Abstract

Supersymmetry is a promising framework in which to explore extensions of the standard model. To date, most studies of supersymmetry at future colliders have been concerned with particle searches. However, if candidates for supersymmetric particles are found, precision measurements of their properties will then be of paramount importance. The prospects for such measurements and their implications are the subject of this thesis.

If charginos are produced at the LEP II collider, they are likely to be one of the few available supersymmetric signals for many years. We consider the possibility of determining fundamental supersymmetry parameters in such a scenario. The study is complicated by the dependence of observables on a large number of these parameters. We propose a straightforward procedure for disentangling these dependences and demonstrate its effectiveness by presenting a number of case studies at representative points in parameter space. For significant regions of parameter space, we find that it is possible to find strong bounds on the mass of the electron sneutrino, to test the assumption of gaugino mass unification, and to examine the viability of the lightest supersymmetric particle as a dark matter candidate.

In addition to determining the properties of supersymmetric particles, precision measurements may also be used to establish that newly-discovered particles are, in fact, supersymmetric. Supersymmetry predicts quantitative relations among the couplings and masses of superparticles. We discuss tests of such relations at a future e^+e^- linear collider, using measurements that exploit the availability of polarizable beams. Stringent tests of supersymmetry from chargino production are demonstrated in two representative cases, and stermion and neutralino processes are also discussed.

Acknowledgements

This work is the end product of many enjoyable years, during which I have benefited from the friendship of several fellow graduate students in the theory group and elsewhere: Mike Boulware, Todd Flynn, Francis Ho, Andrew Lee, Hung Jung Lu, Amanda Peet, Dave Sutter, Matt Strasser, John Uglum, Wing Kai Wong, and especially my coterminous companions on this journey, Don Finnell and Yael Shadmi. Colorful personalities one and all, they have been wonderful sources of knowledge and entertainment, and have made these years both fun and rewarding.

I would like to thank Tim Barklow, Stan Brodsky, Dave Burke, JoAnne Hewett, Andrei Linde, and Tom Rizzo, members of the Stanford and SLAC theory groups who contributed greatly to my time at Stanford and to this thesis. I have also been especially inspired by Savvas Dimopoulos, Lance Dixon, Howie Haber, Renata Kallosh, and Lenny Susskind. It has been a privilege to talk with them throughout my graduate school years, and I thank them for their dear advice and generous encouragement.

It is an absolute pleasure to thank my advisor, Michael Peskin, whose invaluable wisdom, inexhaustible energy, incurable optimism, and completely insatiable curiosity provide the shining example to which I will always aspire. From him I have learned a lot of physics and much more besides, and to him I am forever indebted.

Finally, I would like to thank my parents and brother for their consistently extraordinary love and support. Through them, all blessings flow.

To my parents

Chapter 1

Preamble

In the two decades since its conception [1], supersymmetry has become increasingly important in efforts to extend the standard model of particle physics. From a formal perspective, supersymmetry has a number of beautiful properties: it is, given some mild assumptions, the unique extension of Poincare symmetry in relativistic quantum field theory [2]; it unifies fermions with bosons; and it plays an essential role in all attempts so far to unite gravity with the other interactions.

If supersymmetry exists, it must be broken. While the scale of supersymmetry breaking is, in principle, essentially unconstrained, there are strong arguments in favor of a low energy breaking scale. The hierarchy between the weak and Planck scales is technically unnatural in the standard model [3]. However, because supersymmetric theories are free of quadratic divergences, this problem is solved in supersymmetric theories when supersymmetry is broken at or near the weak scale [4]. It should also be noted that the remarkable unification of coupling constants in supersymmetric models, which is, at present, the only successful quantitative prediction of physics beyond the standard model, is evidence not only for grand unified theories, but also for low energy supersymmetry breaking [5].

Such considerations have stimulated a great deal of activity in supersymmetry phenomenology in recent years. Most of this activity, however, has centered on particle searches. If supersymmetry is discovered, there will be a rich spectrum of superparticles, and detailed studies of their masses and couplings will be the focus of

experimental particle physics well into the next century. Precision measurements of such quantities are crucial to the understanding of the supersymmetry breaking sector and may even inform attempts to understand the mechanism of supersymmetry breaking in supergravity and string theories. It is not, then, premature to investigate the prospects for detailed study of superparticle properties at future facilities.

The clean environment provided by e^+e^- colliders is the most promising setting for precision measurements, and we will consider both the LEP II collider at CERN, which is scheduled to begin operation in a few years, and the Next Linear Collider, a proposed facility currently in its preliminary design stage. In Chapter 2, we assume that supersymmetry has been discovered through chargino production at LEP II and examine the prospects for the determination of fundamental supersymmetry parameters in such a scenario. At first sight, the task is formidable, as there are a multitude of unknown parameters in supersymmetric models and these enter observable quantities in rather complicated ways. However, under some fairly weak and plausible assumptions, the number of parameters entering chargino events may be reduced to six. We then discuss some important observables which may provide powerful constraints on the parameter space and describe a method by which the constraints may be understood and displayed graphically.

The effectiveness of this strategy is presented in a number of case studies at representative points in parameter space. Working in the context of the minimal supersymmetric standard model, we find that chargino production by itself is a fairly sensitive probe of the supersymmetry breaking sector. For significant regions of parameter space, it is possible to test the gaugino mass unification hypothesis and to measure the gaugino contents of the charginos and neutralinos, thereby testing the predictions of grand unification and the viability of the lightest supersymmetric particle as a dark matter candidate. For much of the parameter space, it is also possible to set limits on the mass of the electron sneutrino, which provide a valuable guide for future particle searches.

Up to this point, we have assumed that newly-discovered particles are supersymmetric partners of known particles. A natural question to ask is whether this can be shown to be the case. In Chapter 3, we investigate the possibility of using precision

measurements to quantitatively confirm the existence of supersymmetry itself. Our approach hinges on an important observation: softly broken supersymmetric theories are similar to spontaneously broken gauge theories in that, while the mass relationships implied by the symmetry can be badly violated, the corresponding relations between dimensionless couplings continue to be preserved. It is this feature which provides the best opportunity for quantitative tests of supersymmetry. We discuss the prospects for such tests at the Next Linear Collider, using measurements that exploit the availability of polarized beams. We find that stringent tests of supersymmetry are possible in representative examples, and that, as a by-product, accurate measurements of supersymmetry parameters may again be obtained. If low energy supersymmetry is in fact present in the real world, these results indicate that, in the near future, experiment may again provide precise quantitative hints to lead us in the search for higher theories.

The work presented in Chapter 2 was completed in collaboration with M. Strassler [6], and that in Chapter 3 with H. Murayama, M. Peskin, and X. Tata [7].

Chapter 2

Precision Measurements of Supersymmetry Parameters

2.1 Introduction

The naturalness problem has motivated many approaches to extending the standard model, and, for the reasons outlined in Chapter 1, supersymmetry (SUSY) is one of the most promising. If SUSY is to provide a solution to this problem, it must be broken at energies of order 1 TeV, and so the masses of supersymmetric particles must lie at or below this energy. Because such energies are within reach of existing accelerators or those that are scheduled to operate in the near future, SUSY phenomenology has attracted much attention in recent years [8].

In many of the supersymmetric models that have been explored, charginos are the lightest observable supersymmetric particles, and for this reason, chargino searches have been particularly well-studied [9, 10, 11, 12, 13, 14, 15, 16, 17]. The current lower bound on the mass of the lighter chargino is 45 GeV [18, 19, 20, 21, 22]. Chargino discovery studies have shown that, with the characteristics currently expected to be reached at LEP II, $\sqrt{s} = 175\text{--}190$ GeV and a luminosity of 200–500 $\text{pb}^{-1}/\text{year/experiment}$ [23], the discovery reach will extend nearly to the kinematic limit, significantly extending the accessible region of parameter space. It is also worth noting that there are at present tentative but tantalizing hints of the possible existence

of light charginos from the measurement of A_{LR} at SLC [24, 25] and measurements of $\Gamma(Z \rightarrow b\bar{b})$ at LEP and SLC [26, 27, 28, 29].

If charginos are discovered at LEP II, they will provide one of the first direct signals of supersymmetry and may well prove to be the most promising candidates for precision supersymmetry studies for many years. Although neutralino production is likely to accompany chargino production, it often suffers from a significantly smaller cross section [30] and may be more difficult to separate from backgrounds [13, 14]. It is therefore natural to ask what information about the parameters of supersymmetry can be obtained from the chargino signal alone.

In the case of linear e^+e^- colliders with $\sqrt{s} = 500$ GeV, the question of precision measurements of sparticle masses and underlying SUSY parameters has been addressed in many studies [31, 32, 33, 34, 35, 36, 37, 38, 39]. These studies have shown that if a number of sparticles are light enough to be produced, their masses can be determined to high accuracy, and the sparticle spectrum can provide stringent tests of standard theoretical assumptions. If light charginos exist, thousands of them will be produced at LEP II, and precision measurements might also be possible there. However, in addition to the difficulties present in all studies of SUSY signals, such as unobservable particles in the final state and a wealth of unknown parameters, chargino production at LEP II suffers from other difficulties not present in the 500 GeV collider studies. In particular, the background from W pair production will have a stronger overlap with the chargino signal, and beam polarization, an important diagnostic in linear collider experiments, will not be available. The aim of this chapter is to determine to what extent these difficulties can be overcome, and to explore the prospects for the determination of fundamental SUSY parameters in different regions of parameter space.

A previous study [40] addressed this question with the assumptions that charginos are lighter than W bosons, that the vacuum expectations values of the two Higgs fields are roughly equal, and, for most of the analysis, that sneutrinos are either very heavy or very light. We will relax these assumptions so that we may determine to what extent they may be tested. Our study will be conducted in the context of the minimal supersymmetric standard model (MSSM) without gaugino mass unification.

We will find that for some regions of parameter space, it is possible to test gaugino mass unification, a general prediction of supersymmetric grand unified theories, and also to place strong bounds on the mass of the electron sneutrino, which would provide a valuable guide for designing future sparticle searches. In addition, we will see that it is often possible to measure the gaugino contents of the charginos and neutralinos, which have implications for the viability of the lightest neutralino as a dark matter candidate [41].

Formally, every observable defines a hypersurface in the space of SUSY parameters, and determining the parameters simply consists of finding the intersections of these hyperplanes. Practically, there are many possible observables with varying degrees of dependence on the fundamental parameters and different experimental uncertainties, and reducing the allowed volume to a small region is at first sight far from straightforward. The most effective way to extract the underlying parameters from the data is to perform a binned maximum likelihood fit, and ultimately, this is what should be done. However, such a procedure does not provide much physical understanding of the results, nor does it provide a useful way to visualize how the underlying parameters are constrained by specific measurements. In this study, we will discuss observables one by one in a way that gives a straightforward strategy for disentangling their complicated dependences. In the process we will show which parameters can be tightly constrained by chargino production and which cannot. We hope that this study will provide some general understanding of the results one may hope to achieve. Of course, if light charginos are found, this picture will be considerably sharpened by strategies tailored to the particular point in parameter space that is realized in nature.

In Sec. 2.2 we briefly review the MSSM. We state our assumptions about the MSSM and discuss the theoretical prejudices that we hope to test through our approach. We then describe the region of parameter space in which charginos can be produced at LEP II and present the SUSY parameter space that we hope to constrain. In Sec. 2.3 we describe the salient aspects of chargino events and discuss the observables that will be most central to our analysis. Section 2.4 contains a description of the event simulation and the cuts used in the case studies. The case

studies themselves are presented in Sec. 2.5, where we describe the strategy that we will follow in systematically constraining the SUSY parameters and then apply it to a number of representative points in parameter space. We conclude with some final comments and a summary of our results in Sec. 2.6.

2.2 SUSY Parameter Space and Chargino Production

2.2.1 The Minimal Supersymmetric Standard Model

Our analysis will be performed in the context of the MSSM [8, 42], the simplest extension of the standard model that includes supersymmetry. In this subsection, we explain which assumptions about the MSSM we will make, and we introduce the SUSY parameters that we hope to constrain.

The MSSM includes the usual matter superfields and two Higgs doublet superfields

$$\hat{H}_1 = \begin{pmatrix} \hat{H}_1^0 \\ \hat{H}_1^- \end{pmatrix} \quad \text{and} \quad \hat{H}_2 = \begin{pmatrix} \hat{H}_2^+ \\ \hat{H}_2^0 \end{pmatrix}, \quad (1)$$

where $\hat{H}_1$ and $\hat{H}_2$ give masses to the isospin $-\frac{1}{2}$ and $+\frac{1}{2}$ fields, respectively. These two superfields are coupled in the superpotential through the term $-\mu\epsilon_{ij}\hat{H}_1^i\hat{H}_2^j$, where μ is the supersymmetric Higgs mass parameter. The ratio of the two Higgs scalar vacuum expectation values is defined to be $\tan\beta \equiv \langle H_2^0 \rangle / \langle H_1^0 \rangle$. Soft supersymmetry breaking terms [43] for scalars and gauginos are included in the MSSM with

$$V_{\text{soft}} = \sum_i m_i^2 |\phi_i|^2 + \frac{1}{2} \left\{ \left[M_1 \tilde{B} \tilde{B} + \sum_{j=1}^3 M_2 \tilde{W}^j \tilde{W}^j + \sum_{k=1}^8 M_3 \tilde{g}^k \tilde{g}^k \right] + \text{h.c.} \right\} + [A \text{ terms}], \quad (2)$$

where i runs over all scalar multiplets. The “ A terms” are cubic scalar terms that couple the Higgs scalars to squarks and to sleptons with coefficients A_u , A_d , and A_e , where i is the generation number. Studies of the MSSM often assume a number of

relations among the mass parameters m_i and M_i ; the relatively weak assumptions made in this study will be detailed shortly.

The charginos and neutralinos of the MSSM are the mass eigenstates that result from the mixing of the electroweak gauginos $\tilde{B}$ and $\tilde{W}^j$ with the Higgsinos. The charged mass terms that appear are

$$(\psi^-)^T M_{\tilde{\chi}^\pm} \psi^+ + \text{h.c.}, \quad (3)$$

where $(\psi^\pm)^T \equiv (-i\tilde{W}^\pm, \tilde{H}^\pm)$ and

$$M_{\tilde{\chi}^\pm} = \begin{pmatrix} M_2 & \sqrt{2} M_W \sin\beta \\ \sqrt{2} M_W \cos\beta & \mu \end{pmatrix}. \quad (4)$$

The chargino mass eigenstates are $\tilde{\chi}_i^\pm = V_{ij}\psi_j^\pm$ and $\tilde{\chi}_i^- = U_{ij}\psi_j^-$, where the unitary matrices U and V are chosen to diagonalize $M_{\tilde{\chi}^\pm}$. Neutral mass terms may be written as

$$\frac{1}{2}(\psi^0)^T M_{\tilde{\chi}^0} \psi^0 + \text{h.c.}, \quad (5)$$

where $(\psi^0)^T \equiv (-i\tilde{B}, -i\tilde{W}^3, \tilde{H}_1^0, \tilde{H}_2^0)$ and

$$M_{\tilde{\chi}^0} = \begin{pmatrix} M_1 & 0 & -M_Z \cos\beta \sin\theta_W & M_Z \sin\beta \sin\theta_W \\ 0 & M_2 & M_Z \cos\beta \cos\theta_W & -M_Z \sin\beta \cos\theta_W \\ -M_Z \cos\beta \sin\theta_W & M_Z \cos\beta \cos\theta_W & 0 & -\mu \\ M_Z \sin\beta \sin\theta_W & -M_Z \sin\beta \cos\theta_W & -\mu & 0 \end{pmatrix}, \quad (6)$$

and we introduce the shorthand notation $s_W \equiv \sin\theta_W$, and $c_W \equiv \cos\theta_W$. The neutralino mass eigenstates are $\tilde{\chi}_i^0 = N_{ij}\psi_j^0$, where N diagonalizes $M_{\tilde{\chi}^0}$. In order of increasing mass the four neutralinos are labeled $\tilde{\chi}_1^0$, $\tilde{\chi}_2^0$, $\tilde{\chi}_3^0$, and $\tilde{\chi}_4^0$, and the two charginos, similarly ordered, are $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^\pm$. From the mass matrices in Eqs. (4) and (6), it can be seen that in the limits $\tan\beta \rightarrow 0$ and $\tan\beta \rightarrow \infty$ there is an exact symmetry $\mu \leftrightarrow -\mu$.

In the form outlined above, the MSSM contains many unknown parameters, and typically a number of simplifying assumptions are made. These assumptions are

usually based on grand unified theories or minimal supergravity. As we hope to test such theories, we choose less restrictive and more phenomenological assumptions, which we list below. Having stated our assumptions, we will then explain our reasons for choosing them and explore their implications.

2.2.2 Our Basic Assumptions

In this study, we will make the following assumptions:

- (a) R-parity is conserved.
- (b) The lightest supersymmetric particle (LSP) is the lightest neutralino, $\tilde{\chi}_1^0$.
- (c) Sleptons and squarks have masses beyond the kinematic limit of LEP II.
- (d) The gluino is heavier than the lighter chargino.
- (e) The intergenerational mixing in the squark, slepton, and quark sectors is small and may be neglected in our analysis.
- (f) The four *left-handed* squarks of the first two generations are nearly degenerate at low energy with mass $m_{\tilde{q}}$, as are all six *left-handed* sleptons with mass $m_{\tilde{l}}$:

$$\begin{aligned} m_{\tilde{u}_L} &\approx m_{\tilde{d}_L} \approx m_{\tilde{t}_L} \approx m_{\tilde{b}_L} \approx m_{\tilde{q}} \\ m_{\tilde{\nu}_e L} &\approx m_{\tilde{\nu}_\mu L} \approx m_{\tilde{\nu}_\tau L} \approx m_{\tilde{l}_L} \approx m_{\tilde{l}}. \end{aligned} \quad (7)$$

As will be discussed at length below, chargino production and decay are highly insensitive to the masses of all other scalars, and we may therefore set all squark masses to $m_{\tilde{q}}$ and all slepton masses to $m_{\tilde{l}}$ without loss of generality.

- (g) The gaugino masses M_i and the parameters μ and $\tan \beta$ may be taken to be real, so that CP violation plays no role in chargino events.
- (h) The one-loop corrections to particle masses, chargino production, and chargino decay do not introduce any large new dependences on fundamental SUSY parameters.
- (i) The parameters M_1 and M_2 are independent, i.e., we do *not* assume gaugino mass unification, as we are hoping to test this prediction of grand unified theories.

With the assumptions listed, our analysis is applicable to the bulk of parameter space available for study at LEP II. However, there are a number of small regions in the allowed parameter space where the physics is qualitatively different from the norm, and these will require special treatment. Since our principal aim is to explore the most

general properties of chargino production, we will not study these exceptional regions, though their existence will be noted in the remarks below. In Sec. 2.3.7 we will briefly discuss ways in which the unusual physics present in these cases might be detected.

Assumption (a) is commonly made in supersymmetry studies, as it prevents protons from decaying too quickly. Given R-parity conservation, the LSP is stable and must be among the decay products of any sparticle. The LSP must be uncolored and uncharged, and in many models it is the lightest neutralino $\tilde{\chi}_1^0$, as we have assumed in (b).

Because the LSP is very weakly interacting and unobservable in detectors, the first potentially observable SUSY signal must include the production of other light sparticles. As we would like to study the question of how much information can be obtained from the chargino signal alone, we will limit ourselves to models in which the sleptons and squarks have masses beyond the kinematic limit of LEP II, as given in (c). This assumption, along with the small cross sections for gluino production at e^+e^- colliders, implies that any reasonably large SUSY signal at LEP II must involve either the lighter chargino $\tilde{\chi}_1^\pm$ or the second lightest neutralino $\tilde{\chi}_2^0$. Although it would simplify our analysis, we cannot assume that the second lightest neutralino is heavier than the lighter chargino, since, as can be seen from Eqs. (4) and (6), $m_{\tilde{\chi}_2^0}$ is not independent of $m_{\tilde{\chi}_1^\pm}$ and $m_{\tilde{\chi}_2^0}$. In fact, in the region of parameter space in which chargino production is accessible to LEP II, $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$ are very roughly degenerate, with the mass difference typically in the range $-10 \text{ GeV} \lesssim m_{\tilde{\chi}_2^0} - m_{\tilde{\chi}_1^\pm} \lesssim 20 \text{ GeV}$. When $m_{\tilde{\chi}_2^0} < m_{\tilde{\chi}_1^\pm}$, it is possible for the lighter chargino to decay through a cascade decay, in which it decays to a $\tilde{\chi}_2^0$, which in turn decays to an LSP. If the mass splitting $m_{\tilde{\chi}_1^\pm} - m_{\tilde{\chi}_2^0}$ is small, or direct decays to the LSP are suppressed by small couplings, the branching fraction for chargino cascade decays may be non-negligible. However, as the coincidence of these conditions occurs only in a small fraction of parameter space, we will not consider these decays further.

Under our assumptions, charginos decay to three-body final states consisting of an LSP and either two quarks or two leptons. The current lower bound on $m_{\tilde{\chi}_1^\pm}$ is roughly 20 GeV [8, 19, 20, 21, 22], and so for charginos produced at LEP II with $\sqrt{s} = 190 \text{ GeV}$, $m_{\tilde{\chi}_1^\pm} - m_{\tilde{\chi}_2^0} < 75 \text{ GeV} < M_W$. Along with assumptions (a) – (d), this

10-94

7769A04

Figure 1: The three chargino production diagrams for e^+e^- collisions.

implies that the W bosons, squarks and sleptons in chargino decays must be virtual particles. The tree-level relation $m_{H^\pm} > M_W$ implies the same for charged Higgs bosons. If the tree-level $H^\pm$ mass were very low and its one-loop corrections were large and negative, the two-body decay $\tilde{\chi}_1^\pm \rightarrow H^\pm \tilde{\chi}_1^0$ could occur, but we will assume that this is not the case.

We may now display the production and decay diagrams of charginos. Chargino production from e^+e^- collisions is given by the three processes in Fig. 1 and includes s -channel γ and Z diagrams and t -channel $\tilde{\nu}_e$ exchange. Charginos decay to the LSP either hadronically through virtual W , squark, or $H^\pm$ diagrams,

$$\tilde{\chi}^+ \rightarrow (\tilde{\chi}_1^0 W^{+*}, \tilde{d}^* u, \tilde{d} \tilde{u}^*, \tilde{\chi}_1^0 H^{+*}) \rightarrow \tilde{\chi}_1^0 \bar{d} u, \quad (8)$$

where u (d) represents an up- (down-) type quark, or leptonically through virtual W , slepton, or $H^\pm$ diagrams,

$$\tilde{\chi}^+ \rightarrow (\tilde{\chi}_1^0 W^{+*}, \tilde{\ell}^* \nu, \tilde{\ell} \tilde{\nu}^*, \tilde{\chi}_1^0 H^{+*}) \rightarrow \tilde{\chi}_1^0 \bar{\ell} \nu. \quad (9)$$

These decays are shown in Fig. 2. As each chiral fermion has its own complex scalar

7-94

7739A2

Figure 2: The three-body chargino decay diagrams. There exist separate scalar partners for each chirality of fermion, and so there are a total of six hadronic and five leptonic decay diagrams.

partner, charginos decay hadronically through six channels and leptonically through five (since there is no right-handed sneutrino).

Charginos are too short-lived to be directly observed, so we must infer everything from their decay products. It will be convenient to refer to the different types of chargino events by their decay modes. However, since a τ lepton produced in the leptonic decay of a chargino may itself decay either hadronically or leptonically, we must distinguish between the particles that are directly produced at the chargino decay vertices and those that are actually observed in the detector. To be precise, we establish the following terminology. If both charginos decay through the hadronic diagrams of Fig. 2, we will call the event a "hadronic mode" event. Events where both charginos decay through the leptonic diagrams of Fig. 2 will be called "leptonic mode" events, and those where one chargino decays through a leptonic diagram and one through a hadronic diagram will be called "mixed mode" events. On the other hand, if we wish to group chargino events by their observed final state, we will explicitly refer to the final state partons, using the notation 2ℓ , $2j + \ell$, and $4j$ for two lepton, dijet plus lepton, and four jet final states, respectively. In our notation, we will denote the final state of a hadronically decaying τ lepton as $j\bar{j}$. For example, $2j + \ell$ events will include leptonic mode events in which one chargino decays to a τ that decays hadronically and the other chargino decays to a $\bar{\tau}$ that decays leptonically.

We will also need to identify the subset of $2j + \ell$ events that are mixed mode events, that is, the $2j + \ell$ events in which the hadrons do not come from a τ . These events will be called "Y mode" events, the "Y" representing the topology of the lepton track and the two jets. Hadronically decaying τ leptons produce a collimated hadronic system of low invariant mass and, often, just a single charged prong. In contrast, we will see that few dijet systems from chargino decays have a low invariant mass, and so it is usually possible to separate Y events from the $2j + \ell$ events resulting from hadronic τ decays. As will be discussed below, lepton universality (which follows from assumptions (e) and (f)) implies that a measurement of the number of Y mode events can be directly converted to a measurement of the number of mixed mode events.

Before evaluating the importance of the various chargino decay diagrams, we

digress slightly to consider the possibility of studying other SUSY signals. We have assumed that sleptons and squarks are beyond the kinematic limit of LEP II. If sleptons and squarks are within reach, they clearly will also give valuable information and will improve the results we obtain here. (Of course, if sleptons or squarks are not only within reach of LEP II, but are also less massive than the lighter chargino, the chargino will decay to two-body states containing these particles, and a modified analysis will be necessary.) It is more important to consider neutralino production. As noted above, $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$ are very roughly degenerate, and therefore, if it is possible to produce $\tilde{\chi}_1^\pm \tilde{\chi}_1^\mp$ chargino pairs, it is likely that $\tilde{\chi}_2^0$ pairs can be produced, and, in almost all cases, production of $\tilde{\chi}_1^0 \tilde{\chi}_2^0$ is kinematically allowed. If $M_2 \sim |\mu| \sim M_W$, $\tilde{\chi}_3^0$ or even $\tilde{\chi}_4^0$ production may be possible at LEP II. In principle neutralino pair production should also provide valuable information. However, neutralino production cross sections are typically significantly smaller than those for charginos and may differ by as much as an order of magnitude or more in some regions of parameter space [13, 14, 30]. Furthermore, studies of $\tilde{\chi}_1^0 \tilde{\chi}_2^0$ production at $\sqrt{s} = 190$ GeV have concluded that the signal suffers from a large background from WW production in both hadronic and leptonic modes [13, 14]. For these reasons we will not consider neutralino events further, other than to discuss their impact on our ability to isolate the chargino signal. Insofar as additional information about SUSY parameters can be obtained from slepton, squark, and neutralino signals at LEP II, the results of our study may be considered conservative.

From Figs. 1 and 2, it is clear that the chargino production and decay processes have a complex dependence on the various scalar masses, with the electron sneutrino mass $m_{\tilde{\nu}_e}$ entering the production process, and all slepton and squark masses entering the decay. In many versions of the MSSM, the slepton and squark masses are assumed to be unified at a high energy scale. When they are run down to low energies, typically the squarks acquire a greater mass than the sleptons through their QCD interactions. In principle, one would like to test this assumption. Unfortunately, without some simplifications, the large number of independent squark and slepton masses quickly complicates the analysis. We will make some simple assumptions to bring this dependence under control.

It is first important to note that with the assumption of negligible intergenerational mixings (assumption (e)), chargino events at LEP II are highly insensitive to certain scalar masses, namely, those of the third generation squarks, the right-handed squarks and sleptons, and the charged Higgs boson. To see this, we must discuss the scalar mass spectrum in greater detail. Sfermion masses are given by the following matrices:

$$\mathbf{M}_t^2 = \begin{pmatrix} m_t^2 + m_u^2 + M_Z^2(\frac{1}{2} - \frac{2}{3}s_W^2)\cos 2\beta & m_u(A_u - \mu \cot \beta) \\ m_u(A_u - \mu \cot \beta) & m_u^2 + m_u^2 + M_Z^2(\frac{2}{3}s_W^2)\cos 2\beta \end{pmatrix}, \quad (10)$$

$$\mathbf{M}_d^2 = \begin{pmatrix} m_d^2 + m_d^2 - M_Z^2(\frac{1}{2} - \frac{1}{3}s_W^2)\cos 2\beta & m_d(A_d - \mu \tan \beta) \\ m_d(A_d - \mu \tan \beta) & m_d^2 + m_d^2 - M_Z^2(\frac{1}{3}s_W^2)\cos 2\beta \end{pmatrix}, \quad (11)$$

$$\mathbf{M}_e^2 = \begin{pmatrix} m_l^2 + m_e^2 - M_Z^2(\frac{1}{2} - s_W^2)\cos 2\beta & m_e(A_e - \mu \tan \beta) \\ m_e(A_e - \mu \tan \beta) & m_e^2 + m_e^2 - M_Z^2(s_W^2)\cos 2\beta \end{pmatrix}, \quad (12)$$

$$\mathbf{M}_j^2 = m_j^2 + \frac{1}{2}M_Z^2 \cos 2\beta, \quad (13)$$

where the two-by-two matrices are in the basis $(\tilde{f}_L, \tilde{f}_R)$. The masses $m_{\tilde{Q}}, m_{\tilde{U}}, m_{\tilde{D}}, m_{\tilde{L}},$ and $m_{\tilde{E}}$ are the soft SUSY breaking scalar masses of Eq. (2), and the A_i are the coefficients of the SUSY breaking cubic scalar terms. The mass matrices of the other two generations are identical in form. The off-diagonal terms of the mass matrices of the top and bottom squark sectors can be large, and these can lead to large left-right mass splittings and light top and bottom squarks. However, because the charginos we are studying are lighter than the top quark, and because we have assumed that intergenerational mixings are negligible, decays of charginos through third generation squarks are heavily suppressed. Thus, peculiarities of the third generation are irrelevant for our analysis. Assuming that no coefficient A_i is extremely large relative to A_t and A_b , the left-right mixings of the other squarks and sleptons are usually negligible and the masses of the sparticles are given by the diagonal elements of the matrices. An exception occurs when $m_\tau(A_\tau - \mu \tan \beta) \sim m_{\tilde{L}}^2$, and similarly for muons and strange quarks, which is possible in certain corners of SUSY parameter space (see Sec. 2.2.4). However, we will ignore left-right mixing in this study and merely note in Sec. 2.3.7 that it would have observable consequences.

Let us now consider the right-handed scalars of the three slepton and first two squark generations. Right-handed scalars couple only to the Higgsino component of the chargino. As these couplings are the supersymmetric analogues of Higgs couplings, they are suppressed by either $m_u/(M_W \sin \beta)$ or $m_d/(M_W \cos \beta)$, where m_u and m_d are the masses of the corresponding standard model fermion. Such couplings are important only for extreme values of $\tan \beta$, and so for almost all of parameter space, chargino events are insensitive to the masses of right-handed scalars. The $H^\pm$ amplitude is suppressed by similar couplings, and may also be ignored.

Thus, only the scalar masses listed in Eq. (7) are relevant. Left-handed scalars couple to charginos through their gaugino components, and these couplings are not suppressed. However, in any given generation, the left-handed squarks (sleptons) belong to the same $SU(2)$ doublet, and so have the same soft SUSY breaking mass term $m_{\tilde{Q}} (m_{\tilde{L}})$. Their masses are therefore split only by the last terms of the diagonal entries of the scalar mass matrices, the D terms, which induce a mass splitting that is typically of order 20 GeV or less for the masses we will consider. Such splittings are not important for this study, and so, within each generation, the left-handed squarks and sleptons may be taken to be roughly degenerate. Furthermore, there are bounds on slepton and squark non-degeneracy between *different* generations from $\mu \rightarrow e\gamma$ and flavor changing neutral current constraints [44]. Motivated by these considerations, we adopt assumption (f). Because the scalar masses that are not constrained in assumption (f) are irrelevant for chargino events at LEP II, we may set them to any reasonable values. For convenience only, we will assume throughout our study that *all* sleptons have the same mass $m_{\tilde{l}} = m_{\tilde{\nu}}$, and similarly that *all* squarks have mass $m_{\tilde{q}}$; it should be remembered, however, that our results depend only on the weaker assumption (f).

Throughout this study, we will assume that one-loop corrections do not greatly affect our analysis (assumption (h)). Studies have shown that one-loop effects on chargino and neutralino masses are generically only a few percent [45, 46, 47], and so we do not expect this assumption to be very restrictive. Even if one-loop corrections are substantial, as long as they do not introduce qualitatively new dependences on SUSY parameters into the observables we use, the analysis presented in this study

will still be applicable without large modifications.

Often gauge coupling constants and gaugino masses are assumed to unify at some high scale. This assumption implies that even at lower energy scales we have (to the accuracy of one-loop renormalization group equations) [48]

$$\frac{M_2}{g_2^2} = \frac{3}{5} \frac{M_1}{g_1^2} = \frac{M_3}{g_3^2}, \quad (14)$$

or approximately $M_1 \approx \frac{1}{2}M_2$ and $M_3 \approx \frac{10}{3}M_2$ at M_Z . We may ignore the gluino mass M_3 , since, given assumption (d), gluinos enter chargino production and decay only through loop diagrams, which are likely to be small. As noted previously, since one of our main goals is to test the unification of M_1 and M_2 , we will avoid assuming a universal gaugino mass and will take these parameters to be independent (assumption (i)). It is possible without loss of generality to set $M_2 \geq 0$, and we will follow this convention. Without the gaugino mass unification assumption, however, M_1 may be either positive or negative.

2.2.3 Regions of Parameter Space

Given the discussion above, the SUSY parameter space of the MSSM that is relevant to our study of chargino production is given by the six parameters $(\mu, M_2, \tan \beta, M_1, m_2, m_{\tilde{g}})$. We can now examine the regions of parameter space for which chargino production is kinematically allowed at LEP II with $\sqrt{s} = 190$ GeV. The chargino mass $m_{\tilde{\chi}^\pm}$ is completely determined by the three parameters μ, M_2 , and $\tan \beta$. In Fig. 3, contours of constant $m_{\tilde{\chi}^\pm}$ in the (μ, M_2) plane are plotted for fixed $\tan \beta = 4$; the contours are similar for other values of $\tan \beta$. The cross-hatched regions along the $M_2 = 0$ and $\mu = 0$ axes are experimentally excluded by lower limits on sparticle masses [18, 19, 21, 20, 22], and the hatched region is the inaccessible region where $m_{\tilde{\chi}^\pm} > 95$ GeV. In Fig. 4 we plot constant $m_{\tilde{\chi}^0}$ contours for $\tan \beta = 4$ and, since $m_{\tilde{\chi}^0}$ depends on M_1 , three different values of M_1/M_2 . (For these plots, the experimental limits $m_{\tilde{\chi}^0} > 20$ GeV and $m_{\tilde{\chi}^\pm} > 45$ GeV have again been included [18, 19, 20, 21, 22]. The LSP mass bound is derived in the case of gaugino mass unification, so applies rigorously only to Fig. 4a [18, 19, 20, 21, 22]. However, as some similar bound

Figure 3: Contours of constant $m_{\tilde{\chi}^\pm}$ (in GeV) for $\tan \beta = 4$. The cross-hatched region is excluded by the experimental bounds $m_{\tilde{\chi}^\pm} > 45$ GeV and $m_{\tilde{\chi}^0} > 20$ GeV. In the hatched regions, $m_{\tilde{\chi}^\pm} > 95$ GeV, so charginos are kinematically inaccessible.

likely applies for the other cases, we have included it in all figures. The neutralino mass bound extends the excluded region only slightly, and the exact shape of the experimentally excluded region will be unimportant for this study.)

It is convenient to further divide the (μ, M_2) plane into regions based on the gaugino contents of the light gauginos. To quantify this, we define the gaugino contents of the lighter chargino and LSP to be [41]

$$\begin{aligned} \rho_{\tilde{\chi}^\pm} &\equiv \frac{|\mathbf{V}_{11}|^2}{|\mathbf{N}_{11}|^2 + |\mathbf{N}_{12}|^2} \\ \rho_{\tilde{\chi}^0} &\equiv \frac{|\mathbf{N}_{11}|^2}{|\mathbf{N}_{11}|^2 + |\mathbf{N}_{12}|^2}. \end{aligned} \quad (15)$$

(We have arbitrarily chosen to define $\rho_{\tilde{\chi}^\pm}$ in terms of $\mathbf{V}_{11}$ instead of $\mathbf{U}_{11}$. These differ little throughout parameter space, and for the purposes of defining $\rho_{\tilde{\chi}^\pm}$, the discrepancy is not important.) The variables $\rho_{\tilde{\chi}^\pm}$ and $\rho_{\tilde{\chi}^0}$ lie in the range $0 \leq \rho_{\tilde{\chi}^\pm}, \rho_{\tilde{\chi}^0} \leq 1$; $\rho_{\tilde{\chi}^\pm}$ ($\rho_{\tilde{\chi}^0}$) is zero when $\tilde{\chi}_1^\pm$ ($\tilde{\chi}_1^0$) is pure Higgsino and is one when $\tilde{\chi}_1^\pm$ ($\tilde{\chi}_1^0$) is pure gaugino. Although they may differ substantially in certain regions of parameter space, $\rho_{\tilde{\chi}^\pm}$ and $\rho_{\tilde{\chi}^0}$ are correlated: when $M_2, |M_1| \ll |\mu|$, both $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_1^0$ are essentially gaugino states, while in the opposite limit, $M_2, |M_1| \gg |\mu|$, they are both dominated by their Higgsino components. We will present results for both quantities, and will find that

Figure 4: Contours of constant $m_{\tilde{\chi}_1^0}$ (in GeV) for fixed $\tan \beta = 4$ and three values of the gaugino mass ratio M_1/M_2 : (a) 0.5, (b) 0.75, and (c) -0.5. The hatched and cross-hatched regions are as in Fig. 3.

Figure 5: Contours of constant $\rho_{\tilde{\chi}_1^\pm}$ for $\tan \beta = 4$, with hatched and cross-hatched regions as in Fig. 3. As defined in the text, $0 \leq \rho_{\tilde{\chi}_1^\pm} \leq 0.2$ in the Higgsino region, $0.2 < \rho_{\tilde{\chi}_1^\pm} < 0.9$ in the mixed region, and $0.9 \leq \rho_{\tilde{\chi}_1^\pm} \leq 1.0$ in the gaugino region. The gaugino content approaches one asymptotically as $|\mu| \rightarrow \infty$ in the gaugino region and zero asymptotically as $M_2 \rightarrow \infty$ in the Higgsino region.

the bounds we obtain for them are roughly the same. The quantity $\rho_{\tilde{\chi}_1^0}$ has implications for the viability of the LSP as a dark matter candidate. As shown in a number of studies [41], $\tilde{\chi}_1^0$ is a good dark matter candidate when it is gaugino-like with $\rho_{\tilde{\chi}_1^0} \gtrsim 0.9$. For $\rho_{\tilde{\chi}_1^0} \lesssim 0.9$, the LSPs annihilate so quickly in the early universe that they provide insufficient mass today to be interesting dark matter candidates. The gaugino content $\rho_{\tilde{\chi}_1^0}$ is therefore an important parameter for us to determine. However, because $\rho_{\tilde{\chi}_1^\pm}$ depends only on the three parameters μ , M_2 , and $\tan \beta$, it is the more convenient of the two quantities to use to divide the parameter space. Contours of equal $\rho_{\tilde{\chi}_1^\pm}$ are plotted in Fig. 5. Although the specific boundaries are not particularly important, for definiteness we will refer to the region with $\rho_{\tilde{\chi}_1^\pm} \geq 0.9$ as the gaugino region, the region with $\rho_{\tilde{\chi}_1^\pm} \leq 0.2$ as the Higgsino region, and the region with $0.2 < \rho_{\tilde{\chi}_1^\pm} < 0.9$ as the mixed region. With these definitions, roughly speaking, $\tilde{\chi}_1^0$ is a good dark matter candidate in the gaugino region, but is not a viable candidate in the mixed and Higgsino regions.

It is evident from Figs. 3, 4, and 5 that accurate determinations of $m_{\tilde{\chi}_1^\pm}$ and

$m_{\tilde{\chi}_1^0}$ are not enough to determine the gaugino content $\rho_{\tilde{\chi}_1^\pm}$. While a measurement of $m_{\tilde{\chi}_1^0} \approx \frac{1}{2}m_{\tilde{\chi}_1^\pm}$ might be taken as evidence that the SUSY parameters lie in the gaugino region and that gaugino masses unify, this is not the only possibility. For example, the masses $m_{\tilde{\chi}_1^\pm} \approx 80$ GeV and $m_{\tilde{\chi}_1^0} \approx 40$ GeV can be obtained with the parameters $(\mu, M_2, \tan \beta, M_1/M_2) = (-400, 75, 4, 0.5)$ in the gaugino region with $\rho_{\tilde{\chi}_1^\pm} = 1.00$, and also with the parameters $(-78, 170, 4, 0.25)$ in the mixed region with $\rho_{\tilde{\chi}_1^\pm} = 0.34$. As will be seen below, more careful analysis can differentiate between such possibilities.

We have now found the regions in which chargino production is allowed. However, if the splitting between the masses of the chargino and the LSP is very small, and the charginos are produced with low velocity, the chargino decay products will have very low energy in the laboratory frame and may be too soft to be experimentally useful. The approximate relations [49]

$$m_{\tilde{\chi}_1^0} \approx \min\{|\mu|, M_2, |M_1|\} \quad \text{and} \quad m_{\tilde{\chi}_1^\pm} \approx \min\{|\mu|, M_2\} \quad (16)$$

are valid in the far Higgsino and far gaugino regions. With these in mind, it is easy to see that for increasing M_2 and fixed M_1/M_2 in the Higgsino region, $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_1^0$ become more and more degenerate. Given a beam energy E_b , the maximum and minimum energies for dijet or $\ell\nu$ systems from chargino events are

$$E^{\max, \min} = \frac{E_b}{2} \left[1 \pm \left(1 - \frac{m_{\tilde{\chi}_1^\pm}^2}{E_b^2} \right)^{\frac{1}{2}} \right] \left[1 - \frac{m_{\tilde{\chi}_1^0}^2}{m_{\tilde{\chi}_1^\pm}^2} \right] \quad (17)$$

for $E_b > E_b^{\text{crit}}$, where

$$E_b^{\text{crit}} \equiv \frac{m_{\tilde{\chi}_1^\pm}^2 + m_{\tilde{\chi}_1^0}^2}{2m_{\tilde{\chi}_1^0}} \quad (18)$$

is the critical beam energy below which the LSP may be at rest in the lab frame. When $E_b < E_b^{\text{crit}}$, the expression for $E^{\min}$ is unchanged, but

$$E^{\max} = E_b - m_{\tilde{\chi}_1^0}, \quad E_b < E_b^{\text{crit}}. \quad (19)$$

The maximum energy for single jets and leptons is always given by the expression for $E^{\max}$ in Eq. (17), which is plotted in Fig. 6 for the case $M_1/M_2 = 0.5$, $\tan \beta = 4$.

Figure 6: Contours of constant $E^{\max}$ (in GeV), the maximum jet or lepton energy for decay products from chargino events. The plot is for $M_1/M_2 = 0.5$ and $\tan \beta = 4$. The hatched and cross-hatched regions are as in Fig. 3, and the vertical and horizontal scales are chosen to emphasize the Higgsino region. We see that in the Higgsino region, for points in parameter space with large M_2 or near threshold, the decay products may be too soft to be useful for precision measurements.

We see that, in this case, the far Higgsino region with $M_2 \gtrsim 500$ GeV, contains areas in which all decay products have energies $\lesssim 10$ GeV. Thus, in these regions chargino production may be visible but difficult to use in precision studies. As M_2 increases further, it becomes difficult even to detect the chargino signal above background. The problem of soft decay products is generic only in the far Higgsino region. In all other regions within the bands shown in Fig. 3, as long as $m_{\tilde{\chi}_1^\pm}$ lies somewhat below the beam energy, and the splitting between $m_{\tilde{\chi}_1^\pm}$ and $m_{\tilde{\chi}_1^0}$ is not anomalously small, chargino production can be observed and studied at LEP II.

For extremely large values of M_2 , the lifetime of the chargino becomes long, and one might hope to tag charginos by looking for tracks which do not intersect the interaction point. From the formula for the chargino decay width presented later in Eq. (51), one may estimate the chargino decay length, which is of order the impact parameter for these tracks. Roughly, for charginos to travel 10 (100) μm before decaying requires $M_2 \gtrsim 2$ (3) TeV. Such large values of M_2 are disfavored by fine-tuning considerations, as discussed below.

2.2.4 Boundaries of Parameter Space

In this subsection, we specify the boundary of the region of parameter space that we will investigate. The six SUSY parameters may be restricted on the basis of fine-tuning prejudices and other considerations. We discuss each parameter in turn.

As noted in Sec. 2.1, if SUSY is to naturally explain the electroweak scale, the SUSY breaking masses M_1 and M_2 must be less than or of order 1 TeV. In fact, if charginos are discovered, the parameter M_1 may be further bounded. Eq. (16) implies that in the far gaugino and far Higgsino regions, if $M_1 \gtrsim M_2$, $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_1^0$ are virtually degenerate. Thus, the condition that $m_{\tilde{\chi}_1^\pm} - m_{\tilde{\chi}_1^0}$ be large enough that the decay products are detectable implies to a good approximation that $|M_1| < M_2$, and so we will also impose this constraint. Although μ is not a SUSY breaking parameter, fine-tuning considerations constrain it to lie at or below the TeV scale.

The parameters $m_{\tilde{t}}$ and $m_{\tilde{q}}$ are also SUSY breaking masses, and therefore must also be less than or of order 1 TeV. Sleptons and squarks with masses of 1 TeV are effectively decoupled and are indistinguishable from those with infinite mass. We

therefore limit the analysis to $m_{\tilde{t}}, m_{\tilde{q}} \leq 1$ TeV. As we are considering the scenario in which only charginos are produced at LEP II, we take $m_{\tilde{t}} \geq 100$ GeV. The squark mass lower bound from hadron colliders is likely to be approximately 150 GeV when LEP II begins operation, and we therefore take this as the lower bound on $m_{\tilde{q}}$.

The quantity $\tan \beta$ is more difficult to delimit. If one assumes the desert hypothesis, applies the MSSM renormalization group equations to the Higgs-fermion Yukawa couplings, and demands that the couplings remain finite up to a scale $\Lambda = 10^{16}$ GeV, one finds that for the present top quark mass measurement of $m_t = 176 \pm 8 \pm 10$ GeV [50], the bounds on $\tan \beta$ are $1 \lesssim \tan \beta \lesssim 50$. We will adopt these limits.

In summary, given the assumptions above, our task is to explore and restrict the six-dimensional SUSY parameter space given by

$$\begin{aligned} -1 \text{ TeV} &\lesssim \mu \lesssim 1 \text{ TeV} \\ 0 &\leq M_2 \lesssim 1 \text{ TeV} \\ 1 &\leq \tan \beta \leq 50 \\ -M_2 &\leq M_1 \leq M_2 \\ 100 \text{ GeV} &\leq m_{\tilde{t}} \leq 1 \text{ TeV} \\ 150 \text{ GeV} &\leq m_{\tilde{q}} \leq 1 \text{ TeV}. \end{aligned} \quad (20)$$

2.3 Observables of Chargino Production

In this section, we will discuss the observables that we will use to restrict SUSY parameter space. As stated earlier, our goal is to gain an understanding of chargino pair production by using as much analytic information as possible. For this reason we will not study observables for which no analytic formulae can easily be found, such as the distribution of lepton energies in $2j + \ell$ events, even though these quantities contain information which is not accessible through the observables we consider. It is therefore probable that a global likelihood fit to the data will be able to put tighter bounds on supersymmetry parameter space than we will claim below. In this sense, our results are conservative.

The four quantities that will be central to our analysis are the chargino and neutralino masses, the total cross section for chargino production, and the leptonic

branching fraction:

$$\begin{aligned}
 m_{\tilde{\chi}_1^\pm}(\mu, M_2, \tan \beta), \\
 m_{\tilde{\chi}_1^0}(\mu, M_2, \tan \beta, M_1), \\
 \sigma_{\text{total}}(\mu, M_2, \tan \beta, m_{\tilde{t}} = m_{\tilde{b}}), \\
 B_e(\mu, M_2, \tan \beta, M_1, m_{\tilde{t}}, m_{\tilde{b}}) \equiv \frac{\Gamma(\tilde{\chi}^+ \rightarrow \tilde{\chi}^0 e^+)}{\Gamma(\tilde{\chi}^+ \rightarrow \text{anything})}.
 \end{aligned} \tag{21}$$

Of course, four observables will not allow us to determine six parameters, but, as will be seen in Sec. 2.5, these four observables can often restrict the parameter space to a region in which the quantities of greatest interest are already somewhat constrained. The forward-backward asymmetry of chargino production $A_{FB}^{\tilde{\chi}^\pm}$ will also be discussed, but for a number of reasons to be mentioned below, we will not use this quantity directly. No other variables were found that could be studied without performing Monte Carlo simulations at a large number of points in parameter space. The left-right asymmetry in the production cross section requires polarized electron beams and is inaccessible at LEP II, but has implications for chargino production at threshold and will also be discussed below.

In the following subsections, we will consider each observable, first analyzing its dependence on the underlying SUSY parameters, and then discussing the method by which it may be extracted from chargino event samples. This section will be confined to theoretical considerations; experimental issues will be discussed in Sec. 2.4. In particular, discussion of issues involving experimental efficiencies and minor subtleties involving the hadronic decays of the τ lepton will be deferred to the following sections. In Sec. 2.5, the measurements suggested in this section will be applied to Monte Carlo simulation case studies at specific points in parameter space, and results will be obtained with cuts, finite detector resolution, and finite statistics included.

2.3.1 Chargino and Neutralino Masses

The chargino mass $m_{\tilde{\chi}_1^\pm}(\mu, M_2, \tan \beta)$ and the LSP mass $m_{\tilde{\chi}_1^0}(\mu, M_2, \tan \beta, M_1)$ are sensitive to fundamental parameters of supersymmetry and are relatively easy to determine. Their dependences on the underlying SUSY parameters were discussed in

Sec. 2.2. Here we note only that in the gaugino region $m_{\tilde{\chi}_1^\pm} \approx M_2$ and $m_{\tilde{\chi}_1^0} \approx |M_1|$, and the masses are therefore directly sensitive to two fundamental parameters. In contrast, both masses are close to $|\mu|$ in the Higgsino region (unless $|M_1| < |\mu|$), in which case the LSP can have a mass near $|M_1|$ and the mass splitting $m_{\tilde{\chi}_1^\pm} - m_{\tilde{\chi}_1^0}$ is a complicated function of several parameters.

The masses $m_{\tilde{\chi}_1^\pm}$ and $m_{\tilde{\chi}_1^0}$ can be measured in chargino events in at least two ways. It is impossible to kinematically reconstruct chargino pair production events, since the charginos' decay products include two unobservable LSPs. However, because the unobserved LSPs are typically quite massive and carry off large energies and momenta, chargino events with two jets and an isolated lepton are easily separated from standard model backgrounds by a series of cuts, as we will see in Sec. 2.4. After imposing such cuts, one can find the dijet energy E_{jj} and dijet mass m_{jj} for each of the remaining events. The endpoints of the dijet energy and mass spectra are completely determined by $m_{\tilde{\chi}_1^\pm}$ and $m_{\tilde{\chi}_1^0}$, with the endpoints of the E_{jj} spectrum given by Eq. (17), and the m_{jj} distribution lying between zero and $m_{\tilde{\chi}_1^\pm} - m_{\tilde{\chi}_1^0}$. If at least two of the three endpoints are sufficiently sharp to be well-measured, they can be used to precisely determine $m_{\tilde{\chi}_1^\pm}$ and $m_{\tilde{\chi}_1^0}$. Of course, detector and beam effects will smear the endpoints, but in Sec. 2.5 we will see that the masses may still be measured to a few GeV with this method.

An energy scan at the chargino production threshold provides an alternate determination of $m_{\tilde{\chi}_1^\pm}$ [40]. In Fig. 7, the total cross section as a function of $\sqrt{s}$ (solid curve) is plotted for the particular point in parameter space $(\mu, M_2, \tan \beta, m_{\tilde{t}}) = (-400, 75, 4, 200)$. For comparison, a unit of R is also given (dashed curve). The sudden rise in cross section, characteristic of fermion production, makes possible a highly accurate determination of $m_{\tilde{\chi}_1^\pm}$. Such behavior is common for all points in parameter space. Near threshold the charginos are nearly at rest, so the only unknown momentum in the decay $\tilde{\chi}_1^\pm \rightarrow q\bar{q}\tilde{\chi}_1^0$ is that of the LSP. By reconstructing the hadronically decaying chargino in a mixed mode event, one obtains the mass of the LSP. Although this method is likely to provide a significantly more accurate determination of the chargino mass [40], we will not assume in our case studies that an energy scan will be performed, instead relying solely on the endpoint determinations.

Figure 7: The total cross section σ_{total} before cuts (solid curve) as a function of $\sqrt{s}$ for parameters $(\mu, M_2, \tan \beta, m_{\tilde{\nu}}) = (-400, 75, 4, 200)$ in the gaugino region. For comparison, a unit of R is also plotted (dashed curve). We note the sudden rise in cross section, characteristic of fermion production.

2.3.2 Differential Cross Section and Related Observables

Next we study the differential cross section $\frac{d\sigma}{d\cos\theta}(\mu, M_2, \tan\beta, m_{\tilde{\nu}})$ of chargino production and consider associated observables. As we will emphasize below, only two combinations of the parameters $(\mu, M_2, \tan\beta, m_{\tilde{\nu}})$ can be easily extracted even theoretically. One of these is proportional to the total cross section σ_{total} , while the other is proportional to the production forward-backward asymmetry $A_{FB}^{\tilde{\chi}^\pm}$. To a first approximation, which we will show to be sufficiently accurate, every other quantity that depends only on $\frac{d\sigma}{d\cos\theta}$ gives information which is equivalent to that contained in σ_{total} and $A_{FB}^{\tilde{\chi}^\pm}$. Unfortunately, with the exception of σ_{total} , none of these quantities is observable, since the direction of the charginos cannot be fully reconstructed. The angular distributions of the visible particles depend on the chargino decay vertices as well as on $\frac{d\sigma}{d\cos\theta}$, and although they are of great interest, they are not amenable to analytic study. They can be investigated by Monte Carlo simulations, but this is beyond the scope of the present work. Our approach therefore only allows us to extract a single combination of the four underlying parameters that determine the

differential cross section.

We first present the differential cross section for chargino production and analyze its dependence on the various SUSY parameters in the region of parameter space given by Eq. (20). Formulae for the differential cross section and total cross section have been given in many previous studies [9, 10, 11, 12, 16, 39]. Here we present the differential cross section for completeness and in a form that allows us to highlight certain properties that have particular relevance to our analysis.

The cross section is built from the three ingredients in Fig. 1. The couplings in the virtual photon diagram are, of course, independent of SUSY parameters. To compute the virtual Z diagram, we need the couplings of chargino currents to the Z . The virtual Z amplitude for producing chargino states $\tilde{\chi}_i^+$ and $\tilde{\chi}_j^-$ is given by

$$\bar{v}(e^+)ig\gamma^\mu \frac{1}{\cos\theta_W} \left[\left(\frac{1}{2} - \sin^2\theta_W \right) P_L + (-\sin^2\theta_W) P_R \right] u(e^-) \times \bar{u}(\tilde{\chi}_i^+)ig\gamma_\mu \frac{1}{\cos\theta_W} \left[O'_{Lij} P_L + O'_{Rij} P_R \right] u(\tilde{\chi}_j^-) \times \frac{-i}{s - M_Z^2}, \quad (22)$$

where the dependence on the SUSY parameters is through the quantities that are conventionally labeled O'_{Lij} and O'_{Rij} (see first reference in [8]). These are the combinations of U and V matrices given by

$$\begin{aligned} O'_{Lij} &\equiv -V_{i1}V_{j1}^* - \frac{1}{2}V_{i2}V_{j2}^* + \delta_{ij}\sin^2\theta_W \\ O'_{Rij} &\equiv -U_{i1}^*U_{j1} - \frac{1}{2}U_{i2}^*U_{j2} + \delta_{ij}\sin^2\theta_W, \end{aligned} \quad (23)$$

where the indices i, j are 1 for the lighter chargino and 2 for the heavier. As we will only be concerned with the lighter chargino, we define $O'_L \equiv O'_{L11}$ and $O'_R \equiv O'_{R11}$. After a Fierz transformation, the $\tilde{\nu}$ exchange diagram is also of a similar form, and its amplitude is given by

$$-\frac{1}{2}|V_{11}|^2 \bar{v}(e^+)ig\gamma^\mu P_L u(e^-) \times \bar{u}(\tilde{\chi}_i^+)ig\gamma_\mu P_L u(\tilde{\chi}_j^-) \times \frac{-i}{t - m_{\tilde{\nu}}^2}. \quad (24)$$

Combining these three contributions, one finds that the differential cross section for chargino production from unpolarized e^+e^- beams in units of R is given by

$$\frac{d\sigma}{dx} = \sum_{i=L}^R \frac{3v}{32} \left[R_i^2(1-vx)^2 + S_i^2(1+vx)^2 + 2R_iS_i(1-v^2) \right], \quad (25)$$

where the sum is over the two e^- helicities, v is the chargino velocity, and $x = \cos \theta$, the cosine of the angle between the positive chargino $\tilde{\chi}_1^+$ and the positron beam. The variables $R_{L,R}$ and $S_{L,R}$ are

$$\begin{aligned} R_L &\equiv 1 - K_L O_L^* - c_\nu, \\ S_L &\equiv 1 - K_L O_R^*, \\ R_R &\equiv 1 - K_R O_R^*, \\ S_R &\equiv 1 - K_R O_L^*, \end{aligned} \quad (26)$$

where $K_{L,R}$ are constants associated with Z production from e_L^- , e_R^- ,

$$\begin{aligned} K_L &\equiv \frac{s}{s - M_Z^2} \frac{1}{\sin^2 \theta_W \cos^2 \theta_W} \left(\frac{1}{2} - \sin^2 \theta_W \right), \\ K_R &\equiv \frac{s}{s - M_Z^2} \frac{1}{\sin^2 \theta_W \cos^2 \theta_W} \left(-\sin^2 \theta_W \right), \end{aligned} \quad (27)$$

and the $\tilde{\nu}$ diagram contribution is given by

$$c_\nu \equiv \frac{2|V_{11}|^2}{\sin^2 \theta_W [1 - 2vx + v^2 + 4m_{\tilde{\nu}}^2/s]}. \quad (28)$$

We now analyze these formulae in some detail to determine what can be learned experimentally. We will show that (a) in most of the allowed parameter space only two combinations of O_L^* , O_R^* , $|V_{11}|^2$ and $m_{\tilde{\nu}}$ contribute significantly to the unpolarized cross section; (b) the quantities most sensitive to these two combinations are the total cross section and the forward-backward production asymmetry; and (c) no other quantities involving the unpolarized cross section can be found that add significantly to our knowledge. We will illustrate these points using a perturbative expansion of the differential cross section in variables which we will define below. While the expansion is not always valid, we have found numerically that the conclusions that we draw in the perturbative regime hold throughout the allowed parameter space.

We now identify the small quantities in which to do perturbation theory. We define

$$\begin{aligned} \bar{K} &\equiv \frac{1}{2}(K_L + |K_R|); \quad \kappa \equiv \frac{1}{2}(K_L - |K_R|); \\ \bar{O} &\equiv \frac{1}{2}(O_L + O_R); \quad \omega \equiv \frac{1}{2}(O_L - O_R); \end{aligned} \quad (29)$$

$$\xi_0 \equiv \frac{s}{m_{\tilde{\nu}}^2}.$$

From Eq. (27) we see that $K_L \approx -K_R$, so $\bar{K} \gg \kappa$. Specifically, for $\sqrt{s} = 190$ GeV, $\bar{K} \approx 1.8 \gg \kappa \approx 0.13$, independently of all SUSY parameters. From Sec. 2.2 and Eq. (23) it follows that $O_L \approx O_R$ in both the gaugino and Higgsino regions, so that in most cases $\bar{O}$, which runs between $-1 + \sin^2 \theta_W$ in the gaugino region and $-1/2 + \sin^2 \theta_W$ in the Higgsino region, has absolute value much larger than ω , which is zero in the gaugino and Higgsino regions and whose absolute value never exceeds 0.2. The last small quantity, $\xi_0 \equiv s/m_{\tilde{\nu}}^2$, is small for sneutrino masses much larger than 200 GeV. Because of the form of Eq. (28), the expansion can be slightly improved by using not ξ_0 but

$$\xi \equiv \frac{\xi_0}{1 + (1 + v^2)\xi_0/4}. \quad (30)$$

In the perturbative regime, the unpolarized differential cross section $d\sigma/dx$ is conveniently written

$$\frac{d\sigma}{dx} = \frac{3v}{32} \sum_{k=0}^{\infty} x^k A_k, \quad (31)$$

where, to first order in ξ , κ and ω ,

$$A_0 \approx 4(2-v^2) \left[1 + \bar{K}^2 \bar{O}^2 - 2\bar{O}\kappa - \frac{|V_{11}|^2}{4\sin^2\theta_W} (1 - \bar{K}\bar{O})\xi \right],$$

$$A_1 \approx 16v \left[\bar{K}\omega + \frac{|V_{11}|^2}{8\sin^2\theta_W} (1 - \bar{K}\bar{O})\xi \right],$$

$$A_2 \approx \frac{v^2}{2-v^2} A_0,$$

$$A_k \sim \mathcal{O} \left(\frac{|V_{11}|^2}{4\sin^2\theta_W} v^k \xi^{k-1} \right), k > 2.$$

(Recall that $|V_{11}|^2 \leq 1$.) Thus, to a first approximation it is impossible to measure separately the four quantities of interest — $\bar{O}$, ω , $|V_{11}|^2$, and ξ — since the cross section effectively depends only on $A_0 \propto A_2$ and A_1 . As can easily be seen from the angular dependence of Eq. (31), these coefficients are most sensitively probed by the total cross section

$$\sigma_{\text{total}} \approx \frac{v}{8} \left(\frac{3-v^2}{2-v^2} \right) A_0 \quad (33)$$

and the forward-backward asymmetry

$$A_{FB}^{\chi^\pm} \approx \frac{3A_1}{4A_0} \left(\frac{2-v^2}{3-v^2} \right). \quad (34)$$

The quantities A_k for $k > 2$ are greatly suppressed in the perturbative regime and cannot give additional useful information.

Perhaps surprisingly, the basic conclusions of this perturbative analysis are correct for the entire accessible region of parameter space. The coefficients A_k , $k > 2$, become substantial and the relation $A_0 \propto A_2$ breaks down only for $|V_{11}|$ near one and for large ξ , that is, in the gaugino region with a sneutrino mass near 100 GeV. However, even in this case we find numerically that it is extremely difficult to extract additional information from the differential cross section. For example, consider a simple variable which is orthogonal to $A_{FB}^{\chi^\pm}$ and linearly independent of σ_{total} :

$$A_{\text{central}}^{\chi^\pm} = \frac{\int_{-1/2}^{1/2} dx \frac{d\sigma}{dx}}{\sigma_{\text{total}}}. \quad (35)$$

In the perturbative regime this variable is simply

$$A_{\text{central}}^{\chi^\pm} \approx A_{\text{central}}^{(0)\chi^\pm} \equiv \frac{1}{16} \frac{24 - 11v^2}{3 - v^2}. \quad (36)$$

which follows from Eqs. (31) and (32). Deviations from this prediction would provide new information beyond σ_{total} and $A_{FB}^{\chi^\pm}$. In Fig. 8 the ratio $A_{\text{central}}^{\chi^\pm}/A_{\text{central}}^{(0)\chi^\pm}$ is shown for two light sneutrino masses $m_{\tilde{\nu}} = 200$ GeV and 100 GeV. The figure indicates that $A_{\text{central}}^{\chi^\pm}$ is within a few percent of the perturbative prediction everywhere except in the gaugino region for extremely small sneutrino mass and large chargino mass, where a ten percent deviation is seen. In principle this small effect would be useful, but $A_{\text{central}}^{\chi^\pm}$ like $A_{FB}^{\chi^\pm}$ is not directly observable and must be estimated through its correlation with some observable quantity. Even were this somehow to be overcome through Monte Carlo simulations, the chargino cross section at LEP II provides us with at most a few thousand events; statistical errors on the measured σ_{total} and $A_{FB}^{\chi^\pm}$ are already several percent. We therefore cannot expect to gain much from this variable.

We have searched for other possible observables, but have found none with both large variation and small experimental uncertainties; the behavior of $A_{\text{central}}^{\chi^\pm}$ is typical. Statistical errors alone make any of these variables difficult to use; but the impossibility of directly measuring the chargino momentum axis greatly complicates the determination of any variable based on distributions in chargino production angle. For our purposes, then, the total cross section and the forward-backward chargino production asymmetry are the only potentially useful quantities stemming from the unpolarized differential cross section. In the next subsections we discuss these two quantities in detail.

Figure 8: Contours of constant value of the ratio $A_{\text{central}}^{\tilde{X}^\pm}/A^{(0)\tilde{X}^\pm}$, defined in the text. The hatched and cross-hatched regions are as in Fig. 3. The contours are plotted in the (μ, M_2) plane for fixed $\tan\beta = 4$ and (a) $m_2 = 200$ GeV and (b) $m_2 = 100$ GeV and are chosen to emphasize the range of the ratio. In the case $m_2 = 200$ GeV, where the perturbative analysis is expected to hold, we see that the ratio is approximately one, as expected. For $m_2 = 100$ GeV, beyond the range in which the perturbative analysis can be expected to be valid, we see that this behavior nevertheless persists, and deviations are small.

2.3.3 Total Cross Section

In this subsection we analyze the total cross section in detail. We will find that, as has been noted previously in the literature [9, 10, 11, 12, 13, 14, 15, 16, 17, 31, 32, 40], charginos are produced in the thousands in most areas of the accessible parameter space, and the production cross section is highly sensitive to sneutrino mass.

From Eqs. (32) and (33) it can be seen that in the gaugino region, for small ξ , the cross section is approximately

$$\sigma_{\text{total}} \approx f(v) \left\{ 1 + \left[\frac{s}{s - M_Z^2} \right]^2 \left(\frac{1}{4s_W^2} \right)^2 - \frac{|Y_{11}|^2}{4s_W^2} \left[1 + \frac{s}{s - M_Z^2} \frac{1}{4s_W^2} \right] \xi \right\} \quad (37)$$

$$\approx (3.2 - 2.8\xi) f(v) R \approx (8.8 \text{ pb}) (1 - 0.9\xi) f(v),$$

while in the Higgsino region it is

$$\begin{aligned} \sigma_{\text{total}} &\approx f(v) \left\{ 1 + \left[\frac{s}{s - M_Z^2} \right]^2 \left(\frac{1 - s_W^2}{1 - s_W^2} \right)^2 \right\} \\ &\approx 1.3 f(v) R \approx (3.6 \text{ pb}) f(v), \end{aligned} \quad (38)$$

where $f(v) = \frac{1}{2}v(3 - v^2)$ rises from zero at threshold to one at high energy, ξ is defined in Eq. (30), and where we have taken $\sqrt{s} = 190$ GeV, for which one unit of R is approximately 2.75 pb. Strong sensitivity to m_2 is found in the gaugino region [11, 12, 16], but disappears altogether in the Higgsino region. In the large m_2 limit both expressions are entirely determined by gauge invariance, but the event rate is two and a half times higher in the gaugino region. Notice that while a large cross section is a signal of the gaugino region, a small one can occur both in the Higgsino region and, if the sneutrino is light, in the gaugino region.

These features can all be seen in Fig. 9, where chargino production cross sections for $m_2 = 1$ TeV and 150 GeV are plotted in picobarns. Because the cross section plots do not change substantially for different $\tan\beta$, the plots are presented for $\tan\beta = 4$ only. We see that, in a sample of 1 fb^{-1} , LEP II will produce thousands of chargino events in most of the accessible regions of parameter space. Contrasting Figs. 9a

Figure 9: Contours of constant σ_{total} in picobarns in the (μ, M_2) plane for fixed $\tan \beta = 4$ and (a) $m_{\tilde{\nu}} = 1 \text{ TeV}$ and (b) $m_{\tilde{\nu}} = 150 \text{ GeV}$. The hatched and cross-hatched regions are as in Fig. 3. The cross section rises quickly near threshold. The lower cross sections in (b) are a result of the large destructive interference of the sneutrino diagram.

Figure 10: Cross sections as functions of $m_{\tilde{\nu}}$ are plotted for $\tan \beta = 4$ and four representative (μ, M_2) points: $(-400, 75)$ in the gaugino region (solid), $(-90, 115)$ in the mixed region (dashed), $(-75, 250)$ in the Higgsino region (dot-dashed), and $(-78, 1000)$ in the far Higgsino region (dotted). The $\tilde{\nu}$ diagram gives a large and destructive contribution for the gaugino and mixed points. As the Higgsino component increases, the dependence of the cross section on $m_{\tilde{\nu}}$ decreases.

and b, one can also see the strong dependence on $m_{\tilde{\nu}}$ noted above. This is shown more explicitly in Fig. 10, where we plot the total cross section at four representative (μ, M_2) points as a function of $m_{\tilde{\nu}}$. Clearly the $\tilde{\nu}$ diagram can give a large and destructive contribution to the cross section. For this reason, the infinite sneutrino mass limit is neither representative nor conservative and can lead to a substantial overestimate of the event rate in the gaugino region. This in turn could result in overly optimistic claims concerning the statistical accuracy with which SUSY parameters can be determined.

Having analyzed the dependence of σ_{total} on the fundamental SUSY parameters, we now turn to the issue of how σ_{total} may be extracted from experiment. To measure σ_{total} , it will be necessary to measure the partial cross sections of chargino production in at least two of the hadronic, mixed, and leptonic decay modes. The partial cross sections are given by

$$\begin{aligned}
\sigma_{\text{leptonic}} &= B_l^2 \sigma_{\text{total}} \\
\sigma_{\text{mixed}} &= 2B_l(1 - B_l)\sigma_{\text{total}} \\
\sigma_{\text{hadronic}} &= (1 - B_l)^2 \sigma_{\text{total}},
\end{aligned} \tag{39}$$

where B_l is the leptonic branching fraction defined in Eq. (21). As these three partial cross sections depend on only two variables, they must satisfy the constraint

$$\sigma_{\text{leptonic}} \sigma_{\text{hadronic}} = \frac{1}{4} \sigma_{\text{mixed}}^2. \tag{40}$$

This relation is not dependent on the details of the chargino decay process; if it is not satisfied, it indicates a problem with the estimated detection efficiencies in one or more of the modes. (Such a discrepancy could stem either from an experimental problem or from physics beyond our minimal assumptions that is not included in the Monte Carlo simulation—for example, signal from an additional and unexpected supersymmetric particle.) To determine σ_{total} it is best to use all three partial cross sections, subject to the constraint in Eq. 40, but we will only use the two with the smallest errors (σ_{mixed} and one of the other two). We note that in measuring σ_{leptonic} we obtain also B_l , and it is therefore natural to examine this observable, as we will do in Sec. 2.3.6.

2.3.4 Chargino Forward-Backward Asymmetry

The forward-backward asymmetry $A_{FB}^{\tilde{\chi}^\pm}$ of chargino production is theoretically attractive, since it can be computed analytically and depends on the four parameters ($\mu, M_2, \tan\beta, m_{\tilde{t}}$) in a way which is quite different from the total cross section. In the large $m_{\tilde{t}}$ limit, $A_{FB}^{\tilde{\chi}^\pm}$ is negative in the mixed region and negligible elsewhere, as can be seen from Eqs. (32) and (34); however, a light sneutrino, which appears in a t -channel diagram, can give a large positive contribution to $A_{FB}^{\tilde{\chi}^\pm}$ in the gaugino and mixed regions. This effect is seen in Fig. 11.

Unfortunately, $A_{FB}^{\tilde{\chi}^\pm}$ cannot be directly measured — the velocities of the two charginos cannot be reconstructed because the two LSPs are invisible. Let us consider what might be possible to observe in these events. Since the forward-backward

Figure 11: Contours of constant $A_{FB}^{\tilde{\chi}^\pm}$ in percent for $\tan\beta = 4$ and (a) $m_{\tilde{t}} = 1 \text{ TeV}$ and (b) $m_{\tilde{t}} = 150 \text{ GeV}$. The hatched and cross-hatched regions are as in Fig. 3. In the large $m_{\tilde{t}}$ limit, $A_{FB}^{\tilde{\chi}^\pm} \rightarrow 0$ in both the gaugino and Higgsino limits, with only the mixed region giving a significant negative $A_{FB}^{\tilde{\chi}^\pm}$. For low $m_{\tilde{t}}$, the t -channel sneutrino exchange diagram can lead to large and positive $A_{FB}^{\tilde{\chi}^\pm}$.

asymmetry is odd under charge conjugation, we must discover which chargino is positively charged. The sign of the charge of a single chargino can be determined in a leptonic decay from the charge of the lepton, but is more difficult to measure in a hadronic decay. We must also determine the momentum axis of the chargino. The visible particles in the decay of a chargino can in certain cases indicate the chargino momentum. For example, if the chargino is moving at relativistic velocities, the decay products are highly boosted along the chargino momentum axis. Alternatively, if in the chargino rest frame the total visible momentum, averaged over many events, is distributed isotropically, then the average visible momentum in any frame will give the chargino momentum direction. Unfortunately, neither of these cases applies here; the velocity of the chargino is generally semi- or non-relativistic, and the decays are often far from isotropic.

Still, we might hope that the distribution of the dijet momenta in the hadronic decays of charginos would give a reasonable estimate of the chargino momentum distribution and could be used to measure $A_{FB}^{\chi^\pm}$. Specifically, in mixed mode chargino decays, we may use the dijet momentum to estimate the chargino momentum axis, and the charge of the lepton to determine the direction of the positively charged chargino. The dijet forward-backward asymmetry A_{FB}^{jj} found in this way might well be correlated with $A_{FB}^{\chi^\pm}$. Unfortunately, the correlation is often very weak. As described in Sec. 2.5, for each case study, we have explored via Monte Carlo simulation the region of SUSY parameter space which gives the observed $m_{\tilde{\chi}_1^\pm}$, $m_{\tilde{\chi}_1^0}$, σ_{total} and B_L . We have found that for these points in parameter space it is impossible to estimate $A_{FB}^{\chi^\pm}$ using A_{FB}^{jj} without additional information about the decay process. In fact, the variation of A_{FB}^{jj} around $A_{FB}^{\chi^\pm}$ is so large that it indicates that A_{FB}^{jj} has strong dependence on the parameters in the decay vertices, and possibly can be used to determine them. However, as analytic formulae for this variable are unavailable, and since experimental cuts must be included, this will require a detailed Monte Carlo simulation covering all of the allowed parameter space, which we do not attempt here. (We note that analytic formulae may be found near the threshold of chargino production, which may permit the separation of $A_{FB}^{\chi^\pm}$ from the decay vertices [51].)

Additionally, we have considered a range of cuts on the data to try to improve

the correlation between A_{FB}^{jj} and $A_{FB}^{\chi^\pm}$. In particular, the angle between the dijet and chargino momenta may be determined simply from momentum conservation. By cutting away events where this angle is large, we obtain a sample of events where the dijet and chargino momenta point in roughly the same direction. In some cases the correlation is slightly improved for this sample, but this is counterbalanced by the loss of statistics. We note that this sample of events might be useful for other purposes, such as determining the parameters in the decay vertices.

We find, then, that it is impossible to measure $A_{FB}^{\chi^\pm}$ directly. However, the observable A_{FB}^{jj} , although too complicated to explore without a Monte Carlo simulation, contains a mixture of information about $A_{FB}^{\chi^\pm}$ and the decay vertices that will certainly be of interest. We will discuss this further in Sec. 2.5.

2.3.5 Polarization Asymmetry

While the unpolarized cross section essentially contains only two separable parameters, a third independent observable,

$$\frac{\sigma_R}{\sigma_L} \equiv \frac{\sigma(e_R^+ e_L^- \rightarrow \tilde{\chi}^+ \tilde{\chi}^-)}{\sigma(e_L^+ e_R^- \rightarrow \tilde{\chi}^+ \tilde{\chi}^-)}, \quad (41)$$

can be studied when polarized electron beams are available. Unfortunately, this is not expected to be the case at LEP II. Still, this observable has important implications for chargino threshold studies.

The ratio σ_R/σ_L is less than 15% throughout the allowed region of parameter space, and so, even with unpolarized beams, charginos are always produced largely by left-handed electrons [10, 39, 40]. In the large m_ν limit, $\sigma_R/\sigma_L \sim 1\%$ in the gaugino and $\sim 15\%$ in the Higgsino region; it varies widely in the mixed region, but is generally small. A light sneutrino can increase the ratio in the gaugino and mixed region. In Fig. 12 we show σ_R/σ_L for $m_\nu = 150$ GeV, for which the ratio takes values near its maximum. Nevertheless, we see that σ_R/σ_L is still small, and is approximately 2% in much of the gaugino region. While this ratio is independent of σ_{total} and $A_{FB}^{\chi^\pm}$, it is not uncorrelated with the total cross section $\sigma_{\text{total}} = \sigma_R + \sigma_L$, since m_ν enters only in σ_L and $\sigma_L \gg \sigma_R$. Still, the correlation is imperfect and it is

Figure 12: Contours of constant σ_R/σ_L in percent in the (μ, M_2) plane for $\tan \beta = 4$ and $m_2 = 150$ GeV. The ratio never rises above 15% in the allowed bands, and is approximately 2% in much of the gaugino region. The hatched and cross-hatched regions are as in Fig. 3.

possible to gain some amount of new information.

It is possible to exploit experimentally the theoretical prediction that σ_R/σ_L is small. Near threshold, this implies that charginos are produced dominantly polarized along the beam axis, and the study of their decays is therefore greatly simplified. As the combinations of the SUSY parameters that enter the decay are different from those that enter the production process, measurements at threshold can give valuable information to supplement the analysis presented so far [51]. At this point, we have assumed a fixed center-of-mass energy, which means that in much of the parameter region the charginos have substantial velocities, and near-threshold analysis is not applicable.

2.3.6 Leptonic Branching Fraction

To measure the total cross section, we must determine at least two of the partial cross sections for the hadronic, mixed, and leptonic modes. These also provide us with a measurement of the leptonic branching fraction $B_\ell(\mu, M_2, \tan \beta, M_1, m_{\tilde{t}}, m_{\tilde{d}})$, which can vary greatly in the SUSY parameter space [52]. We now analyze the dependence of B_ℓ on the underlying SUSY parameters.

As discussed earlier, charginos decay to a neutralino and either two hadrons or two leptons. The hadronic decays occur via intermediate W bosons and squarks (Fig. 2). The decay $\tilde{\chi}_1^\pm \rightarrow \tilde{\chi}_1^0 u \bar{d}$ through a virtual W has amplitude

$$\bar{u}(\tilde{\chi}_1^0) i g^\mu (O_L P_L + O_R P_R) u(\tilde{\chi}_1^\pm) \times \bar{u}(u) \frac{-i g}{\sqrt{2}} \gamma_\mu P_L v(\bar{d}) \times \frac{-i}{[(p_u + p_d)^2 - M_W^2]}, \quad (42)$$

where

$$\begin{aligned} O_L &\equiv N_{12} V_{11}^* - \frac{1}{\sqrt{2}} N_{14} V_{12}^* \\ O_R &\equiv N_{12}^* U_{11} + \frac{1}{\sqrt{2}} N_{13}^* U_{12}. \end{aligned} \quad (43)$$

The decay mediated by a left-handed up squark has amplitude

$$\begin{aligned} \bar{v}(\tilde{\chi}_1^\pm) (-i g) V_{11}^* P_L v(\bar{d}) \times \frac{i}{[(p_{\tilde{u}} + p_d)^2 - m_{\tilde{u}_L}^2]} \\ \times \bar{u}(u) (-i g \sqrt{2}) (Y_q \tan \theta_W N_{11} + I_u N_{12}) P_R v(\tilde{\chi}_1^\pm), \end{aligned} \quad (44)$$

while that mediated by a left-handed down squark takes the form

$$\begin{aligned} -\bar{u}(u) (-i g) U_{11} P_R u(\tilde{\chi}_1^\pm) \times \frac{i}{[(p_{\tilde{d}} + p_d)^2 - m_{\tilde{d}_L}^2]} \\ \times \bar{u}(\tilde{\chi}_1^\pm) (-i g \sqrt{2}) (Y_q \tan \theta_W N_{11}^* + I_d N_{12}^*) P_L v(\bar{d}). \end{aligned} \quad (45)$$

The overall minus sign of the down squark amplitude results from the odd permutation of the spinors of the down squark amplitude relative to the spinors of the other two diagrams. In these formulae $Y_q = \frac{1}{6}$ is the hypercharge of left-handed quarks, while $I_u(I_d) = \frac{1}{2} (-\frac{1}{2})$ is the weak isospin of up (down) quarks. We remind the reader that only the first two generations of squarks participate in chargino decays, since we have assumed that squark mixing angles are small and that the chargino is lighter than the top quark.

In Eqs. (44) and (45) we have omitted the couplings of squarks to the Higgsino component of the gauginos, because they are suppressed by $m_d/(M_W \cos \beta)$ or $m_u/(M_W \sin \beta)$, and are therefore negligible. As discussed in Sec. 2.2, the right-handed squark diagrams are similarly suppressed and may also be ignored. (We note, however, that the very small effects of the Higgsino couplings and the right-handed sfermion diagrams are included in our Monte Carlo simulation.)

The squark diagram contributions may be Fierz transformed into the same form as the W diagram amplitude; the full hadronic decay amplitude may then be written as

$$\frac{i^2 g^2}{\sqrt{2}} \bar{u}(\tilde{\chi}_1^0) \gamma^\mu (D_L P_L + D_R P_R) u(\tilde{\chi}_1^+) \times \bar{u}(u) \gamma_\mu P_L v(\bar{d}), \quad (46)$$

where

$$D_L(q) = \frac{O_L}{(p_u + p_d)^2 - M_W^2} + \frac{V_{11}^* \left(\frac{1}{6} \tan \theta_W N_{11} + \frac{1}{2} N_{12} \right)}{(p_{\tilde{\chi}_1^0} + p_u)^2 - m_{\tilde{u}_L}^2}, \quad (47)$$

and

$$D_R(q) = \frac{O_R}{(p_u + p_d)^2 - M_W^2} - \frac{U_{11} \left(\frac{1}{6} \tan \theta_W N_{11}^* - \frac{1}{2} N_{12}^* \right)}{(p_{\tilde{\chi}_1^0} + p_d)^2 - m_{\tilde{d}_L}^2}. \quad (48)$$

Notice that up(down)-type squarks contribute only to $D_L(D_R)$.

For leptonic decays, in which all three generations of sleptons participate, the full amplitude has the same form as Eq. (46) but with hypercharge $Y_t = -\frac{1}{2}$:

$$D_L(\ell) = \frac{O_L}{(p_\nu + p_e)^2 - M_W^2} + \frac{V_{11}^* \left(-\frac{1}{2} \tan \theta_W N_{11} + \frac{1}{2} N_{12} \right)}{(p_{\tilde{\chi}_1^0} + p_\nu)^2 - m_{\tilde{\nu}_L}^2}, \quad (49)$$

and

$$D_R(\ell) = \frac{O_R}{(p_\nu + p_e)^2 - M_W^2} - \frac{U_{11} \left(-\frac{1}{2} \tan \theta_W N_{11}^* - \frac{1}{2} N_{12}^* \right)}{(p_{\tilde{\chi}_1^0} + p_e)^2 - m_{\tilde{e}_L}^2}. \quad (50)$$

As above, the isospin $+\frac{1}{2}$ ($-\frac{1}{2}$) left-handed slepton contributes to $D_L(D_R)$.

In the approximation that the momentum dependences of the W and scalar propagators are ignored, the partial widths of the chargino can be written down in closed form. In this limit, the width, in terms of $r = m_{\tilde{\chi}_1^\pm}/m_{\tilde{\chi}_1^\mp}$, is

$$\Gamma(\tilde{\chi}^+ \rightarrow \tilde{\chi}^0 f \bar{f}) \approx N_f N_c \frac{g^4 m_{\tilde{\chi}_1^\pm}^5}{3072\pi^3} G(r) \left[D_L(f)^2 + D_R(f)^2 - g(r) D_L(f) D_R(f) \right], \quad (51)$$

where

$$\begin{aligned} G(r) &= 1 - 8r^2 - 24r^4 \log r + 8r^6 - r^8, \\ g(r) &= 4r(1 + 9r^2 + 12r^2 \log r - 9r^4 + 12r^6 \log(r) - r^6)/G(r), \end{aligned} \quad (52)$$

and where for hadrons (leptons), $f = q(\ell)$, the number of flavors N_f is 2(3), and the number of colors N_c is 3(1). The function $g(r)$ is well approximated by $1 - (1 - r)^4$, while for $r \rightarrow 1$, $G(r) \sim (1 - r)^5$. The ratio of leptonic to hadronic branching fractions is given by

$$\frac{B_\ell}{1 - B_\ell} = \frac{1}{2} \frac{D_L^2(\ell) + D_R^2(\ell) - g(r) D_L(\ell) D_R(\ell)}{D_L^2(q) + D_R^2(q) - g(r) D_L(q) D_R(q)}. \quad (53)$$

The dependence of B_ℓ on the parameters of supersymmetry is quite complicated, and there are few regions of parameter space in which a useful perturbative expansion may be performed. However, it is possible to make some broad statements about its behavior. In Fig. 13 we present B_ℓ for three different values of the parameters. Note that B_ℓ is unlike the other three variables we have looked at, in that it can have strong $\tan \beta$ dependence in the gaugino region. In the following we will discuss some of the most notable features in the figures.

In the Higgsino region of Figs. 13a-c, the branching fraction is approximately $\frac{1}{3}$. This is a general phenomenon. As the Higgsino region is approached from the gaugino region, the couplings of the chargino to squarks and sleptons decrease, while the couplings to the W boson increase. In the far Higgsino region, the sfermion couplings to the chargino are completely negligible, so chargino decay is dominated by virtual W bosons for which the branching ratio B_ℓ is $\frac{1}{3}$. (Recall that we include in B_ℓ all chargino decays to τ leptons, even if the τ itself decays hadronically.) Even outside the Higgsino region, effects of heavy squarks and sleptons are suppressed relative to the intermediate W boson; the large sfermion mass limit again leads to $B_\ell \approx \frac{1}{3}$. Thus, we cannot draw any conclusions if $B_\ell \approx \frac{1}{3}$, but if B_ℓ is not equal to $\frac{1}{3}$, it immediately rules out both the Higgsino region and ultraheavy sfermions.

In the gaugino region, where $|\mu| \gg M_2$, the matrix elements U_{11} , V_{11} and N_{11} are all very close to unity, while the couplings O_L and O_R of the chargino to the W are of order the mixing angle N_{12} , as are the isospin-dependent terms in $D_{L,R}(\ell, q)$. All other relevant elements of the U , V and N matrices are small. A perturbative

Figure 13: Contours of constant value of the leptonic branching fraction B_l in the (μ, M_2) plane for $M_1/M_2 = 0.5$ and three sets of parameters $(\tan \beta, m_{\tilde{t}}, m_{\tilde{d}})$: (a) (2, 200, 200), (b) (2, 200, 800), and (c) (10, 200, 200). The gaugino region has been magnified, and the hatched and cross-hatched regions are as in Fig. 3. For all figures, the value of B_l is $\frac{1}{3}$ in the Higgsino region and grows as one approaches the gaugino region. The growth is faster for large $\tan \beta$ (c) than for low $\tan \beta$ (a). In (a) and (b) the B_l contours differ by approximately 5% in the far gaugino region, consistent with Eq. (57). Note also the “pocket” in the $\mu < 0$ near gaugino region, where $B_l < \frac{1}{3}$.

diagonalization of the matrix in Eq. (6) shows that in the range of parameters we consider,

$$N_{12} \sim \left(\frac{M_Z}{\mu} \right)^n, \quad (54)$$

where $n = 1$ for $M_Z \tan \beta \ll |\mu|$, and $n = 2$ for $M_Z \tan \beta \gg |\mu|$. The latter reflects the $\mu \rightarrow -\mu$ symmetry for large $\tan \beta$.

It follows that for very large $|\mu|$ and sufficiently small slepton and squark masses, the W diagram and the isospin terms in the squark and the slepton diagrams are negligible, as can be seen from Eqs. (44) and (45). Keeping only the hypercharge terms in $D_L \bar{r}(\ell, q)$ and noting $(Y_\ell/Y_q)^2 = 9$, one finds

$$B_l \approx \frac{m_q^4}{m_q^4 + \frac{2}{3}m_{\tilde{t}}^4} \quad (55)$$

in the far gaugino region. This is larger than $\frac{1}{3}$ for each of the cases plotted in Fig. 13, in which the growth of B_l at large $|\mu|$ is evident. Notice, however, that the growth is much faster in the large $\tan \beta$ case (Fig. 13c) than in the small $\tan \beta$ case (Figs. 13a, b). Note also that the figures at $\tan \beta = 2$ with two different squark masses (Figs. 13a, b) have B_l contours that are shifted by a constant factor. We explain these features below.

It is possible to estimate roughly where the crossover occurs from isospin dominated chargino decays, which are close to $B_l = \frac{1}{3}$ for $m_{\tilde{d}} \sim m_{\tilde{t}}$, to hypercharge dominated decays, which have a B_l given by Eq. (55). We first consider small $\tan \beta$. Take $|\mu| \gg M_Z \tan \beta$, but in the near gaugino region, where $B_l \sim \frac{1}{3}$. Now raise $|\mu|$ until N_{12} is so small that the hypercharge terms in Eqs. (44) and (45) dominate the decay amplitudes. Since, for small $\tan \beta$, $N_{12} \sim M_Z/\mu$, we may estimate that this occurs for

$$|\mu| \sim \frac{1}{\tan \theta_W |Y_f|} \frac{m_f^2}{M_W^2} M_Z. \quad (56)$$

This rough estimate is accurate only within a factor of four or so. Since $\tan \theta_W |Y_f|$ is approximately 1/4 for leptons and 1/12 for quarks, the required $|\mu|$ is generally larger than a TeV except for the lightest sfermions, and is smaller for sleptons than

for squarks of the same mass. We therefore expect that for small $\tan \beta$, B_t will not stray too far from $\frac{1}{3}$. In the limit $\tan \beta = 1$ we may quantify this; for large squark and slepton masses, the leading hypercharge terms in the $D_{L,R}(\ell, q)$ cancel, with the isospin terms giving

$$B_t \approx \frac{1}{3} \left[1 + \frac{2}{3} \left(\frac{M_W^2}{m_t^2} - \frac{M_W^2}{m_q^2} \right) \right], \quad (57)$$

to first order in M_W^2/m_t^2 and M_W^2/m_q^2 . This shows that even within the isospin terms there is sensitivity, independent of $\sin \theta_W$ and $\tan \beta$, to the difference between m_q and m_t . This is a general feature of small $\tan \beta$, as is reflected in Figs. 13a and b, where the B_t contours differ by approximately 5% and are consistent with Eq. (57).

Suppose instead that $\tan \beta$ is large and take $|\mu| \ll M_Z \tan \beta$, again in the near gaugino region with $B_t \sim \frac{1}{3}$. Let us again consider increasing $|\mu|$. Now $N_{12} \sim (M_Z/\mu)^2$ vanishes much more quickly as $|\mu|$ grows; the crossover to Eq. (55) occurs near

$$|\mu| \sim \frac{1}{\sqrt{\tan \theta_W |Y_f|}} \frac{m_f}{M_W} M_Z \quad (58)$$

The dependence on the sfermion mass is now linear, and the coefficient has become smaller as well. For large $\tan \beta$, the leptonic branching fraction will therefore deviate strongly from $\frac{1}{3}$ at much smaller values of $|\mu|$ than is the case for small $\tan \beta$. This is clearly seen in the difference between Figs. 13a and c. We note that in the near gaugino region, B_t is also shifted by the correction term in Eq. (57) even for large $\tan \beta$.

Another feature worth noting is a “pocket” in which B_t drops below $\frac{1}{3}$, which occurs in the near gaugino region for negative μ , where simple perturbation theory is not applicable. In this region, the slepton diagrams interfere destructively with the W diagram in the decay amplitude. The “pocket” can be deep for intermediate values of $\tan \beta$, where B_t can take values as low as 10%. This feature has important implications for the case studies of Sec. 2.5.

As noted above, B_t can be determined by measuring the partial cross sections. The leptonic branching fraction is given by

$$B_t = \frac{2\sigma_{\text{leptonic}}}{2\sigma_{\text{leptonic}} + \sigma_{\text{mixed}}} = \frac{\sigma_{\text{mixed}}}{\sigma_{\text{mixed}} + 2\sigma_{\text{hadronic}}}. \quad (59)$$

Again, all three partial cross sections should be employed, though we will only use the two that are likely to have the smallest errors for our measurement of B_t . Strictly speaking, the partial cross sections must be adjusted to account for the fact that τ leptons can decay hadronically. As the corrections depend solely on the well-measured τ branching fractions, the required adjustments are very reliable.

2.3.7 Other Observables

There are many other quantities that could be extracted from the data which depend on the details of the chargino decay vertices. For $2j + \ell$ events, distributions of θ_ℓ , the angle between the lepton and the beam axis, E_ℓ , the energy of the lepton, and corresponding dijet variables θ_{jj} and E_{jj} , are observables that are likely to yield useful information. Correlations between ℓ and $\bar{\ell}$ angles in dilepton events and between lepton and dijet angles in $2j + \ell$ events may also provide information [53]. However, to obtain analytic expressions for these variables one would have to convolve the angular velocity and spin distribution of the production process with the three-body spin-dependent phase space of the decay. The complexity of dealing with these observables is regrettable, since the angular distributions of the chargino decay products are sensitive to $D_L(q)/D_R(q)$ and $D_L(\ell)/D_R(\ell)$ (see Sec. 2.3.6), which cannot be probed using the quantities $m_{\tilde{\chi}_1^\pm}$, $m_{\tilde{\chi}_1^0}$, σ_{total} and B_t . Furthermore, the angular distributions might help determine the angle and spin dependence of the differential cross section, and might be noticeably affected by the propagators of very light sfermions. Restrictions on SUSY parameter space using these observables will probably require detailed Monte Carlo simulations, which we will not attempt to carry out. It seems plausible to us that a global maximum likelihood fit to the data, on the basis of a sufficiently thorough Monte Carlo search, should be able to pick out information that we have not been able to extract in our analysis; we will bolster this claim in Sec. 2.5. It remains to be seen whether the additional knowledge will lead to significantly improved constraints on the underlying parameters.

There are other variables worthy of study which allow the assumptions of our analysis to be tested. If the LSP is a sneutrino instead of a neutralino, chargino decays are qualitatively different, since the two-body decay $\tilde{\chi}_1^\pm \rightarrow \ell\nu$ becomes available. If there is substantial mixing between any of the right- and left-handed stfermions, the chargino decay amplitude will no longer have the form of Eq. (46); the resulting angular distribution of the observed fermions will be identifiably different. Mixing of the third generation of squarks into the other generations could cause many b quarks to appear in the dijets; under our assumptions, very few are expected. A significant breakdown of the universal slepton mass assumption would affect lepton universality in the decays; similarly, a violation of our universal squark mass assumption for the first two generations might be detected by studying the abundance of charm quarks in the dijets. Lastly, a significant contribution by intermediate charged Higgs bosons to the chargino decay amplitude would both affect the angular distributions of the observed fermions and lead to extra heavy fermions among the decay products.

2.3.8 Summary of Observables

We have now concluded the discussion of the four primary observables that will be used in the case studies below. These observables, with their dependences on the underlying SUSY parameters, are the chargino mass $m_{\tilde{\chi}_1^\pm}(\mu, M_2, \tan\beta)$, the LSP mass $m_{\tilde{\chi}_1^0}(\mu, M_2, \tan\beta, M_1)$, the total cross section $\sigma_{\text{total}}(\mu, M_2, \tan\beta, m_{\tilde{t}} = m_{\tilde{b}})$, and the leptonic branching fraction $B_\ell(\mu, M_2, \tan\beta, M_1, m_{\tilde{t}}, m_{\tilde{b}})$. We have also studied the forward-backward asymmetry $A_{FB}^{\tilde{\chi}_1^\pm}(\mu, M_2, \tan\beta, m_{\tilde{t}} = m_{\tilde{b}})$ and have explained why it is difficult to use.

To close this section, we review the sensitivity of these parameters in the different regions. In the gaugino region, where $|\mu| \gg M_2, |M_1|$, we are sensitive to all six parameters: $m_{\tilde{\chi}_1^\pm} \sim M_2$; $m_{\tilde{\chi}_1^0} \sim |M_1|$; $\sigma_{\text{total}} \approx f(v) \times [3.2 - 2.8(s/m_{\tilde{t}}^2)]R$ to leading order in $s/m_{\tilde{t}}^2$, where $f(v)$ is a definite function of the chargino velocity; and B_ℓ is a non-trivial function which is sensitive to several combinations of SUSY parameters. When $m_{\tilde{t}} (= m_{\tilde{b}})$ and $m_{\tilde{t}}$ are both very large, the total cross section $\sigma_{\text{total}} = f(v) \times 3.2R$ and $B_\ell = \frac{1}{3}$. In the Higgsino region, where $|\mu| \ll M_2$, the following relationships

hold: $m_{\tilde{\chi}_1^\pm} \sim |\mu|$; $m_{\tilde{\chi}_1^0} \sim \min\{|\mu|, |M_1|\}$; $\sigma_{\text{total}} = f(v) \times 1.3R$, and $B_\ell = \frac{1}{3}$. There is no sensitivity in this region to $m_{\tilde{t}}$ or $m_{\tilde{b}}$, and very little to M_1/M_2 , unless $|M_1|$ is less than or of order $|\mu|$. In the mixed region, the observables are all complicated functions of the SUSY parameters, and there are few general statements to be made. From this discussion it can be guessed that we can put the fewest constraints on parameter space if the physics lies in the Higgsino region, whereas the gaugino region is more promising for our analysis. Intermediate results are found in the mixed region. We will see this explicitly in the case studies in Sec. 2.5.

2.4 Event Simulation and Backgrounds

For this study, chargino events are generated by a simple parton level Monte Carlo event generator. For a given set of parameters, we first calculate the chargino decay width and branching ratios. The SAGE subroutines [54] are used to generate three-body final state momenta and phase space weightings, and the matrix elements for the decay are calculated with the explicit helicity spinor method, using subroutines that are patterned after the HELAS package [55]. We find that typically the chargino width $\Gamma_{\tilde{\chi}_1^\pm}$ is roughly 1-100 keV. Using the same subroutines, we therefore generate the six-body events $e^+e^- \rightarrow \tilde{\chi}_1^0 \tilde{\chi}_1^- \rightarrow (\tilde{\chi}_1^0 q' q, \tilde{\chi}_1^0 \ell' \nu) (\tilde{\chi}_1^+ q' q, \tilde{\chi}_1^+ \ell' \nu)$ in the zero width approximation for the intermediate charginos. In this approximation the total amplitude factorizes into production and decay amplitudes and is given by

$$\mathcal{M}^{\text{tot}} = \sum_{h^+, h^- = -1}^1 \mathcal{M}_{h^+ h^-}^{\text{prod}} \mathcal{M}_{h^+}^{\text{decay}} \mathcal{M}_{h^-}^{\text{decay}} \frac{\pi}{m_{\tilde{\chi}_1^\pm} \Gamma_{\tilde{\chi}_1^\pm}}, \quad (60)$$

where

$$\begin{aligned} \mathcal{M}_{h^+ h^-}^{\text{prod}} &= \mathcal{M}^{\text{prod}}(e^+ e^- \rightarrow \tilde{\chi}_{h^+}^\pm \tilde{\chi}_{h^-}^\mp), \\ \mathcal{M}_{h^\pm}^{\text{decay}} &= \mathcal{M}^{\text{decay}}(\tilde{\chi}_{h^\pm}^\pm \rightarrow \tilde{\chi}_1^0 q' q, \tilde{\chi}_1^0 \ell' \nu), \end{aligned} \quad (61)$$

and $h^\pm$ is the helicity of $\tilde{\chi}_1^\pm$. Without factorization the amplitude consists of up to 108 diagrams, since 3 diagrams contribute to the production process and 6 (5) diagrams contribute to each hadronic (leptonic) decay. (Of course, with the assumptions

of Sec. 2.2, only 3 (3) diagrams contribute substantially to the hadronic (leptonic) decay.) Factorization allows us to calculate $\mathcal{M}_{h^+h^-}^{\text{prod}}$ and $\mathcal{M}_{h^+h^-}^{\text{decay}}$ separately, which is a great simplification and considerably improves the efficiency of the event generator. After calculating these amplitudes, we sum over internal chargino helicities to get $\mathcal{M}^{\text{tot}}$, which is then squared and summed over external helicities to obtain the total differential cross section. By summing over internal helicities before squaring, we retain the important spin correlations between production and decay.

In this study, we ignore effects due to the Majorana nature of the $\tilde{\chi}_1^0$. Because the $\tilde{\chi}_1^0$ is a Majorana fermion, one should in principle include for every Feynman diagram a diagram with the $\tilde{\chi}_1^0$ momenta interchanged. In our Monte Carlo simulation, the momenta are preferentially picked such that the charginos are very nearly on-shell. The chargino rest frames are boosted with respect to each other, and most events are produced with the two LSPs having different momenta. Thus, in almost all cases, the diagram with interchanged LSP momenta has chargino momenta that are far out of their narrow Breit-Wigner peaks and can be ignored.

The event generator was checked in a number of ways. In the explicit spinor method, Lorentz invariance is not manifest. We have checked that the total amplitude squared is invariant under arbitrary Lorentz boosts, and this provides a powerful check. In addition, the amplitudes must transform into their complex conjugates, up to a sign, when all helicities are reversed, and this was verified as well. The production cross section was found to agree with the analytic results presented in Sec. 2.3 and with those previously published [12] for many sets of parameters. The decay amplitudes were also verified in a number of ways. The differential decay width $d\Gamma/dE d\cos\theta$ was found to agree with muon decay in the appropriate limit, and also with the decay of a “muon” with V+A coupling. This provides a check of the W diagram and the overall normalization. Finally, the total decay amplitude, summed over all diagrams, was verified to reproduce the chargino branching ratio results given in Ref. [52].

The effects of initial state radiation (ISR) are not included in our simulation. Hadronization and detector effects are crudely simulated by smearing quark parton and lepton energies. The detector resolutions currently available at the ALEPH

detector at LEP are [21]

$$\sigma_E^{\text{had}}/E = 80\%/\sqrt{E} \quad \text{and} \quad \sigma_E^{\text{lept}}/E = 19\%/\sqrt{E}, \quad (62)$$

where E is in GeV. In the Monte Carlo simulation, we smear the lepton parton energies by the leptonic resolution. For the typical energies of our simulation, the resulting leptonic resolutions are numerically a good approximation to those that will be achieved for both muons and electrons by current LEP detectors. We also smear the hadronic parton energies by the hadronic resolution. By doing so, we implicitly assume that the quark jet energy is measured by the hadronic calorimeter only. In fact, however, quark jets are detected by a combination of the tracking chamber, the electromagnetic calorimeter, and the hadronic calorimeter, and, in particular, the addition of tracking chamber measurements can improve the jet energy resolution substantially. This improvement was studied in Ref. [56] for W mass resolution at a $\sqrt{s} = 500$ GeV e^+e^- collider. For a detector with energy resolutions $\sigma_E^{\text{had}}/E = 50\%/\sqrt{E} + 2\%$ and $\sigma_E^{\text{lept}}/E = 10\%/\sqrt{E} + 2\%$, the resolution of M_W , as measured by the dijet mass, was found to improve by 33% from 4.1 GeV to 2.7 GeV when the tracking chamber measurements were included. Similar studies for the L3 detector at LEP have shown that when the momentum measurement from the central tracking detector is included, the resolution for the total energy in hadronic events improves by about 20% from 9.2 GeV to 7.6 GeV [22, 57]. To simply account for the improvements from tracking chamber measurements, we will reduce our resolutions for m_{jj} and E_{jj} endpoint determinations by 25% by hand in the case studies presented below.

To study the observables presented in Sec. 2.3, we must find the m_{jj} and E_{jj} distributions in $2j + \ell$ chargino events and determine two of the partial cross sections, including that of the mixed mode. Three of these measurements can be made with Y mode events, the subset of $2j + \ell$ events in which the hadrons do not come from a tau lepton, since the Y mode cross section can be converted to a mixed mode cross section (under the assumption that lepton universality holds). It is therefore important to include realistic cuts that isolate the Y mode chargino events. We will now show that $2j + \ell$ events may be easily resolved. In Sec. 2.5 we will see that the Y mode events in this sample may be isolated by simply eliminating events with low invariant hadronic

mass.

The $2j+l$ mode is the most promising for chargino discovery and has been carefully studied [13, 14, 15]. In Ref. [15] cuts have been designed for the parameters $\sqrt{s} = 175 \text{ GeV}$, $\mu = -100 \text{ GeV}$, $\tan\beta = 2$, $m_{\tilde{\chi}_1^\pm} = 80 \text{ GeV}$, and $m_{\tilde{\chi}_2^0} = 20\text{--}60 \text{ GeV}$. These cuts include the following requirements:

- 1) The missing transverse momentum $\cancel{p}_T$ is required to be greater than 10 GeV .
- 2) The event must contain an isolated electron or muon with a momentum larger than 5 GeV and with no hadronic activity within 30° .
- 3) The squared missing mass m_{missing}^2 must be greater than 4000 GeV^2 .
- 4) The hadronic system mass m_{jj} must be less than 45 GeV .
- 5) Under the assumption that the missing momentum in the event is due to a "neutrino", the mass of the lepton-"neutrino" system is required to be less than 70 GeV . This removes most WW events. Actually, one can do even better than this, since it is possible to allow for two unobserved massless particles, one an undetected ISR photon along the beam axis and the other a missing "neutrino," and still determine all of the momenta in the event. In this case, forcing the lepton-"neutrino" invariant mass to be less than 70 GeV removes many $WW\gamma_{\text{ISR}}$ events as well.

As shown in Ref. [15], cuts 1 and 2 reduce the WW background to 2.8 pb . Cuts 3–5 are specifically designed to reduce this background further. After additionally imposing cuts 3, 4, and 5, the WW background is reduced to 180 fb , 17 fb , and 7 fb , respectively. After all cuts, the other standard model backgrounds contribute only 2 fb . Applying these same cuts to a chargino sample, we have found that typically the mixed mode is reduced by about $25\text{--}75\%$ after cut 4, but 40% of these are eliminated by cut 5. Although the additional 40% loss in statistics is not extremely large, typically the signal to background ratio is greater than or of order 50 after cut 4 and the background is already negligible. Thus, of the five cuts listed, we will use cuts 1–4 and ignore cut 5 in our analysis. This leaves the standard model background at approximately 20 fb .

As we do not include the effects of hadronization, we will also require that each final state quark parton have energy greater than 5 GeV so that its hadronization products are detected.

In addition to standard model backgrounds, there may be supersymmetric backgrounds that will need to be distinguished from chargino pairs. In particular, as noted in Sec. 2.2, if charginos are produced, neutralino production is almost certainly allowed. It is first worth noting that the neutralino background is highly suppressed in a significant portion of parameter space [30]. Neutralinos are produced through a Z annihilation diagram and t -channel selectron exchange. However, as the Z couples only to the Higgsino components of the neutralinos, neutralino production is suppressed in the gaugino region unless the selection mass is low. It may happen, then, that neutralino production, though kinematically allowed, is a negligible background to chargino production. For other regions of parameter space, it should still be possible to separate the neutralino and chargino events. Production of $\tilde{\chi}_1^0\tilde{\chi}_2^0$ is not a significant background to Y mode chargino events, because these neutralino events produce exactly one isolated charged lepton only when $\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0\tau^\pm$, and one τ decays leptonically and the other hadronically. These should be easily distinguished from Y mode chargino events, based on the small invariant mass of the hadrons. Production of $\tilde{\chi}_2^0\tilde{\chi}_3^0$ may be problematic if one neutralino decays to $\tilde{\chi}_1^0\tau^\pm$ while the other decays to $\tilde{\chi}_1^0q\bar{q}$, which can lead to an isolated lepton and an assortment of hadrons. However, even if the hadrons cannot be resolved into three isolated jets, kinematics often distinguish these events from chargino events, since the total hadronic energy or invariant mass may exceed what is allowed in $\tilde{\chi}_1^\pm \rightarrow \tilde{\chi}_1^0q\bar{q}$. In any case, the number of these events is usually very small. Both types of neutralino events may be backgrounds for the purely leptonic chargino events, and $\tilde{\chi}_2^0\tilde{\chi}_3^0$ may also be a background for the four-jet events. However, neutralino events do not produce significant numbers of $e\mu$ events, nor do they produce $\tilde{\ell}\ell$ events with $m_{\tilde{\ell}\ell} > m_{\tilde{\chi}_2^0} - m_{\tilde{\chi}_1^0}$, and these may therefore be identified as chargino events. Assuming lepton universality, one can then determine both the total leptonic and total hadronic cross section from chargino pairs.

If cascade decays occur with a substantial branching fraction, they may also make it difficult to isolate the chargino signal. Such decays are prominent, for example, in certain regions with $M_2 \sim |\mu| \sim M_W$, where the mass separation between the $\tilde{\chi}_1^\pm$ and the $\tilde{\chi}_2^0$ is large, and where $\tilde{\chi}_1^0\tilde{\chi}_3^0$ production may be possible. We assumed in Sec. 2.2

that cascade decays of the chargino itself have a small branching fraction; for points where this is not true our analysis must be modified. For $m_{\tilde{\chi}_2^0} > m_{\tilde{\chi}_1^0}$ the decay of the $\tilde{\chi}_2^0$ through a chargino, which then decays to an LSP, can be prominent, and can be a background to chargino events. The $\tilde{\chi}_3^0$ may also undergo cascade decays. To distinguish these cases, and to isolate the chargino signal, one should vary the beam energy and make use of the fact that each signal has a unique energy dependence. Our Monte Carlo simulation does not include these supersymmetric backgrounds, and we have not studied the effectiveness of changing the beam energy, but we will assume that an energy scan will allow the separation of the chargino signal from cascade decays. In any event, as the SUSY parameters become roughly known, it is possible that improved cuts could be devised to efficiently separate the chargino and neutralino signals.

Approximate knowledge of the SUSY parameters may also be relevant for the isolation of the chargino signal from standard model backgrounds. The most obvious example is the possibility of a chargino with mass less than M_W , in which case one could work below the WW threshold, dispense with cuts 3-5, and increase the number of signal events by approximately a factor of 2. However, for simplicity in this exploratory study, we will use cuts 1-4 and the requirement on quark energies in all regions of parameter space.

2.5 Case Studies

In this section, we present a number of case studies at representative points in SUSY parameter space. In the first subsection, we discuss the general procedure that will be used to find the allowed regions of SUSY parameter space. We also describe the way in which our results will be presented graphically. In the remaining subsections, we consider points in the gaugino, Higgsino, and mixed regions, and determine for each case how well the observables may be measured and what bounds on underlying SUSY parameters may be obtained. Throughout this section, we present results for $\sqrt{s} = 190$ GeV and an event sample of 1 fb^{-1} .

Figure 14: The $m_{\tilde{\chi}_i^\pm}$ measurement restricts the $(\mu, M_2, \tan \beta)$ space to two thin sheets S , which are then flattened into the plane T with the transformation $(\mu, M_2, \tan \beta) \rightarrow (\alpha, \tan \beta)$, where $\alpha = \arctan(M_2/\mu)$. This transformation is illustrated schematically here. For large $\tan \beta$, observables are symmetric under $\mu \leftrightarrow -\mu$, that is, under $\alpha \leftrightarrow 180^\circ - \alpha$.

2.5.1 Strategy for Finding Allowed Parameter Space

After the observables $m_{\tilde{\chi}_i^\pm}$, $m_{\tilde{\chi}_1^0}$, σ_{total} , and B_I are measured, one must determine how the SUSY parameter space is restricted. As the parameter space is six-dimensional, it is important to outline a method by which such restrictions are easily applied and understood.

The dependence of $m_{\tilde{\chi}_i^\pm}$ on only three SUSY parameters allows us a simple starting point. First, consider the three-dimensional space $(\mu, M_2, \tan \beta)$. A point P in this space survives the chargino mass measurement if it predicts the chargino mass correctly, within experimental uncertainties. The allowed region is then confined to two thin sheets which we will label as S , one with $\mu < 0$ and another with $\mu > 0$. This is shown schematically in Fig. 14.

To display our results, it will be necessary to plot contours in the allowed region,

and it will therefore be convenient to flatten the two sheets $\mathcal{S}$ into a plane $\mathcal{T}$ with the coordinate transformation

$$(\mu, M_2, \tan \beta) \in \mathcal{S} \rightarrow \left(\alpha \equiv \arctan \frac{M_2}{\mu}, \tan \beta \right) \in \mathcal{T}, \quad (63)$$

as shown in Fig. 14. Since the sheets are not infinitely thin, a short segment of points in $\mathcal{S}$ is projected into every point in $\mathcal{T}$. The far gaugino regions are then transformed to the areas with $\alpha \approx 0^\circ, 180^\circ$, and the far Higgsino regions now correspond to the region with $\alpha \approx 90^\circ$. The symmetry $\mu \leftrightarrow -\mu$ for $\tan \beta \rightarrow \infty$ implies that, at large $\tan \beta$, observables at α are nearly equal to those at $180^\circ - \alpha$.

The allowed region is restricted further by the other measurements. The LSP mass $m_{\tilde{\chi}_1^0}$ is a function of $\mu, M_2, \tan \beta$, and M_1 , and so the $m_{\tilde{\chi}_1^0}$ measurement limits M_1 to a certain range. To graphically represent this restriction of M_1 , or equivalently, M_1/M_2 , we will do the following. For a point $\mathcal{P} = (\alpha, \tan \beta) \in \mathcal{T}$, we find all parameters $(\mu, M_2 = \mu \tan \alpha, \tan \beta, M_1/M_2)$ such that the corresponding values of $m_{\tilde{\chi}_1^\pm}$ and $m_{\tilde{\chi}_1^0}$ are within the experimental limits. The allowed values of M_1/M_2 will lie in some range $(M_1/M_2)_{\min} < M_1/M_2 < (M_1/M_2)_{\max}$. To display this range, we will plot contours in $\mathcal{T}$ of $(M_1/M_2)_{\min}$ and $(M_1/M_2)_{\max}$. If no value for M_1 in the range given in Eq. (20) leads to the correct $m_{\tilde{\chi}_1^0}$, the point $\mathcal{P}$ is excluded.

In a similar manner, the measurement of $\sigma_{\text{had}}(\mu, M_2, \tan \beta, m_{\tilde{t}})$ will limit the allowed range of $m_{\tilde{t}}$, and this range can be represented in contour plots of $(m_{\tilde{t}})_{\min}$ and $(m_{\tilde{t}})_{\max}$. If no value of $m_{\tilde{t}}$ gives the correct σ_{had} , $\mathcal{P}$ is not allowed. Finally, given $\mathcal{P}$ and the ranges of M_1 and $m_{\tilde{t}}$ as determined above, the measured value of B_t restricts the range of $m_{\tilde{t}}$ to a certain range, and we will also present contours of $(m_{\tilde{t}})_{\min}$ and $(m_{\tilde{t}})_{\max}$. If no value of $m_{\tilde{t}}$ yields the appropriate B_t , then the point $\mathcal{P}$ is excluded. In principle, measurement of $A_{FB}^{t\ell}$ may also be used to limit the allowed region, but we defer discussion of this observable to the individual case studies below.

The remaining points $\mathcal{P} = (\alpha, \tan \beta) \in \mathcal{T}$, for which there exist parameters $(\mu, M_2 = \mu \tan \alpha, \tan \beta, M_1, m_{\tilde{t}}, m_{\tilde{t}})$ that are consistent with all measurements, form the allowed region. We will plot this region in the $\mathcal{T}$ plane. From this plot, the allowed ranges of $\rho_{\tilde{\chi}_1^\pm}$ and $\tan \beta$ may be quickly determined. The ranges of and correlations between the other variables may be found from the contour plots of their

minimum and maximum allowed values.

2.5.2 Gaugino Region

The first case we consider is a set of SUSY parameters in the gaugino region with gaugino mass unification. We choose

$$(\mu, M_2, \tan \beta, M_1/M_2, m_{\tilde{t}}, m_{\tilde{t}}) = (-400, 75, 4, 0.5, 200, 300). \quad (64)$$

With these parameters, $\alpha = 169^\circ$, and the underlying values and ranges of the most important quantities are

$$\begin{aligned} m_{\tilde{\chi}_1^\pm} &= 79.6 \text{ GeV} \\ m_{\tilde{\chi}_1^0} &= 39.1 \text{ GeV} \\ \sigma_{\text{total}} &= 1.16\text{R} = 3200 \text{ fb} \\ \rho_{\tilde{\chi}_1^\pm} &= 1.00 \\ \rho_{\tilde{\chi}_1^0} &= 0.99 \\ B_t &= 0.42 \\ m_{\tilde{t}} &< 40.5 \text{ GeV} \\ 16.4 \text{ GeV} &< E_{\tilde{t}} < 55.8 \text{ GeV}. \end{aligned} \quad (65)$$

Since $m_{\tilde{\chi}_1^\pm} \approx M_W$, it is not possible to work below the WW threshold, and the cuts for $2j + l$ events described in Sec. 2.4 are likely to be nearly ideal. Note that the sneutrino mass has been taken near the low end of the range. This value leads to substantial destructive interference in the production amplitude; higher values for $m_{\tilde{\nu}}$ would give considerably larger cross sections.

With an integrated luminosity of 1 fb^{-1} , there are 3203 chargino events, and the Monte Carlo simulation yields 1493 mixed mode events. Some of these events include hadronically-decaying τ leptons, but the rest of them are Y mode events, as defined in Sec. 2.2. In the Monte Carlo simulation we are left with 1184 Y events, of which 889 (75%) survive the cuts described in Sec. 2.4. In addition to these Y mode events, some leptonic mode chargino events with hadronically-decaying τ leptons will also pass the cuts. However, hadrons resulting from τ decays are highly collimated with

invariant mass less than m_τ . The m_{jj} spectrum for the 889 Y events is shown in Fig. 15a. Clearly, very few Y mode events have dijet masses consistent with τ decays, and Y events should be easily separated on this basis. We will therefore assume that we have an event sample of Y events that is virtually free of background and may be used to determine the values of chargino event observables.

We may now determine the masses $m_{\tilde{\chi}_1^\pm}$ and $m_{\tilde{\chi}_1^0}$ from the endpoints of dijet mass and energy distributions, as discussed in Sec. 2.3. These distributions are given in Fig. 15. We see that finite detector resolution effects cause the spectra to have tails that exceed the theoretical limits, but despite this, the endpoints are fairly sharp. The $m_{jj}^{\max}$ endpoint almost certainly lies within a 8 GeV range, and we therefore estimate its 1σ error to be 2 GeV. Similarly, we estimate that the 1σ error for the maximum endpoint of E_{jj} is 3 GeV. As noted in Sec. 2.4, these resolutions are expected to improve with the addition of tracking chamber momentum measurements [56, 22, 57], and we therefore take the actual resolutions to be reduced by 25% to $\Delta m_{jj}^{\max} = 1.5$ GeV and $\Delta E_{jj}^{\max} = 2.3$ GeV. (In the next subsection we will examine the effect on our results of increasing these uncertainties.) We must now propagate these uncertainties into the determinations of the underlying masses. The relevant formulae for the uncertainty calculations are collected in Appendix A. As the beam energy is below $E_0^{\text{crit}} = 100.5$ GeV, we use Eq. (125) to find

$$\Delta m_{\tilde{\chi}_1^\pm} = 2.7 \text{ GeV} \quad \text{and} \quad \Delta m_{\tilde{\chi}_1^0} = 2.3 \text{ GeV}. \quad (66)$$

For simplicity, we have assumed that the central values for endpoint measurements are their underlying physical values. We note also that, although $E_{jj}^{\min}$ provides a useful cross check and may also improve the mass determinations, we will not use it here.

Next we must determine σ_{total} and B_ℓ and the uncertainties in their measurements. To do this, as discussed in Sec. 2.3, we must measure at least two of the three partial cross sections σ_{mixed} , σ_{hadronic} , and σ_{leptonic} . The partial cross section σ_{mixed} is always one of the two largest, and we will consider this mode in detail. As noted above, we do not measure σ_{mixed} directly, but rather σ_Y . Under the assumptions of Sec. 2.2, which imply lepton universality, $\sigma_Y = \frac{2.0 \pm 0.4}{3.0} \sigma_{\text{mixed}} = \frac{4}{5} \sigma_{\text{mixed}}$ and $\frac{\Delta \sigma_Y}{\sigma_Y} = \frac{\Delta \sigma_{\text{mixed}}}{\sigma_{\text{mixed}}}$.

Figure 15: The dijet (a) mass spectrum and (b) energy spectrum, after cuts, for the gaugino case ($\mu, M_2, \tan \beta, M_1/M_2, m_{\tilde{t}}, m_{\tilde{d}} = (-400, 75, 4, 0.5, 200, 300)$) with integrated luminosity 1 fb^{-1} . In these distributions, hadrons from τ lepton decays have not been included. We see that finite detector resolution effects cause the spectra to have tails that exceed the theoretical limits, but despite this, the endpoints are fairly sharp. We estimate that the 1σ uncertainty of $m_{jj}^{\max}$ is 2 GeV, and that for $E_{jj}^{\max}$ is 3 GeV. Note that very few events have dijets with low invariant mass, and it is therefore possible to distinguish hadrons that result from τ decays and those that result from hadronic chargino decays.

We will then assume that similar errors, in a sense to be defined precisely below, may be obtained for the hadronic mode. With these assumptions, we then find the uncertainties of σ_{total} and B_r . (The consistency of our assumption of lepton universality may be checked by verifying that, for example, $B(\tilde{\chi}_1^+ \tilde{\chi}_1^- \rightarrow 2j + e) = B(\tilde{\chi}_1^+ \tilde{\chi}_1^- \rightarrow 2j + \mu)$. Furthermore, if additional branching ratios can be measured, one may determine directly whether lepton universality indeed holds.)

We must now determine the uncertainty for measurements of σ_r . For any mode i , the cross section and fractional uncertainty are

$$\sigma_i = N_i \eta_i^{-1} \mathcal{L}^{-1} \quad (67)$$

and

$$\frac{\Delta \sigma_i}{\sigma_i} = \left[\left(\frac{\Delta N_i}{N_i} \right)^2 + \left(\frac{\Delta \eta_i}{\eta_i} \right)^2 + \left(\frac{\Delta \mathcal{L}}{\mathcal{L}} \right)^2 \right]^{\frac{1}{2}}, \quad (68)$$

where N_i is the number of i mode events passing the cuts, η_i is the efficiency of the cuts for i mode events, and $\mathcal{L}$ is the collider luminosity. The number of Y mode events passing the cuts is 889, so $\Delta N_Y / N_Y = 1/\sqrt{N_Y} = 3.4\%$. The efficiency η_r is not known and, in principle, depends on all the SUSY parameters that we are trying to determine. However, by running Monte Carlo simulations for many points in SUSY parameter space with the measured $m_{\tilde{\chi}_1^\pm}$ and $m_{\tilde{\chi}_2^0}$, we can determine how much the efficiency varies throughout the allowed parameter space. We have done this for points in the gaugino, Higgsino, and mixed regions, for both positive and negative μ , various $\tan \beta$, and $(m_{\tilde{t}}, m_{\tilde{q}}) = (100, 150)$, $(200, 300)$, and $(500, 700)$, with the sole restriction being that these points give $m_{\tilde{\chi}_1^\pm} \approx 80$ GeV and $m_{\tilde{\chi}_2^0} \approx 39$ GeV. For all of these cases, the efficiency of the cuts varies only between 70% and 77%. Thus, the cut efficiency is determined primarily by kinematics and varies only slightly for fixed $m_{\tilde{\chi}_1^\pm}$ and $m_{\tilde{\chi}_2^0}$. We take the efficiency to be $\eta_r = 73.5\%$ and its variation to be $\Delta \eta_r = 3.5\%$. The uncertainty in the luminosity, which at LEP II is $\Delta \mathcal{L} / \mathcal{L} = 0.3\%$, and which is not expected to increase substantially for LEP II [58], is much smaller than the other errors. Substituting these values into Eq. (68), we find that $\Delta \sigma_r / \sigma_r = 5.8\%$.

Although we do not have specific cuts for the hadronic and leptonic modes, we

will assume that cuts with similar η and $\Delta \eta$ may be devised for at least one of the other modes. Such an assumption is certainly not to be taken for granted as the other two modes have large backgrounds. In the four jet mode, it may be possible to reduce backgrounds substantially by demanding that no pairing of jets yields two dijet masses consistent with M_W or M_Z . The leptonic mode is plagued by an irreducible background from W pair production [14]. As can be seen from Eq. (68), the best cuts for the purposes of this study are those that balance uniformity (low $\frac{\Delta \eta}{\eta}$) with background suppression and efficiency (low $\frac{\Delta N}{N}$). It is clear that detailed studies of cuts for the $4j$ and 2ℓ events are necessary for future work in this area. For this study, however, we will calculate the fractional uncertainty in σ_{hadronic} assuming that cuts may be devised with values of η and $\Delta \eta$ similar to those obtained in the mixed mode. It is important to note that significantly worse values of η_{hadronic} need not change our main results dramatically. We will demonstrate this explicitly in the following subsection, where results are presented for lower values of η_{hadronic} . We will assume in our case studies that the errors for the leptonic mode are larger than those for the hadronic mode, and so we will use only the mixed and hadronic modes for our determinations of σ_{total} and B_r . In a complete analysis the leptonic mode should be combined with the others to further constrain the determinations of σ_{total} and B_r .

The Monte Carlo simulation yields 1095 hadronic mode events. The assumption $\eta_{\text{hadronic}} = \eta_r = 73.5\%$ implies $N_{\text{hadronic}} = 804$, and assuming also that $\Delta \eta_{\text{hadronic}} = 3.5\%$, we find that $\Delta \sigma_{\text{hadronic}} / \sigma_{\text{hadronic}} = 5.9\%$. We may now proceed to determine the uncertainties in σ_{total} and B_r . Using the formulae in Appendix A, we find

$$\Delta \sigma_{\text{total}} / \sigma_{\text{total}} = 5.0\% \quad \text{and} \quad \Delta B_r / B_r = 4.8\%. \quad (69)$$

We have now determined the uncertainties with which the four observables may be measured and can apply the strategy outlined in Sec. 2.5.1 to determine the allowed region in SUSY parameter space. To recapitulate, the $m_{\tilde{\chi}_1^\pm}$ measurement restricts the $(\mu, M_2, \tan \beta)$ space to two thin sheets, one with $\mu < 0$ and another with $\mu > 0$. These sheets are then flattened into the $(\alpha, \tan \beta)$ plane, where α is the angle given by $\tan \alpha = M_2 / \mu$. The far gaugino regions are at $\alpha \approx 0^\circ, 180^\circ$, while the far Higgsino region lies near $\alpha \approx 90^\circ$.

Figure 16: Gaugino example contours for the (a) minimum and (b) maximum values of M_1/M_2 in the $(\alpha, \tan \beta)$ plane, as defined in Sec. 2.5.1. The cross-hatched area in the $\alpha > 90^\circ$ mixed region with $\tan \beta \approx 1$ is excluded by the $m_{\tilde{\chi}_1^0}$ measurement. The approximate symmetry $\alpha \leftrightarrow 180^\circ - \alpha$ ($\mu \leftrightarrow -\mu$) for large $\tan \beta$ is already in evidence at $\tan \beta = 10$.

For any given point $\mathcal{P}$ in the $(\alpha, \tan \beta)$ plane, we determine values of M_1/M_2 that give the measured value of $m_{\tilde{\chi}_1^0}$ within 1σ bounds. In general, there will be an allowed range for $M_1 > 0$ and another for $M_1 < 0$. These are distinct branches, as there are no symmetries connecting positive and negative M_1 . For now, let us investigate the $M_1 > 0$ possibility only.

In Fig. 16 we plot constant contours of the minimum and maximum allowed values of M_1/M_2 in the $(\alpha, \tan \beta)$ plane. The approximate symmetry $\mu \leftrightarrow -\mu$ for large $\tan \beta$ is already in evidence at $\tan \beta = 10$, and the contour lines are approximately independent of $\tan \beta$ above this value. If no value of M_1/M_2 gives the correct $m_{\tilde{\chi}_1^0}$,

the point $(\alpha, \tan \beta)$ is excluded, as happens in the small cross-hatched area in the $\alpha > 90^\circ$ ($\mu < 0$) mixed region with $\tan \beta \approx 1$, where it is not possible to raise M_1/M_2 sufficiently to produce the required $m_{\tilde{\chi}_1^0}$. For the areas of the plane that are not excluded, the range of allowed M_1/M_2 values is quite restricted. In the far gaugino region, the allowed range of M_1/M_2 is roughly $0.45 \lesssim M_1/M_2 \lesssim 0.55$ and is centered around 0.5, as expected. In the Higgsino region, for decreasing $\rho_{\tilde{\chi}_1^\pm}$, M_1/M_2 drops to zero. This is easily understood, since, as we approach the far Higgsino region, for which M_2 is large, M_1 must remain roughly constant at $M_1 \sim 40$ GeV to accommodate the neutralino mass $m_{\tilde{\chi}_1^0} \approx 40$ GeV. We also see that, for $\tan \beta \gtrsim 2.5$, only values of M_1/M_2 less than 0.6 are allowed.

We now determine the values of $m_{\tilde{t}}$ that give the observed σ_{total} within 1σ bounds. In Fig. 17 we plot the minimum and maximum allowed values of $m_{\tilde{t}}$ for points in the $(\alpha, \tan \beta)$ plane. In the far gaugino region, the slepton mass range is $180 \text{ GeV} \lesssim m_{\tilde{t}} \lesssim 220 \text{ GeV}$. The bounds are quite stringent because the cross section is very sensitive to $m_{\tilde{t}}$ in the gaugino region, as was shown in Fig. 10. As one moves from the gaugino region to the Higgsino region, the cross section for a fixed $m_{\tilde{t}}$ decreases, and therefore $m_{\tilde{t}}$ increases to compensate. In addition, the cross sections become less sensitive to $m_{\tilde{t}}$, and the uncertainty for the $m_{\tilde{t}}$ determination grows. Finally, at a certain point, $m_{\tilde{t}}$ cannot be large enough to prevent the cross section from dipping below the measured value, and thus the far Higgsino region is excluded. The σ_{total} measurement alone is therefore enough to exclude the cross-hatched region of the $(\alpha, \tan \beta)$ plane in Fig. 17.

For the remaining allowed regions of the $(\alpha, \tan \beta)$ plane, we use the determined ranges of M_1 and $m_{\tilde{t}}$ to find the values of $m_{\tilde{t}}$ that give the correct B_t within 1σ . Contours of constant $(m_{\tilde{t}})_{\text{min}}$ and $(m_{\tilde{t}})_{\text{max}}$ are plotted in Fig. 18, where the $\alpha > 90^\circ$ ($\mu < 0$) gaugino region has been enlarged. (Similar features are seen in the $\alpha < 90^\circ$ ($\mu > 0$) gaugino region.) As one approaches the far gaugino region, the leptonic branching fraction grows for fixed $m_{\tilde{t}}$, and the maximum allowed squark mass $(m_{\tilde{q}})_{\text{max}}$ decreases. At some point, no squark mass greater than 150 GeV is allowed, and the hatched region is therefore excluded. Since B_t grows more quickly for large $\tan \beta$, as predicted by Eqs. (56) and (58), the excluded region is larger for high $\tan \beta$.

Figure 17: Gaugino example contours for the (a) minimum and (b) maximum values of m_t in the $(\alpha, \tan\beta)$ plane, as defined in Sec. 2.5.1. The cross-hatched area in the Higgsino region is excluded because the measured σ_{total} is too large to be compatible with any m_t .

Figure 18: Gaugino example contours for the (a) minimum and (b) maximum values of m_t in the $(\alpha, \tan\beta)$ plane, as defined in Sec. 2.5.1. The $\alpha > 90^\circ$ ($\mu < 0$) gaugino region has been magnified. (Similar features are seen in the $\alpha < 90^\circ$ ($\mu > 0$) gaugino region.) The hatched and cross-hatched regions are excluded by the B_t measurement: in the hatched region B_t is too large, and in the cross-hatched region B_t is too small.

Figure 19: The allowed region in the $(\alpha, \tan \beta)$ plane for the gaugino case study with both signs of M_1 allowed. The hatched regions are excluded by the measurements of $m_{\tilde{X}_1^\pm}, m_{\tilde{X}_1^0}, \sigma_{\text{total}}$, and B_ℓ , which confine the allowed region to narrow strips in the gaugino region. The dot indicates the underlying value of $(\alpha, \tan \beta)$ for the gaugino case study.

Conversely, if one moves from the far gaugino region to the gaugino region, B_ℓ drops, and to stay within the 1σ bounds on B_ℓ , $(m_{\tilde{q}})_{\text{min}}$ grows. At a certain point, no $m_{\tilde{q}}$ is large enough to accommodate the measured B_ℓ , and so the cross-hatched region is also excluded.

The resulting allowed regions are shown in Fig. 19, where the cross-hatched regions are excluded. We see immediately that the allowed regions lie completely in the gaugino region. (A subtle point should be mentioned here. The B_ℓ measurement not only constrains the allowed region in the $(\alpha, \tan \beta)$ plane, but also, for a fixed point in the allowed region, further limits the acceptable values of M_1 and $m_{\tilde{q}}$. Therefore the allowed ranges may be somewhat reduced from those in Figs. 16 and 17. The effect is typically small, however, and so we do not present updated figures for M_1 and $m_{\tilde{q}}$ with the B_ℓ constraint imposed. Nonetheless, the full B_ℓ constraint is included in the results presented below.)

It is evident from the figures that the four measurements constrain the parameter space significantly, and the allowed ranges of the SUSY parameters are highly correlated. It is also useful to determine the global bounds that may be placed on the various quantities of interest, independent of their correlations. To determine the allowed ranges of these quantities, we pick points randomly in the allowed volume, and verify graphically that enough points have been picked to adequately sample the region. We find the following global bounds:

$$\begin{aligned}
 0.97 &< \rho_{\tilde{X}_1^\pm} < 1.00 \\
 0.97 &< \rho_{\tilde{X}_1^0} < 1.00 \\
 180 \text{ GeV} &< m_{\tilde{q}} < 225 \text{ GeV} \\
 0.43 &< \frac{M_1}{M_2} < 0.58 \\
 -1 \text{ TeV} &< \mu < -290 \text{ GeV} \quad \text{or} \quad 300 \text{ GeV} < \mu < 1 \text{ TeV} \\
 63 \text{ GeV} &< M_2 < 93 \text{ GeV} \\
 1 &< \tan \beta < 50 \\
 150 \text{ GeV} &< m_{\tilde{g}} < 1 \text{ TeV} .
 \end{aligned} \tag{70}$$

To understand the confidence level of these bounds, recall that the uncertainties in observables we have used are one standard deviation. The allowed region consists of all points in parameter space for which the central values of all observables are within 1σ of the underlying physical values. Typically, the extremes of the quantities given in Eq. (70) are reached in corners of the allowed region for which more than one of the observables deviates by 1σ .

These bounds follow from the assumption that $M_1 > 0$. For the case of $M_1 < 0$, the resulting bounds are only very slightly weaker. For general M_1 , we find that for the gaugino region point we have chosen, the global bounds are

$$\begin{aligned}
& 0.97 < \rho_{\tilde{\chi}_1^\pm} < 1.00 \\
& 0.97 < \rho_{\tilde{\chi}_1^0} < 1.00 \\
& 179 \text{ GeV} < m_{\tilde{t}} < 227 \text{ GeV} \\
& -0.61 < \frac{M_1}{M_2} < -0.45 \quad \text{or} \quad 0.43 < \frac{M_1}{M_2} < .58 \\
& -1 \text{ TeV} < \mu < -290 \text{ GeV} \quad \text{or} \quad 300 \text{ GeV} < \mu < 1 \text{ TeV} \\
& 63 \text{ GeV} < M_2 < 93 \text{ GeV} \\
& 1 < \tan \beta < 50, \\
& 150 \text{ GeV} < m_{\tilde{g}} < 1 \text{ TeV}.
\end{aligned} \tag{71}$$

The allowed regions in Fig. 19 are virtually unchanged when negative M_1 is included.

Even though correlations between variables are ignored, the global bounds of Eq. (71) have interesting implications. The gaugino content has been tightly constrained to be greater than 0.9, which supports the LSP as a dark matter candidate. For the case of $M_1 > 0$, the ratio M_1/M_2 has been determined to be compatible with grand unification to within approximately 15%. There is, however, an allowed range of negative M_1 . (In general, it is very difficult to exclude negative M_1 with the four observables we have explored.) The bound on $m_{\tilde{t}}$ is strong, as a result of the large destructive effect of the electron sneutrino on the total cross section. In many models the sneutrino is the next lightest observable SUSY particle, and this bound provides an important guide for future sparticle searches. Finally, $\tan \beta$ is unrestricted, and there is no global bound on $m_{\tilde{g}}$ — the squark mass may lie anywhere in the range we have considered. However, as seen in Fig. 18, at a given point in the $(\alpha, \tan \beta)$ plane, the bounds on $m_{\tilde{g}}$ may be quite strong.

We now turn to $A_{FB}^{\tilde{\chi}^\pm}$ and $A_{FB}^{\tilde{t}}$, the forward-backward asymmetries discussed in Sec. 2.3. We remind the reader that the former, while unobservable, depends only on the production amplitude, while the latter is observable but depends on the decay vertices as well. In Fig. 20, we plot $A_{FB}^{\tilde{t}}$ vs. $A_{FB}^{\tilde{\chi}^\pm}$ for a number of points in the allowed region. The value of $A_{FB}^{\tilde{t}}$ for our case study, measured from the Y mode events that pass the cuts, is given by the solid line. Its 1σ deviation, as determined from Eq. (132), is given by the dashed lines.

Because the previous four observables have already restricted the allowed region

Figure 20: Plot of $A_{FB}^{\tilde{t}}$ vs. $A_{FB}^{\tilde{\chi}^\pm}$ for several points in the allowed region of the gaugino case study. The solid line is the measured $A_{FB}^{\tilde{t}}$ from the Monte Carlo simulation, and the dashed lines give the 1σ uncertainties in this measurement. Points with $\mu < 0$ are given by filled circles, and all points with $\mu > 0$ (open circles) are seen to be excluded by the $A_{FB}^{\tilde{t}}$ measurement. The case study is indicated by a star.

to a small volume in the gaugino region with a light sneutrino, $A_{FB}^{\tilde{\chi}^\pm}$ is limited to the fairly narrow range $0.12 \lesssim A_{FB}^{\tilde{\chi}^\pm} \lesssim 0.21$. As discussed in Sec. 2.3, $A_{FB}^{\tilde{\chi}^\pm}$ and σ_{tot} are the only production quantities with much resolving power, so the fact that $A_{FB}^{\tilde{\chi}^\pm}$ is limited to a small range is evidence that we have already obtained nearly all of the information contained in the production amplitude.

We also see that the correlation between $A_{FB}^{\tilde{t}}$ and $A_{FB}^{\tilde{\chi}^\pm}$ is weak, and that $A_{FB}^{\tilde{t}}$ lies in a much broader range, $-0.06 \lesssim A_{FB}^{\tilde{t}} \lesssim 0.3$. Clearly the decay amplitude plays a crucial role in determining the value of $A_{FB}^{\tilde{t}}$, and the large variation in $A_{FB}^{\tilde{t}}$ is an indication that detailed studies of chargino decays may improve the bounds on parameter space and tighten the correlations between variables. By running Monte Carlo simulations for a large number of points that densely populate the allowed region, one could presumably form a detailed picture of the regions that may be excluded on the basis of $A_{FB}^{\tilde{t}}$. However, as our goal in this study is to study chargino events analytically, we will not discuss this possibility further. Still, even from our sparse sampling of the allowed region it is possible to draw some tentative conclusions.

For example, in Fig. 20, points with positive μ have been marked with open circles, and those with negative μ have been marked with filled circles. We see that all of the points with $\mu > 0$ may be excluded based on the A_{FB}^{jj} measurement, which suggests that the $\mu > 0$ portion of the allowed region may be eliminated by the A_{FB}^{jj} measurement.

2.5.3 Variations in $\frac{M_1}{M_2}$ and Experimental Assumptions

We will now briefly explore two simple variations on the previous case study. In that example, we assumed gaugino mass unification and saw that it could be verified to 15% (assuming $M_1 > 0$). In our first variation below, we take $M_1/M_2 = 0.7$ and find how strongly the gaugino mass unification condition may be disfavored. In the second variation, we determine the impact of more pessimistic assumptions about detector resolutions and backgrounds. As these are only slight variations on the previous example, few new features appear in the analysis, and we will only present a few intermediate results and the final conclusions.

We begin by taking the parameters

$$(\mu, M_2, \tan \beta, M_1/M_2, m_{\tilde{t}}, m_{\tilde{b}}) = (-400, 75, 4, 0.7, 200, 300), \quad (72)$$

where the only change from the previous example is that we choose $M_1/M_2 = 0.7$. Many of the basic quantities remain the same, but we list them all for convenience:

$$\begin{aligned} m_{\tilde{\chi}_1^\pm} &= 79.6 \text{ GeV} \\ m_{\tilde{\chi}_1^0} &= 53.8 \text{ GeV} \\ \sigma_{\text{total}} &= 1.16R = 3202 \text{ fb} \\ \rho_{\tilde{\chi}_1^\pm} &= 1.00 \\ \rho_{\tilde{\chi}_1^0} &= 0.99 \\ B_t &= 0.40 \\ m_{jj} &< 25.7 \text{ GeV} \\ 11.7 \text{ GeV} &< E_{jj} < 39.9 \text{ GeV} . \end{aligned} \quad (73)$$

Of the 3203 chargino events, the Monte Carlo simulation yields 1528 mixed mode events. 1210 of these are Y mode events, and 715 (59%) of these survive the cuts.

Because the LSP is heavier, the ranges of the dijet mass and energy are smaller than in the original example. From plots of the dijet mass and energy distributions similar to those previously presented, we estimate that both m_{jj}^{max} and E_{jj}^{max} may be determined to 2 GeV. Including the 25% reduction in these uncertainties from the tracking chamber measurements, and using Eqs. (124) and (126) since $E_b^{\text{cut}} = 85.8 \text{ GeV}$ is now below the beam energy, we find that the chargino and LSP masses are determined to

$$\Delta m_{\tilde{\chi}_1^\pm} = 2.9 \text{ GeV} \quad \text{and} \quad \Delta m_{\tilde{\chi}_1^0} = 2.0 \text{ GeV} . \quad (74)$$

The efficiency η_γ is found, as in the previous example, by running Monte Carlo simulations for a large number of points in SUSY parameter space with the correct $m_{\tilde{\chi}_1^\pm}$ and $m_{\tilde{\chi}_1^0}$. We find once again that the efficiency is principally determined by kinematics and lies in the range 54–62%. We take $\eta_\gamma = 58\%$ and $\Delta\eta_\gamma = 4\%$, and assume similar values for the hadronic mode. Applying Eqs. (68) and (128), we find the uncertainties

$$\Delta\sigma_{\text{total}}/\sigma_{\text{total}} = 6.6\% \quad \text{and} \quad \Delta B_t/B_t = 6.4\% . \quad (75)$$

We now apply these measurements to the SUSY parameter space. By randomly sampling SUSY parameter space with both signs of M_1 , we have found the following bounds in the allowed region:

$$\begin{aligned} 0.78 &< \rho_{\tilde{\chi}_1^\pm} < 1.00 \\ 0.84 &< \rho_{\tilde{\chi}_1^0} < 1.00 \\ 175 \text{ GeV} &< m_{\tilde{t}} < 233 \text{ GeV} \\ -1.00 &< \frac{M_1}{M_2} < -0.38 \quad \text{or} \quad 0.60 < \frac{M_1}{M_2} < 1.00 \\ -1 \text{ TeV} &< \mu < -188 \text{ GeV} \quad \text{or} \quad 230 \text{ GeV} < \mu < 1 \text{ TeV} \\ 54 \text{ GeV} &< M_2 < 119 \text{ GeV} \\ 1 &< \tan \beta < 50, \\ 150 \text{ GeV} &< m_{\tilde{g}} < 1 \text{ TeV} . \end{aligned} \quad (76)$$

The bounds on M_1/M_2 disfavor the gaugino mass unification hypothesis. The other conclusions and bounds are slightly weakened relative to the original gaugino case

study, but we still obtain strong bounds on $m_{\tilde{t}}$ and find that the allowed region lies primarily in the gaugino region.

We now study the effects of varying our experimental assumptions. In the analysis above we have attempted to estimate the effects of finite detector resolutions and of backgrounds in the hadronic mode. Detailed studies and simulations are needed to significantly improve the accuracy of these estimates. We will show here, however, that most of the global bounds presented in the previous section are robust and are not altered greatly by assuming poorer experimental conditions. First, we modify the case study of Sec. 2.5.2 by assuming that the backgrounds to the hadronic mode are very large, and that the optimal cuts have an efficiency $\eta_{\text{hadronic}} = 18\%$, which is $1/4$ of the value we took previously. We retain the estimate $\Delta\eta = 3.5\%$. The uncertainties in $m_{\tilde{t}}$ and $m_{\tilde{\chi}_1^\pm}$ remain the same, but we now find

$$\begin{aligned}\Delta\sigma_{\text{hadronic}}/\sigma_{\text{hadronic}} &= 20.3\% \\ \Delta\sigma_{\text{total}}/\sigma_{\text{total}} &= 5.9\% \\ \Delta B_t/B_t &= 12.2\%.\end{aligned}\quad (77)$$

Because we have assumed a low η_{hadronic} , the uncertainties in σ_{hadronic} and B_t are large. However, the uncertainty in σ_{total} is not strongly affected because $1 - 2B_t$ is small for this case study (see Eq. (128)).

The analysis is identical to the previous example, so we skip the intermediate steps and present the end result. In the allowed region with both positive and negative M_1 values, the bounds on selected quantities are:

$$\begin{aligned}0.88 &< \rho_{\tilde{\chi}_1^\pm} < 1.00 \\ 0.94 &< \rho_{\tilde{\chi}_1^0} < 1.00 \\ 176 \text{ GeV} &< m_{\tilde{t}} < 231 \text{ GeV} \\ -1.00 &< \frac{M_1}{M_2} < -0.30 \quad \text{or} \quad 0.42 < \frac{M_1}{M_2} < 0.80.\end{aligned}\quad (78)$$

We see that the bounds are for the most part only slightly weakened, with the exception that the upper bound on positive M_1/M_2 is now 0.8, and the lower bound on negative M_1/M_2 is -1.0 .

We have also investigated the implications of doubling the estimated uncertainties on the dijet mass and energy endpoint determinations. In this variation, we take

$\Delta m_{jj}^{\text{max}} = 4.0 \text{ GeV}$ and $\Delta E_{jj}^{\text{max}} = 6.0 \text{ GeV}$. In addition, we assume no improvement from tracking chamber measurements, and retain the "poor" hadronic mode efficiency of $\eta_{\text{hadronic}} = 18\%$. The uncertainties in σ_{total} and B_t are as in Eq. (77), and the new uncertainties in $m_{\tilde{t}}$ and $m_{\tilde{\chi}_1^\pm}$ are

$$\Delta m_{\tilde{\chi}_1^\pm} = 7.2 \text{ GeV} \quad \text{and} \quad \Delta m_{\tilde{\chi}_1^0} = 6.0 \text{ GeV}.\quad (79)$$

The resulting bounds are

$$\begin{aligned}0.83 &< \rho_{\tilde{\chi}_1^\pm} < 1.00 \\ 0.91 &< \rho_{\tilde{\chi}_1^0} < 1.00 \\ 162 \text{ GeV} &< m_{\tilde{t}} < 274 \text{ GeV} \\ -1.00 &< \frac{M_1}{M_2} < -0.26 \quad \text{or} \quad 0.37 < \frac{M_1}{M_2} < 1.00.\end{aligned}\quad (80)$$

In this case, we find that the bounds M_1/M_2 are weak. However, we find that we are still able to constrain the parameter space to the gaugino region and can place an upper bound on the sneutrino mass of 274 GeV . Thus, at least in the gaugino region, where our global bounds are expected to be the strongest, the limits on ρ and $m_{\tilde{t}}$ are robust under variations in efficiency for the hadronic mode and in detector resolution.

2.5.4 Higgsino Region

For the Higgsino region case study, we choose the parameters

$$(\mu, M_2, \tan\beta, M_1/M_2, m_{\tilde{t}}, m_{\tilde{\chi}}) = (-75, 250, 4, 0.5, 200, 300).\quad (81)$$

For this point, the angle $\alpha = 107^\circ$, and

$$\begin{aligned}
m_{\tilde{\chi}_1^\pm} &= 79.7 \text{ GeV} \\
m_{\tilde{\chi}_1^0} &= 62.3 \text{ GeV} \\
\sigma_{\text{total}} &= 0.89 \text{ R} = 2450 \text{ fb} \\
\rho_{\tilde{\chi}_1^\pm} &= 0.17 \\
\rho_{\tilde{\chi}_1^0} &= 0.087 \\
B_t &= 0.34 \\
m_{jj} &< 17.4 \text{ GeV} \\
8.4 \text{ GeV} &< E_{jj} < 28.6 \text{ GeV} .
\end{aligned} \tag{82}$$

This point in parameter space is again fairly central in the accessible band, with $m_{\tilde{\chi}_1^\pm} \approx M_W$. It is possible to study points in parameter space that are closer to the pure Higgsino limit $\rho_{\tilde{\chi}_1^\pm} = 0$. However, as discussed in Sec. 2.3, as one increases $\rho_{\tilde{\chi}_1^\pm}$ and M_2 , $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_1^0$ become more nearly degenerate, and the number of events with soft jets increases. These events are eliminated by our requirement that jet energies be greater than 5 GeV, and the resulting event sample is small. The point in parameter space given in Eq. (81) has been chosen to have properties characteristic of the Higgsino region, without being so far in the Higgsino region that low statistics become the primary concern.

Given a sample of 1 fb^{-1} , there are 2454 events of which 1119 are mixed mode events. Considering only Y mode events, that is, excluding the mixed events in which a τ decays hadronically, we are left with 893 events, of which 287 (32%) survive the cuts described in Sec. 2.4. The efficiency of the cuts is lower than in the gaugino example because the smaller chargino-LSP mass splitting leads to more events with soft jets. In addition, since the LSPs are produced with lower velocities in the chargino rest frames and are more back-to-back in the lab frame, more events are eliminated by the $\cancel{E}_T$ cut.

We must now determine the masses from the endpoints of the m_{jj} and E_{jj} spectra, which are shown in Fig. 21. As in the gaugino case, finite detector resolution effects smear the endpoints, but we estimate that the maximum m_{jj} endpoint almost certainly lies within a 4 GeV range, and therefore we takes its 1σ error to be 1 GeV. Similarly, we estimate that the 1σ error for the maximum endpoint of E_{jj} is 2 GeV.

Figure 21: The dijet (a) mass spectrum and (b) energy spectrum, after cuts, for the Higgsino case ($\mu, M_2, \tan \beta, M_1/M_2, m_{\tilde{t}}, m_{\tilde{b}} = (-75, 250, 4, 0.5, 200, 300)$ with integrated luminosity 1 fb^{-1} . We estimate that the 1σ uncertainty of m_{jj}^{max} is 1 GeV, and that for E_{jj}^{max} is 2 GeV.

As noted in Sec. 2.4, these resolutions are expected to improve with the addition of tracking chamber momentum measurements, and we therefore take the actual resolutions to be reduced by 25% to $\Delta m_{jj}^{\text{max}} = 0.75 \text{ GeV}$ and $\Delta E_{jj}^{\text{max}} = 1.5 \text{ GeV}$. (Again, we will not consider the lower E_{jj} endpoint in the analysis here, although we expect it to be useful at least as a cross check.) The resulting uncertainties from Eqs. (124) and (126) for $m_{\tilde{\chi}_1^\pm}$ and $m_{\tilde{\chi}_1^0}$ are

$$\Delta m_{\tilde{\chi}_1^\pm} = 3.0 \text{ GeV} \quad \text{and} \quad \Delta m_{\tilde{\chi}_1^0} = 2.6 \text{ GeV}. \quad (83)$$

We now turn to the determination of σ_{total} and B_i . As in the gaugino region, the accuracy of these determinations depends on the statistical uncertainties and the variation of the cut efficiencies in the subvolume of SUSY parameter space with the given $m_{\tilde{\chi}_1^\pm}$ and $m_{\tilde{\chi}_1^0}$. With 287 events, the statistical uncertainty is $\Delta N_{\gamma}/N_{\gamma} = 5.9\%$. To determine the efficiency of the cuts, we have run Monte Carlo simulations for a wide range of representative points with $m_{\tilde{\chi}_1^\pm} \approx 80 \text{ GeV}$ and $m_{\tilde{\chi}_1^0} \approx 62 \text{ GeV}$, and find that the cut efficiencies are fairly uniform and in the range of 26–34%. We take the efficiency to be $\eta_{\gamma} = 30\%$ and its variation to be $\Delta\eta_{\gamma} = 4\%$. Combining these uncertainties as in the gaugino case, we find that $\Delta\sigma_{\gamma}/\sigma_{\gamma} = 15\%$. Finally, we will assume that the formulae in Eq. (128) using the hadronic cross section are the ones with the smallest uncertainties. There are 1057 hadronic mode events in the Monte Carlo simulation. Again taking the assumption that $\eta_{\text{hadronic}} \approx \eta_{\gamma}$ and $\Delta\eta_{\text{hadronic}} \approx \Delta\eta_{\gamma}$, we find $\Delta\sigma_{\text{hadronic}}/\sigma_{\text{hadronic}} = 14\%$, and, from Eq. (128),

$$\Delta\sigma_{\text{total}}/\sigma_{\text{total}} = 11\% \quad \text{and} \quad \Delta B_i/B_i = 14\%. \quad (84)$$

We may now use these four measurements to find the allowed parameter space. As in the gaugino example, $m_{\tilde{\chi}_1^\pm}$ limits us to two thin sheets in $(\mu, M_2, \tan\beta)$ space, and these are flattened into the plane $(\alpha, \tan\beta)$. We then determine the allowed region as in the gaugino case by applying the bounds on $m_{\tilde{\chi}_1^0}$, σ_{total} , and B_i to determine ranges of M_1 , $m_{\tilde{t}_2}$ and $m_{\tilde{t}_1}$ for every point in the plane. We will proceed as in the gaugino region case, first considering only $M_1 > 0$, and then including the possibility $M_1 < 0$ in the final determination of the allowed region.

The allowed range of M_1/M_2 from the $m_{\tilde{\chi}_1^0}$ measurement is shown in Fig. 22. As

Figure 22: Higgsino example contours for the (a) minimum and (b) maximum values of M_1/M_2 . In (b), two $M_1/M_2 = 0.8$ contours have been removed from the Higgsino region for clarity. The cross-hatched area in the $\alpha > 90^\circ$ mixed region with $\tan\beta \approx 1$ is excluded by the $m_{\tilde{\chi}_1^0}$ measurement alone.

in Fig. 16 of the gaugino example, a portion of the low $\tan\beta$, $\mu < 0$, mixed region is excluded, and the allowed ratio drops to zero in the far Higgsino region. Relative to the gaugino example, however, the central value of the allowed range of M_1/M_2 is increased in the Higgsino region because now $m_{\tilde{\chi}_1^0}/m_{\tilde{\chi}_1^\pm} = 0.78$. The gaugino regions, in which $\rho_{\tilde{\chi}_1^\pm}^2, \rho_{\tilde{\chi}_1^0}^2 > 0.9$, can be determined to lie within the regions $\alpha > 135^\circ$ and $\alpha < 30^\circ$. From Fig. 22, we see that $M_1/M_2 \gtrsim 0.55$ in the gaugino region, and therefore, even including experimental uncertainties in the mass determinations, it is possible from measurements of $m_{\tilde{\chi}_1^\pm}$ and $m_{\tilde{\chi}_1^0}$ to determine that *either* the LSP is not a good dark matter candidate *or* the grand unification prediction of $M_1/M_2 = 0.5$ is not satisfied.

The $m_{\tilde{t}}$ bounds from σ_{total} are shown in Fig. 23. The bounds in the gaugino region are again strong, as σ_{total} is sensitive to $m_{\tilde{t}}$ in that region. We see that if the underlying parameters lie in the gaugino region, the bound $m_{\tilde{t}} \lesssim 250$ GeV applies, a promising result for scalar particle searches. The limits near $\alpha = 90^\circ$ are not as strong, which is hardly surprising, since in the Higgsino region σ_{total} is highly insensitive to $m_{\tilde{t}}$.

The bounds on $m_{\tilde{q}}$ from B_t are presented in Fig. 24, where we have magnified two regions of parameter space that may be excluded based on the B_t measurement. As we saw in Sec. 2.3.6, there is generically a pocket of small B_t in the mixed $\mu < 0$ region for moderate $\tan\beta$. In the cross-hatched, crescent-shaped excluded region in Fig. 24a, B_t would be much smaller than the observed measurement of 0.34 even for the largest values of $m_{\tilde{q}}$. In Fig. 24b, we see that the hatched far gaugino region is excluded because B_t would be too high, even for the lowest allowed value of $m_{\tilde{q}}$. For $\tan\beta = 1$, this excluded region is for $\alpha \gtrsim 177^\circ$ ($\mu \lesssim -1.5$ TeV), a region that is already disfavored by fine-tuning considerations. However, for larger $\tan\beta$, as discussed in Sec. 2.3.6, B_t grows more quickly as one approaches the far gaugino limit. The excluded region is therefore larger for higher $\tan\beta$, and, for $\tan\beta = 10$, points with $\alpha \gtrsim 170^\circ$ ($\mu \lesssim -450$ GeV) are excluded.

Compiling these results, along with those for $M_1 < 0$, we find that the allowed regions are as given in Fig. 25. Although we have seen that a number of interesting correlations hold, it is clear that the global bounds will not be as impressive as in the

Figure 23: Higgsino example contours for the (a) minimum and (b) maximum values of $m_{\tilde{t}}$. Stringent bounds are found in the gaugino region, but no limits are obtained in the Higgsino region.

Figure 24: Higgsino contours for the (a) minimum and (b) maximum values of m_t . Two areas in the $\alpha > 90^\circ$ ($\mu < 0$) gaugino region has been magnified. The cross-hatched region of (a) and the hatched region of (b) have B_τ values that are too low and too high, respectively, and are excluded.

Figure 25: The allowed region in the $(\alpha, \tan \beta)$ plane for the Higgsino case study, with both signs of M_1 allowed. The cross-hatched regions are excluded by the measurements of $m_{\tilde{\chi}_1^\pm}$, $m_{\tilde{\chi}_1^0}$, σ_{total} and B_τ . The dot indicates the value of $(\alpha, \tan \beta)$ for the case study.

gaugino case. Nevertheless, we present them here for completeness:

$$\begin{aligned}
 0.00 &< \rho_{\tilde{\chi}_1^\pm} < 1.00 \\
 0.01 &< \rho_{\tilde{\chi}_1^0} < 1.00 \\
 100 \text{ GeV} &< m_{\tilde{t}} < 1 \text{ TeV} \\
 -1.00 &< \frac{M_1}{M_2} < -0.03 & \text{or} & 0.10 < \frac{M_1}{M_2} < 0.99 \\
 -870 \text{ GeV} &< \mu < -65 \text{ GeV} & \text{or} & 79 \text{ GeV} < \mu < 1 \text{ TeV} \\
 62 \text{ GeV} &< M_2 < 1 \text{ TeV} \\
 1 &< \tan \beta < 50, \\
 150 \text{ GeV} &< m_{\tilde{g}} < 1 \text{ TeV}.
 \end{aligned} \tag{85}$$

In Fig. 26 we plot A_{FB}^{ij} vs. $A_{FB}^{\tilde{\chi}_1^\pm}$ for a number of points in the allowed region. The solid line is the measured value of A_{FB}^{ij} , and the dashed lines are the 1σ bounds. Although the points only sparsely sample the allowed region, it is evident that the relation between the production quantity $A_{FB}^{\tilde{\chi}_1^\pm}$ and the observed A_{FB}^{ij} is heavily dependent on the decay process, and in fact, for the measured A_{FB}^{ij} , the full range of

Figure 26: Plot of A_{FB}^{ij} vs. A_{FB}^{ij*} for several points in the allowed region of the Higgsino case study. The solid line is the measured A_{FB}^{ij} from the Monte Carlo simulation, and the dashed lines give the 1σ uncertainties in this measurement. The case study is indicated by a star.

A_{FB}^{ij*} values is possible. Without densely sampling the allowed region, it is difficult to reach any clear conclusions about the specific shape of the regions excluded by A_{FB}^{ij} , but it is likely that properties of the decay process will be useful in further reducing the allowed parameter space.

2.5.5 Mixed Region

Finally, we turn to an example in the mixed region with parameters

$$(\mu, M_2, \tan \beta, M_1/M_2, m_t, m_d) = (-90, 115, 4, 0.5, 200, 300), \quad (86)$$

for which $\alpha = 128^\circ$ and

$$\begin{aligned}
 m_{\tilde{\chi}_1^\pm} &= 80.3 \text{ GeV} \\
 m_{\tilde{\chi}_2^0} &= 52.8 \text{ GeV} \\
 \sigma_{\text{total}} &= 0.75 \text{ R} = 2070 \text{ fb} \\
 \rho_{\tilde{\chi}_1^\pm} &= 0.64 \\
 \rho_{\tilde{\chi}_2^0} &= 0.60 \\
 B_t &= 0.32 \\
 m_{jj} &< 27.6 \text{ GeV} \\
 12.6 \text{ GeV} &< E_{jj} < 41.4 \text{ GeV}.
 \end{aligned} \quad (87)$$

This point in parameter space has been chosen to give the same $m_{\tilde{\chi}_1^\pm}$ as in the previous cases, and a value of ρ that is between those of the earlier examples. For this point, the mass spectrum of the charginos and neutralinos has two features not present in the previous two cases. The second neutralino has mass $m_{\tilde{\chi}_2^0} = 76.6 \text{ GeV}$, and is therefore lighter than the lighter chargino. This means that cascade decays of the chargino are kinematically possible. However, as $m_{\tilde{\chi}_1^\pm} - m_{\tilde{\chi}_2^0} \gg m_{\tilde{\chi}_1^\pm} - m_{\tilde{\chi}_2^\pm}$, and direct decays are not suppressed by any small couplings in the mixed region, cascade decays are highly suppressed relative to direct decays to the LSP, and we do not expect them to alter our analysis. The second new feature is that, since neither M_2 nor μ is large, even $\tilde{\chi}_3^0$ is light with mass 119 GeV . Thus, in this case not only are $\tilde{\chi}_1^0 \tilde{\chi}_2^0$ and $\tilde{\chi}_2^0 \tilde{\chi}_2^0$ production possible, but even $\tilde{\chi}_1^0 \tilde{\chi}_3^0$ production is possible. The simultaneous production of all these signals may make chargino production difficult to resolve. However, we may remove part of this background by reducing the beam energy below the $\tilde{\chi}_1^0 \tilde{\chi}_3^0$ production threshold. In this study we will assume that $\tilde{\chi}_3^0$ production can be separated from chargino production through this procedure, and we will ignore the effects of $\tilde{\chi}_3^0$ production as a background to chargino events. Despite possible difficulties from an entanglement of many supersymmetric signals, it should be kept in mind that every signal brings a wealth of new information, and generically the mixed region is the most, not the least, optimistic scenario. Though we will consider only the constraints that may be extracted from the chargino signal, the neutralino signals will lead to additional restrictions that should be imposed on the parameter space, and the full set of constraints from LEP II will most likely be stronger than

our results would suggest.

In arriving at bounds for the more interesting quantities, we will skip many details as the method is identical to that employed in the previous cases. Given a sample of 1 fb^{-1} , there are 2072 events of which 907 are mixed mode events. Of these, 741 are Y mode events, and 444 (60%) of these survive the cuts of Sec. 2.4.

From plots of the distributions of m_{jj} and E_{jj} , we estimate the endpoint uncertainties to be 3 GeV for m_{jj}^{max} and 2 GeV for E_{jj}^{max} . Again assuming that tracking chamber measurements reduce these uncertainties by 25%, we find that $\Delta m_{jj}^{\text{max}} = 1.5\text{ GeV}$ and $\Delta E_{jj}^{\text{max}} = 2.3\text{ GeV}$. The resulting uncertainties for $m_{\tilde{\chi}_1^\pm}$ and $m_{\tilde{\chi}_1^0}$ are

$$\Delta m_{\tilde{\chi}_1^\pm} = 3.3\text{ GeV} \quad \text{and} \quad \Delta m_{\tilde{\chi}_1^0} = 2.7\text{ GeV}. \quad (88)$$

To determine the uncertainties in the determinations of σ_{total} and B_i , we must first determine $\Delta\sigma_Y/\sigma_Y$ from Eq. (67). With 444 Y mode events, the statistical uncertainty is $\Delta N_Y/N_Y = 4.7\%$. The efficiencies of the cuts for a wide range of representative points in SUSY parameter space, subject only to the restriction $m_{\tilde{\chi}_1^\pm} \approx 80\text{ GeV}$ and $m_{\tilde{\chi}_1^0} \approx 53\text{ GeV}$, range from 54–62%, and we therefore take the efficiency to be $\eta_Y = 58\%$ and its variation to be $\Delta\eta_Y = 4\%$. Combining these uncertainties, we find that $\Delta\sigma_Y/\sigma_Y = 8.4\%$. There are 975 Monte Carlo hadronic mode events before cuts, and again taking η and $\Delta\eta$ to be approximately equal for the Y and hadronic modes, we find $\Delta\sigma_{\text{hadronic}}/\sigma_{\text{hadronic}} = 8.1\%$. Using Eq. (128) we determine that

$$\Delta\sigma_{\text{total}}/\sigma_{\text{total}} = 6.1\% \quad \text{and} \quad \Delta B_i/B_i = 7.9\%. \quad (89)$$

Given these ranges for the four observables, we may now bound the parameter space. The allowed range of M_1/M_2 is shown in Fig. 27. In the gaugino region, the minimum value of M_1/M_2 is roughly 0.5; though values of $M_1/M_2 > 0.5$ are favored, the prediction of grand unified theories cannot be excluded. As in the previous two examples, a small $\mu < 0$, $\tan\beta \approx 1$ region is ruled out.

The m_t bounds from σ_{total} are shown in Fig. 28. For this example σ_{total} lies below the value of σ_{total} approached in the pure Higgsino limit, as may be seen from Eq. (38) or Fig. 10. Thus, not only is some of the Higgsino region excluded, but also we obtain,

Figure 27: Mixed example contours for the (a) minimum and (b) maximum values of M_1/M_2 . The cross-hatched area in the mixed region with $\tan\beta \approx 1$ is excluded by the $m_{\tilde{\chi}_1^0}$ measurement alone.

Figure 28: Mixed example contours for the (a) minimum and (b) maximum values of m_t . The cross-hatched area in the Higgsino region has σ_{total} values that are higher than that measured and is excluded. In this case, an upper bound on m_t may be obtained from the σ_{total} measurement alone.

Figure 29: The allowed region in the $(\alpha, \tan \beta)$ plane for the mixed region case study with both signs of M_1 allowed. The cross-hatched regions are excluded by the measurements of $m_{\tilde{\chi}_1^\pm}$, $m_{\tilde{\chi}_1^0}$, σ_{total} , and B_ℓ , and the dot indicates the value of $(\alpha, \tan \beta)$ for the case study.

from the σ_{total} measurement alone, an upper bound on m_t . For $\tan \beta > 4$ we see that the low value of σ_{total} gives the bound $m_t < 250$ GeV.

Because B_ℓ is approximately $\frac{1}{3}$ as it was in the Higgsino example, the bounds on m_t are fairly similar to those obtained in Fig. 24, so we will not present the $(m_t)_{\text{min}}$ and $(m_t)_{\text{max}}$ contours for this case study. It is again possible to rule out a crescent-shaped region in which B_ℓ is too small, and the far gaugino region in which B_ℓ is too large. The allowed region for the mixed region case study, considering both negative and positive M_1 , is given in Fig. 29. By randomly sampling the allowed region, we find the following global bounds:

$$\begin{aligned}
& 0.05 < \rho_{\tilde{\chi}_1^\pm} < 1.00 \\
& 0.01 < \rho_{\tilde{\chi}_1^0} < 1.00 \\
& 100 \text{ GeV} < m_{\tilde{t}} < 257 \text{ GeV} \\
& -1.00 < \frac{M_2}{M_t} < -0.12 \quad \text{or} \quad 0.16 < \frac{M_2}{M_t} < 1.00 \\
& -339 \text{ GeV} < \mu < -52 \text{ GeV} \quad \text{or} \quad 85 \text{ GeV} < \mu < 355 \text{ GeV} \quad (90) \\
& 51 \text{ GeV} < M_2 < 500 \text{ GeV} \\
& 1 < \tan \beta < 50, \\
& 150 \text{ GeV} < m_{\tilde{t}} < 1 \text{ TeV}.
\end{aligned}$$

Again, the correlations among the various parameters are not represented in these limits. As already noted from Fig. 28, we see that the sneutrino mass bound is very stringent, with a maximum value of 257 GeV, as in the gaugino case. The other global bounds are weak.

Finally, we plot A_{FB}^{ij} vs. $A_{FB}^{\tilde{\chi}^\pm}$ for a few points in the allowed region in Fig. 30. As in the previous figures, the solid line is the measured value of A_{FB}^{ij} , and the dashed lines are the 1σ bounds. Although definite conclusions would require a more thorough sampling of the allowed region, Fig. 30 suggests that the point we have picked has an extreme value of A_{FB}^{ij} , and could therefore be distinguished from most other points in the allowed region by decay process considerations.

2.6 Final Comments and Summary

We have explored the potential for precise determinations of fundamental SUSY parameters from chargino production at LEP II. We have found that chargino events can be well-described by six underlying SUSY parameters: μ , M_2 , $\tan \beta$, M_1 , $m_{\tilde{t}}$, and $m_{\tilde{q}}$. A number of observables were investigated, and four — the chargino mass, the LSP mass, the total cross section, and the leptonic branching fraction — were found to be particularly useful in most areas of parameter space. These four observables, with their accompanying uncertainties, were used to restrict the allowed SUSY parameter space for representative points in the gaugino, Higgsino, and mixed regions, and a simple method for representing the results graphically was used.

Figure 30: Plot of A_{FB}^{ij} vs. $A_{FB}^{\tilde{\chi}^\pm}$ for several points in the allowed region of the mixed region case study. The solid line is the measured A_{FB}^{ij} from the Monte Carlo simulation, and the dashed lines give the 1σ uncertainties in this measurement. The specific parameters chosen for the case study lie at an extreme value of A_{FB}^{ij} and indicate that this measurement may be able to reduce the allowed region substantially. The case study is indicated by a star.

In the gaugino region, we found stringent global bounds on SUSY parameters. In particular, $\rho_{\tilde{X}_1^0}$ was restricted to ranges in which the LSP is a good dark matter candidate, the gaugino mass unification condition could be verified or disproved at the level of 15%, and an upper limit for the sneutrino mass could be obtained for an underlying value of $m_{\tilde{\nu}} = 200$ GeV. We also found that the results for $\rho_{\tilde{X}_1^0}$ and $m_{\tilde{\nu}}$ were not altered substantially when significantly worse experimental conditions were assumed. In the Higgsino case study, stringent *global* bounds were not found for any of the combinations of SUSY parameters. However, a number of interesting correlations were found, making it possible, for example, to exclude the grand unification condition $M_1/M_2 = 0.5$ in the gaugino region. In the mixed region example, results similar to those for the Higgsino region were achieved, with the exception that it was once again possible to set a stringent global upper bound on $m_{\tilde{\nu}}$.

In this study, we have only crudely simulated chargino events and detector effects. Although we have shown that, at least in some cases, our results are not very sensitive to the exact experimental assumptions, detailed event simulations and detector modeling would sharpen our results. Other work that may improve the results obtained here includes a study of chargino production at threshold [51], where chargino decays are more easily analyzed, and investigations of other SUSY processes, notably neutralino production, which may provide useful constraints in some regions of SUSY parameter space.

In summary, our results imply that if charginos are discovered at LEP II, they will bring not only the first experimental evidence for SUSY, but will also significantly restrict SUSY parameter space and may provide bounds on SUSY parameters of relevance to cosmology, grand unified theories, and future sparticle searches.

Chapter 3

Tests of Supersymmetry

3.1 Introduction

In the previous chapter, we showed how fundamental SUSY parameters may be determined from the signals of newly-discovered particles. Implicit in the analysis was the assumption that the newly-discovered particles were, in fact, supersymmetric. In this chapter, we investigate the possibility of testing this assumption at a future linear e^+e^- collider.

Such tests could play an important role in confirming the existence of SUSY. The phenomenological predictions of SUSY may be divided into three categories: (I) reflections of the supersymmetric Lagrangian in standard model phenomenology, including relations among the gauge coupling constants from SUSY grand unification and the presence of a heavy top quark and a light Higgs scalar; (II) the prediction of new particles with the correct spin and quantum number assignments to be superpartners of the standard model particles; and (III) well-defined quantitative relations among the couplings and masses of these new particles. While the predictions of (I) are of great interest, their verification is clearly no substitute for direct evidence. The discovery of a large number of particles in category (II) would be strong support for SUSY. On the other hand, the most compelling confirmation of SUSY would likely be the precise verification of the relations of category (III). This would be especially true if, initially, only a small set of candidate SUSY partners are observed.

Supersymmetry provides a particularly interesting subject for studies of the detailed analysis of physics beyond the standard model. SUSY models are weakly coupled, so their consequences can be worked out straightforwardly using perturbative computations. At the same time, as was evident in Chapter 2, SUSY models depend on a large number of unknown parameters, and different choices for these parameters yield qualitatively different realizations of possible new physics. Thus, the phenomenology of SUSY is quite complex. We suggest that similar complexity should be found in any realistic extension of the standard model, and that similar investigations will be needed to understand the next, more fundamental, level.

One consequence of the complexity of the parameter space of SUSY models is that it is not trivial to identify experimentally the specific quantities which are related by supersymmetry. Faraggi, Hagelin, Kelley, and Nanopoulos [59], Martin and Ramond [60], and Kawamura, Murayama, and Yamaguchi [61] have discussed in general terms the exploration of the spectroscopy of supersymmetry partners, and the latter two groups have suggested particular mass relations which test supersymmetry independently of more detailed hypotheses. These tests are very ambitious, since they require mass measurements for the heaviest and most elusive particles of the superspectrum — the squarks, the heaviest partners of the Higgs and gauge bosons, and the sneutrino — at the 1% level. In these papers, very little attention was given to the question of how these experiments will be done. In this chapter, we will present some alternative tests of supersymmetry that involve only the lightest observable states of the superspectrum, and we will argue that these should be straightforward to carry out at colliders of the next generation.

Our tests will exploit the advantages of the proposed Next Linear Collider (NLC), a linear e^+e^- collider with $\sqrt{s} = 500$ GeV and a design luminosity of $50 \text{ fb}^{-1}/\text{year}$ [62]. This machine has already been shown to be a powerful tool for probing new physics [31, 33, 63, 64]. In particular, previous work has shown that such a machine provides an excellent environment for measuring particle masses under the assumption that newly-discovered particles are sparticles [32, 34, 35, 37, 38, 39, 65]. In this study, we add to this body of work by showing how to test this assumption. Our analysis will take into account the relation of observable properties of the final state to the

underlying reaction; as in the earlier NLC studies, we will be helped dramatically by the clean experimental environment expected at this machine. In addition, the expected availability of highly polarized electron beams should provide a powerful diagnostic tool.

It is a reasonable expectation that charginos will be among the lightest supersymmetric states, and that these will be accessible to the NLC. Thus, we concentrate here on tests of supersymmetry that involve the properties of charginos. The crucial problem we will face is that the mass eigenstates of charginos are in general a mixture of weak eigenstates, and their mixing pattern must be resolved before the quantitative implications of supersymmetry become clear. To understand the experimental aspects of chargino reactions needed in this study, we have again studied simulations of chargino production and decay using the parton-level Monte Carlo event generator described in Sec. 2.4.

The outline of this chapter is as follows: In Sec. 3.2 we briefly review the MSSM and state our assumptions. In Sec. 3.3 we divide the parameter space into characteristic regions. In Secs. 3.4 and 3.5, we present two different strategies for supersymmetry tests in two of these regions and analyze the experimental prospects for these tests in particular cases studied. In Sec. 3.6, we comment on other possible supersymmetry tests involving the properties of matter scalars and neutralinos. We present our conclusions in Sec. 3.7.

3.2 The MSSM and our Assumptions

Though our goal is to test supersymmetry, we cannot begin without narrowing the phenomenological context. SUSY can, in principle, be realized in many ways. Here we assume that the observed particle content and qualitative phenomenology is that of the MSSM, with conserved R-parity and therefore a stable lightest supersymmetric particle (LSP). R-parity conservation and the existence of only two Higgs doublets will be our two primary assumptions and will be essential for much of the following analysis. We will also incorporate some minor additional restrictions for simplicity. These restrictions closely parallel those of Chapter 2 and are explained in detail in

Secs. 2.2.1 and 2.2.2. We will therefore only list the salient points here for completeness and to introduce the mixing angles ϕ_+ and ϕ_- , which will be important for the analysis of this chapter.

As in the previous study, the parameters that will enter our analysis include the supersymmetric Higgs mass μ , the ratio of scalar vevs $\tan \beta$, the scalar masses m_i , and the gaugino masses M_1 and M_2 . Given the assumptions listed below, this study will also be very insensitive to parameters entering through the A terms.

The chargino and neutralino mixing matrices are as given in Eqs. (4) and (6), and are displayed here again as they will play a central role in this study:

$$M_{\tilde{\chi}^\pm} = \begin{pmatrix} M_2 & \sqrt{2} M_W \sin \beta \\ \sqrt{2} M_W \cos \beta & \mu \end{pmatrix}, \quad (91)$$

$$M_{\tilde{\chi}^0} = \begin{pmatrix} M_1 & 0 & -M_Z \cos \beta \sin \beta & M_Z \sin \beta \sin \beta \\ 0 & M_2 & M_Z \cos \beta \cos \beta & -M_Z \sin \beta \cos \beta \\ -M_Z \cos \beta \sin \beta & M_Z \cos \beta \cos \beta & 0 & -\mu \\ M_Z \sin \beta \sin \beta & -M_Z \sin \beta \cos \beta & -\mu & 0 \end{pmatrix}. \quad (92)$$

Recall that the chargino mass matrix is diagonalized by two matrices $\mathbf{V}$ and $\mathbf{U}$, so that the chargino mass eigenstates are $\tilde{\chi}_i^\pm = \mathbf{V}_{ij} \psi_j^\pm$ and $\tilde{\chi}_i^\mp = \mathbf{U}_{ij} \psi_j^\mp$, where $(\psi^\pm)^T = (-i\tilde{W}^\pm, \tilde{H}^\pm)$ and, by convention, $m_{\tilde{\chi}_i^\pm} < m_{\tilde{\chi}_j^\pm}$. Ignoring some subtleties in this diagonalization having to do with negative mass values and the ordering of the eigenstates (see, for example, the first reference in [8]), $\mathbf{V}$ and $\mathbf{U}$ are orthogonal matrices which can be parametrized by rotation angles ϕ_+ and ϕ_- . We will define these angles such that, for $\phi_\pm = 0$, the chargino $\tilde{\chi}_1^\pm$ is pure gaugino, and for $\phi_\pm = \frac{\pi}{2}$, $\tilde{\chi}_1^\pm$ is pure Higgsino.

To reduce the number of arbitrary parameters, we follow the previous chapter in introducing some phenomenologically motivated assumptions. As noted above, we assume R-parity conservation and the presence of a stable LSP, which we identify as the lightest neutralino $\tilde{\chi}_1^0$. In addition, we will ignore the intergenerational mixing in the quark and sfermion sectors, and we will assume that CP -violating phases in the SUSY parameters are negligible. We will also assume that one-loop effects do

not introduce large and qualitatively new dependences on SUSY parameters. If these effects are large but may be absorbed by redefinitions of the tree level parameters, our analysis can be applied with only minor modifications. The assumptions listed above will be in effect throughout this study. Additional conditions that are appropriate to the study of specific processes and scenarios will be given below.

3.3 The Parameter Space of Charginos

In many supersymmetric models, charginos are the lightest observable sparticles, and we now consider the possibilities for tests of SUSY from chargino production. As we are interested in what may be learned from the chargino signal, we will make, in this and the following two sections, the additional assumptions that gluinos, sfermions, and the Higgs scalars H^0 , A^0 , and $H^\pm$ are beyond the kinematic reach of the NLC. Neutralino masses must be comparable to chargino masses, and below we will address the problem of removing neutralino backgrounds to the chargino signal. If a number of additional SUSY signals are available at NLC energies, their detection would be exciting in their own right, and would make possible the measurement of several sparticle masses. However, the procedure we outline below for measuring chargino couplings would not directly apply. Since we think it would be somewhat optimistic to expect a plethora of sparticles to be accessible at NLC energies, we have not explored this scenario further.

We now summarize the most important qualitative features of chargino processes. Using the picture of chargino production derived from this analysis, we will divide the parameter space into characteristic regions. In the following two sections, we will define and analyze tests of supersymmetry which rely on the particular characteristics of the chargino in each of these regions.

Though the observables we will discuss involve only the chargino pair production cross section, the problems of experimental detection of the chargino signal necessarily bring in parameters of the chargino decay processes. In this section, we simplify our treatment of these processes in the following way: motivated by $\mu \rightarrow e\gamma$ and flavor changing neutral current constraints [44], we assume that all left-handed sleptons of

different generations are roughly degenerate (to within, say, 20 GeV) with mass $m_{\tilde{t}_1}$, and the left-handed squarks of the first two generations are roughly degenerate with mass $m_{\tilde{q}}$. The analysis of Sec. 2.2.2 may again be applied to show that chargino events are usually insensitive to all other sfermion masses: decays through third generation squarks are suppressed because, even for NLC energies, the mass difference $m_{\tilde{q}_1^\pm} - m_{\tilde{q}_2^\pm}$ is almost always less than the top quark mass, and for the remaining sfermions, the right-handed sfermion diagrams are suppressed by Higgs couplings m_f/M_W and are negligible. With these assumptions, there are again only six parameters that enter the complete description of chargino pair production: μ , M_2 , $\tan\beta$, M_1 , $m_{\tilde{t}_1}$, and $m_{\tilde{q}}$.

We may now analyze the dependence of various observable quantities on these parameters. With an e_L^- beam, $\tilde{\chi}_1^+ \tilde{\chi}_1^-$ production occurs through the s -channel Z and γ diagrams and the t -channel $\tilde{t}_e$ exchange diagram of Fig. 1, and so the left-handed differential cross section is governed by four parameters:

$$\frac{d\sigma_L}{d\cos\theta} (e_L^- e^+ \rightarrow \tilde{\chi}_1^+ \tilde{\chi}_1^-) = \frac{d\sigma_R}{d\cos\theta} (\mu, M_2, \tan\beta, m_{\tilde{t}_1}). \quad (93)$$

However, in the case of an e_R^- beam, the $\tilde{t}_e$ diagram is absent, and so the right-handed differential cross section is dependent on only the first three parameters:

$$\frac{d\sigma_R}{d\cos\theta} (e_R^- e^+ \rightarrow \tilde{\chi}_1^+ \tilde{\chi}_1^-) = \frac{d\sigma_R}{d\cos\theta} (\mu, M_2, \tan\beta). \quad (94)$$

Charginos decay to the LSP either leptonically through W bosons or virtual sleptons,

$$\tilde{\chi}_1^\pm \rightarrow (\tilde{\chi}_1^0 W^\pm, \tilde{\ell}^* \nu, \tilde{\ell} \nu^*) \rightarrow \tilde{\chi}_1^0 \tilde{\ell} \nu, \quad (95)$$

or hadronically through W bosons or virtual squarks,

$$\tilde{\chi}_1^\pm \rightarrow (\tilde{\chi}_1^0 W^\pm, \tilde{q}^* q, \tilde{q} \bar{q}^*) \rightarrow \tilde{\chi}_1^0 \tilde{q} q', \quad (96)$$

and so all six parameters enter the decay process. The lighter chargino may also decay to LSPs through a virtual charged Higgs $H^\pm$, but this diagram is suppressed by Higgs couplings and is negligible for all but the most extreme choices of parameters. The heavier chargino may decay through complicated cascade decays. However, when $\tilde{\chi}_2^\pm$ production is kinematically accessible, the only information we will use about $\tilde{\chi}_2^\pm$

Figure 31: Contours of constant σ_R (in fb) for fixed $\tan\beta = 4$ in the (μ, M_2) plane. Chargino production is inaccessible for $\sqrt{s} = 500$ GeV in the hatched region, and the cross-hatched region is excluded by the current experimental mass limit $m_{\tilde{\chi}_1^\pm} > 45$ GeV. The cross section σ_R quickly drops to zero in the $|\mu| \lesssim M_2$ regions.

is its mass, which we will assume may be measured through threshold scans. The analysis will therefore be independent of $\tilde{\chi}_2^\pm$ branching fractions and other observables dependent on the details of the $\tilde{\chi}_2^\pm$ decay.

The chargino masses $m_{\tilde{\chi}_1^\pm}$ and $m_{\tilde{\chi}_2^\pm}$ and the right-handed cross section σ_R depend only on the parameters μ , M_2 , and $\tan\beta$, and these parameters may be used to define regions with qualitatively different behavior. To understand this, note first that, when $M_2 \gg |\mu|$ or $|\mu| \gg M_2$, the following relations hold [49]:

$$m_{\tilde{\chi}_1^\pm} \approx \min\{|\mu|, M_2\} \quad \text{and} \quad m_{\tilde{\chi}_2^\pm} \approx \max\{|\mu|, M_2\}. \quad (97)$$

These relations are in fact approximately valid in most of the available parameter space. The dependence of σ_R on the parameters is more complicated. In Fig. 31 we plot contours of constant σ_R for fixed $\tan\beta$ in the (μ, M_2) plane. The dependence on $\tan\beta$ is fairly weak; we choose the representative value $\tan\beta = 4$ for illustration. Chargino production is inaccessible for $\sqrt{s} = 500$ GeV in the hatched region, and the cross-hatched region is excluded by the current experimental mass limit $m_{\tilde{\chi}_1^\pm} > 45$ GeV [18, 19, 20, 21, 22]. This leaves two bands, one on each side of the $\mu = 0$ axis.

Figure 32: The three characteristic regions for fixed $\tan \beta = 4$ in the (μ, M_2) plane, as defined in the text. (The corresponding $\mu > 0$ parts of these regions are unlabeled.) The hatched and cross-hatched regions are as in Fig. 31. The dashed curve is the contour $m_{\tilde{\chi}_1^\pm} = 172 \text{ GeV}$.

At the top of each band, where $M_2 \gg |\mu|$, the chargino is Higgsino-like, $\tilde{\chi}_1^\pm \approx \tilde{H}^\pm$, and we see that σ_R is substantial. However as one moves into the region with $M_2 \lesssim |\mu|$, σ_R quickly drops. This may be understood by noting that, because $\sqrt{s} \gg M_Z$, the γ and Z production diagrams may be replaced to a good approximation by diagrams in which the $U(1)$ and $SU(2)$ gauge bosons B and W^3 are exchanged. However, the e_R^- couples only to B , and the $\tilde{W}^\pm$ couples only to W^3 . Thus, in the region with $M_2 \lesssim |\mu|$, where the chargino is dominated by its wino component and $\tilde{\chi}_1^\pm \approx \tilde{W}^\pm$, the cross section σ_R is highly suppressed.

We are now in a position to define characteristic regions in the parameter space. These are shown for $\tan \beta = 4$ in the (μ, M_2) plane in Fig. 32. The hatched and cross-hatched regions are as in Fig. 31. In the remaining area, we define the following three regions, each of which includes a $\mu < 0$ part and a corresponding $\mu > 0$ part that is unlabeled:

Region 1: $m_{\tilde{\chi}_1^\pm} + m_{\tilde{\chi}_2^\pm} < \sqrt{s}$. Here $\tilde{\chi}_1^\pm \tilde{\chi}_2^\mp$ production is possible, and so both chargino masses can be measured.

Region 2 (shaded): $m_{\tilde{\chi}_1^\pm} + m_{\tilde{\chi}_2^\pm} > \sqrt{s}$, and $\sigma_R \lesssim 10 \text{ fb}$.

Region 3 (shaded): $m_{\tilde{\chi}_1^\pm} + m_{\tilde{\chi}_2^\pm} > \sqrt{s}$, and $\sigma_R \gtrsim 50 \text{ fb}$.

These three regions almost completely fill the region of parameter space in which chargino pair production is allowed at a 500 GeV e^+e^- collider, leaving only a small region in which the mixing is large and the chargino $\tilde{\chi}_2^\pm$ is just above threshold. In this study, we will ignore this small gap. In the two cases we will study in detail, we will assume $m_{\tilde{\chi}_1^\pm} \approx 172 \text{ GeV}$. For this value, the measurement of $m_{\tilde{\chi}_1^\pm}$ constrains the parameters to lie on the dashed curves shown in Fig. 32. Then, if $\tilde{\chi}_2^\pm$ is not seen, $\sigma_R < 10 \text{ fb}$ or $\sigma_R > 70 \text{ fb}$ for $\tan \beta \geq 4$, and further, for $1 < \tan \beta < 4$, only small areas of the (μ, M_2) plane lie outside regions 1–3. For masses $m_{\tilde{\chi}_1^\pm}$ nearer to threshold, the areas not covered by regions 1–3 are larger. However, this can be compensated by raising the collider center-of-mass energy, which increases the size of region 1.

In region 3, if the ratio M_1/M_2 is fixed, $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_1^0$ become increasingly degenerate as M_2 grows. Charginos then decay to invisible LSPs and very soft jets and leptons. It is therefore difficult to choose a representative point in this region, as even the identification of the chargino signal can be difficult in some areas. More generally, if M_1 and M_2 are unrelated (and, of course, independent of μ), $m_{\tilde{\chi}_1^\pm} - m_{\tilde{\chi}_1^0}$ need not be small, even if the chargino is Higgsino-like. Although it may then be possible to verify SUSY relations in region 3, we will not consider this possibility further. However, we note that the MSSM makes a number of nontrivial predictions for region 3. Since $\tilde{\chi}_1^\pm \approx \tilde{H}^\pm$, the $\tilde{\nu}$ production diagram becomes negligible. The production forward-backward asymmetry is thus approximately zero. In addition, since the chargino is Higgsino-like, it decays predominantly through a virtual W , and so the ratio of hadronic to leptonic decays of the chargino should be equal to the corresponding ratio for W bosons. These characteristic features should distinguish a chargino candidate from new particles of other, non-supersymmetric origin.

3.4 A Supersymmetry Test in the Mixed Region

We now study a representative point in region 1 in detail. The characteristic property of region 1 is that both chargino eigenstates can be produced, and so both masses are measurable. Thus, in this region, a promising approach will be to test the detailed

form of the chargino mass matrix. In particular, notice that the matrix of Eq. (91) contains, in addition to the new parameters M_2 , μ , and $\tan\beta$, a dependence on the W mass. This is no accident. The off-diagonal matrix elements of Eq. (91) result from the $H\tilde{W}\tilde{H}$ vertex. This is related by supersymmetry to the $HW\partial H$ vertex, which is related by gauge invariance to the term which gives mass to the W through the Higgs mechanism. Thus, verification that this parameter of Eq. (91) is indeed equal to M_W would be a quantitative test of supersymmetry. This test is formally independent of the neutralino sector and is therefore applicable to models with gauge singlets.

We now investigate the extent to which we can realistically verify this correspondence at the NLC. In this example, and for the rest of this chapter, we will assume $\sqrt{s} = 500$ GeV. We will present results for integrated luminosities of 30 and 100 fb $^{-1}$, corresponding roughly to $\frac{1}{2}$ to 2 years running at design luminosity.

For our case study, we choose the underlying supersymmetry parameters to be

$$(\mu, M_2, \tan\beta, M_1/M_2, m_t, m_{\tilde{g}}) = (-195, 210, 4, 0.5, 400, 700). \quad (98)$$

For these values, the MSSM gives

$$\begin{aligned} m_{\tilde{\chi}_1^\pm} &= 172 \text{ GeV} \\ m_{\tilde{\chi}_2^\pm} &= 105 \text{ GeV} \\ m_{\tilde{\chi}_3^\pm} &= 255 \text{ GeV} \\ (\phi_+, \phi_-) &= (40.8^\circ, 59.5^\circ) \\ \sigma_R &= 48 \text{ fb} \\ \sigma_L &= 513 \text{ fb}. \end{aligned} \quad (99)$$

For comparison, the QED $\mu^+\mu^-$ production cross section is 397 fb.

To investigate the expected sensitivity to the form for the chargino mass matrix, we generalize Eq. (91) to an arbitrary real 2×2 matrix, which we parametrize as

$$M'_{\tilde{\chi}\tilde{\chi}} = \begin{pmatrix} M_2 & \sqrt{2} M'_W \sin\beta^\times \\ \sqrt{2} M'_W \cos\beta^\times & \mu \end{pmatrix}. \quad (100)$$

Without SUSY, the ratio of off-diagonal elements need not be the ratio of vevs $\tan\beta \equiv \langle H_2^0 \rangle / \langle H_1^0 \rangle$, and we have therefore replaced β by $\beta^\times$. As demanded by

gauge invariance, we also replace M_2 by $M_2^X \equiv M_2(M'_W/M_W)$ in the neutralino mass matrix of Eq. (92).¹

We will investigate to what extent the NLC experiments may confirm the SUSY relation $M'_W = M_W$. More explicitly, we have extended the six-dimensional SUSY parameter space to a seven-dimensional parameter space, and we will investigate how well experiments may reduce the allowed region of this space to the supersymmetric subvolume in which $M'_W = M_W$. Formally, this is a simple task. The four parameters entering Eq. (100) may be exchanged for the two masses and two mixing angles, $(m_{\tilde{\chi}_1^\pm}, m_{\tilde{\chi}_2^\pm}, \phi_+, \phi_-)$. By determining these four quantities from experiment, we can recover a constraint on M'_W .

To determine the chargino masses and mixing angles from experiment, we will need to make assumptions about the decay properties of charginos. In our analysis, we will assume that these properties are those of a supersymmetric model at some point in parameter space, with the exception that the new chargino and neutralino mass matrices are used. Because we have not generalized the decay completely, this assumption is a compromise, but we feel, a reasonable one — it gives us a large but well-defined space of possibilities to consider. In addition, we will see below, by explicitly scanning this space, that our results depend only weakly on the decay parameters. The main dependences are kinematic and would be expected in more general models of chargino decays. It is also worth noting that many of our assumptions may be checked a posteriori; for example, the assumption of a universal left-handed slepton mass may be checked by observing the universality of leptonic branching fractions in chargino decay.

The precision with which $m_{\tilde{\chi}_1^\pm}$ and $m_{\tilde{\chi}_2^\pm}$ can be determined was studied by the JLC group [31]. Using a method that depends on kinematic arguments only, they found that, for an integrated luminosity of 20 fb $^{-1}$, these masses could be determined to approximately 2 GeV, an uncertainty that is negligible for this study. The mass $m_{\tilde{\chi}_2^\pm}$ may be determined by scanning near $\tilde{\chi}_1^\pm \tilde{\chi}_2^\mp$ threshold. Although $\sigma(e^+e^- \rightarrow \tilde{\chi}_1^\pm \tilde{\chi}_2^\mp)$ is suppressed by about an order of magnitude from mixing angles, we will assume that

¹The resulting neutralino mass matrix is not the most general allowed by gauge invariance. The fully general neutralino mass matrix will be considered briefly when neutralino events are considered in Sec. 3.6.

an energy scan will be able to determine $m_{\tilde{\chi}_2^\pm}$ to a few GeV, and we will therefore also neglect this uncertainty in the following analysis.

The crucial difficulty will be that of determining the two mixing angles. In principle, these can be extracted by measuring the right-polarized differential cross section for $\tilde{\chi}_1^\pm$ pair production, which is completely determined by the $\tilde{\chi}_1^\pm$ mass and the two mixing angles. The right-polarized cross section σ_R , though an order of magnitude smaller than σ_L , is still large enough to yield a sufficient number of events for precision studies. In particular, we will examine two quantities based on $d\sigma_R/d\cos\theta$: the total cross section σ_R , and a truncated forward-backward asymmetry

$$A_R^\chi \equiv \frac{\sigma_R(0 < \cos\theta < 0.755) - \sigma_R(-1 < \cos\theta < 0)}{\sigma_R(-1 < \cos\theta < 0.755)}, \quad (101)$$

where θ is defined as the angle between the e^+ beam and the positive chargino $\tilde{\chi}_1^+$. (The motivation for this peculiar definition of A_R^χ will be given below.) With $m_{\tilde{\chi}_1^\pm}$ known, the values of σ_R and A_R^χ determine the variables (ϕ_+, ϕ_-) and may therefore bound M_W^χ . This strategy is appealing, because we have seemingly eliminated all dependence on three of the undetermined parameters of the theory: M_1 , m_i , and m_j .

Unfortunately, the analysis is not independent of these three parameters when we consider what quantities are actually observable. Cuts must be imposed to reduce standard model backgrounds. In this study, we will rely on a standard set of cuts which have been previously suggested to isolate the chargino pair production signal. These cuts select chargino events in which one chargino decays to an isolated final state lepton, and the other decays *directly* to hadrons. (Charginos may also decay indirectly to hadrons through τ leptons.) We will call such events "Y" mode events," with the letter "Y" chosen to suggest the typical $2j + \ell$ topology of these events. What is actually measured is not σ_R , but the Y mode partial cross section after cuts,

$$\eta\sigma_Y \equiv 2\eta B_L B_h \sigma_R, \quad (102)$$

where η is the efficiency of the cuts for Y events, B_h is the chargino branching ratio for direct hadronic decays, and B_L is the branching ratio for decays to a final-state lepton. These fractions both exclude decays to a τ which subsequently decays hadronically.

Since the charginos decay very quickly, with typical widths of 1–100 keV, the chargino direction and the asymmetry A_R^χ cannot be determined directly. We will measure A_R^χ through its correlation to A^{had} , the forward-backward asymmetry of the hadronic system in Y events. The asymmetry A^{had} is the same quantity as the observable A_{FB}^{jj} used in Chapter 2, and is defined using all Y events that pass the cuts. However, we will see below that the cuts for the higher energies of this chapter remove events with forward-peaked hadronic systems, and so A^{had} is effectively truncated as in Eq. (101). In principle, the experimentally observable quantities A^{had} and $\eta\sigma_Y$ depend on the decay distributions, and thus reintroduce dependence on the parameters M_1 , m_i , and m_j . To understand the extent of this problem, we have performed Monte Carlo simulations at a number of points in parameter space. These points have been chosen randomly, subject only to the constraints that they give values of $m_{\tilde{\chi}_1^\pm}$, $m_{\tilde{\chi}_2^\pm}$, and $m_{\tilde{\chi}_3^\pm}$ consistent with those that would be measured in our case study. We will show below that, in the resulting subvolume of parameter space, the experimental observables turn out to be rather insensitive to M_1 , m_i , and m_j , and therefore the virtues of our strategy in fact remain.

To simulate chargino events, we used the parton level Monte Carlo event generator described in Sec. 2.4. This generator includes the spin correlations between production and decay processes. To simulate hadronization and detector effects, the final state partons were smeared with detector parameters as chosen in the JLC study [31]:

$$\frac{\sigma_E^{\text{had}}}{E} = \frac{40\%}{\sqrt{E}} \quad \text{and} \quad \frac{\sigma_E^{\text{lepton}}}{E} = \frac{15\%}{\sqrt{E}}, \quad (103)$$

where E is in GeV.

The Y chargino events were selected by first using a system of cuts presented in Ref. [32]. These cuts are designed for charginos that decay through off-shell W bosons, and include the following:

- (a) $|\cos\theta_i| < 0.9$ for every final state parton, where θ_i is the polar angle of parton i with respect to the e^+ beam axis.
- (b) $E_t > 5 \text{ GeV}$, $\theta_{e\ell} > 30^\circ$, that is, there must be an energetic e or μ with no hadronic activity within a cone of half angle 30° .

- (c) $20 \text{ GeV} < E_{\text{visible}} < \sqrt{s} - 100 \text{ GeV}$.
- (d) $\theta_{\text{acoplanarity}} < 150^\circ$.
- (e) $m_{\text{had}} < 68 \text{ GeV}$, $E_{\text{had}} < \frac{1}{2}(\sqrt{s} - 100) \text{ GeV}$, where m_{had} and E_{had} are the mass and energy of the hadronic system.
- (f) $|m_{\nu} - M_W| > 10 \text{ GeV}$, where the ν momentum is taken to be equal to the missing momentum.
- (g) $-Q_i \cos \theta_{\text{had},i} Q_i \cos \theta_i < \cos 41^\circ = 0.755$, where Q_i is the charge of the isolated lepton, and θ_i is as defined in cut (a).

These cuts isolate chargino events that have hadrons and an isolated lepton in the final state. We would like to isolate Y events, and we therefore need to eliminate events in which the hadronic system results from charginos decaying through τ leptons. This may be done by imposing the additional requirement that the mass of the hadronic system m_{had} be greater than m_τ . As was shown in Chapter 2, Y events very rarely have low m_{had} at LEP II energies, and we have verified that this is also true for NLC energies. We will therefore simply assume that this additional cut on m_{had} cleanly isolates the Y mode events.

Cuts (c) and (d) are efficient for supersymmetric signals because of the large momentum and energy that are carried off by the unobserved massive LSPs. Cuts (e)–(g) reduce the dominant standard model background, W pair production. In particular, cut (g) is designed to remove the large forward peak of WW events. Because the hadronic system's polar angle distribution is truncated by cut (g), we choose $A_{\tilde{H}}^{\text{had}}$ as defined in Eq. (101), as the theoretical quantity with which we expect A^{had} to be well-correlated. Since W pair production results primarily from $e_L^+ e^-$ annihilation, the use of these cuts in conjunction with a very highly right-polarized e^- beam results in a negligible background rate. The analysis of Ref. [32] included $t\bar{t}$ events with a top quark mass of 150 GeV and found negligible background from this source.

We caution the reader that the cuts (a)–(g) above have been designed to separate the chargino signal from standard model backgrounds, but have not been optimized to discriminate between $\tilde{\chi}_1^\pm \tilde{\chi}_1^\mp$ production and other SUSY sources of Y events. In principle, these could include $\tilde{\chi}_1^\pm \tilde{\chi}_3^\mp$ and $\tilde{\chi}_2^\pm \tilde{\chi}_2^\mp$ production, as well as the production

of neutralino pairs $\tilde{\chi}_i^0 \tilde{\chi}_j^0$. Ignoring effects of resolution smearing, the neutralino events will be backgrounds to Y events only when a heavy neutralino decays into a chargino and a W boson, which then decays leptonically to provide the single isolated lepton. While we have not simulated these events, we do not expect neutralinos to be a severe background because their production cross sections are generally small, and further, their decays to $h \tilde{\chi}_1^0$ and $Z \tilde{\chi}_1^0$ are usually favored by phase space and therefore dominate. For the point that we are studying, the masses of the heavy neutralinos are $m_{\tilde{\chi}_2^0} = 169 \text{ GeV}$, $m_{\tilde{\chi}_3^0} = 211 \text{ GeV}$, and $m_{\tilde{\chi}_4^0} = 253 \text{ GeV}$. The decay $\tilde{\chi}_4^0 \rightarrow W \tilde{\chi}_1^\pm$ is barely open, and the production of heavy chargino pairs is kinematically forbidden. Thus, $\tilde{\chi}_1^\pm \tilde{\chi}_2^\mp$ production, with $\tilde{\chi}_2^\pm \rightarrow W^\pm \tilde{\chi}_1^0 \rightarrow \ell^\pm \nu \tilde{\chi}_1^0$ is the main SUSY contamination in the present case study. This background is restricted by phase space and mixing angles and can be eliminated entirely by running below the $\tilde{\chi}_1^\pm \tilde{\chi}_2^\mp$ production threshold.

Throughout this study, we have assumed 100% beam polarization in our simulations. In the present case, however, because σ_L is an order of magnitude larger than σ_R , the left-handed contamination of the right-handed beam could be substantial if the beam polarization is not nearly 100%. If beam polarization near 100% is unobtainable, the e_R^- signal may be determined by first measuring the e_L^- signal to high accuracy, and then subtracting the left-handed contamination from the right-polarized e^- beam's signal. For a beam polarization of 95%, these errors will not be large, and we have not included the statistical errors resulting from such a subtraction. It is clear, however, that highly polarized beams play a critical role in reducing such errors.

We now determine the correlation of $A_{\tilde{H}}^{\text{had}}$ with A^{had} through Monte Carlo simulations. A description of our method and the relevant formulae are contained in Appendix B. We sample random points in the seven dimensional parameter space, with only the restriction that $m_{\tilde{\chi}_1^\pm}$, $m_{\tilde{\chi}_2^0}$, and $m_{\tilde{\chi}_3^\pm}$ are each within 2 GeV of their values in Eq. (99). For each set of parameters, we calculate $A_{\tilde{H}}^{\text{had}}$ from explicit analytical formulae and determine A^{had} through Monte Carlo simulation. The results for 38 simulations are plotted in Fig. 33. A simple linear fit yields $A^{\text{had}} = 0.717 A_{\tilde{H}}^{\text{had}} + 0.042 \pm 0.036$, where $\Delta A_{\tilde{H}}^{\text{had}} = 0.036$ is the 1σ deviation in A^{had} for a fixed $A_{\tilde{H}}^{\text{had}}$. The best fit is given

Figure 33: The correlation of A_R^{had} and A_R^X for 38 points in the seven-dimensional parameter space ($\mu, M_2, \tan \beta^X, M_1, m_{\tilde{t}}, m_{\tilde{q}}, M_W^X$). These points have been picked randomly, subject only to the constraints that $m_{\tilde{\chi}_1^0}, m_{\tilde{\chi}_2^0}$, and $m_{\tilde{\chi}_3^0}$ are within 2 GeV of their underlying values in the case study. The linear best fit is given by the solid line, and the 1σ deviations are given by the dashed lines.

by the solid line in Fig. 33, and the 1σ deviations are shown by the dashed lines.

However, this quoted error overestimates the deviation from perfect correlation between A_R^X and A_R^{had} , because each point in Fig. 33 was computed from a finite sample of Monte Carlo events and therefore contains a non-negligible statistical fluctuation. The average effective number of Monte Carlo events for the simulations was $N_{\text{MC}} \approx 1400$. Using the formulae contained in Appendix B, we find that the Monte Carlo statistical error is $\Delta A_{\text{MC}}^{\text{stat}} = 0.026$; when this is removed, the systematic error in assuming perfect correlation is found to be $\Delta A^{\text{sys}} = 0.025$. In marked contrast to the examples presented in Chapter 2, the correlation between A_R^X and A_R^{had} is high. This discrepancy can be understood as follows. In both chapters we have assumed that all sfermion pair production is kinematically forbidden. However, in the present chapter, this assumption implies that sfermions masses are above 250 GeV, and decays through sfermions are therefore relatively unimportant compared to decays through W bosons. The decay distributions are therefore sufficiently similar for all allowed values of the underlying sfermion masses (and all other parameters) that A_R^{had} is highly insensitive

to the decay process and is well-determined for a fixed A_R^X . It should also be noted that the boost of the chargino rest frame relative to the lab frame also increases the correlation between A_R^X and A_R^{had} . If the beam energy is slightly reduced to run below the $\tilde{\chi}_1^0 \tilde{\chi}_2^0$ threshold, the charginos will be less boosted. However, we do not expect the correlation between A_R^X and A_R^{had} to deteriorate much, since, even in the present case with $\sqrt{s} = 500$ GeV and only slightly boosted charginos, the correlation is high.

To determine the bounds that may be placed on A_R^X experimentally, we must add the experimental statistical error to ΔA^{sys} . For our representative point, a Monte Carlo simulation gives

$$\begin{aligned} A_R^{\text{had}} &= -0.233 \\ \eta &= 35.5\% \\ N_{\text{exp}} &= 6.0 \mathcal{L}_R, \end{aligned} \quad (104)$$

where N_{exp} is the number of Y events surviving the cuts, and $\mathcal{L}_R$ is the right-handed integrated luminosity in fb^{-1} . The total experimental uncertainties for two values of right-polarized integrated luminosity are found to be

$$\mathcal{L}_R = 30 (100) \text{ fb}^{-1} \implies A_R^X = -0.37 \pm 0.107 (0.065). \quad (105)$$

The efficiency η also depends on the decay process. We determine η by finding its range in the subvolume of parameter space in which the three masses and A_R^X are within the experimental bounds of their underlying values. Each simulation gives a point in the (A_R^X, η) plane, and the distribution of points is plotted in Fig. 34. A linear fit gives $\eta = -6.48 A_R^X + 34.35 \pm 1.07\%$, where $\Delta \eta_{\text{MC}}^{\text{tot}} = 1.07\%$ is the 1σ deviation in η for a fixed A_R^X . As in the previous figure, the best linear fit is given by the solid line, and the dashed lines give the 1σ deviations. We see that there is a dependence on A_R^X — in cases in which chargino production is forward peaked, cut (g) lowers the efficiency. However, since we have already bounded A_R^X in the analysis above, we may use this measurement to restrict the range of η . To determine the systematic error, we remove the Monte Carlo statistical error from $\Delta \eta_{\text{MC}}^{\text{tot}}$. Following the analysis of Appendix B, we find that $\Delta \eta_{\text{MC}}^{\text{stat}} = 0.77\%$ and $\Delta \eta^{\text{sys}} = 0.75\%$, and, including experimental statistical errors, we find

Figure 34: The correlation of η and A_R^χ for the 38 points in the seven-dimensional parameter space ($\mu, M_2, \tan \beta^\chi, M_1, m_{\tilde{t}}, m_{\tilde{q}}, M_W^\chi$), selected as in Fig. 33. The linear best fit is given by the solid line, and the 1σ deviations are given by the dashed lines.

$$\mathcal{L}_R = 30(100) \text{ fb}^{-1} \Rightarrow \frac{\Delta\sigma_Y}{\sigma_Y} = 8.0(4.7) \%. \quad (106)$$

To convert a measurement of σ_Y into a measurement of σ_R , we must also take into account the uncertainty in the branching ratios B_t and B_b . These again depend on the parameters of the chargino decay matrix elements and, in particular, on the masses $m_{\tilde{t}}$ and $m_{\tilde{q}}$. We have varied these masses to permit as a large a variation in σ_R as possible. However, the measurements of $m_{\tilde{t}^\pm}, m_{\tilde{q}_2^\pm}, A_R^\chi$ and σ_Y constrain the allowed parameter ranges to regions where $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_1^\mp$ have substantial Higgsino components. Recall that B_t and B_b take fixed values (equal to those for the W) in the Higgsino limit. These facts and the bounds $m_{\tilde{t}}, m_{\tilde{q}} > 250 \text{ GeV}$ constrain the Y mode branching fraction to the region in which $29\% < 2B_t B_b < 36\%$. Thus, the σ_Y contours are rather insensitive to variations in the sfermion mass parameters.

The measurements of A_R^χ and σ_R constrain the (ϕ_+, ϕ_-) plane to the shaded regions in Fig. 35. The lightly (heavily) shaded region is the allowed region for $\mathcal{L}_R = 30(100) \text{ fb}^{-1}$. Contours of constant M_W^χ are also plotted in GeV, with the SUSY contour $M_W^\chi = M_W$ given by the dotted curves. The contours of constant σ_R that

Figure 35: The allowed region of the (ϕ_+, ϕ_-) plane from measurements of A_R^χ and σ_Y . The lightly (heavily) shaded region is allowed for $\mathcal{L}_R = 30(100) \text{ fb}^{-1}$. Contours of constant M_W^χ are plotted in GeV. On the dotted contours, the SUSY relation $M_W^\chi = M_W$ holds.

bound the allowed region run roughly northwest to southeast; contours of constant A_R^χ run roughly southwest to northeast. The indicated boundaries correspond to 1σ deviations in each quantity.

Given the chargino masses of this case study, the theoretically possible range of M_W^χ is

$$0 \leq M_W^\chi \leq \left(\frac{m_\pm^2 + m_\mp^2}{2} \right)^{\frac{1}{2}} = 218 \text{ GeV} . \quad (107)$$

In the allowed region for $\mathcal{L}_R = 100 \text{ fb}^{-1}$,

$$60 \text{ GeV} < M_W^\chi < 105 \text{ GeV} . \quad (108)$$

The measurement of M_W^χ , therefore, provides a quantitative confirmation of SUSY.

As an aside, we note that our analysis simultaneously bounds the parameters μ , M_2 , and $\tan \beta^x$. In the heavily shaded region, the allowed ranges for these parameters are

$$\begin{aligned} -204 \text{ GeV} &< \mu < -183 \text{ GeV} \\ 199 \text{ GeV} &< M_2 < 217 \text{ GeV} \\ 2.4 &< \tan \beta^x . \end{aligned} \quad (109)$$

If one is led by the bounds on M_W^χ (or other considerations) to view SUSY and the MSSM as confirmed, one might then consider only the contour $M_W^\chi = M_W$ within the allowed region. One would also be led to identify $\tan \beta^x$ with the ratio of Higgs scalar vevs, and so we will replace β^x with β . On the contour $M_W^\chi = M_W$, the bounds on the SUSY parameters are extremely strong:

$$\begin{aligned} -196 \text{ GeV} &< \mu < -193 \text{ GeV} \\ 208 \text{ GeV} &< M_2 < 211 \text{ GeV} \\ 3.9 &< \tan \beta < 4.1 . \end{aligned} \quad (110)$$

These bounds are very strong, and the limits on $\tan \beta$ are particularly impressive given our inability to determine $\tan \beta$ in the examples of Chapter 2. The availability of measurements of both chargino masses is clearly an extremely powerful constraint

on parameter space. It should also be noted, however, that these bounds are so strong that it is likely that the uncertainties in chargino masses will be a significant source of uncertainty. (Recall that, while the uncertainties in chargino masses were included in the determination of systematic errors, the parameter bounds are determined from Fig. 35, in which the chargino masses are fixed.) Nevertheless, it is clear that the discovery of both chargino mass eigenstates will allow one to place tight bounds on these three central SUSY parameters. In particular, the bound on $\tan \beta$ would be one of the most stringent and model-independent; the difficulty of determining $\tan \beta$ from the Higgs scalar sector is explained in Ref. [66]. Given the bounds of Eq. (110), other SUSY parameters may be restricted by additional measurements. For example, $m_{\tilde{g}}$ may be used to determine M_1 , and σ_L may be used to find m_t . Such determinations may help lead us to an understanding of the SUSY breaking mechanism and other aspects of higher theories.

We have now completed the case study for our chosen representative point. We conclude this section with comments concerning the power of this analysis for other points in region 1. If one moves from the point given in Eq. (98) toward region 3, the results of the analysis become stronger for two reasons. First, σ_R increases, and the experimental statistical errors decrease. Second, as a direct consequence of electroweak gauge invariance, such large values of σ_R can only be achieved for Higgsino-like $\tilde{\chi}_1^\pm$, even in the generalized (seven-dimensional) parameter space where one lets M_W^χ vary. This implies that chargino decay is dominated by the W diagram, and the sensitivity to the decay process parameters becomes even weaker than in our case study. In particular, the systematic errors related to determining A_R^χ and η become smaller, and the branching ratios B_t and B_h take their W decay values.

If one moves in the opposite direction toward region 2, the number of right-polarized events deteriorates rapidly. In addition, $\tilde{\chi}_1^\pm$ may be gaugino-like, and the branching fractions therefore depend more strongly on decay parameters, leading to a larger uncertainty in the determination of σ_R from σ_V . These problems can potentially be remedied by changing the analysis method. Since a highly right-polarized e^- beam leads to a very small level of background, it may be possible to use a looser system of cuts, and to measure the hadronic and leptonic branching fractions directly.

The analysis in the gaugino-like portion of region 1 would then be limited only by statistics and systematic errors in the determination of $A_{\tilde{g}}$ and η , and the statistical uncertainties in the measurements of the branching fractions for chargino decays.

Finally, having considered variations of the Higgsino-gaugino content of $\tilde{\chi}_1^\pm$, one might consider variations orthogonal to these in the plane of Fig. 32, namely, variations in $m_{\tilde{\chi}_1^\pm}$. If $\tilde{\chi}_1^\pm$ is heavier, the chargino rest frame is less boosted relative to the lab frame. The decay process will then have a bigger effect on the correlation of A^{had} with $A_{\tilde{g}}$, and ΔA^{sys} will increase. However, we have already considered a case with a fairly heavy $\tilde{\chi}_1^\pm$, and we see that the charginos need not be highly relativistic for ΔA^{sys} to be small. In the opposite limit of lighter $\tilde{\chi}_1^\pm$, the chargino rest frame is more boosted relative to the lab frame, decay effects become less important, and the results of our analysis can be expected to improve.

3.5 A Supersymmetry Test in the Gaugino Region

In the previous section, we considered the case in which both charginos were discovered, and found that the SUSY constraint on the chargino mass matrix could be verified to fairly high precision. In this section, we examine region 2, in which only one chargino is seen and its production cross section from $e\bar{\nu}$ is small. Here we must rely on the chargino pair production cross section from $e\bar{L}$, which introduces a strong dependence on $m_{\tilde{\nu}}$ from the second diagram in Fig. 1. Fortunately, there is an important compensating simplification: in this region, the charginos are very nearly pure gauginos, and, in fact, it is a good approximation to neglect the deviations of $\cos \phi_\pm$ from 1. In this limit, the coupling constant of the $e\bar{\nu}\tilde{\chi}_1^\pm$ vertex is related by supersymmetry to the $e\bar{\nu}W^\pm$ coupling constant g . Verification that this coupling constant is indeed equal to g would be a quantitative test of supersymmetry.

For our case study in region 2, we take the underlying supersymmetry parameters to be

$$(\mu, M_2, \tan \beta, M_1/M_2, m_t, m_{\tilde{t}}) = (-500, 170, 4, 0.5, 400, 700). \quad (111)$$

For these values, the MSSM gives

$$\begin{aligned} m_{\tilde{\chi}_1^\pm} &= 172 \text{ GeV} \\ m_{\tilde{\chi}_2^0} &= 86 \text{ GeV} \\ m_{\tilde{\chi}_2^\pm} &= 512 \text{ GeV} \\ (\phi_+, \phi_-) &= (1.2^\circ, 12.8^\circ) \\ \sigma_R &= 0.15 \text{ fb} \\ \sigma_L &= 612 \text{ fb}. \end{aligned} \quad (112)$$

For the point we have chosen (and for a significant part of region 2), the two-body chargino decay $\tilde{\chi}_1^\pm \rightarrow W^\pm \tilde{\chi}_1^0$ is open. The branching fractions B_t and B_b are then fixed to their values in W decay, unless $|\mu|$ is very large, a possibility discussed at the end of this section. The case in which on-shell W decays are not allowed will also be discussed briefly at that point.

To investigate the sensitivity of experiments to the value of the $e\bar{\nu}\tilde{\chi}_1^\pm$ coupling, we generalize this coupling from its SUSY value gV_{11} to $g^X V_{11}$. We then test the SUSY relation $g^X = g$. The differential cross section $d\sigma_L/d\cos \theta$ is then a function of $(m_{\tilde{\chi}_1^\pm}, \phi_+, \phi_-, m_{\tilde{\nu}}, g^X)$, but because $\phi_+, \phi_- \approx 0$ and we can measure $m_{\tilde{\chi}_1^\pm}$, we have only two unknowns. These may be constrained with two quantities formed from $d\sigma_L/d\cos \theta$, which we choose to be σ_L and

$$A_{\tilde{g}}^X \equiv \frac{\sigma_L(0 < \cos \theta < 0.707) - \sigma_L(-1 < \cos \theta < 0)}{\sigma_L(-1 < \cos \theta < 0.707)}. \quad (113)$$

It is important to note that the parameters g^X and $m_{\tilde{\nu}}$ enter $d\sigma_L/d\cos \theta$ only through the $\tilde{\nu}$ diagram amplitude, which has the form

$$A_{\tilde{\nu}} \sim \frac{|g^X V_{11}|^2}{t - m_{\tilde{\nu}}^2}. \quad (114)$$

Thus, for very large values of $m_{\tilde{\nu}}$, only the ratio $g^X/m_{\tilde{\nu}}$ can be determined. However, we will see that even for the rather large value of $m_{\tilde{\nu}}$ that we have chosen, the two parameters g^X and $m_{\tilde{\nu}}$ can be distinguished. In general, these parameters can be

bounded independently when $m_{\tilde{\nu}}$ is comparable to the collider center-of-mass energy (though still possibly above the pair production threshold).

We follow the procedure of the previous section, with the exception of using the cuts of Ref. [17], which are appropriate for charginos decaying through on-shell W bosons. These include the following:

- (a) $E_{\ell} > 5 \text{ GeV}$, $\theta_{\ell} > 60^\circ$.
- (b) $p_T > 35 \text{ GeV}$.
- (c) $\theta_{\text{acoplanarity}} < 150^\circ$.
- (d) $m_{\ell\nu_{\text{SR}}} > 120 \text{ GeV}$, where ν_{SR} is defined to be the massless particle which, along with an initial state radiated photon in the $\pm z$ direction, makes up the missing momentum.
- (e) $\theta_{\text{sphericity}} < 45^\circ$, which we approximate in the Monte Carlo simulation by demanding $-Q_{\ell} \cos \theta_{\text{had}}, Q_{\ell} \cos \theta_{\ell} < \cos 45^\circ = 0.707$.

This system of cuts isolates chargino events containing hadrons and an isolated lepton. Again, the subset of these events that are Y mode events may be cleanly separated by demanding that m_{had} be significantly larger than m_{τ} . After these cuts, the WW background is reduced to roughly 25 fb for an $e\bar{\nu}$ beam, which is approximately the size of the signal after cuts. We will assume that the WW background is well-understood and may be subtracted up to statistical fluctuations. As the WW background is strongly forward-peaked, we will also assume in computing statistical errors that it contributes completely to the set of events with $\cos \theta > 0$. The $t\bar{t}$ background, computed with $m_t = 140 \text{ GeV}$, is again negligible [17]. In the gaugino region, the other SUSY signals do not provide a significant background to Y events, because the only kinematically accessible SUSY backgrounds are $\tilde{\chi}_2^0 \chi_1^0$ and $\tilde{\chi}_2^0 \chi_3^0$, with $m_{\tilde{\chi}_2^0} \approx m_{\tilde{\chi}_1^+}$. The neutralinos $\tilde{\chi}_2^0$ then decay to LSPs and an even number of leptons, and the number of events with one isolated lepton is highly suppressed.

To determine the correlation between A^{had} and $A_{\tilde{X}}^{\text{had}}$, we perform Monte Carlo simulations at a number of randomly chosen points in the seven-dimensional parameter space $(\mu, M_2, \tan \beta, M_1/M_2, m_{\tilde{t}}, m_{\tilde{q}}, m_{\tilde{g}}, g^X)$, subject to the constraints that $m_{\tilde{X}_1^+}$ and $m_{\tilde{X}_2^0}$ are within 2 GeV of their measured values and $\sigma_R < 1 \text{ fb}$. Again the experimental observable A^{had} is determined to be an excellent estimator of $A_{\tilde{X}}^{\text{had}}$, with $\Delta A^{\text{sys}} = 0.034$.

A Monte Carlo simulation at our representative point gives

$$\begin{aligned} A^{\text{had}} &= 0.034 \\ \eta &= 11.9\% \\ N_{\text{exp}} &= 25.8 \mathcal{L}_L, \end{aligned} \quad (115)$$

where $\mathcal{L}_L$ is the left-handed integrated luminosity in fb^{-1} . We now calculate the uncertainties in determining $A_{\tilde{X}}^{\text{had}}$ and σ_Y using the equations found in Appendix B, this time including also the errors arising from a substantial number of background events $N_{\text{back}} \approx N_{\text{exp}}$. We find that for two values of left-polarized integrated luminosity,

$$\mathcal{L}_L = 30 (100) \text{ fb}^{-1} \implies A_{\tilde{X}}^{\text{had}} = 0.20 \pm 0.067 (0.048). \quad (116)$$

As in the previous case, the efficiency η is found to be highly constrained by the measurements of $m_{\tilde{X}_1^+}$, $m_{\tilde{X}_2^0}$, σ_L , and $A_{\tilde{X}}^{\text{had}}$, and the resulting systematic error is $\Delta\eta^{\text{sys}} = 0.55\%$. Including experimental statistical errors and those resulting from background subtraction, we find

$$\mathcal{L}_L = 30 (100) \text{ fb}^{-1} \implies \frac{\Delta\sigma_Y}{\sigma_Y} = 7.2 (5.6) \%. \quad (117)$$

For $\mathcal{L}_L = 30$ and 100 fb^{-1} these measurements constrain the allowed region of the $(m_{\tilde{\nu}}, g^X)$ plane to the shaded areas shown in Fig. 36. Because the charginos decay through on-shell W bosons, in contrast to the region 1 analysis, B_{ℓ} and B_h are fixed at their values in W decay, and thus the contours for σ_L inferred from σ_Y are independent of sfermion masses. For $\mathcal{L}_L = 100 \text{ fb}^{-1}$, if $m_{\tilde{\nu}} < 250 \text{ GeV}$ is excluded by the non-observation of any other threshold for heavy particle production, the allowed region is only the largest of the three shaded regions in Fig. 36b. For this region, we find the constraint

$$0.85g \leq g^X \leq 1.3g. \quad (118)$$

Such a result would be an important quantitative confirmation of SUSY.

Fig. 36 also illustrates a number of other interesting features. It is clear from Fig. 36 that, without assuming SUSY, the analysis above has simultaneously bounded

Figure 36: Allowed regions (shaded) of the (m_2, g^X) plane for $\mathcal{L}_L =$ (a) 30 fb^{-1} and (b) 100 fb^{-1} . Solid (dashed) curves are contours of constant $\sigma_L(A_L^X)$ that bound the allowed regions. On the dotted lines, the SUSY relation $g^X = g$ is satisfied.

the mass m_2 of a t -channel resonance, a useful result for future particle searches. If, on the other hand, we assume the validity of SUSY, then we are restricted to the dotted line at $g^X/g = 1$, and the A_L^X measurement alone restricts m_2 . Alternatively, the σ_L measurement alone restricts m_2 to two different ranges, of which one can be immediately excluded. Finally, as expected from earlier comments, this analysis is significantly weakened if m_2 is large. For large m_2 , the contours of Fig. 36 approach contours of constant g^X/m_2 , and only the ratio g^X/m_2 can be determined. On the other hand, if it is possible to measure m_2 independently, for example, from $e^+e^- \rightarrow \chi_1^0 \chi_1^0$ production, then the bounds on g^X/g can be significantly improved.

In the example above, we have considered a point for which chargino decays through on-shell W bosons are allowed. This choice was motivated by two considerations. First, in region 1, we considered a point for which only off-shell W decays were possible, and appropriate cuts were used. Our choice in region 2 illustrates that tests of SUSY are also possible when cuts appropriate to on-shell W decays must be used. Second, the scenario in which on-shell W decays are possible becomes more and more typical as the chargino mass rises, and the analysis presented is thus generalizable to higher chargino masses and beam energies. It is easy, however, to find points in region 2 where the chargino cannot decay to an on-shell W . For example, if one assumes the GUT relation $M_2 = 2M_1$, on-shell W decays are excluded for $m_{\chi_1^\pm} \lesssim 160 \text{ GeV}$. In this case, we must use the cuts presented in Sec. 3.4. In addition, chargino decays through virtual sfermions are not negligible, and one must consider the dependences of the branching ratios on sfermion masses. Such dependences will introduce systematic errors that may considerably weaken our results. However, as in the case of the gaugino portion of region 1, if these branching ratios can be measured, the systematic errors in their determination may be greatly reduced. In contrast to the region 1 case, the e_L^- beam, with its accompanying WW background, must be used. However, because WW events do not usually have $\cancel{p}_T$ without isolated leptons, they are likely to be a small background to purely hadronic chargino events. Although further study is required, it again seems probable that the Y mode branching fraction can be measured directly, and, with these modifications, the previous analysis may be applied to region 2 scenarios in which only off-shell W decays are allowed.

It is also true that in the very far gaugino region with $|\mu| \gg M_2$, where $\tilde{\chi}_1^\pm \approx \tilde{W}^\pm$ and $\tilde{\chi}_1^0 \approx \tilde{B}$, the W decay diagram is suppressed by mixing angles, and, even when decays through on-shell W bosons are kinematically allowed, virtual sfermion diagrams may be important. This requires that $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_1^0$ be very nearly pure gauginos, however, and this occurs only for $|\mu| \gtrsim 1 \text{ TeV}$, a condition that is disfavored by fine-tuning constraints.

3.6 Sfermions and Neutralinos

Up to this point, we have considered only precision SUSY tests from studies of the properties of charginos. Other particles may be produced at NLC energies, however, and we now examine the possibility of testing SUSY through the properties of sfermions and neutralinos. The discussion will be limited to brief remarks and, in contrast to the previous sections, no attempt will be made to perform detailed studies.

We first investigate the possibility of identifying a few newly-discovered scalars as sfermions. We are most interested in the scenario in which these scalars provide the first opportunity for precision tests of SUSY, and we therefore consider the case in which these scalars are lighter than charginos. In contrast to the previous sections, we will not impose any constraints on intergenerational slepton and squark mass degeneracies. However, if the problem is considered in full generality, it is complicated by many arbitrary parameters associated with sfermion intergenerational mixing. Simply to make the problem tractable, we will assume that intergenerational mixing is absent. We will also assume that left-right mixings may be neglected, with the understanding that the discussion that follows may not be applicable to the sfermions of the third generation. Probes of the left-right mixing of scalar taus have recently been discussed by Nojiri [67].

With these assumptions, the properties of these sfermions are completely specified by their quantum numbers and their masses. The only category (III) tests involving sfermion properties are therefore verifications of mass relations. Given the assumptions above, the masses of sfermions are

$$\begin{aligned}
 m_{\tilde{u}_L}^2 &= m_{\tilde{Q}}^2 + m_u^2 + M_2^2 \left(\frac{1}{2} - \frac{2}{3} \sin^2 \theta_W \right) \cos 2\beta \\
 m_{\tilde{d}_L}^2 &= m_{\tilde{Q}}^2 + m_d^2 + M_2^2 \left(-\frac{1}{2} + \frac{1}{3} \sin^2 \theta_W \right) \cos 2\beta \\
 m_{\tilde{u}_R}^2 &= m_{\tilde{U}}^2 + m_u^2 + M_2^2 \left(\frac{2}{3} \sin^2 \theta_W \right) \cos 2\beta \\
 m_{\tilde{d}_R}^2 &= m_{\tilde{D}}^2 + m_d^2 + M_2^2 \left(-\frac{1}{3} \sin^2 \theta_W \right) \cos 2\beta \\
 m_{\tilde{e}_L}^2 &= m_{\tilde{L}}^2 + m_e^2 + M_2^2 \left(-\frac{1}{2} + \sin^2 \theta_W \right) \cos 2\beta \\
 m_{\tilde{\nu}_\tau}^2 &= m_{\tilde{L}}^2 + \frac{1}{2} M_2^2 \cos 2\beta \\
 m_{\tilde{e}_R}^2 &= m_{\tilde{E}}^2 + m_e^2 + M_2^2 \left(-\sin^2 \theta_W \right) \cos 2\beta,
 \end{aligned} \tag{119}$$

where $m_{\tilde{Q}}$, $m_{\tilde{U}}$, $m_{\tilde{D}}$, $m_{\tilde{L}}$, and $m_{\tilde{E}}$ are soft SUSY breaking scalar masses. Similar relations hold for second and third generation sfermions. With additional relations from grand unification, there are a number of relations among these scalar masses [60]. However, we will continue to eschew assumptions that are not phenomenologically motivated. Without GUT assumptions, the right-handed masses are unrelated to the other masses, and the left-handed masses are related only by

$$\begin{aligned}
 m_{\tilde{e}_L}^2 - m_{\tilde{\nu}_\tau}^2 &= -M_W^2 \cos 2\beta \\
 m_{\tilde{d}_L}^2 - m_{\tilde{u}_L}^2 &= -M_W^2 \cos 2\beta,
 \end{aligned} \tag{120}$$

where we have omitted the small fermion mass terms. For $\tan \beta > 1$, these mass differences are positive, but we will consider all possible values of $\tan \beta$ below. The relations of Eq. (120) are quantitative predictions of SUSY that we may try to test.

Unfortunately, if the newly-discovered scalars are sleptons, it will be impossible to test these relations, because the sneutrinos will decay invisibly through $\tilde{\nu}_L \rightarrow \nu \tilde{\chi}_1^0$. We are assuming that charginos are heavier than sneutrinos, and so the decay $\tilde{\nu} \rightarrow e_L \tilde{\chi}_1^+$ is excluded. Also, even if $\tan \beta < 1$ and $m_{\tilde{\nu}_L} > m_{\tilde{e}_L}$, the experimental lower bound $m_{\tilde{e}_L} > 45 \text{ GeV}$ [18, 19, 20, 21, 22] implies $m_{\tilde{\nu}_L} - m_{\tilde{e}_L} < 47 \text{ GeV}$, and the decay $\tilde{\nu}_L \rightarrow \tilde{e}_L W^+$ is also greatly suppressed. The masses of sleptons are therefore highly unlikely to provide the first category (III) verifications of SUSY. Of course, if sneutrinos are heavier than charginos, precise verifications of slepton mass relations could be used to supplement measurements of chargino properties. It should also be noted that other properties of slepton *events* may provide additional precision measurements in the gaugino region. It may be possible, for example, to measure

some neutralino properties through the t -channel $\tilde{\chi}_1^0 \tilde{\chi}_2^0$ exchange diagrams for charged slepton pair production [32].

On the other hand, if the scalars are squarks, both left-handed species will decay visibly. A previous study of squark mass determination found that at the NLC, in most regions of parameter space, squark masses can be measured to approximately 2 GeV with an integrated luminosity of 10 fb^{-1} , even in scenarios with cascade decays [38]. This study also found that left-handed squarks can be effectively separated from right-handed squarks using beam polarization. It may be difficult to properly assign flavors to the different squark mass thresholds, however, especially if these thresholds are not well-separated. Let us first suppose that the masses of only two left-handed squarks are determined. To verify SUSY quantitatively, one must assume that the squarks are in the same generation, and must also independently determine $\tan \beta$ from the Higgs scalar sector. This is by no means always possible, and most likely requires, for example, that $m_{A^0} \lesssim 300 \text{ GeV}$ so that a heavy Higgs boson is kinematically accessible [66]. Even if all of these measurements can be made, the precision of the test is not high. For example, if $m_{\tilde{t}} > 200 \text{ GeV}$, the mass difference is $|m_{\tilde{t}_L} - m_{\tilde{t}_R}| < 15 \text{ GeV}$, and so in the best case scenario where $\tan \beta$ is determined exactly, the squark mass relation can be verified to approximately 20%. If it is not possible to measure $\tan \beta$ from the Higgs boson sector, a precision test of squark mass relations is only possible if one measures four left-handed squark masses. One can then check that there exists some flavor assignment consistent with

$$m_{\tilde{t}_L}^2 - m_{\tilde{t}_R}^2 \approx m_{\tilde{b}_L}^2 - m_{\tilde{b}_R}^2 \equiv \Delta(m^2), \quad (121)$$

where $|\Delta(m^2)| \leq M_W^2$.

The possibility of making the first quantitative tests of SUSY from stfermion properties is therefore not very promising. In the case of sleptons, the prospects are bleak, while in the case of squarks, even after assuming that intergenerational mixing is absent, precision tests are complicated by difficulties in flavor determination and rely on many MSSM scalars being kinematically accessible. However, the stfermion sector provides a number of opportunities for disproving the MSSM and SUSY. For example, if sneutrino decay is observed, one of our assumptions must be invalid. Also,

the relations of Eq. (120) are valid not just for the MSSM, but are extremely general predictions of SUSY. If they are found to be violated, not only will the MSSM be excluded, but almost all supersymmetric models will be strongly disfavored. On the other hand, of SUSY is favored by experiment, measurements of the squark and slepton masses will give important information about the flavor dependence of the SUSY breaking mechanism.

Neutralinos are natural candidates for precision SUSY tests, because, with the assumption that the lightest neutralino $\tilde{\chi}_1^0$ is the LSP, all sparticle event observables depend, at least formally, on the parameters that determine neutralino properties. In addition, neutralinos are light in many models, and, in fact, throughout parameter space, if charginos are produced, $\tilde{\chi}_1^0 \tilde{\chi}_2^0$ production is kinematically possible.

One might hope to follow the procedure in Sec. 3.4 by generalizing the neutralino mass matrix. If we relax SUSY, the most general form of Eq. (92) consistent with gauge invariance is

$$M'_{\tilde{\chi}^0} = \begin{pmatrix} M_1 & 0 & \mathcal{M} \\ 0 & M_2 & \\ \mathcal{M}^T & 0 & -\mu \\ -\mu & 0 & 0 \end{pmatrix}, \quad (122)$$

where $\mathcal{M}$ is an arbitrary 2×2 matrix that may be parametrized as

$$\mathcal{M} = \begin{pmatrix} -M_{\tilde{Z}}^X \cos \beta^X \sin \theta_W^X & M_{\tilde{Z}}^X \sin \beta^X \sin \theta_W^X \\ M_{\tilde{Z}}^X \cos \beta^X \cos \theta_W^X & -C^X M_{\tilde{Z}}^X \sin \beta^X \cos \theta_W^X \end{pmatrix}. \quad (123)$$

There are then seven parameters that enter neutralino events, and one must try to check the SUSY relations $M_{\tilde{Z}}^X = M_Z$, $\theta_W^X = \theta_W$ and $C^X = 1$. A general analysis is likely to be complicated. One possible simplification would be to consider a less than fully general neutralino mass matrix by setting, for example, $C^X = 1$. On the other hand, one might wish to assume the standard SUSY neutralino mass matrix, generalize the neutralino-fermion-stfermion coupling to g^X , and check that $g^X = g$. However, even this analysis is more complicated than the chargino case, because the SUSY neutralino mass matrix contains an additional parameter. In addition, an important caveat to all analyses based on the neutralino mass matrix is that

such analyses rely on the absence of gauge singlets, and are therefore more model-dependent than the chargino analyses of previous sections.

Without detailed study, it is not possible to dismiss the possibility that precision studies of sfermion and neutralino properties may be useful for testing SUSY. However, even from the brief comments presented above, it is clear that the sfermion and neutralino sectors are significantly less promising than the chargino sector. Category (III) tests from chargino properties are likely to be the least model dependent and may be the first strong quantitative tests even if some other sparticles are lighter than charginos.

3.7 Conclusions

Theories with unbroken gauge symmetry or unbroken supersymmetry have beautiful properties, but these symmetries lead to phenomenologically disastrous mass relations. These relations may be avoided, and the desirable properties retained, by breaking these symmetries: spontaneously, in the case of gauge theories, or softly, in the case of supersymmetric theories. However, such symmetry breaking mechanisms also preserve the relationships among dimensionless couplings imposed by the original symmetries, and it is this feature which provides the best opportunity for quantitative tests of supersymmetry.

In this study we have examined the possibilities for testing various SUSY relations in a number of scenarios. These studies have been conducted in the experimental setting provided by a linear e^+e^- collider with polarizable beams, and results have been presented for $\sqrt{s} = 500$ GeV and integrated luminosities of 30 and 100 fb^{-1} . In the scenario in which charginos are the first sparticles to be discovered, we have analyzed two representative cases. In the first, we probed the form of the chargino mass matrix, and in the second, we tested the $\tilde{\chi}_1^\pm f \bar{f}$ coupling. In both examples, we found that the test led to rather strong quantitative confirmations of the MSSM and SUSY. As a by-product, interesting bounds on some SUSY parameters were also obtained. The availability of polarizable beams was found to play a vital role, allowing us to define characteristic regions, effectively eliminate dependences on certain SUSY

parameters, and remove background. Our analysis was performed using a parton level Monte Carlo event generator and did not incorporate possible contamination of chargino pair events from other SUSY processes. Of course, a more detailed analysis that includes the simultaneous production of all possible SUSY events together with a more realistic simulation is needed before definitive conclusions about precision SUSY tests may be drawn.

The prospects for obtaining the first quantitative tests of SUSY from sfermion and neutralino properties were also considered. Sleptons were found to be poor candidates for such tests because of the difficulty in detecting sneutrinos, and precision tests from squarks were found to rely on the discovery of at least four squarks or two squarks and, most likely, two Higgs bosons. The analysis of neutralino properties is complicated by its dependence on a large number of parameters. Whether these complications may be overcome in certain scenarios remains to be seen in further studies. However, while falsification of sfermion mass relations is the least model-dependent disproof of SUSY, it is likely that the chargino sector is the simplest and most powerful for verifying the quantitative predictions of SUSY.

We have not considered the possibilities for quantitative SUSY tests at other colliders, nor have we examined the additional constraints that come with the adoption of GUT and supergravity assumptions. Even with fairly weak assumptions, however, we have found that, if sparticles are produced at future e^+e^- colliders, measurements of their properties may allow us to quantitatively verify SUSY, a valuable first step in the exploration of the full structure of supersymmetric theories.

$$\Delta m_{\tilde{\chi}_1^\pm} = \left[\left(\frac{\partial m_{\tilde{\chi}_1^\pm}}{\partial m_{jj}^{\max}} \Delta m_{jj}^{\max} \right)^2 + \left(\frac{\partial m_{\tilde{\chi}_1^\pm}}{\partial E_{jj}^0} \Delta E_{jj}^0 \right)^2 \right]^{\frac{1}{2}}, \quad (126)$$

and similarly for $\Delta m_{\tilde{\chi}_1^0}$.

To calculate σ_{total} and B_ℓ , one must measure at least two partial cross sections. If one has measured the mixed and hadronic partial cross sections σ_{mixed} and σ_{hadronic} , the total cross section and leptonic branching fraction are

$$\sigma_{\text{total}} = \frac{(\sigma_{\text{mixed}} + 2\sigma_{\text{hadronic}})^2}{4\sigma_{\text{hadronic}}}, \quad (127)$$

$B_\ell = \frac{\sigma_{\text{mixed}}}{\sigma_{\text{mixed}} + 2\sigma_{\text{hadronic}}}$, and their fractional uncertainties are given by

$$\left(\frac{\Delta \sigma_{\text{total}}}{\sigma_{\text{total}}} \right)^2 = 4B_\ell^2 \left(\frac{\Delta \sigma_{\text{mixed}}}{\sigma_{\text{mixed}}} \right)^2 + (1 - 2B_\ell)^2 \left(\frac{\Delta \sigma_{\text{hadronic}}}{\sigma_{\text{hadronic}}} \right)^2, \quad (128)$$

$$\left(\frac{\Delta B_\ell}{B_\ell} \right)^2 = (1 - B_\ell)^2 \left[\left(\frac{\Delta \sigma_{\text{mixed}}}{\sigma_{\text{mixed}}} \right)^2 + \left(\frac{\Delta \sigma_{\text{hadronic}}}{\sigma_{\text{hadronic}}} \right)^2 \right].$$

If σ_{mixed} and σ_{leptonic} are measured instead,

$$\sigma_{\text{total}} = \frac{(\sigma_{\text{mixed}} + 2\sigma_{\text{leptonic}})^2}{4\sigma_{\text{leptonic}}}, \quad (129)$$

$$B_\ell = \frac{2\sigma_{\text{leptonic}}}{2\sigma_{\text{leptonic}} + \sigma_{\text{mixed}}},$$

and

$$\begin{aligned} \left(\frac{\Delta \sigma_{\text{total}}}{\sigma_{\text{total}}} \right)^2 &= 4(1 - B_\ell)^2 \left(\frac{\Delta \sigma_{\text{mixed}}}{\sigma_{\text{mixed}}} \right)^2 + (1 - 2B_\ell)^2 \left(\frac{\Delta \sigma_{\text{leptonic}}}{\sigma_{\text{leptonic}}} \right)^2, \\ \left(\frac{\Delta B_\ell}{B_\ell} \right)^2 &= (1 - B_\ell)^2 \left[\left(\frac{\Delta \sigma_{\text{mixed}}}{\sigma_{\text{mixed}}} \right)^2 + \left(\frac{\Delta \sigma_{\text{leptonic}}}{\sigma_{\text{leptonic}}} \right)^2 \right]. \end{aligned} \quad (130)$$

If all three partial cross sections are measured, they may all be used to improve the determinations of σ_{total} and B_ℓ . In this study, the Y mode partial cross section is

Appendix A

Uncertainty Analysis: Observables

In this appendix we collect the various formulae needed in Chapter 2 to calculate uncertainties in observables.

The chargino and LSP masses determine the maximum and minimum dijet energies, $E_{jj}^{\max}$ and $E_{jj}^{\min}$, and the maximum dijet mass, $m_{jj}^{\max}$. Thus, if two of these three endpoints are measured, one can determine $m_{\tilde{\chi}_1^\pm}$ and $m_{\tilde{\chi}_1^0}$.

If $E_b > E_b^{\text{crit}}$, the critical beam energy defined in Eq. (18), the masses $m_{\tilde{\chi}_1^\pm}$ and $m_{\tilde{\chi}_1^0}$ are given by

$$m_{\tilde{\chi}_1^\pm}(m_{jj}^{\max}, E_{jj}^0) = \frac{m_{jj}^{\max} 2E_{jj}^0 E_b + (m_{jj}^{\max})^2 + E_{jj}^0 \sqrt{4E_b^2 - 4E_{jj}^0 E_b - m^2}}{2(E_{jj}^0)^2 + (m_{jj}^{\max})^2}, \quad (124)$$

$$m_{\tilde{\chi}_1^0}(m_{jj}^{\max}, E_{jj}^0) = m_{\tilde{\chi}_1^\pm}(m_{jj}^{\max}, E_{jj}^0) - m_{jj}^{\max},$$

where $E_{jj}^0 \equiv E_{jj}^{\max}$ or $E_{jj}^{\min}$. For $E_b \leq E_b^{\text{crit}}$, the mass expressions are simply

$$\begin{aligned} m_{\tilde{\chi}_1^\pm}(m_{jj}^{\max}, E_{jj}^{\max}) &= E_b - E_{jj}^{\max} + m_{jj}^{\max}, \\ m_{\tilde{\chi}_1^0}(m_{jj}^{\max}, E_{jj}^{\max}) &= E_b - E_{jj}^{\max}. \end{aligned} \quad (125)$$

For all E_b , the uncertainties in the mass determinations are given by adding the endpoint uncertainties in quadrature:

measured instead of the mixed mode. After lepton universality is verified, $\sigma_{\text{mixed}} = \frac{5}{4}\sigma_Y$, and one can simply replace σ_{mixed} by σ_Y in the above formulae.

Finally, we must calculate the uncertainty of A_{FB}^{ij} . The forward-backward asymmetry is $A_{FB}^{ij} = 2p - 1$, where p is the fraction of events in the forward hemisphere, and the standard error of an estimate of a population proportion is

$$\sigma(p) = \sqrt{\frac{p(1-p)}{N}}, \quad (131)$$

where N is the number of samples. The 1σ uncertainty in the measurement of A_{FB}^{ij} is therefore given by

$$\sigma(A_{FB}^{ij}) = 2\sigma(p) = \sqrt{\frac{1 - (A_{FB}^{ij})^2}{N}}. \quad (132)$$

Appendix B

Uncertainty Analysis: Correlations

In Chapter 3 we used the truncated forward-backward asymmetry $A^x \equiv A_i^x$, where $i = L$ or R , and the Y mode partial cross section σ_Y to constrain parameter space. These theoretical quantities are found through their correlations to experimental observables. The uncertainties in determining A^x and σ_Y therefore receive contributions from two sources: systematic errors, that is, uncertainties arising from the lack of perfect correlation between the theoretical quantities and the experimental observables, and experimental statistical errors. In this appendix we collect the formulae used to estimate the systematic and statistical errors.

Systematic errors are determined by performing Monte Carlo simulations at a number of points in parameter space. The truncated forward-backward asymmetry of chargino production before cuts, A^x , is determined through its correlation to A^{had} , the forward-backward asymmetry of the hadronic system's direction after cuts. The theoretical quantity A^x depends only on parameters that enter the production process, while A^{had} depends on both production and decay, and on cuts and detector effects. The systematic uncertainty in A^x is therefore determined by the sensitivity of A^{had} to the decay process, cuts, and detector effects, and this sensitivity is measured through simulations. For each of N_{pts} points in parameter space, A^x is determined from exact analytical expressions, and A^{had} is found from a Monte Carlo simulation. A linear fit

to the resulting distribution in the (A^X, A^{had}) plane is parametrized by

$$A^{\text{had}} = aA^X + b \pm \Delta A_{\text{MC}}^{\text{tot}}, \quad (133)$$

where $\Delta A_{\text{MC}}^{\text{tot}}$ is the 1σ uncertainty in A^{had} for a fixed A^X . The total Monte Carlo uncertainty $\Delta A_{\text{MC}}^{\text{tot}}$ includes both the systematic error and fluctuations from finite Monte Carlo statistics. The contribution from Monte Carlo statistical fluctuations is

$$\Delta A_{\text{MC}}^{\text{stat}} = \left[\frac{1}{N_{\text{pts}}} \sum_{i=1}^{N_{\text{pts}}} (\Delta A_i^{\text{had}})^2 \right]^{\frac{1}{2}}, \quad (134)$$

where

$$\Delta A_i^{\text{had}} = \sqrt{\frac{1 - (A_i^{\text{had}})^2}{N_{\text{MC};i}}} \quad (135)$$

is the Monte Carlo statistical uncertainty in A_i^{had} for simulation i , and $N_{\text{MC};i}$ is the effective number of events in simulation i . The systematic error of the distribution is then

$$\Delta A_{\text{exp}}^{\text{sys}} = \sqrt{(\Delta A_{\text{MC}}^{\text{tot}})^2 - (\Delta A_{\text{MC}}^{\text{stat}})^2}. \quad (136)$$

To the systematic error must be added the experimental statistical error. This error is given by

$$\Delta A_{\text{exp}}^{\text{stat}} = \sqrt{\frac{1 - (A^{\text{had}})^2}{N_{\text{exp}}} + \frac{(1 - A^{\text{had}})^2 N_{\text{back}}}{N_{\text{exp}} N_{\text{exp}}}}, \quad (137)$$

where A^{had} is the forward-backward asymmetry for our case study, and N_{exp} (N_{back}) is the number of signal (background) events that pass all cuts and is proportional to the integrated luminosity. (Here we have assumed that the background is well-understood and may be subtracted up to statistical uncertainties. We also assume that all background events are in the forward hemisphere, a good approximation for the dominant background, W pair production.) We estimate the total experimental uncertainty in A^{had} for a given A^X to be

$$\Delta A_{\text{exp}}^{\text{tot}} = \sqrt{(\Delta A_{\text{exp}}^{\text{sys}})^2 + (\Delta A_{\text{exp}}^{\text{stat}})^2}. \quad (138)$$

What we actually measure is A^{had} , however. We therefore are more interested in the experimental uncertainty in A^X for a fixed A^{had} , which is

$$\Delta A^X = |a|^{-1} \Delta A_{\text{exp}}^{\text{tot}}, \quad (139)$$

where a is the slope of the linear fit in Eq. (133).

The efficiency of the cuts η is found simply by its correlation to previous measurements. To determine the uncertainty in η , we reduce the parameter space to the region in which the previous measurements have their appropriate values and determine the variation of η within this subspace. We determine η for each of the simulations and obtain a distribution of points in the (A^X, η) plane. The best linear fit to this distribution is

$$\eta = a'A^X + b' \pm \Delta\eta_{\text{MC}}^{\text{tot}}, \quad (140)$$

where $\Delta\eta_{\text{MC}}^{\text{tot}}$ is the 1σ error in η for a fixed A^X . To find the systematic error, we must again remove the fluctuations that arise solely from finite Monte Carlo statistics. The Monte Carlo statistical error is

$$\Delta\eta_{\text{MC}}^{\text{stat}} = \left[\frac{1}{N_{\text{pts}}} \sum_{i=1}^{N_{\text{pts}}} (\Delta\eta_i)^2 \right]^{\frac{1}{2}}, \quad (141)$$

where the statistical error for simulation i is given by

$$\Delta\eta_i = \sqrt{\frac{\eta_i(1-\eta_i)}{N_{\text{MC}}}}. \quad (142)$$

The systematic error in η for a fixed A^X is then

$$\Delta\eta^{\text{sys}} = \sqrt{(\Delta\eta_{\text{MC}}^{\text{tot}})^2 - (\Delta\eta_{\text{MC}}^{\text{stat}})^2}. \quad (143)$$

However, as seen above, A^X is not determined exactly. The uncertainty in A^X weakens the determination of η , and the total uncertainty in η is

$$\Delta\eta = \sqrt{(a'\Delta Ax)^2 + (\Delta\eta^{sys})^2}. \quad (144)$$

We must now convert the uncertainty in η into an uncertainty in σ_Y . The Y mode partial cross section and its fractional uncertainty are given by

$$\sigma_Y = N_{\text{exp}} \eta^{-1} \mathcal{L}^{-1} \quad (145)$$

and

$$\frac{\Delta\sigma_Y}{\sigma_Y} = \left[\left(\frac{\Delta N_{\text{exp}}}{N_{\text{exp}}} \right)^2 + \left(\frac{\Delta\eta}{\eta} \right)^2 + \left(\frac{\Delta\mathcal{L}}{\mathcal{L}} \right)^2 \right]^{\frac{1}{2}}, \quad (146)$$

where $\mathcal{L}$ is the integrated luminosity. For the purposes of this study, $\Delta\mathcal{L}/\mathcal{L}$ is negligible. The uncertainty in the number of Y events passing the cuts is $\Delta N_{\text{exp}} = \sqrt{N_{\text{exp}} + N_{\text{back}}}$, where N_{exp} (N_{back}) is the number of Y mode (background) events passing the cuts, respectively, and we have again assumed that the background is well-understood and may be subtracted up to statistical uncertainties.
