

Booster Cavity Damper Redesign for PIP-II

Dustin Pieper, Brian Vaughn, Robyn Madrak, Fermilab

Introduction

- Under PIP-II's higher intensity, beam excitation of the Booster cavity at 105 MHz could excite the cavity's 2nd order mode, leading to beam instability.
- There's currently a Higher Order Mode (HOM) damper on the cavity at 83 MHz. If this could be extended to cover 105 MHz, the beam instability could be mitigated.

HOM Damping

- The existing damper is composed of three parts.
 1. A coupling loop which extracts energy from the cavity
 2. A coaxial loop filter which reflects the desired fundamental mode back into the cavity while passing HOMs
 3. A dump load which burns off the unwanted HOMs.
- By replacing the filter with a wider band design, the 105 MHz mode can also be covered

Filter Redesign

- Instead of using a cable-loop notch filter for the wider band system, a component-based PCB design was pursued instead.
- Ideally this would allow a smaller form factor for the filter while also being easier to design for the wide band

Schematic of initial design

High Voltage Testing and Path Forward

- Although the filter achieved the desired damping at low power, there was a destructive arcing event at the connector during high power testing on the cavity.
- This is likely due to the filter impedance acting like an open circuit at the fundamental, causing a voltage spike on the input.
- This sparked a new design iteration to mitigate this voltage, which is awaiting testing.
- Changing to a DIN connector may also help.
