this study would be  
179 problematical. All but two PRB-derived samples in this study have Ba/Eu < 1000 and one of the  
180 two is >3X the world average (Supplementary Information, Ba and Ba/Eu data in columns CW  
181 and CZ, respectively). The distribution of Eu<sub>N</sub> vs. Ba/Eu for the PRB-derived samples show  
182 disparate trends (Figure 5). Plant G, with a common coal source for all the fly ashes, shows an  
183 increase in Eu<sub>N</sub> with an increase in Ba/Eu. By themselves, the other five plants show an increase  
184 in Eu<sub>N</sub> with a decrease in Ba/Eu. The variation is understandable since each of the other points  
185 represents with an individual plant or a different acquisition time for the same plant; sources vary  
186 between plants, with the coals potentially coming from different mines within the PRB, and,  
187 even with the same mines supplying the coal, through time the variation is expected.

188 **Figure 6** shows the UCC-corrected REE concentrations for several power plants burning  
189 Powder River Basin subbituminous coals. The average REE for the fly ashes plotted on **Figure 6**  
190 is 281 ppm. The most striking aspect of the UCC plot is the sharp Eu peak for all of the ashes  
191 except the Plant G/ mechanical (cyclone) ash. Except for the Eu peak, this is a much more even  
192 distribution than the Central Appalachian (**Figure 1**) distributions. As noted above, though,  
193 owing to the high Ba/Eu in most of the ashes, all but the data for the Plant G/ mechanical ash is  
194 suspect, so the REE distributions are flatter than the data would suggest. The ashes have L-type  
195 to indistinct H-type vs. L-type distributions. The plot of  $Nd_N/Sm_N$  vs.  $Gd_N/Sm_N$  (**Figure 7**) shows  
196 a relatively tight distribution for Plant G compared to the other fly ash sources. Owing to the  
197 complications imposed by the Ba interferences in the Eu determination, the  $Gd_N/Gd_N^*$  vs.  
198  $Eu_N/Eu_N^*$  and  $Ce_N/Ce_N^*$  vs.  $Eu_N/Eu_N^*$  plots are not considered for the PRB-derived fly ashes.

### 199 3.4 Discussion

200 While it is well established that various types of fly ash, both ashes from coals within and  
201 between basins, can have different REE concentrations, there has been less discussion about the  
202 differences in the REE distributions between fly ashes. The REE-distribution signatures seen in  
203 the examples discussed here have some distinct aspects, whether it is the relative concentration  
204 of heavy versus light REE; the concentrations of individual elements, such as Eu or Gd; or the  
205 ratios of the elements. Just as much as the relative extraction of REE from the fly ashes, as noted  
206 in the Introduction, all the latter aspects contribute to the relative values of an ash. For example,  
207 the Fire Clay coal-derived fly ashes have a higher percentage of critical REE than the PRB coal-  
208 derived ashes (**Supplementary Information**; after definitions by Seredin and Dai<sup>56</sup>) while the PRB  
209 ashes are more easily extracted.<sup>20, 22</sup> Just considering the critical REE concentrations of the

210 Central Appalachian- (*not* including the Fire Clay coal-derived ashes), Illinois Basin-, and PRB-  
211 coal derived fly ashes along with the approximate HNO<sub>3</sub>-extractable REE for each fly ash type,<sup>33</sup>  
212 the PRB and Central Appalachian fly ashes are both in the 75- to 80-ppm range while the Illinois  
213 Basin fly ashes were in the 50- to 55-ppm range. The caveat is that the number of sources for  
214 each basin were limited, therefore, this is only an approximation of the recovery of critical REE.  
215 Such balances between the percent of economically extractable REE versus the value of the  
216 recovered REE need to be addressed in the evaluation of REE-processing tests.

217         The relative mineralogy of the coals and the resultant ashes, while not directly addressed  
218 here, is an underlying factor in the variation between the ashes. While many of the REE-bearing  
219 minerals and, perhaps, amorphous phases in fly ash appear to be finely (few-nm to sub-nm) or  
220 heterogeneously dispersed in glass,<sup>47, 51, 57-62</sup> a few minerals have been noted. Aside from the  
221 common occurrences of minerals such as monazite, high resolution transmission electron  
222 microscopy (HRTEM) studies by Hower et al.<sup>58</sup> noted variations of the proportions of Ce, Nd,  
223 Pr, and Sm in a fly ash glassy phase from a Fire Clay coal-derived fly ash. A Ce-rich phosphate  
224 was found in a high-REE stoker ash.<sup>57</sup> Lanthanum-, Ce-, and Nd-bearing monazite; Y-bearing  
225 zircon; and La- and Ce-bearing davidite (with trace Nd and Y) (Figure 8) were found in a stoker  
226 ash from a possible Fire Clay coal source.<sup>58</sup> Resolution of REE-bearing minerals in the PRB fly  
227 ashes has proven to be more elusive. Figure 9 (after the study by Hood et al.<sup>51</sup>) shows a Ca-Mg-  
228 Al-Si sphere (Figure 9A) with no apparent REE (Figure 9B) and a solid sphere with Nd L $\alpha$  and  
229 L $\beta$  peaks and the Pr L $\beta$  peak (Pr L $\alpha$  would be in the Ba – Nd L $\alpha$  region). If Ce is present, it is  
230 obscured in the Ba L $\beta$  (the higher keV Ba peak) and the Nd L $\alpha$  peaks.

231           Ultimately, the energy dispersive spectroscopy (EDS) resolution of heavier even-number  
232 REE is difficult; for example, in an HRTEM study <sup>footnote 2</sup> of the REE-bearing phosphate  
233 rhabdophane in an eastern Kentucky coal, Gd could be determined with certainty but the Dy  
234 concentration did not meet the standard of the peak being three-times the background and neither  
235 Er nor Yb were detectable above the background.<sup>63</sup> It is possible, given the limitations of the  
236 ultra-fine mineral sizes and the vanishing resolution of lower-concentration REE elements, the  
237 descriptions of the distribution of REE within fly ash will remain in the realm of the bulk  
238 chemistry of the samples.

#### 239           4. Summary

240           For Central Appalachian coal-derived fly ashes, comparison of the fly ash from a blend  
241 of coals versus the Fire Clay coal, a coal known to be a REE resource, shows that the fly ashes  
242 have parallel REE-distribution patterns from La through Sm and Tb through Lu. The Fire Clay-  
243 derived fly ash shows a negative Eu anomaly and a strong Gd peak compared to the blended coal  
244 ash. Both are H-type ashes, with the Fire Clay fly ash have a greater proportion of heavy REE  
245 compared to the blended coal ash. In contrast, the previously investigated Illinois Basin coal-  
246 derived fly ashes,<sup>32</sup> in general, have a lower concentration of the lanthanides (about 350 ppm vs.  
247 over 400 ppm for the Central Appalachian blend-derived fly ashes and over 600 ppm for the Fire  
248 Clay coal-derived fly ash studied here and 1000-1400 ppm for the Fire Clay coal-derived fly  
249 ashes studied by Mardon and Hower<sup>36</sup>). The Illinois Basin coal-derived fly ashes have relatively  
250 high Gd concentrations and an overall H-type distribution.

---

<sup>2</sup> FEI Talos F200X operating at 200 keV, operated by University of Kentucky Electron Microscopy Center.

251 With the exception of a strong Eu peak, which, as noted, is likely to be an anomaly  
252 related to the high-Ba content of the PRB ashes, the Class C PRB coal-derived fly ashes studied  
253 here show a substantially more muted REE distribution than the Class F Central Appalachian and  
254 Illinois Basin coal-derived fly ashes. The REE pattern shows L-type to indistinct H-type vs. L-  
255 type distributions. The  $Gd_N/Gd_N^*$  vs.  $Eu_N/Eu_N^*$ ,  $Ce_N/Ce_N^*$  vs.  $Eu_N/Eu_N^*$ , and  $Nd_N/Sm_N$  vs.  $Gd_N/Sm_N$   
256 plots show a clustering of the points for Kentucky Plant G. This is not a surprise since a  
257 common coal source was used to produce all of those ashes. In contrast, while the other fly  
258 ashes all were the product of the combustion of PRB coals, the broader elemental distributions  
259 were the consequence of coal deliveries from different mines or, at least, different times than the  
260 coal deliveries to Plant G.

261 Overall, the signatures of the REE distributions are immutably the consequence of the  
262 different and varying modes of emplacement of REE into coals.<sup>45-46, 56</sup> Coals from the same basin  
263 might have similar patterns, but differences, however subtle, in the patterns are the rule. An  
264 extraordinary event, such as the volcanic ash deposit (tonstein) in the Fire Clay coal, might not  
265 be repeated in volume, distribution, or at all in any other coal in the basin. There is no reason to  
266 expect that another coal bed at the same location would be equally enriched, and, without the  
267 proper level of exploration, there is no justification to extrapolate results, good or bad, from one  
268 location to another within the same coal bed. As with most other elements, the concentrations of  
269 REE in the fly ash are the product of the input coals with the modification of the combustion and  
270 ash-collection systems. During the combustion process, the lanthanides present within coal will  
271 partition exclusively to the fly ash and bottom ash at a coal-burning power plant.<sup>64-65</sup>  
272 Nevertheless, the extraordinary complexity of a modern coal-fired power plant, often employing

273 coal preparation, fuel additives, and various sorbents, can complicate interpretation of rare earth  
274 distributions found in the fly ash.

520 Figure captions:

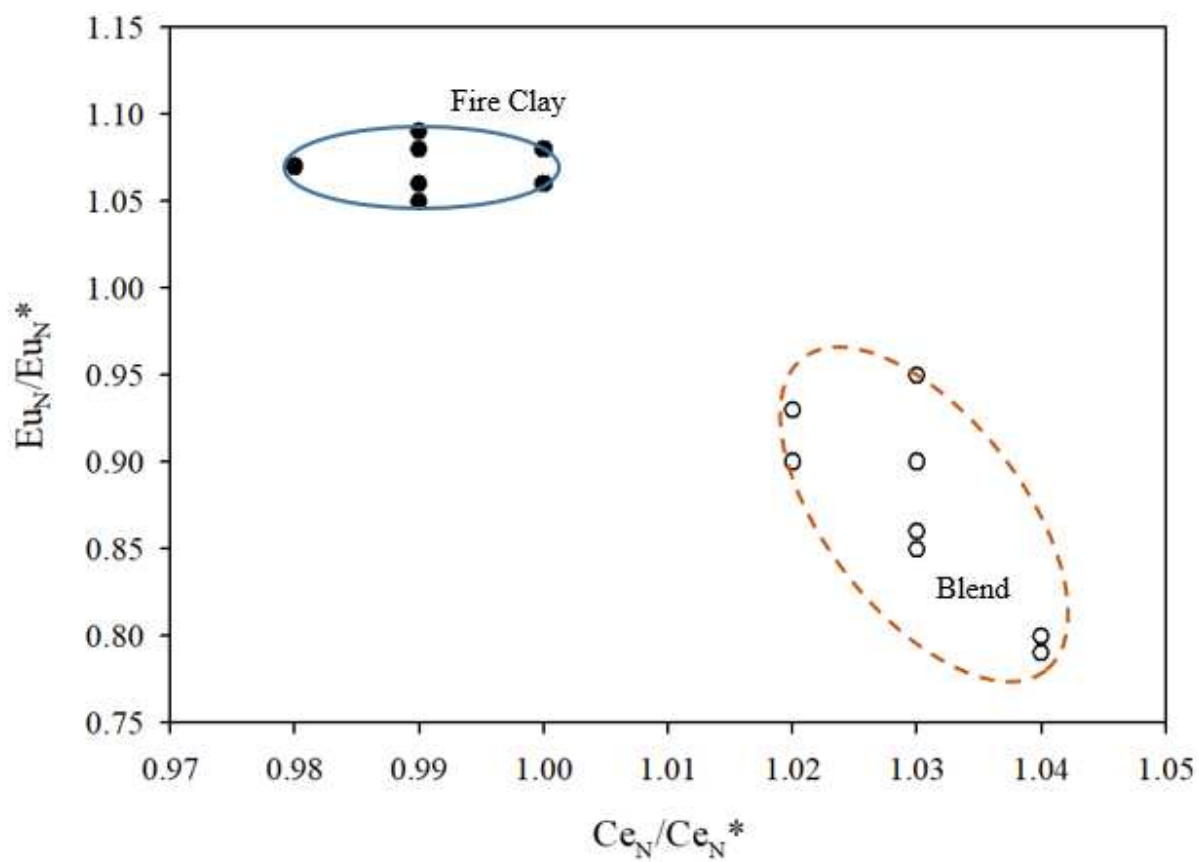

521

522 1. Upper continental crust-corrected rare earth concentrations (after McLennan and Taylor<sup>38</sup>) for  
 523 the fly ashes from the combustion of an Eastern Kentucky coal blend collected in 2007 and the  
 524 Fire Clay coal collected in 2014. The collections were from units 1 and 2 (2007) and unit 1  
 525 (2014) of Kentucky Plant I.

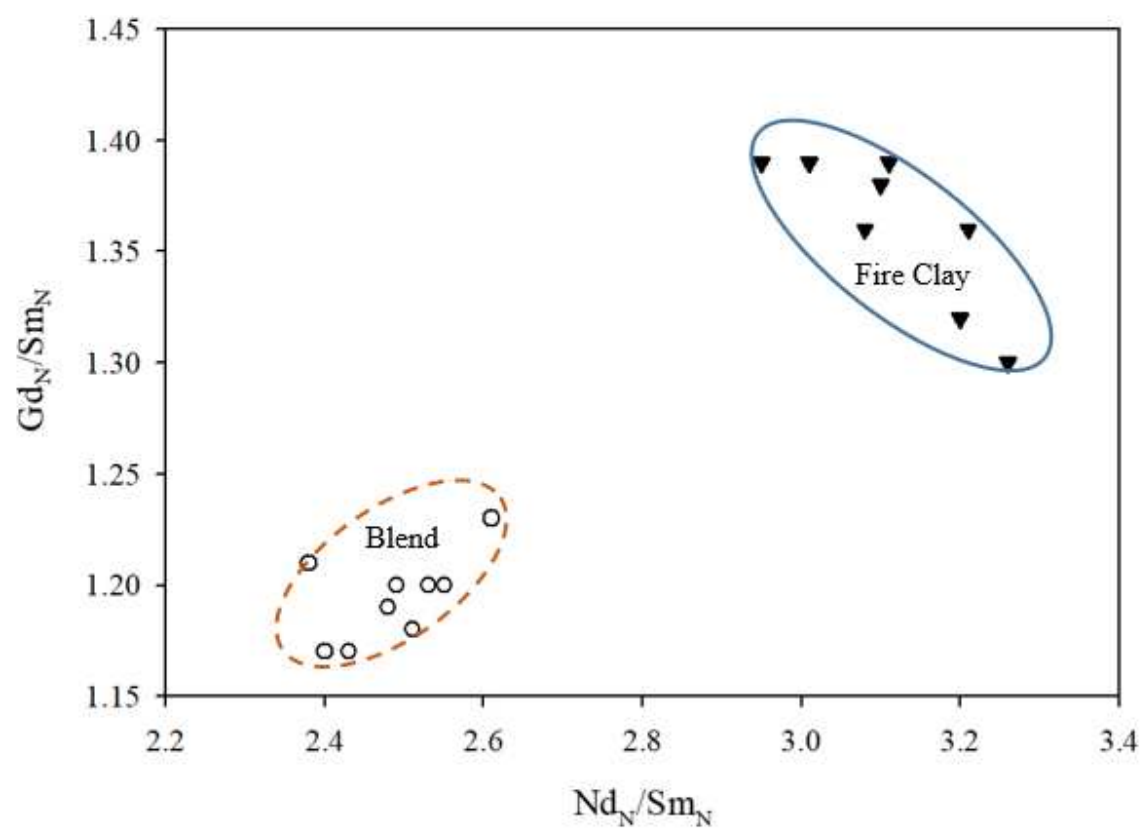

526

527 2.  $Gd_N/Gd_N^*$  vs.  $Eu_N/Eu_N^*$  for the fly ashes from the combustion of an Eastern Kentucky coal  
528 blend collected in 2007 and the Fire Clay coal collected in 2014.

529

530 3.  $Ce_N/Ce_N^*$  vs.  $Eu_N/Eu_N^*$  for the fly ashes from the combustion of an Eastern Kentucky coal  
531 blend collected in 2007 and the Fire Clay coal collected in 2014.

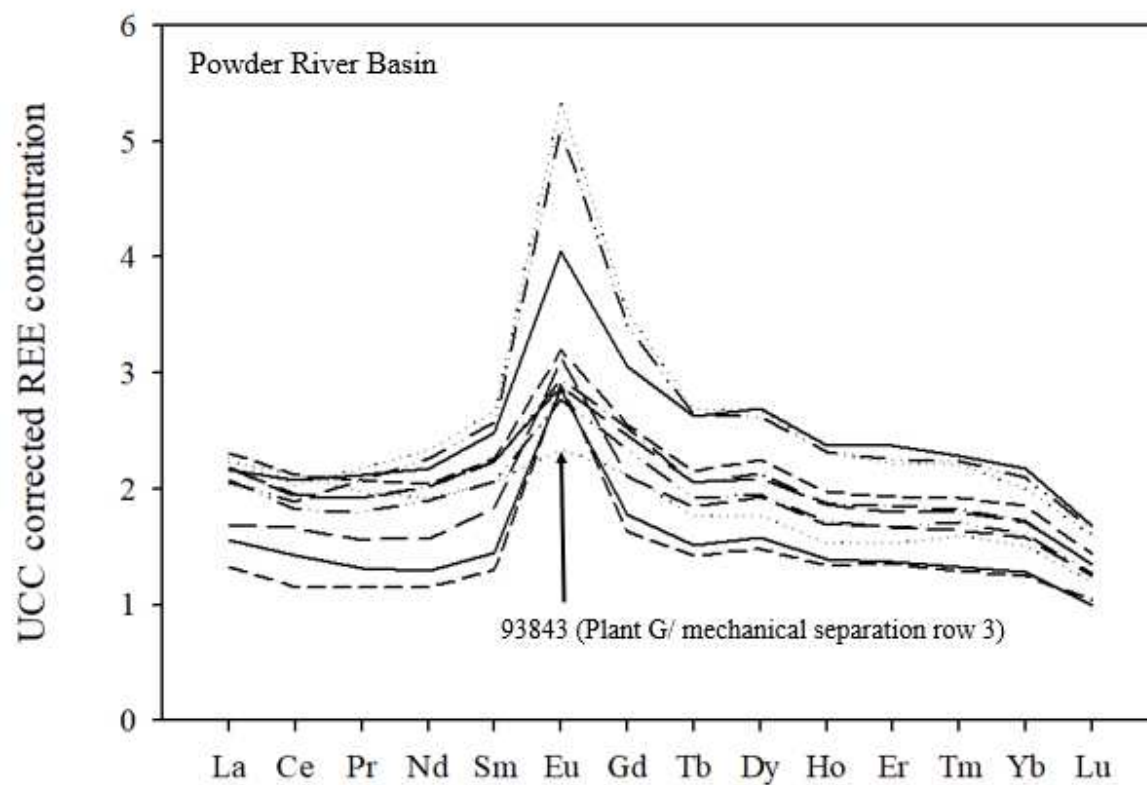

532

533 4. Nd<sub>N</sub>/Sm<sub>N</sub>\* vs. Gd<sub>N</sub>/Sm<sub>N</sub>\* for the fly ashes from the combustion of an Eastern Kentucky coal  
534 blend collected in 2007 and the Fire Clay coal collected in 2014.

535

536 5. Eu<sub>v</sub> vs. Ba/Eu for Powder River Basin coal-derived fly ashes.

537

538 6. Upper continental crust-corrected rare earth concentrations (after McLennan and Taylor<sup>38</sup>) for  
 539 the fly ashes from the combustion of subbituminous Powder River Basin coals.

540

541 7.  $Nd_N/Sm_N^*$  vs.  $Gd_N/Sm_N^*$  for the fly ashes from the combustion subbituminous Powder River  
542 Basin coals.

546

547 9. Back-scatter image (A) and energy-dispersive spectroscopy scan (B) for Mg-Ca-Al-Si sphere  
 548 from a Powder River Basin coal-derived fly ash. Back-scatter image (C) and energy-dispersive  
 549 spectroscopy scan (D) for Nd- and Pr-bearing grain from a Powder River Basin coal-derived fly  
 550 ash. Both from study by Hood et al.<sup>51</sup>

551

552

553

554

555 Supplementary data. Selected analyses from Taggart et al.,<sup>33</sup> supplemented by ultimate analysis,  
 556 major oxide, and selected minor element data from the Center for Applied Energy Research.
