### ABSTRACT

The electrical resistivity and magnetic susceptibility of the cubic intermetallic compounds  $\text{UIr}_2$  ( $\text{MgCu}_2$ -type) and  $\text{UIr}_3$  (ordered,  $\text{AuCu}_3$ -type) have been measured between 2-300K. The susceptibility of  $\text{UIr}_3$  is temperature independent and substantially lower than that of isoelectronic  $\text{URh}_3$  being  $0.57$  vs  $0.97 \times 10^{-3}$  emu/mole at room temperature. The susceptibility of  $\text{UIr}_2$  is very weakly temperature dependent above 100K, and has a value of  $1.18 \times 10^{-3}$  emu/mole at room temperature. The electrical resistivities of both compounds follow power law dependences at low temperatures, of the form  $\rho - \rho_0 = AT^n$ , with  $n = 1.9$  for  $\text{UIr}_2$  and  $n = 3.7$  for  $\text{UIr}_3$ . These results indicate that  $\text{UIr}_2$  may be a spin fluctuation compound, while  $\text{UIr}_3$  behaves as a simple transition metal compound, with even less d-f character than  $\text{URh}_3$  ( $n = 3.0$ ). The specific heat of  $\text{UIr}_2$  was measured between 1-4K and may be fit to  $C = \gamma T + \beta T^3$ , with a large value of  $\gamma$ ,  $62.5 \text{ mJ}/(\text{mole-K}^2)$ , which is consistent with a narrow 5f band at the Fermi level. The lack of any magnetic phenomena in  $\text{UIr}_3$  is explained by the hybridization of the 5f electrons into f-d bands, which mostly lie below the Fermi level.

### INTRODUCTION

In view of the large variety of magnetic phenomena found in metallic actinides, it is desirable to systematically study actinide systems to help unravel the physics underlying the various phenomena. This paper presents the results of a study of the electrical resistivity and magnetic susceptibility of  $\text{UIr}_2$  and  $\text{UIr}_3$  between approximately 2 and 300K. Specific heat measurements were also made on  $\text{UIr}_2$  between 1.5 and 4.2K.  $\text{UIr}_3$  forms peritectically in the  $\text{MgCu}_2$ -type cubic Laves phase, and  $\text{UIr}_3$  crystallizes congruently in the ordered  $\text{AuCu}_3$  structure. The measurements on  $\text{UIr}_3$  are of special interest since they may be compared with preliminary deHaas-van Alphen (dHvA) results for this compound,<sup>1</sup> and with the fairly complete dHvA and band structure results for isoelectronic  $\text{URh}_3$ .<sup>2</sup>

## EXPERIMENTAL

Samples were prepared by arc-melting the constituents, followed by electrolytic machining where necessary. The correct single phase structures were verified by x-ray diffraction methods. The  $\text{UIr}_2$  was annealed at  $1040^\circ\text{C}$  for ten days. Experimental techniques used in this work have been described previously.<sup>3,4,5</sup>

## RESULTS

The temperature dependence of the susceptibility is given in Fig. 1 for both compounds. Although both sets of data are essentially temperature-independent, there is a slight maximum in the  $\text{UIr}_2$  data at  $60 \pm 2\text{K}$ . The room temperature value for  $\text{UIr}_3$  ( $0.570 \times 10^{-3}$  emu/mole) is about 0.6 as large as the value for  $\text{URh}_3$  ( $0.973 \times 10^{-3}$  emu/mole),<sup>6</sup> and the  $\text{UIr}_2$  value is slightly higher ( $1.176 \times 10^{-3}$  emu/mole) than the  $\text{URh}_3$  value.

The low temperature resistivities are plotted as  $\log(\rho - \rho_0)$  vs  $\log T$  in Fig. 2. Both sets of data may be represented by  $\rho - \rho_0 = AT^n$ , with  $n = 1.9$  for  $\text{UIr}_2$  and  $n = 3.7$  for  $\text{UIr}_3$ .<sup>6</sup> The latter value is to be compared to  $n = 3.0$  for isoelectronic  $\text{URh}_3$ .<sup>6</sup> The values of  $\rho_{300} - \rho_0$  are  $122 \mu\Omega\text{cm}$  for  $\text{UIr}_2$  and  $34 \mu\Omega\text{cm}$  for  $\text{UIr}_3$  (vs 54 for  $\text{URh}_3$ ). There is a small bump in the  $\rho$ - $T$  curve for  $\text{UIr}_2$  with a height of only 0.5 out of 60  $\mu\Omega\text{cm}$ , and centered at 57K, with a width of 2-3K.

The specific heat data for  $\text{UIr}_2$  are well represented by  $C = \gamma T + \beta T^3$ , with  $\gamma = 62.5 \pm 1.0 \text{ mJ}/(\text{mole-K}^2)$  and  $\beta = 0.50 \pm 0.03 \text{ mJ}/(\text{mole-K}^4)$ , corresponding to a Debye temperature,  $\Theta_D = 227 \pm 5\text{K}$ .

## DISCUSSION

The higher power law exponent for the  $\text{UIr}_3$  resistivity data versus  $\text{URh}_3$  indicates significant s-s or p-p scattering in addition to s-d scattering. The much smaller  $\rho_{300} - \rho_0$  for  $\text{UIr}_3$  vs  $\text{URh}_3$  is in agreement with this proposal. This conclusion is supported further by the dHvA data, which show more s-like orbits than are found in  $\text{URh}_3$ . The tentative band structure for  $\text{UIr}_3$  (based strongly on the  $\text{URh}_3$  results) explains the lack of magnetism in  $\text{UIr}_3$ , also, since the f-electrons are all strongly hybridized into f-d bands, which mostly lie well below the Fermi level.

The small maximum in the  $\text{UIr}_2$  susceptibility accompanied by the small resistivity anomaly, is probably not associated with a magnetic transition. Most likely it is due to a slight cubic to tetragonal distortion as is found in other actinide cubic Laves phase compounds with transition metals.<sup>7</sup> The lack of magnetic ordering is

supported further by an almost trivial temperature dependent susceptibility between 150-300K. Additional measurements on  $\text{UIr}_2$  in the temperature region near 60K are necessary to determine the cause of the susceptibility maximum. Among these are x-ray diffraction and specific heat.

However, the low-temperature  $T^2$  resistivity for  $\text{UIr}_2$  indicates a magnetic phenomenon. By analogy with many other actinide compounds, it is likely that  $\text{UIr}_2$  is a spin fluctuation compound.<sup>8,9</sup> The slope of the  $T^2$  regime yields a spin fluctuation temperature,  $T_{\text{sf}}$ , of 200K, while the limit of the  $T^2$  regime only yields  $T_{\text{sf}} \sim 60\text{K}$ . However, for a  $T_{\text{sf}}$  this large an upper limit to the  $T^2$  dependence becomes hard to separate from the total resistivity. We point out that since the spin fluctuation contribution to the specific heat,  $T^3 \ln T/T_{\text{sf}}$ , goes to  $T = 0$  as  $T^3$ , a spin fluctuation contribution would be inseparable from the lattice contribution for  $T \ll T_{\text{sf}}$ . For  $\text{UAl}_2$ , a  $T_{\text{sf}} = 23\text{K}$  permitted the observation of a low temperature upturn in  $C/T$  due to the spin fluctuation term.<sup>9</sup> The large value for  $\gamma$  is in agreement with a spin fluctuation model which requires a narrow 5f band at or near the Fermi level. An estimate of the exchange enhancement factor,  $S = \chi/\gamma$ , of 2.3 is obtained from the experimental data. This does not allow for the unknown electron-phonon enhancement of the electronic specific heat or orbital contribution to the susceptibility.

One mechanism which has been widely used to explain the lack of magnetism in many actinide compounds is broadening due to 5f-5f direct overlap as a consequence of relatively short interactinide distances.<sup>10</sup> This mechanism is certainly operable in the cubic Laves phase structure where the U-U distance in  $\text{UIr}_2$ , for example, is only 3.25Å. In the case of  $\text{AuCu}_3$ -type compounds, the larger U-U distance, e.g., 4.023Å for  $\text{UIr}_3$ , should lead to local moment behavior if 5f-5f overlap is the only mechanism for broadening. However, in some actinide-transition metal compounds additional broadening occurs via 5f-6d hybridization which is favorable in this structure, and is stronger than 5f-5f overlap. Hence, there may be no magnetic behavior. By adding more 5f electrons as in going from  $\text{URh}_3$  to  $\text{PuRh}_3$ , one may obtain a situation with some unhybridized, localized 5f electrons. Thus,  $\text{PuRh}_3$  is a good example of 5f local moment behavior.<sup>6,11</sup>
