MEDICAL SURVEY OF RONGELAP PEOPLE SEVEN YEARS AFTER EXPOSURE TO FALLOUT

Introduction

The results of a medical survey of the people of Rongelap in the Marshall Islands, carried out in March 1961 at 7 years after the accident, are presented in this report. These people had been accidentally exposed to fallout radiation following a detonation of a high yield thermonuclear device during experiments at Bikini in the Pacific Proving Grounds in March 1954. An unpredicted shift in winds caused a deposition of significant amounts of fallout on four inhabited Marshall Islands to the east of Bikini (see Figure 1) and also on 23 Japanese fishermen aboard their fishing vessel, the *Lucky Dragon*. Of the inhabitants of the island of Rongelap, 105 nautical miles away from the detonation, 64 received the largest fallout exposure: an estimated dose of 175 r of whole-body gamma radiation, contamination of the skin sufficient to result in beta burns, and slight internal absorption of radioactive materials through inhalation and ingestion. Another 18 Rongelap people away on a nearby island (Ailingnae), where less fallout occurred, received only an external gamma dose of about 69 r. There were 28 American servicemen on the island of Rongerik further to the east who received about the same amount of radiation as did the Rongelap people on Ailingnae. Lastly, 157 Marshallese on Utirik Island, about 200 miles further east, received about an estimated 14 r of whole-body radiation. The fallout was not visible on this island and no skin effects developed.

The exposed people were evacuated from these islands by plane and ship about two days after the accident and taken to Kwajalein Naval Base about 150 miles to the south, where they received extensive examinations for the following three months. In view of the generally negative findings on the American servicemen, they were later returned to their duty stations. The Utirik people were also allowed to return to their home island, where radioactive contamination was slight enough to allow safe habitation. Because Rongelap Atoll was considered to be too highly contaminated, a

temporary village was constructed for the Rongelap people on Majuro Atoll several hundred miles to the south, where they lived for the following 3½ years and were examined at yearly intervals by a special medical team. In July 1957, after careful evaluation of the radioactive contamination situation, Rongelap Island was considered safe for habitation. A new village was constructed, and the Rongelap people were moved there by Navy ship. The annual medical surveys have since been carried out on Rongelap Island.

A group of more than 100 Rongelap people, who were relatives of the exposed people but had been away from the island at the time of the accident, moved back with the Rongelap people to their home island and have served as an ideal comparison population for the studies. Following the initial survey of the Utirik people on Kwajalein in 1954, a repeat survey was carried out in March 1957. In addition, during the past survey, as in the previous surveys, a visit was made to Majuro Atoll to examine a group of children who represent part of the control group used for the growth and development studies of the exposed children.

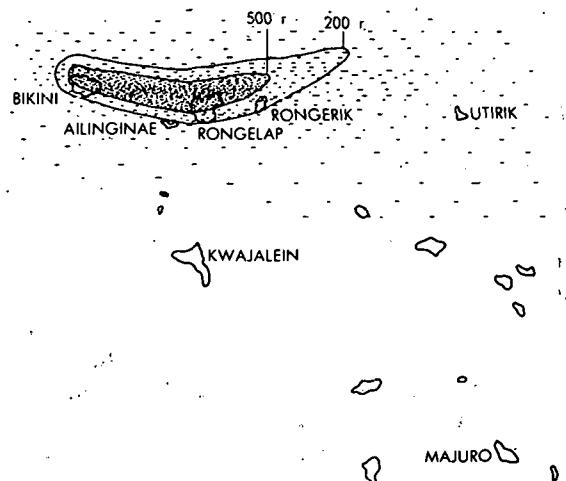

Figure 1. Map of fallout area (March 1, 1954), Marshall Islands.

The accumulation of data from these surveys is becoming increasingly voluminous. Since conditions have not been favorable for performance of extensive statistical analyses or use of electronic computing procedures to store and manipulate the data, the annual survey reports published by this Laboratory are made as complete as possible. This report, therefore, includes a considerable amount of raw data, much of it in appendices, so that others may have an opportunity to make further calculations if desired.

Summary of Past Findings

Reports have been published on the findings of surveys made at the following times after exposure: initial examination,¹ 6 months,² 1 year,³ 2 years,⁴ 3 years,⁵ 4 years,⁶ and 5 and 6 years.⁷ The following is a brief summary of the findings previously reported.

During the first 24 to 48 hr after exposure, about $\frac{2}{3}$ of the Rongelap people experienced anorexia and nausea. A few vomited and had diarrhea. Many also experienced itching and burning of the skin, and a few complained of lachrymation and burning of the eyes. Following this, the people remained asymptomatic until about 2 weeks after the accident, when cutaneous lesions and loss of hair developed, due largely to beta irradiation of the skin. It was apparent when the people were first examined, a few days after exposure, that the lymphocytes were considerably depressed and that significant doses of radiation had probably been received. In addition to the whole-body dose of radiation and the beta irradiation of the skin, radiochemical analyses of the urine showed that measurable amounts of radioactive material had also been absorbed internally. The effects of the radiation can best be summarized under three headings according to the mode of exposure: penetrating irradiation, skin irradiation, and internal irradiation.

PENETRATING IRRADIATION

The changes in the peripheral blood of the more heavily exposed Rongelap people who received 175 r will be reviewed in the section on hematological examinations (see Figures 34, 39, and 43, and Appendices 1 and 2). The changes in the Ailingnae and Utirik groups were similar but less

marked. Certain unexplained fluctuations have occurred from year to year in the peripheral blood levels of the comparison populations as well as of the exposed groups. The mean *leukocyte* level of the exposed group showed a marked decrease at the time of the 1960 survey (no unexposed people were examined). Depression of the peripheral blood elements as represented by mean population levels occurred as follows.

Lymphocytes fell promptly and by the third day were about 55% of the control values in adults, and slightly lower in children. There was only slight recovery after six months. At 2 years, although further recovery was evident, the mean values of these cells were still found to be below the comparison population levels (75 to 80%). At 3 years the mean lymphocyte counts were slightly below those of the comparison population. At 4 years the mean level appeared to be about the same as that of the comparison population, but many counts remained lower. However, at 5 years, *lymphocyte* levels appeared for the first time to equal those of the unexposed group, except that analyses showed more counts below the average of the unexposed group.

Neutrophil levels fluctuated considerably during the first few weeks but fell gradually to a low of about 50% of comparison population levels by the 6th week after exposure. Slow recovery ensued, but at 6 months they were still slightly below the unexposed levels. However, by 1 year post exposure they had returned to the level of the comparison population and have remained so, with the possible exception of those of children <12 years old, which generally have been lower than those of the unexposed children of comparable age.

Platelets fell to about 30% of the unexposed values by the 4th week. By 6 months they had reached 75% of the controls; at 1 year the mean platelet count was still below that of the control population but higher than at the 6-month survey. Although further increases were apparent at the 2-, 3-, and 4-year examinations, the levels were still below those of the comparison population. At 5 years post exposure, exposed people still had mean *platelet* levels 10 to 15% below those of the unexposed group.

Changes in hematocrit were not remarkable in any of the groups during the period of maximum depression of leukocytes. However, it appeared

that in 1959 the mean *erythrocyte* levels were slightly lower in the exposed people. These blood elements in the Ailingnae group also showed some slight depression below the unexposed levels but not quite so marked as seen in the Rongelap exposed group. A general anemic tendency was noted in the Marshallese, both exposed and unexposed. *Price-Jones curves*, on the average, showed a slight microcytic tendency. *Serum iron* levels were generally normal. The fact that some of the blood elements in the exposed group have not yet returned to the levels in the unexposed group raises the possibility that a residual radiation effect on the bone marrow persists, but other, not immediately apparent, factors may be involved.

Reticulocyte counts have been about the same in the exposed and unexposed people.

Bone marrow examinations on a number of exposed individuals at 6 months and 3 years post exposure showed no abnormalities or deficiencies of cellular elements.

Clinical examinations revealed no disease processes or symptoms which could be attributed to radiation effects, aside from skin lesions, loss of hair, and early symptoms. No specific therapy was given. Epidemics of chicken pox and measles occurred. The diseases encountered were no more severe or frequent in the irradiated group than in the unexposed group, even during the period of greatest depression of peripheral blood elements.

At 3 years post exposure the immune response to primary and secondary tetanus antitoxin was tested and found not to be significantly different in the exposed compared to the unexposed populations.

Four persons in the exposed population died of disease: (1) a 46-year-old man with a hypertensive heart disease which had been present at the time of exposure, who died 2 years after the accident; (2) a 78-year-old man who died, 3 years after exposure, of coronary heart disease complicating diabetes; (3) a 36-year-old man who died of acute varicella, 4 years after exposure, who had received only 69 r, having been on Ailingnae at the time of the fallout; and (4) a 60-year-old woman who died of a cancer of the ovary at 5 years after exposure. There was no apparent relationship between any of these deaths and radiation exposure. Four deaths have occurred in the comparison population. The four deaths that have occurred in the exposed people since exposure represent a *mortality*

rate of 8.1 per 1000 population, compared with 8.3 for the comparison population and 6.8 for the Marshall Islands as a whole.

Certain findings were possibly related to the radiation exposure, such as loss in weight of several pounds in most of the people during the first several months after exposure and suggestive evidence of slight lag in growth and development of the children based on studies of height, weight, and bone development (but inconclusive pending verification of more exact ages of some of the children).

In connection with *growth and development studies*, a project on the verification of accuracy of ages of the children has not been completed and, therefore, the suggestive evidence previously presented of possible lag in statural growth in the exposed children must await confirmation. It was noted, however, that in the 6-year chronological age group, three boys and one girl out of five boys and two girls in the exposed group exhibited significantly retarded skeletal maturation as judged by x-ray examination. The birth dates of these children seemed to be fairly well established.

It was difficult to evaluate the effects on fertility. However, a review of the *birth rate* of the exposed group over the past 6 years seems to indicate no noticeable effect of their exposure on fertility. The 24 births represent a rate of 48 per 1000 population, compared with 37.3 for the Marshall Islands (1957). The 20 births over a 3-year period for the comparison population represent a rate of 62 per 1000 population. A somewhat greater incidence of *miscarriages and stillbirths* has been noted in the exposed women, but because of the paucity of vital statistics in the Marshallese and the small number of people involved, the data are not readily amenable to statistical analysis.

A *cardiovascular survey* of the adults (1959) showed no outstanding differences between the exposed and unexposed groups. The people appeared to have less hypertension on the whole than is noted in people in the continental United States.

An *arthritis survey* (1959) showed no great differences between the exposed and the unexposed people, and about the same incidence as is seen in American populations.

Ophthalmological surveys showed no remarkable differences between the exposed and unexposed groups except possibly a slightly greater number of cases of *pterygia*, *pingueculae*, and *corneal scars*.

in the exposed group. It is not known whether this finding is of any significance in relation to their radiation exposure. Slit-lamp observations showed no opacities of the lens characteristic of radiation exposure. As a whole, visual and accommodation levels in the Marshallese appeared to be above the average in the U.S. population.

Dental surveys showed no significant differences in either caries rate or incidence of periodontal disease between exposed and unexposed groups. The poor oral hygiene generally observed in the Marshallese had its usual results, namely, high caries rate in teen-age children, severe periodontal lesions in adults (heavy calculus and loss of alveolar bone), and edentulous mouths in the aged. Radiation exposure did not appear to have affected developing dentition in the exposed children.

Late effects of radiation. Various parameters usually associated with *aging* were measured or estimated on a 0 to 4+ scale (skin looseness, elasticity, and senile changes; greying of the hair and balding; accommodation, visual acuity, and arcus senilis; hearing; cardiovascular changes including blood pressure and degrees of peripheral and retinal arteriosclerosis; neuromuscular function; and hand strength). Comparison of these measurements in exposed and unexposed individuals of the same age groups showed no apparent differences. A biological age score was calculated for individuals and groups by use of an average percentage score. *Life shortening* effects of radiation have not been apparent. As noted, the mortality rate was about the same in the exposed as in the unexposed people.

The one case of *cancer* that developed in the exposed group occurred at 5 years after exposure, too soon, it is believed, to bear any particular relation to radiation exposure. *Leukemia* surveys including physical findings, studies of white cell counts and types, alkaline phosphatase staining, and basophil counts of 4000 white cells showed no evidence of leukemia or leukemic tendency. One child in the irradiated group had 3% basophils but no other positive findings. The *cardiovascular* and *arthritis* surveys, as well as the general results of the physical examinations, have not shown any apparent increased incidence of *degenerative diseases* in the exposed people. No radiation-induced *cataracts* have been observed in any of the exposed people.

Genetic effects have not been specifically studied because of the small number of people involved.

No apparent radiation-induced genetic changes have been detected on routine physical examination in the first-generation children of exposed parents. If the suggestive evidence of increased miscarriages and stillbirths in the exposed women is true, this may represent a genetic effect of exposure.

BETA IRRADIATION OF THE SKIN

It was impossible to get an accurate estimate of the radiation dose to the skin. Beta burns of the skin and epilation appeared about 2 weeks after exposure, largely on parts of the body not covered by clothing. About 90% of the people had these burns, and a smaller number developed spotty epilation of the scalp. Most of the lesions were superficial; they exhibited pigmentation and dry, scaly desquamation, and were associated with little pain. Rapid healing and repigmentation followed. Some lesions were deeper, showed wet desquamation, and were more painful. A few burns became secondarily infected and had to be treated with antibiotics. Repigmentation of the lesions gradually took place in most instances, and the skin appeared normal within a few weeks. However, in about 15% of the people, deeper lesions, particularly noted on the dorsum of the feet, continued to show lack of repigmentation with varying degrees of scarring and atrophy of the skin. By 6 years the only residual effects of beta radiation of the skin were seen in 10 cases which showed varying degrees of pigment aberrations, scarring, and atrophy at the site of the former burns. Numerous histopathological studies have been made,^{1,4,5} and the changes found have been consistent with radiation damage. At no time have changes been observed either grossly or microscopically indicative of malignant or premalignant change. Spotty epilation on the heads was short lived, regrowth of hair occurring about 3 months after exposure and complete regrowth of normal hair by six months. No further evidence of epilation has been seen.

An interesting observation was the appearance of a bluish-brown pigmentation of the semilunar areas of the fingernails and toenails in about 90% of the people, beginning about 3 weeks after exposure. By 6 months, this pigmentation had largely grown out with the nail and had disappeared in most cases. The cause of this phenomenon has not been explained.

INTERNAL IRRADIATION

Radiochemical analyses of numerous urine samples of the exposed population showed internal absorption of radioactive materials, probably brought about largely through eating and drinking contaminated food and water and to a lesser extent through inhalation. During the first few days when the body levels were at their highest, the maximum permissible concentrations were approached or slightly exceeded only in the case of strontium-89 and the isotopes of iodine. The concentrations were believed to be too low to result in any serious effects. Body levels fell rapidly, so that by 2 and 3 years post exposure, they were far below the accepted maximum permissible level; by 6 months activity in the urine was barely detectable.

In 1957 analyses of bone samples on one of the men who died showed 3.7 strontium-90 units/g calcium. Beginning in 1957, gamma spectroscopy by use of a low-level counting chamber was added to the techniques of radiochemical analysis. The return of the Rongelapese to their home island (which after careful survey was considered safe for habitation, despite a persisting low level of radioactive contamination) was reflected in a rise in their body burdens and increased urinary excretion of certain radionuclides. During the years since the original contaminating event, additional weapons tests held in the area have contributed to the fission products in the environment. Since the diet includes a variety of imported foods, the people are not living in a "closed" environment, and therefore may not be rapidly approaching equilibrium with the environmental fission products, as might be expected under other circumstances.

Body burdens of gamma-emitting fission products (such as Cs¹³⁷ and Zn⁶⁵) were measured in a whole-body counter and checked by radiochemical analysis of urine specimens. Body burdens of Sr⁹⁰ were estimated from urinary excretion as determined by radiochemical analyses. Both the external dose measurements on Rongelap Island and the levels of radioactive isotopes in the food on the island indicated that some increase in Cs¹³⁷, Zn⁶⁵, and Sr⁹⁰ body burdens was to be expected when the people returned there in 1957. The Cs¹³⁷ body burden in 1958 was about 0.68 μ C, about 60 times as great as in 1957, and the urinary Cs¹³⁷ level rose by a factor of 140; the mean body bur-

den for 1959 was 0.57 μ C. The mean body burden of Zn⁶⁵ estimated from whole-body counting data was, in 1958, after the return to Rongelap, 0.36 μ C, 8 times as high as in 1957, and 0.44 μ C in 1959. Thus, whereas the Cs¹³⁷ levels appear to have reached a maximum and actually to have dropped in 1959, the Zn⁶⁵ levels have shown a continued increase which is probably related to the long biological half-life of the latter. The Sr⁹⁰ level in 1958 estimated from excretion data was 2 μ C, about 20 times as high as in 1957 before the return to Rongelap. The estimated body burden in 1959 increased to 6.0 μ C, about 20% of the estimated ultimate equilibrium value. Little of the body burden of the exposed group is apparently due to their initial exposure, since at present there is little difference between the levels of the exposed and unexposed populations living on Rongelap Island. When these three isotopes have reached their estimated equilibrium values, the body burdens will still be of small significance in terms of radiation hazard.

OTHER STUDIES

Studies of genetically inherited characteristics. Blood grouping studies in the Marshallese showed a relatively high B gene frequency, a high N gene frequency, an extremely high R¹ gene frequency, and total absence of Kell and Diego factors. These characteristics differ from those of Polynesians and suggest relationship with Southeast Asians and Indonesians. *Haptoglobin studies* showed the frequency of the Hp¹ gene to be higher than in European populations thus far tested and consistent with populations living near the equator. The distribution of haptoglobin types showed the population to be relatively homogeneous. *Transferrins* in all sera were type CC, the common European type. *β -Amino-iso-butyric acid* urinary levels showed the Marshallese to be the highest excretors of this acid of any population thus far reported. Levels in the exposed group were about the same as in the unexposed group, and no correlation was found with body burden level of radionuclides; this indicates that there is probably no correlation with radiation exposure. *Hemoglobin types* were considered normal. *Sickling tests* showed no sickling tendency in any of the people. *Glucose-6-phosphate dehydrogenase* of the red cells appeared to be deficient in the Marshallese. Considerable cau-

tion must be exercised in evaluating the results of these studies on genetically inherited characteristics because of the small number of samples tested. The data do seem to indicate relative homogeneity of the population and closest kinship with people of Southeast Asia. These data also may be useful as a base line should genetic changes appear in later generations, possibly related to radiation exposure.

Results of other laboratory studies included the following: *Serum protein* levels were generally on the high side of normal; electrophoretic patterns showed the increase in proteins was largely due to an increase in the gamma globulin fraction. The reason for this is not apparent. Numerous chronic infections may be an explanation.

Sodium levels in the urine and food indicated about the same consumption of NaCl as in Americans. The generally lower incidence of hypertension in the Marshallese might be related to the fact that the former native diet was probably lower in salt content than the present, more westernized diet. It will be interesting to see whether the incidence of hypertension will later increase.

Serum cholesterol levels (1957, 1959) were somewhat lower in the exposed population than in the comparison or Utirik populations, but were in the low normal range. No abnormally low readings were noted.

Serum creatinine levels (1957) were in the normal range with no abnormal levels noted.

Serum vitamin B₁₂ concentrations (1958, 1959) were generally significantly higher than American levels. The possibility of contamination of the samples with bacteria producing vitamin B₁₂ must be considered, since myeloproliferative and liver diseases were not seen.

Serum protein bound iodine levels (1957, 1959) were generally slightly elevated. Evidence for thyroid dysfunction was not apparent in the people.

Glucosuria and elevated blood sugar were found in 4 unexposed individuals, which indicated a rather high incidence of diabetes.

A survey for *intestinal parasites* (1958) showed 75% of the people to be infected with various types. For the three major pathogens found, the overall infection rates were, for *Entamoeba histolytica*, 18.2%; for hookworm, 5.5%; and for *Trichuris trichiura*, 34.3%.

Eosinophilia >5% has consistently been noted in about half the people. The fact that half the

cases with eosinophilia showed no helminthic infections at all suggests that other factors besides parasitic infections must be responsible. The eosinophilia may be related to chronic fungus and other infections, particularly of the skin.

Complement fixation studies for parainfluenza 1, 2, and 3, respiratory syncitial, psittacosis, and Q fever showed antibodies to all groups of viruses except that for Asian influenza, which probably had not yet seriously involved the people of the Marshall Islands. The antibody titers appeared to be somewhat lower in the exposed people.

DIFFICULTIES ASSOCIATED WITH THE EXAMINATIONS

As mentioned in previous reports, several difficulties were associated with carrying out the examinations as well as interpreting the findings.

1. The language barrier made examinations difficult, since very little English is spoken by the Marshallese. However, there were sufficient English-speaking Marshallese to assist the medical team in most instances.

2. The lack of vital statistics or demographic data on the Marshallese imposed a serious difficulty in interpretation and evaluation of the medical data. Records of births, deaths, etc., have been made by the health aides or magistrates of the villages and supposedly forwarded to the district administrator; however, such records have been incomplete or lost in most instances, and vital statistics are therefore inadequate. Trust Territory officials are now attempting to assemble such data.

3. There is uncertainty on the part of some of the Marshallese as to their exact ages, particularly among the older group. This imposes certain difficulties in interpreting some of the studies to be outlined.

COMPARISON POPULATIONS

During the first 2 years, two separate groups of Marshallese people were used for comparison, each of comparable size to the exposed Rongelap group and matched for age and sex. However, this population was found to be unstable, with a large attrition rate over the 2 years, which made it unsatisfactory. At the time of the 3-year survey, it was found that during the preceding 12 months the Rongelap population at Majuro Atoll had

doubled because of the influx of relatives who had come back from other islands to live with them. These people had been away from Rongelap Atoll at the time of the accidental exposure. This group matched reasonably well for age and sex and was of comparable size. Since the return of the people to Rongelap, however, this group has about doubled in size.

Since the people are of the same stock genetically, they are uniquely appropriate to serve as a comparison population and have, therefore, been used since 1957.

1961 Survey – Organization and Procedures

The medical team consisted of six medical specialists, five from the United States and one from the Trust Territory; one dentist from the Trust Territory; one Marshallese practitioner; and ten technicians, five from the United States and five from the Trust Territory (Figure 2).

The medical equipment had been sent out to the Islands prior to the team's arrival, and preliminary preparations had been made for logistic support of the operation by the Navy Pacific Missile Range group and the Holmes and Narver contractors at Eniwetok.

Before the survey at Rongelap, the team visited Kwajalein and Majuro for several days to carry out examinations on a number of Rongelap people who had moved to these islands.

The Trust Territory provided a cargo ship, the M/V *Roque* (Figure 5), to transport the team and to serve as a base of operations. In mid-March the ship proceeded from Majuro to Eniwetok, where the medical equipment and the 21-ton steel room for whole-body gamma measurements (Figure 6), which was stored there, were loaded on the ship. The onloading of the latter was a difficult and exacting procedure, but was carried out remarkably smoothly by the Holmes and Narver personnel. The steel room and a wooden room to house the electronic equipment were placed in the cargo hold of the ship, and wooden stairs were installed for access into the hold.

On completion of loading the ship, refueling, and taking on fresh water, the team boarded the ship and proceeded to Rongelap. The one-day

trip was quite rough, since the ship was heading into the strong prevailing trade winds, but the steel room and equipment remained secure. The ship dropped anchor about 1000 yards off shore at Rongelap village.

On arrival, an outrigger canoe came alongside the ship with the Magistrate of the village, who came aboard. The objectives of our visit to Rongelap were discussed with him, and it was considered advisable to hold a village meeting so that the proposed examinations could be explained to the people and any questions they might have could be answered.

During the village meeting, held in the Council House, the medical examinations to be conducted and the reasons for them were explained. The people expressed continued concern about the effects of fallout on their health, but to no greater extent than at meetings during past surveys. As in the past, they claimed that fish poisoning was related to the fallout, and said that certain fish have a black spot in their abdomens, which they believe to be due to radioactivity and to cause sickness in those eating such fish. It was again explained to them that fish poisoning was in no way related to the fallout. A new complaint was that several families had developed inflammation and blistering of the mouth and upset stomachs from eating arrowroot flour which they felt was affected by fallout. It was explained that this type of effect has been noted in other islands when the flour is not properly prepared. They asked whether coconut crabs could be eaten yet and were told that these were still not safe but that continuous tests would be carried out and that they would be informed when the crabs had reached a low enough level of contamination. This is the only item in their diet which they are forbidden to eat. Another complaint was that the coconuts were small and that certain changes had been noted in the coconut and pandanus trees which they believed resulted from fallout.

Despite the above complaints the people were very friendly and cooperated with the examining team in all aspects of the examination that followed.

EXAMINATION FACILITIES

Whole-body gamma spectroscopy was carried out in the cargo hold of the ship. The air-condi-

Figure 7. Hematology laboratory, Rongelap Island.

tioned wooden room containing the hundred-channel analyzers and other electronic equipment was located close to the steel room. A shower facility was available on the upper deck. The people were brought to the ship in a motor launch and, after taking a soap and water shower and donning paper coveralls, they went down into the hold to the steel room. Taped music was piped in during the procedure. From past experience the people were accustomed to the procedure and showed no fear, with the possible exception of a few of the younger children. Further description of the gamma spectrographic methods will be presented later.

The other examinations were carried out ashore at Rongelap village. As in the past the dispensary was used as a laboratory for the hematological and other laboratory procedures (Figure 7). The adjacent school building was used for taking histories and performing physical examinations on the people. The council house next door was used for special examinations of the skin, aging studies, urine collections and analyses, and x-ray examinations.

HISTORY AND PHYSICAL EXAMINATIONS

Histories were taken by a Marshallese practitioner and an interpreter, with particular emphasis on the interval history during the past year. A special survey was again conducted by the pediatrician to attempt to ascertain more accurately the birth dates of the Rongelap people, particularly the children. Complete physical examinations were carried out including growth and development studies on the children (anthropometric measurements and x-ray examinations of the left wrist and hand for bone development studies); studies of aging criteria; special examinations of the skin with color photography of selected lesions; a special cancer detection survey; and a dental survey.

CANCER DETECTION SURVEY

In the cancer detection survey, procedures included an evaluation of the history, special physical examination, and certain laboratory tests. The family history did not yield satisfactory informa-

tion, since the incidence of familial diseases including cancer was generally unknown by the people. The history yielded some information on changes in weight, history of illness, and, in the case of women, menstrual, obstetric, and nursing history. In the physical examination particular emphasis was placed on examination of the skin, node-bearing areas, head and neck, chest, breast, abdomen, and external genitalia. Pelvic examinations were carried out on all mature females, and vaginal and cervical smears for Papanicolaou examination were obtained.* Rectal examinations were carried out on all persons >40 years of age. This included examination of the feces for blood (guaiac testing of the feces on finger cot) and, in the case of men, palpation of the prostate gland. Chest plates were not taken routinely but were obtained on about 30 adults >40 years of age (and on certain other cases were indicated).** Hematological data were obtained and were available for evaluation.

In detection of possible leukemia (or preclinical evidence of incipient leukemia) the lymph nodes and spleen were carefully examined, and hematological data were taken including routine hemograms, percent basophils in a 4000 white cell count, and alkaline phosphatase examinations of the white blood cells on differential smears.

GROWTH AND DEVELOPMENT STUDIES IN CHILDREN

In addition to the routine pediatric examinations, certain special anthropometric measurements on the children were recorded. Such data included age, weight, stature, sitting height, head circumference, biacromial width, biiliac width, and calf circumference. Roentgenographs of the left wrists were studied for skeletal maturation.

AGING STUDIES

A detailed report of the procedures used in the studies of aging criteria in the Rongelap people was published in the last report⁷ and will not be repeated here. The battery of tests that had been

*We wish to thank Dr. Genevieve Bader of Memorial Sloan-Kettering Cancer Center, N.Y.C., for interpretation of the Papanicolaou smears.

**We are grateful to Dr. Paul Lichtblau of Rockville Centre, L.I., N.Y., for interpretation of the chest roentgenograms.

used in previous surveys, except those for hearing loss and retinal arteriosclerosis, were used again during this survey, since interesting trends of age-dependent changes had been observed. During this survey, as in the past, aging criteria were recorded on adults aged 20 years and over. Of the 130 adults examined 45 were in the exposed group and 85 in the larger comparison population. From Table 2, which shows the age distribution, it can be seen that it would have been desirable to have had more people in the upper age bracket of the comparison group.

Of the 15 aging criteria studied, 8 were measured directly and 6 were estimated on a 0 to 4+ scale. Five tests involved the integument: (1) skin looseness, (2) skin elasticity (retraction time), (3) senile changes in the skin, (4) graying of the hair, and (5) baldness. Three tests involved the special sense organs: (1) accommodation, (2) visual acuity, and (3) arcus senilis. The cardiovascular system was tested by (1) systolic and (2) diastolic pressure readings, and (3) estimation of degree of peripheral arteriosclerosis. There was one test of neuromuscular function (hand tally count). Vigor was measured by hand strength measurements with a dynamometer.

Because of sex differences some of the above criteria were evaluated separately for the two sexes; those were baldness, neuromuscular function, and hand strength.

In order that the estimated and measured data could be compared and combined, both types of data were converted to a percentage scale. The estimated values 0, 1+, 2+, 3+, and 4+ were presented also as 0, 25, 50, 75, and 100% respectively. In the case of the measured data, the values associated with least aging were taken as 0% (sometimes the highest reading as with hand strength; sometimes the lowest, as with visual acuity), and those indicating most aging as 100%.

The data were examined on both an individual basis and a population basis. A mean age score was obtained for each individual by averaging all his percent test values. In studying population trends, means were calculated for each criterion by 5-year age groups (in most cases) including combined exposed and unexposed populations; these were plotted and a curve was drawn according to the best fit by eye. A curve was obtained in the same way of the 5-year group means of the individual mean age scores. The combining of

scores into 5-year age groups was done to reduce possible errors due to the uncertainty of the exact age of some individuals.

DENTAL SURVEY

Dental examinations were carried out on most of the people on the island, particularly those requiring dental attention.

LABORATORY PROCEDURES

Hematological Examinations

Complete routine blood counts were carried out with repeat counts on any persons showing abnormalities. White blood counts and red blood counts were obtained with the electronic Coulter, which again proved to be a very satisfactory instrument for examinations of this type in the field. Differential counts were performed in the usual manner after staining with Wright's fluid. Platelet counts were done by phase microscopy. Hemoglobin was determined by the cyan-hemoglobin technique with the Lumitron colorimeter, but only 49 determinations were possible because of breakdown of the Lumitron. Hematocrits were obtained by the microhematocrit method. Reticulocyte counts were carried out in 16 people who had low hemoglobin values. Serum proteins were determined with the Hitachi refractometer. Blood and serum samples for certain studies to be described below were collected and kept under refrigeration and finally shipped back for study.

Urine Analysis

Routine urine analyses were done on almost all people receiving physical examinations. These included determinations of protein and hyperglucosuria by reagent paper strips.*

Serum Examinations for Calcium, Phosphorus, and Protein Bound Iodine

These studies were carried out in six of the children in the exposed group of the growth and development study.**

*Combistix, Ames Company, Inc., Elkhart, Indiana.

**We are grateful to Drs. D.D. Van Slyke and L.V. Hankes of this Laboratory for carrying out these determinations.

Serum Iron

Serum iron determinations were performed in the 16 people who were found to have an anemic tendency to see whether deficiency of this element might be responsible.*

Serum Gamma Globulin Studies

In previous surveys extensive studies have been made on certain genetically inherited characteristics such as blood groupings, haptoglobin and transferrin, hemoglobin types, glucose-6-phosphate dehydrogenase activity of red cells, β -amino-isobutyric acid excretion, etc. One type of gamma globulin had not been previously studied in the Rongelap people, and 149 sera were collected during this survey for determination of the Gm type of gamma globulin. The determinations were carried out by Dr. A.G. Steinberg of Western Reserve University and his collaborators and reported along with the same observations on other populations;⁸ the methods used were also reported.

Radionuclide Body Burden Evaluation

The methods used in the radionuclide body burden evaluation are described later in a separate section.

Results and Discussion

The census of Rongelap people in March 1961 was 334, of which 81 were in the exposed group (including 4 children exposed *in utero* at the time of the accident); 33 were children of exposed parents, and 220 were unexposed people; Table 1 shows their location. In Table 2 the population is broken down according to percent distribution in various age groups and compared with that of the Marshall Islands as a whole for 1948-1950 and of the United States for 1960. The table also shows the median age. The lower median age of the Marshallese would tend to support the impression that their life span is shorter than that of people in the continental United States, but there has been a "population explosion" in those islands which might account for this discrepancy.

*We are grateful to Mrs. Ruth Saart of South Nassau Communities Hospital, Rockville Centre, L.I., N.Y., for carrying out the serum iron determinations.

Table 1
Location of Rongelap People

	Exposed			Unexposed		
	Adult	Children	Children of exposed parents	Adult	Children	Total

Table 2
Percent Distribution of Population by Age Groups

Age, yr	Rongelap unexposed (220 people, 1961)		Rongelap exposed (116 people, 1961; includes children of exposed adults)		Marshall Islands (1948-50) U.S. (1960)	
	<15	15-24	<15	15-24	<15	15-24
<15	45.4%	50.0%	33.8%	28.7%		
15-24	12.3	13.8	18.9	13.8		
25-44	23.6	17.2	25.9	27.1		
45-64	14.1	10.3	15.5	20.8		
>65	4.5	8.6	5.9	9.6		
Median age, yr	19.5	14.5	23.6	29.5		

Of the 334 Rongelap people, 267 were examined during the survey on Kwajalein, Majuro, and Rongelap. In the exposed group 47 adults, 25 children (age <20), 4 children exposed *in utero*, and 28 children of exposed parents were examined, and in the unexposed comparison population 77 adults and 86 children.

INTERVAL MEDICAL HISTORY

Mortality

No deaths occurred during 1960 in the exposed or comparison population except for two infant deaths. The four deaths that had occurred in the exposed group over the 7-year post-exposure period represent a rate of 7.1 per 1000 population, which is about the same as that reported for the Marshall Islands as a whole (6.8 per 1000). The unexposed population on Rongelap Island has

varied, but generally increased, since these people were first examined in 1957, but the death rate in this group appears to be about the same as in the exposed Rongelap group.

Births

Since the number of child-bearing females was not the same in the exposed and unexposed populations, the birth rate for 1960 was calculated on the basis of number of births per woman of child-bearing age, considered to be from 16 through 45 years. There were 20 such women in the exposed group and 29 in the unexposed group (not included in either group were 4 unexposed women whose spouses were exposed males). In the exposed group 7 babies were born, giving an average of 0.35 births per women, and in the unexposed group 11 babies, giving about the same average (0.38). The deliveries were reported to be full term and normal, except that one unexposed women (No. 867) developed severe post-partum hemorrhage and shock and was sent to the Memorial Hospital at Majuro, where her Fallopian tubes were tied.

Congenital Anomalies

One baby, born of unexposed parents, was anencephalic and died several days after birth. The first instance of congenital anomaly in a child of exposed parents was reported during the past year. This was a congenital heart defect in a baby born of an exposed mother (No. 75) but unexposed father. The baby died at four months of age. Unfortunately the diagnosis was not confirmed by autopsy. A low incidence of patent ductus arteriosus, congenital deformity of the hip, and congenital hypoplasia of the middle phalanx of the fifth

finger has been noted previously in children in the unexposed group, but not in children of exposed parents.

Miscarriages and Stillbirths

During the past year two questionable miscarriages occurred in the exposed women, and two miscarriages and one other questionable one occurred in the unexposed women. Thus, during the past two years the incidence of miscarriage appears to be no greater in the exposed than in the unexposed women, and the previously reported suggestive increase in incidence in the exposed women is no longer apparent. Unfortunately it was not possible to have a physician examine the products of miscarriage.

Illnesses

There were few major illnesses reported in the Rongelap population during the past year. Two unexposed people were hospitalized for surgical procedures: No. 867, as mentioned above, had her Fallopian tubes tied following severe post-partum hemorrhage, and No. 855 had a hemorrhoidectomy; recovery in both cases was uneventful. No epidemics of disease occurred in the population, and the dispensary record of the health aide showed the usual number of cases of upper respiratory infections including a notable number of cases of acute bronchitis. Gastroenteritis was frequent as noted in the past. A number of cases of otitis media and skin infections including the prevalent fungus and impetigenous lesions were treated, and also a small number of minor wounds and injuries.

In spite of the complaint at the village meeting of sickness from eating fish, the health aide reported no cases of fish poisoning during the past year. He did report that several members of a few families had developed a sickness 8 to 24 hours after eating arrowroot flour (as mentioned at the village meeting). The affected people developed inflammation and burning of the mucous membranes of the mouth which persisted for about a week. Several also had diarrhea of one-day duration shortly after eating the flour. These illness occurred at two separate times, in June and September 1960. Since most families were not sick from eating the arrowroot flour, it was concluded that in the families in which sickness developed the flour had not been properly prepared. It is known

that improper preparation may result in the type of sickness described.

During the interview the health aide admitted that some of the people had at times eaten coconut crabs in spite of the fact that they had been requested not to. Since the individuals involved were not named, it was not possible to attempt to correlate Sr⁹⁰ urinary levels with crab ingestion.

ADULT EXAMINATIONS

Table 3 shows the various abnormalities noted in the exposed and unexposed adult population examined. In Appendix 6 the various clinical findings are enumerated for each individual.

Certain abnormalities such as moderate to severe arteriosclerosis and cataracts showed a higher percentage incidence in the exposed group; however, the increases in both cases were likely related to the larger percentage of older people in the exposed group. In the exposed group 20% of the adults were >65 years of age compared with 7% of the unexposed adults. Taking this into consideration, it does not appear that the abnormalities in the two groups are very different, and no evidence of any increased incidence of degenerative diseases or other diseases is apparent in the exposed group. Several of the older people in the exposed group (No. 57, F, age 107; No. 46, M, age 86; No. 55, M, age 82; No. 56, F, age 78; and No. 28, F, age 75) showed marked infirmities of old age with such findings as arteriosclerotic heart disease, kyphoscoliosis, osteoarthritis, and cataracts with blindness and had to be assisted to the examination room. Only two unexposed people were in this age bracket (No. 862, M, age 88 and No. 946, M, age 85). They showed similar infirmities, but could walk alone.

Cancer Detection Survey

Examinations as thorough as possible under field conditions were carried out for the detection of malignancy. All tumors including presumably benign tumors were recorded. No malignant lesions were detected in either the exposed or unexposed groups.

Pelvic examinations were carried out on the sexually mature females (except when pregnant). Cervical erosions, lacerations, and prolapse were noted with great frequency. Papanicolaou's staining was done on vaginal and cervical smears.

Table 3
Physical Findings in Rongelap Adults, 1961

	Exposed (47 examined)		Control (77 examined)	
	Subject Nos.	%	Subject Nos.	%

Varicose veins	13	2.2		
Vitiligo			853	2.2

None was positive for malignant cells. It was noted that the secretions were scanty in most of the women, and the smears were consequently somewhat dry. Inflammatory reaction with the presence of blood in the smears was common. Endocervical atypia was noted in a number of cases. The results of these examinations are reported in Appendix 6.

Rectal examinations were carried out on all adults, and proctoscopic examinations when indicated. Several cases of prostatic enlargement were noted, but no evidence of malignancy was apparent. An ulcerating lesion was noted in a 66-year-old female in the exposed group (No. 30) in the upper rectum. Scrapings from this area indicated that it was an inflammatory lesion and not malignant.

PEDIATRIC EXAMINATIONS

During the 1961 survey, 155 children were examined (Table 4). All exposed subjects in the pediatric age group (<20 years) were seen except for two (No. 67 and No. 76) who had moved to other atolls. The increase in number of nonexposed children of exposed parents represents new babies born since the previous survey. New babies also increased the total of nonexposed Rongelap controls, even though a number of children either became old enough to be transferred to the adult study or were lost to the study because of migration. The exposed and nonexposed group at Majuro were all 6 years of age or older. All nonexposed children of exposed parents were <6 years old. Of the 88 nonexposed Rongelap children, 38 were <6 years of age.

The incidence of various physical findings is summarized in Table 5. Adenopathy was defined for the purposes of this tabulation as the presence of (a) nodes 0.5 cm or larger in all areas (cervical, axillary, and inguinal), or (b) nodes 1.0 cm or larger in the axillary regions, or (c) nodes 2.0 cm or larger in either the cervical or inguinal areas. The term "active chronic impetigo" includes several types of superficial skin infections. Many of these lesions probably represented secondary infections of lacerations and abrasions. The incidences of otitis media and adenopathy were related to age, both being more common in younger children. Clinically active chronic impetigo was also found more often in the younger children;

Table 4

Children Examined

	at Rongelap	at Majuro	at Kwajalein	Total
Exposed	22	2	2	26
Exposed <i>in utero</i>	2	0	2	4
Nonexposed (exposed parents)	19	2	3	24
Control				
Rongelap series	67	8	13	88
Majuro series	0	13	0	13
Total	110	25	20	155

however, its incidence was higher in the exposed children (although the group was older) than in nonexposed Rongelap children of comparable ages. Its incidence was also higher among the nonexposed Majuro children, who were all in the older group. As in 1959, the pattern of physical findings seemed unrelated to exposure to radiation.

Growth and Development

During the past several surveys considerable effort has been expended to establish as firmly as possible the accuracy of the date of birth for each child. The medical survey records provided reliable written data for children born after March 1954 and for some born immediately before the fallout. For the other children, however, the task of determining birth dates proved to be difficult, frustrating, and unsatisfactory. The reconstruction of the birth chronology was based on an intensive study and evaluation of very frequently contradictory information derived from the following sources:

1. Dates of birth as reported by parents.
2. Dates of birth as recorded occasionally in the village ledgers used for various purposes.
3. Limited number of birth certificates on file at the court house on Majuro.
4. Birth order of children within each family unit.
5. Ranking of childhood population in terms of age by parents.
6. Ranking of childhood population in terms of age by children.
7. Correlation with memorable environmental events.

Table 5
Summary of Physical Findings in Children

	Exposed (26)*	Exposed <i>in utero</i> (4)	Nonexposed of exposed parents (24)	Nonexposed Rongelap		Nonexposed Majuro (12)
				<6 years (38)	>6 years (50)

Rash	0	0	0	2	0	0

*Number examined.

For the Rongelap population a table of most probable birth dates was eventually worked out. Although a few inconsistencies and uncertainties still persisted, these dates of birth were considered to be best estimates and were used in calculating the ages of the children for the analyses. Biologic compatibility of the birth dates within each family group was carefully checked, and physiologic compatibility of status and age for each child was examined.

With the establishment of a presumptive date of birth for each child, analysis of the growth and development data was undertaken. Anthropometric data obtained during 1958, 1959, 1960, and 1961 were used in the initial analysis.* Growth data from examinations prior to 1958 had been collected by several different observers, and this earlier material will be tabulated and analyzed in a subsequent study. Although a number of physical and physiological parameters were measured, the present analysis was limited to stature, weight, and skeletal age. In the very young age groups head circumference data were also evaluated.

The study population was divided into 5 groups: (1) children born before the fallout and living on Rongelap at the time of fallout (exposed group), (2) children born before the fallout but not living on Rongelap at the time of fallout (control group),

(3) children born to mothers who were pregnant when exposed to fallout (exposed *in utero* group), (4) children born subsequent to 1 January 1955 to parents one or both of whom were exposed to fallout (exposed parents group), (5) children born subsequent to 1 January 1955 to parents neither of whom were exposed to fallout (control group for exposed parents group).

Because some of the distributions encountered in these data did not grossly approximate normality or even symmetry of distribution, and because many of the groups were too small to justify making any assumptions about the parameters of the populations from which the samples were drawn (and in many instances too small to permit calculations of any meaningful measure of variability), all analysis of data was done by nonparametric statistical methods.* All measures of central tendency mentioned were medians, and all graphic presentations comparing groups were plotted in terms of medians of the groups. Any descriptive differences between groups mentioned were differences between medians. All tests for significance of differences between groups, unless otherwise specified, utilized the Kruskal-Wallis one-way analysis of variance.⁹

Because the comparisons of skeletal ages and chronological ages involved related distributions, the Walsh test¹⁰ and the Wilcoxon matched-pairs

*The present pediatrician (W.W.S.) actively participated in each of these surveys except the one in 1960.

*We are grateful to Dr. Kenneth Griffith of the M.D. Anderson Hospital, Houston, Texas, for carrying out the statistical analysis.

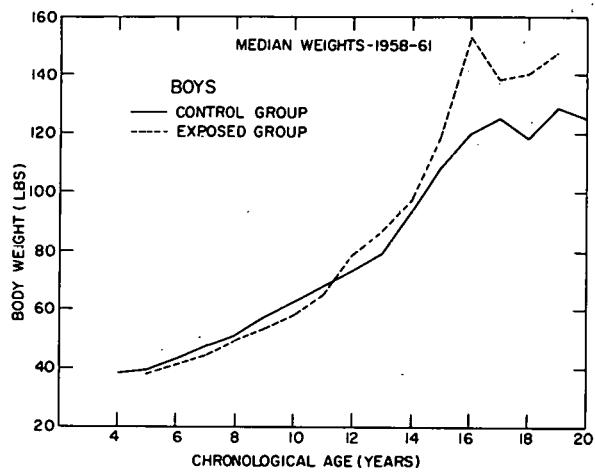

Figure 8.

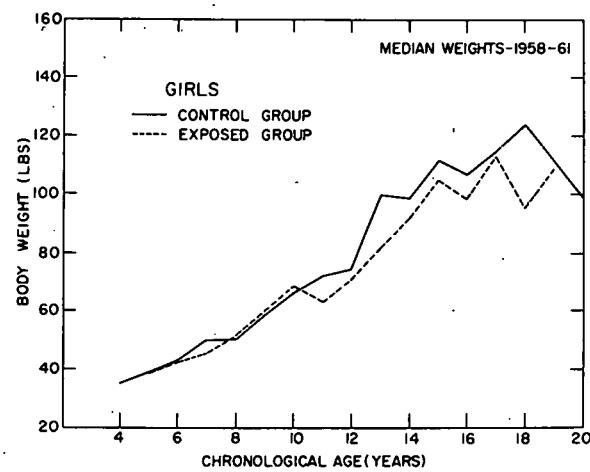

Figure 9.

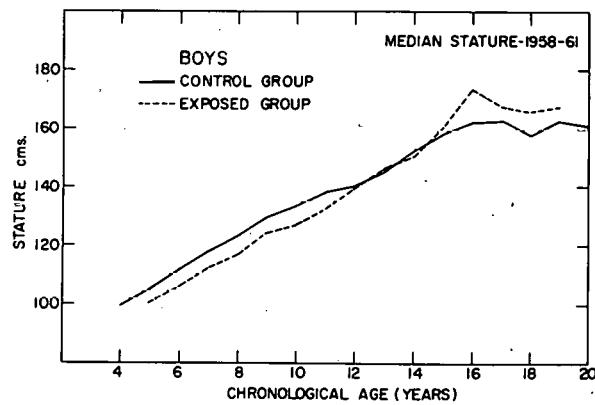

Figure 10.

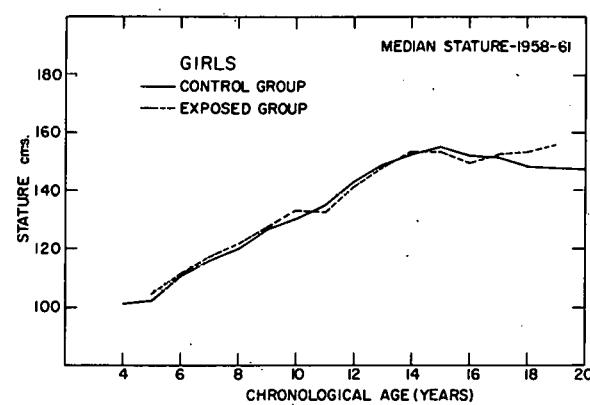

Figure 11.

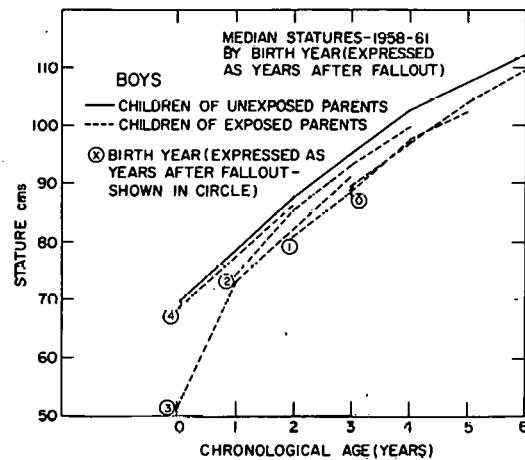

Figure 13.

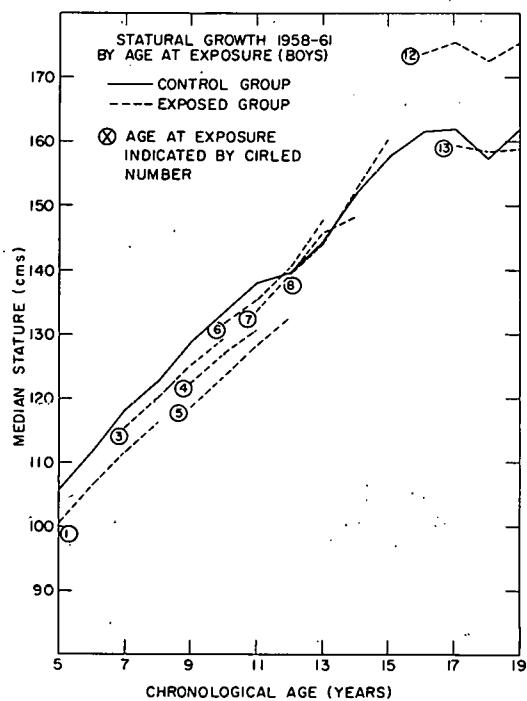

Figure 14.

signed-ranks test¹¹ were utilized in testing differences in these data. The more powerful Walsh test was used for the comparisons on children exposed at between 12 and 18 months of age because of the very small samples involved. The Wilcoxon test was used for the comparisons on the other children because the larger samples were beyond the functional range of the Walsh test. The Spearman rank correlation coefficient was utilized as the nonparametric measure of correlation.

Comparisons were made (a) between the two sexes for each age separately, (b) between exposed and control groups for each sex and age separately, (c) between exposed and control groups for each age separately with the sexes combined, and (d) between exposed and control groups for each sex, age, and year of birth (or age at exposure) separately. These comparisons have been summarized graphically (Figures 8 to 15), and the results of the comparisons are shown in Tables 6 and 7.

Height and weight data on children born before the fallout showed the expected pattern of pubertal growth spurt occurring earlier in girls than in boys and the eventual superiority in size of boys

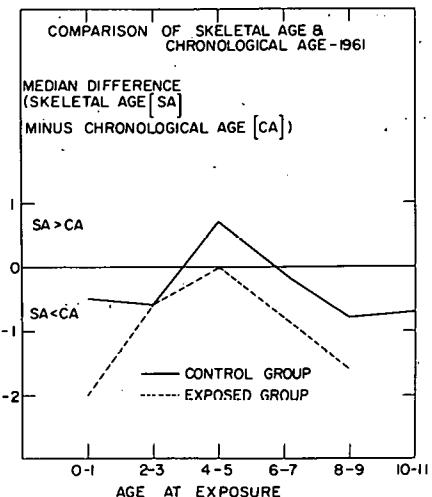

Figure 15.

at maturity. In addition, with respect to stature, there was a distinct tendency, among the boys only, at <12 years of age, for the exposed group to be shorter than the unexposed. This difference was prominent in boys exposed at <6 years and most marked among those exposed at age 1 year, the latter being those aged 12 to 18 months at the time of the fallout. A similar trend, but much less distinct, was also noted in body weight among the boys. No such patterns in growth curve variations between exposed and control groups were noted among the girls.

Among the children born after the fallout, the males with exposed parents were smaller in stature at all ages than those with unexposed parents. The difference was most marked at ages 1, 3, and 4 years. The difference in stature was greatest in boys born <2 years after the fallout. The magnitude of the difference decreased with increasing age. No difference between children with and without history of parental exposure was noted for head circumferences and body weight.

Although the growth data for children exposed *in utero* were examined separately, the small number of individuals in this category prevented adequate statistical analysis. Hereafter the children exposed *in utero* will be included in the group directly exposed to fallout.

Roentgenograms of the left hand and wrist were obtained in 1959 and 1961. In the limited 1960 survey, no x-ray studies were done. The available roentgenograms were assessed by using the inspec-

Table 6

Comparisons of Body Weight and Stature Between Exposed Children and Their Controls
(M = Male; F = Female; E = Exposed; C = Unexposed)

Comparisons	Body weight	Stature
M vs. F (each age separately) E & C combined	F spurt at puberty earlier than M, but M>F after puberty. F>M at age 13. M>F at age 7.	F spurt at puberty earlier than M, but M>F after puberty. F>M at age 13. M>F at age 15, 16, 17, and 19.
E vs. C M only (each age separately)	No significant difference.	Tendency toward E<C before age 12 by 4.4 to 8.5 cm. E<C significant at age 7 and 8.
E vs. C F only (each age separately)	No significant difference.	No significant difference.
E vs. C M & F combined (each age separately)	No significant difference.	No significant difference.
E vs. C* M only (each age separately, each age at exposure separately)	No apparent difference.	Tendency toward E<C in children exposed before age 6, most apparent in those exposed at age 1, who were 4.9 to 6.3 cm shorter with the difference increasing with increasing age, and E<C significant at age 7 and 8.
E vs. C* F only (each age separately, each age at exposure separately)	No apparent difference.	No apparent difference.

Because of small numbers in each group, the groups were compared graphically, except where the graphs suggested certain combinations which could be compared statistically.

Table 7

Comparison of Body Weight, Stature, and Head Circumference Between Children Born
to Exposed Parents and Those Born to Unexposed Parents
(M = Male; F = Female; E = Children of exposed parents; C = Children of unexposed parents)

Comparison	Head circumference	Body weight	Stature
M vs. F (each age separately) E & C combined	M>F at age 3. Tendency toward M>F at older ages but not significant.	No significant difference.	No significant difference.
E vs. C M only (each age separately)	No significant difference.	No significant difference.	Tendency toward E<C at all ages by 1.8 to 9.9 cm. Significant at ages 1, 3, and 4.
E vs. C F only (each age separately)	No significant difference.	No significant difference.	No significant difference.
E vs. C M & F combined (each age separately)	No significant difference.	No significant difference.	No significant difference.
E vs. C* M only (each age and each year of birth separately)	No apparent difference.	No apparent difference.	E<C difference greatest in children born 2 years after fallout. In these children, difference is significant at ages 3 and 4. E<C difference diminishes with increasing age.
E vs. C* F only (each age and each year of birth separately)	No apparent difference.	No apparent difference.	No significant difference.

*For these comparisons, most of the groups being compared were so small that it would have been impossible to demonstrate statistically significant differences. These groups were therefore compared graphically, except where the graphs suggested certain combinations which could be compared statistically.

Table 8

Comparison of Stature (1958 Through 1961) of Children With Retarded Osseous Development
With That of Their Next Younger Sibs

	Sex	Born	Stature, cm			
			1958	1959	1960	1961
Subject (#5)	M	10/20/52	95.7	98.8	102.2	104.8

tional method and the standards published by Greulich and Pyle.¹² As shown in Figure 15, the following general trends were noted: (1) Both the exposed and control Marshallese children tended to be less mature skeletally at comparable chronological ages than the norms published by Greulich and Pyle. (2) Boys tended to be consistently less mature skeletally than girls at comparable chronological ages. (3) Exposed children, both boys and

Table 10

Laboratory Data (1961) on Children Exposed to Fallout at Ages 12 to 18 Months

Subject No.	Serum calcium, mg %	Serum phosphorus, mg %	Protein bound iodine, $\gamma/100$ ml
2	9.40	4.61	8.0
3	9.24	4.06	8.8
6	8.36	3.25	10.7
65	8.56	4.34	7.1
83	8.84	4.26	8.1
86	9.80	4.12	12.0

girls, tended to be less mature than control children. (4) When the children were grouped according to age at exposure, the exposed compared to the control group of both boys and girls tended to be less mature. Although these trends suggested that the exposed children may be inferior in skeletal maturation to unexposed children, the differences did not reach the level of statistical significance. The retardation in skeletal development was most prominent in the group of children exposed to fallout at ages 12 to 18 months. As expected, there was a high correlation between retardation in skeletal age and inferiority in statural growth.

Of special interest was the group of children now 8 years old who were exposed to fallout at ages 12 to 18 months. The statural measurements for these 5 children from 1958 through 1961 com-

pared to those of their sibs are shown in Table 8. Median height for controls at the chronological age of 8 years was 122.5 cm for males and 120.0 for females. The skeletal ages for these same children as compared to those of chronological age peers are shown in Table 9. Subjects #3 and #5 continued to show marked retardation in physical and skeletal growth. Subject #65 has shown a spurt in statural growth but continued to lack somewhat in skeletal maturation. Calcium, phosphorus, and protein bound iodine determinations on these children are given in Table 10. Clinically no indication of any disorder involving mineral metabolism or thyroid function was apparent.

LEUKEMIA SURVEY

On physical examination no evidence of lymphadenopathy, spleenomegaly, or other signs of leukemia were detected. Hematological examinations showed no excessive leukocytosis or increased numbers of immature leukocytes in smears. Basophil counts on 4000 leukocytes on each individual showed no elevation of the basophil counts. Alkaline phosphatase studies* on the blood smears showed that, although some people had low levels, this finding was not associated with any other findings suggestive of leukemia.

STUDIES OF AGING CRITERIA

The results of aging criteria studies are plotted in Figures 16 to 32. Individual readings are plotted (circles), and also mean values for each 5-year group combining exposed and unexposed people (squares). The trend of each criterion with increasing age is represented by a line of approximate best fit by eye except in the case of handgrip data for males and females (Figures 30 and 31), which were found to fit the following formulas:**

$$Y = 60 - 0.405A \quad (\text{males});$$

$$Y = 42 - 0.405A \quad (\text{females})$$

where Y = handgrip in kilograms and A = age.

The values of the criteria either increase or decrease generally with increasing age. Since the re-

sults are similar to those in last year's report,⁷ which were given in considerable detail, a lengthy discussion of the various changes will not be included here. Again, little or no difference was apparent between the exposed and comparison groups of the same age, and therefore no discernible effect of radiation on the aging process was noted. Further statistical analysis is needed for more adequate evaluation of the various parameters and better estimates of biological age scores for individuals. It is planned to repeat studies of aging criteria every 2 to 3 years.

RESIDUAL BETA BURNS

Residual skin changes from beta burns sustained in 1954 were observed with certainty in about 10 individuals. Most of these residua consisted of mild changes such as varying degrees of pigment alteration giving a mottled or blotchy appearance, sometimes accompanied by hyperkeratosis (increased rugosity) of the skin. Some showed more pronounced changes than others, such as atrophy and scarring. None of the residual lesions showed any gross tendency to changes associated with the development of chronic radiation dermatitis, nor was there any evidence of malignant change in any of the lesions. As noted last year, in a few cases previously affected areas showed some dark pigmented maculae (lentigo-like). A few appeared as raised moles. It is uncertain whether these lesions are of casual development or related to previous exposure. This type of pigmentation was observed less extensively in the unexposed comparison population. In 10 cases comparison of pictures of these areas taken soon after the appearance of lesions in 1954 and then more recently showed that the maculae had developed subsequent to the lesions. (See Figure 33.) Biopsies were not taken this year but may be considered at a later date for study of the histological appearance of the lesions. In Table 11 are listed descriptions of the residual lesions.

DENTAL SURVEY

A total of 59 school children were examined and treated for caries prevention. Of these, 29 required treatment such as fillings, extractions, and prophylaxis. In the total group 17 showed some evidence of enamel hypoplasia and indication of possible carious lesions in the near future.

*We are indebted to Dr. W.C. Moloney and Miss Lila Fliegelman of Boston City Hospital for carrying out the alkaline phosphatase analysis of blood smears.

**We are grateful to Dr. R. Hinchcliffe of the State University of Iowa for making this observation.

(Subject #78).

A few adults were also examined and treated. As noted in the past, people of age >40 show a considerable amount of periodontal disease. A few cases of arrested enamel development involving the occlusal surface of molar teeth were noted, probably due to faulty nutrition during the formative period of the teeth.

No significant differences were found between the Rongelap children and children of the same age group on outlying islands in caries rate, eruption time, or morphology of the teeth. It was estimated that only about 10% of the Rongelap adults practiced good oral hygiene.

Laboratory Examinations

HEMATOLOGICAL

Summary tables of the hematological data are presented in tables and graphs in the text, and the

Table 11

Residual Beta Burns

Subject No.	Sex	Age	Description
17	F	10	Slight scarring and pigmentation on left antecubital fossa.
24	F	20	Mottled spots of pigmentation and depigmentation on dorsum of feet.
26	M	19	Marked pink-colored depigmented scars on dorsum of right foot, particularly between 1st and 2nd toes. Skin tight in scarred areas - bound to subcutaneous tissues.
39	F	21	Considerable pigment variation and hyperkeratosis on back of neck. Pigmented macular areas on left antecubital fossa and dorsum of feet.
49	F	22	Pigmented maculae (freckle-like) on necklace area of neck, particularly on right side. Increasing in number?
59	F	41	Mottled hyperkeratosis and pigment variation on back of neck.
63	F	43	Considerable pigment variation on back of neck and to a slight degree on right forearm.
67	F	21	Not seen this survey. Previously showed atrophy and scarring on dorsum of feet.
78	F	43	Pigment variation and hyperkeratosis on back of neck. Raised pigmented mole-like lesions on sides of neck, particularly on left side. Appear to be increasing in number (see Figure 33).
79	M	46	White nodular scar and generalized scarring and pigment variation on back of left ear. Area of spotty alopecia on lower occipital region of head.

raw data on all individuals are presented in the appendices. The more heavily exposed Rongelap group, who received 175 r, are designated as "Rongelap exposed," the Rongelap people who received a smaller exposure of 69 r as "Ailinglapex exposed," and the larger unexposed comparison population of Rongelap as "unexposed." Because of the small number of people in the Ailinglapex group (15 examined of 18), their data were not treated as fully as those for the larger groups, and are briefly summarized below in a separate para-

Table 12

Mean Levels of Peripheral Blood Elements
of Exposed Groups Compared to Those of Unexposed Groups

graph. The data are handled somewhat differently this year: because of certain differences noted in age and sex groups between the exposed and the unexposed, in addition to the comparisons of mean levels for entire groups, comparisons are also made for the age and sex groups of age 7 to 15, 16 to 40, and >40 years.

The data are summarized in Tables 12 and 13 and in Figures 34 to 50. In Appendices 1 and 2 are presented summaries of the mean blood counts of the exposed population and the various comparison populations since exposure in March 1954. In Appendix 3 are listed the individual blood counts for 1961. It should be noted that in 1960 only the exposed group were examined; therefore, the last complete data on both exposed and unexposed groups are for 1959. In Appendix 4 the individual alkaline phosphatase and basophil counts are presented.

Leukocytes

The mean leukocyte levels in 1961 were somewhat below the 1959 levels in the population at large, while both exposed groups (the only groups examined in 1960) showed a slight increase over the 1960 level. Changing neutrophil and lymphocyte mean levels were generally parallel. As will be brought out, a slight deficit in both neutrophils and lymphocytes in certain age groups of the more heavily exposed Rongelap people largely accounted for the lower leukocyte levels. The Ailingnæ group (69 r) showed about the same levels of the various leukocytes as the unexposed group. The mean level of leukocytes in the exposed Rongelap people (175 r) was about 6% below that in the unexposed group. The percentage distribution of the various white cell levels in all groups was not very different from that previously reported. Table 12 and Figure 34 show leukocyte levels.

Neutrophils

The mean neutrophil count for the exposed population was slightly (7.3%) below the mean count of the unexposed comparison population. (See Table 12 and Figure 34.) However, examination of the mean counts by age and sex groups made it apparent that the deficit was largely accounted for in the young (age 7 to 15) and older males (age >40 years). This is demonstrated in the histogram (Figure 35) showing the percentage differences in the exposed and unexposed groups

classified according to age and sex, and in the scattergram (Figure 36) showing the larger number of individual counts below rather than above the mean line of the unexposed. A cumulative percentage distribution curve of counts combining the younger and older males (Figure 38) shows the curve for exposed males definitely displaced to the left of the curve for unexposed males of the same age groups. Among the females, only in the older group were the neutrophils slightly depressed (see Figures 35 and 37). In groups aged 15 to 40 years, both sexes showed slightly higher neutrophil levels than unexposed people of the same age.

Lymphocytes

As with neutrophils, the exposed population at large showed a slight (6.3%) deficit of lymphocytes compared with the unexposed population (see Table 12 and Figure 39). Among the males, only the younger age group showed slightly lower levels, while the three female groups all showed lower levels. This may be seen in the histogram (Figure 35), the scattergrams (Figures 40 and 41), and the cumulative percentage distribution curve (Figure 42).

Eosinophils, Monocytes, and Basophils

These all showed slightly lower levels than in 1959. The levels of monocytes and eosinophils in the exposed group were somewhat lower than in the unexposed group. As has been noted previously, eosinophil counts $>5\%$ of the total white count were common in both groups.

Platelets

The mean levels of platelets in the various age groups in both exposed and unexposed populations were about the same as two years previously (see Table 12 and Figure 43). However, the level in the exposed group as a whole, as in the past, remained below the unexposed level by about 12%. Age distribution scattergrams for the individual platelet counts in both males and females of the exposed population showed more counts below than above the unexposed mean curves (see Figures 44 and 45). This was also borne out by comparison of the cumulative distribution curves of the exposed and unexposed populations, the former showing a continued displacement to the left (Figure 46). The platelet levels showed most depression in the exposed male groups of ages 7 to 15

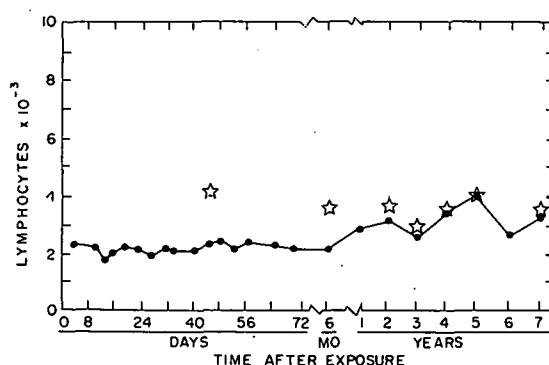

Figure 39. Mean lymphocyte counts of exposed Rongelap people from time of exposure through 7 years post exposure. Stars represent mean values of comparison population.

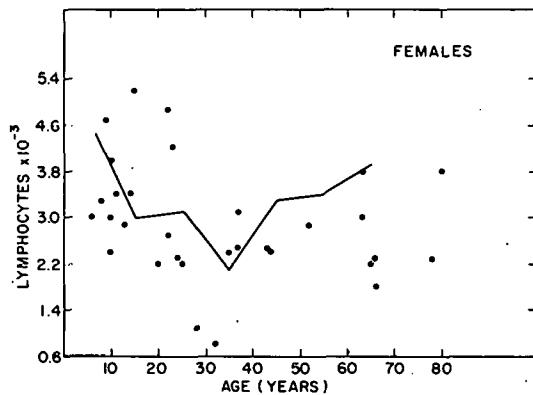

Figure 41. Lymphocyte counts of exposed Rongelap females plotted against age. Solid line represents mean level of unexposed female population.

and >40 years (see Figures 35 and 38). The continued depression is also indicated by the finding of levels of $<250,000$ in 44% of the exposed group (including Ailingnae) but in only 25% of the unexposed group.

Erythrocytes

The mean levels of hematocrit, red blood count, and hemoglobin by sex and age group (Table 12) showed generally lower levels in the exposed males of age >15 and females of age >40 years. These differences were not marked as in the case of some of the other peripheral blood elements. The scattergrams (Figures 47 and 48), cumulative percentage distribution curves (Figures 49 and 50) and histogram (Figure 35) demonstrate this.

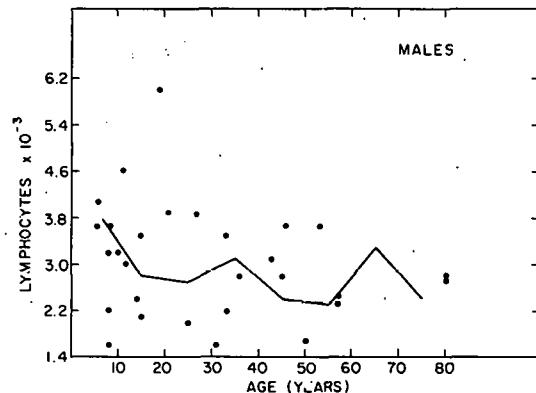

Figure 40. Lymphocyte counts of exposed Rongelap males plotted against age. Solid line represents mean level of unexposed male population.

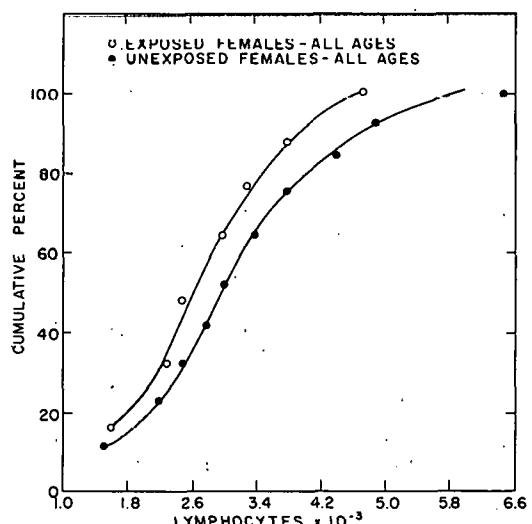

Figure 42. Lymphocyte cumulative percent distribution curves for exposed compared with unexposed population.

Morphology

No very unusual morphological changes in blood cells were noted. A few bilobed lymphocytes were seen in differential smears of both exposed and unexposed people, but no counts were made. Price-Jones curves in the past have shown a slight microcytic tendency of the red cells.

Ailingnae Blood Counts

Of the 17 Ailingnae people, 15 were available for examination. The levels of peripheral blood elements in this group were generally very nearly the same as in the unexposed population, except that the platelets were still somewhat below the unexposed mean levels for most of the age and sex groups (see Table 12 and Appendix 3).

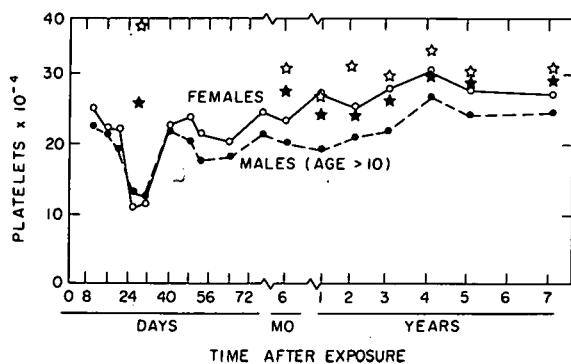

Figure 43. Mean platelet values of exposed Rongelap people from time of exposure through 7 years post-exposure. Stars represent mean values of unexposed comparison population.

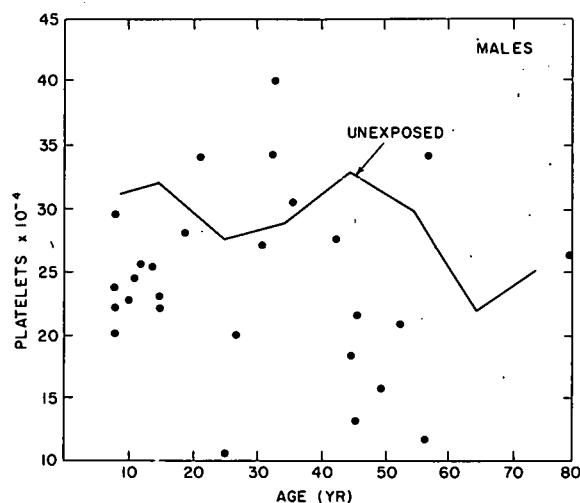

Figure 44. Platelet counts of exposed Rongelap males plotted against age. Solid line represents mean level of unexposed male population.

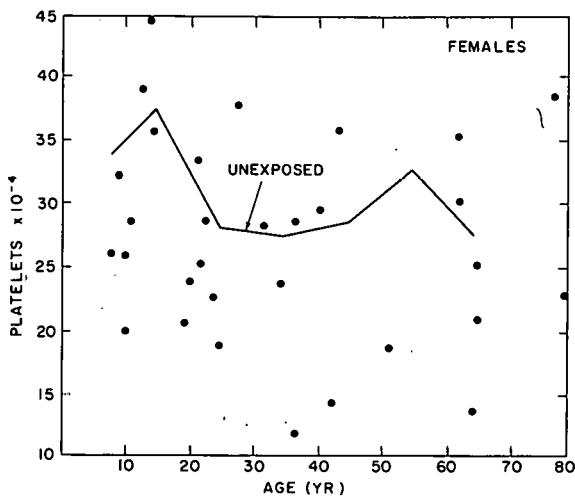

Figure 45. Platelet counts of exposed Rongelap females plotted against age. Solid line represents mean level of unexposed female population.

Children of Exposed Parents

Peripheral blood elements of children with parents of whom one or both had been exposed were compared with those of children with unexposed parents. These children were < 7 years old. The results are presented in Table 13 and Figure 51. The male children of exposed parents showed lower levels of leukocytes and platelets, but not the female children.

Hematological Leukemia Survey

No evidence of leukemia was detected in any of the population studied based on leukocyte counts,

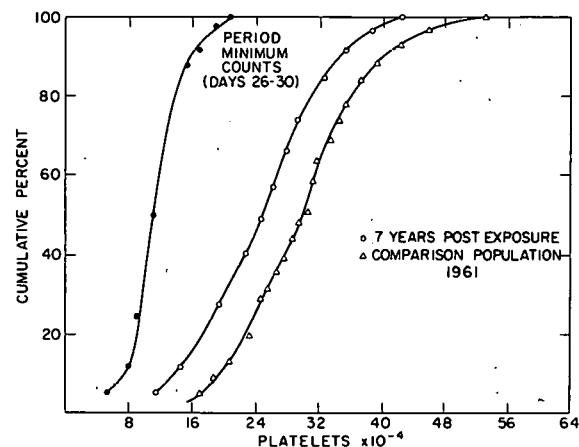

Figure 46. Platelet cumulative percent distribution curves for exposed compared with unexposed population.

differential counts, alkaline phosphatase staining of leukocytes, and counts of basophils in 4000 white cells. No marked leukocytosis or immature forms of white cells were observed. Relatively low scoring for alkaline phosphatase was recorded in some people, but in no case was it associated with other findings suggestive of leukemia. Basophil counts were elevated slightly (to 2.48%) in a 7-year-old exposed male (No. 3) who had showed a similar elevation in past surveys but no other sign suggestive of leukemia. The individual values for

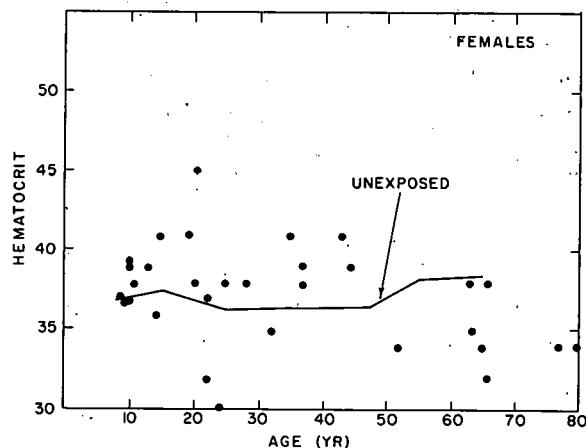

Figure 48. Hematocrit values of exposed females plotted against age. Solid line represents mean level of unexposed female population.

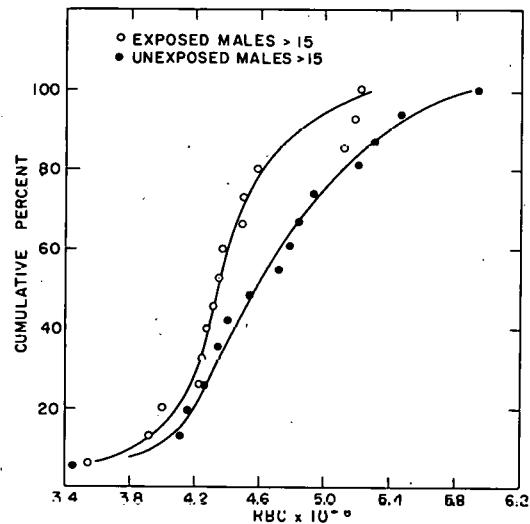

Figure 49. Red blood count cumulative percent distribution of exposed males >15 years of age compared with unexposed males of the same age group.

the basophil and alkaline phosphatase counts are presented in Appendix 4.

Comments on Hematological Data

The 1961 leukocyte and red blood counts remained slightly below the 1959 levels in the population at large, while the platelets were at about the same level. Such fluctuations have been noted before and have not been explained. The exposed group continued to show slight depression of cer-

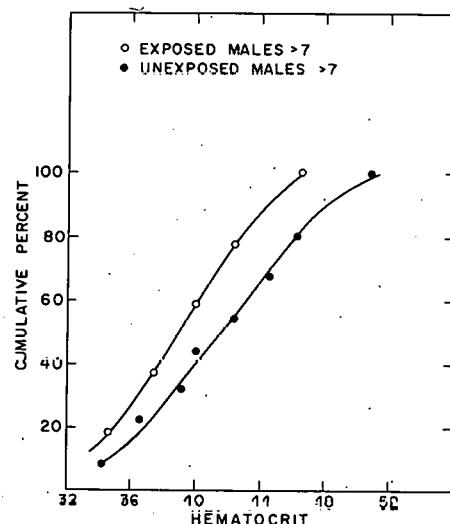

Figure 50. Cumulative percent distribution curves for hematocrit values in exposed males compared with unexposed males.

tain blood elements compared with the unexposed group. Though the mean levels were only slightly below those of the controls, more pronounced differences were brought out by comparison of sex and age groups. Thus, it appeared that the exposed male children (age 7 to 15 years) and the exposed older people of both sexes (age >40) showed lower levels, particularly of neutrophils and platelets, than did the other age-sex groups (see Figure 35). It is interesting that these blood

elements in the male children of exposed parents (age <7 years) also are lower than levels in male children of unexposed parents (Table 13), and that these same children appeared to show suggestive evidence of retardation of growth and development (see section on Growth and Development).

The slight anemic tendency in the Rongelap people, noted in the past, was still evident, though the explanation was not clear. Serum iron levels were generally not depressed. It is possible that another type of nutritional deficiency exists. However, their serum protein (particularly gamma globulin) and serum vitamin B₁₂ levels tended to be high. The high incidence of eosinophilia may be related to chronic fungus infection of the skin, intestinal parasites, or other causes.

OTHER LABORATORY STUDIES

Serum Iron

Serum iron levels were determined in 16 people (11 exposed and 5 control unexposed) who had an anemic tendency. The results are presented in Table 14 along with the hematocrit. With 83 μ g considered as the lower limit of normal, only Nos.

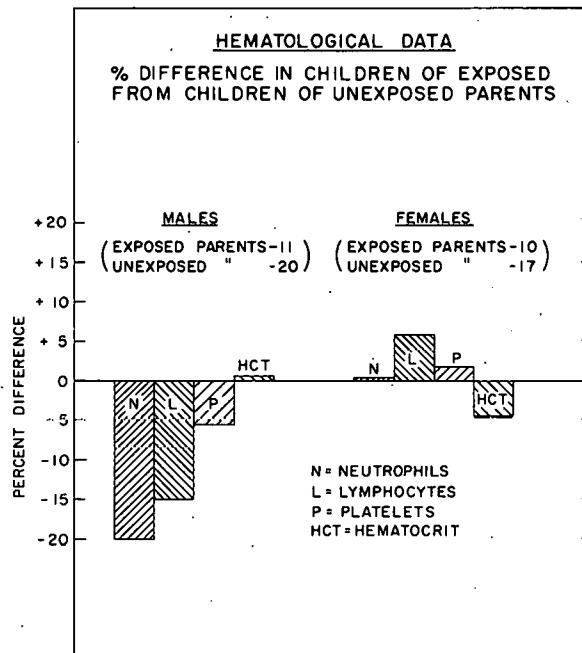

Figure 51. Sex and age distribution of percent differences of peripheral blood elements in children of exposed parents (one or both exposed) compared with children of unexposed parents.

69 and 78 (both with low hematocrits) were subnormal.

Glucosuria

Routine urine analysis carried out on 87 individuals showed positive sugar reactions in 8 persons, one exposed (No. 66, age 36) and 7 unexposed (No. 853, age 56; No. 893, age 40; No. 916, age 39; No. 920, age 29; No. 956, age 53; No. 961, age 68; and No. 991, age 53). Unfortunately, blood sugar determinations were not possible. As noted before, the incidence of diabetes in the Marshallese appears to be higher than in the United States population. These cases were of the chronic type with no acute manifestations. In 1959, as reported previously, however, an unexposed woman died of uterine infection complicating diabetes.

Protein Bound Iodine; Serum Phosphorus and Calcium

These levels were determined in 6 children, 4 of whom showed evidence of retarded growth and development (Nos. 2, 3, 6, and 65; see Table 10). The PBI values found varied from 8.0 to 12.0 $\gamma/100 \text{ ml}$. Since particular care had been taken and specially cleaned glassware used, the slightly high values found appeared to be valid and substantiated the earlier findings of slightly increased levels, particularly since the samples were analysed at a different laboratory than previously. No ex-

planation is apparent for this finding. The calcium levels were a little on the high side of normal and the phosphorus levels, normal. Thus there was no indication that the impairment in growth and development noted in these children was related to these findings.

STUDIES OF GENETICALLY INHERITED TRAITS

Gm Phenotypes

These determinations were run on sera that had been obtained in 1959. No further studies of genetically inherited traits were carried out during the 1961 survey. The results on Gm phenotypes on each individual are presented in Appendix 5. The Micronesians were found to be 100% $\text{Gm}^{(a+)}$ and nearly 100% $\text{Gm}^{(b+)}$. There was a complete absence of Gm^x and a high frequency of Gm-like (Gm^c). Table 15 shows the frequencies in percent of Gm factors in the Marshallese (Micronesians) and various other populations.

The following is taken from a summary of the paper by Steinberg et al.⁸

"Whites have a relatively low frequency of Gm^a , high frequency of Gm^x and Gm^b , and have no Gm-like. The African and Micronesian populations have a high frequency of Gm^a , Gm^b , and Gm-like, and have no Gm^x . North American Indians have a high frequency of Gm^a and Gm^x (higher than whites), a low frequency of Gm^b , and have no Gm-like. Eskimos have a similar pattern, but may have a lower frequency of Gm^x .

"The genetic aspects of the Gm factors are discussed. Whites appear to have alleles Gm^a , Gm^{ax} , and Gm^b . It is tentatively suggested that among colored populations, alleles Gm^{ab} , Gm^{bc} , and Gm^{abc} may occur, where c represents Gm-like."

Estimation of Internal Body Burden of Radionuclides

BACKGROUND

For large scale surveys, such as the Marshallese surveys, measurement with whole-body gamma counters (both liquid scintillation detectors and crystal detectors) has proved to be the most satisfactory technique. Early evaluation of the body burdens of the people of Rongelap was carried out by radiochemical urinalysis, which is time con-

suming and difficult. In 1957, several Rongelap people were brought to Argonne National Laboratory, where it was demonstrated that their body burdens of gamma emitters could be measured in the whole-body counter. Cs^{137} and Zn^{65} were shown to be the prominent isotopes in the Marshallese at that time.

The Rongelap people, originally evacuated to another island in 1954, were returned to their home island in July 1957. Since the island and the indigenous food sources still had a low level of persisting radionuclides, continued evaluation of the body burdens in these people was of considerable interest.

A portable whole-body counter was designed and constructed at Brookhaven National Laboratory and transported to the Marshall Islands, where it has since been employed during the annual medical surveys to ascertain the level of internally-deposited gamma-emitting isotopes. In 1958, 100 Marshallese people were counted, and the procedure was repeated one year later to ob-

tain gamma spectra on 227 people. Details of the exposure and findings of these medical studies have been reported.¹⁻⁷

During the 1961 survey the portable shield was used in conjunction with an improved detection and data-recording apparatus. The gamma-ray spectra of 110 people were obtained. Half the people measured had been exposed to the fallout in 1954; the other half were unexposed.

METHOD

Shielding was provided by a 21-ton room with walls constructed of laminated $\frac{1}{4}$ -in.-thick steel panels bolted together, which can be disassembled. The inside dimensions of the room are 5×5 ft and 6 ft high. Figure 52 shows the steel room (as set up for the 1959 survey). In 1961 the room was set up in the cargo hold of the *Roque* (Figure 6). Along with the steel room, an air-conditioned prefabricated wooden room $7 \times 8 \times 10$ ft was set up to house the pulse-height analyzer and other elec-

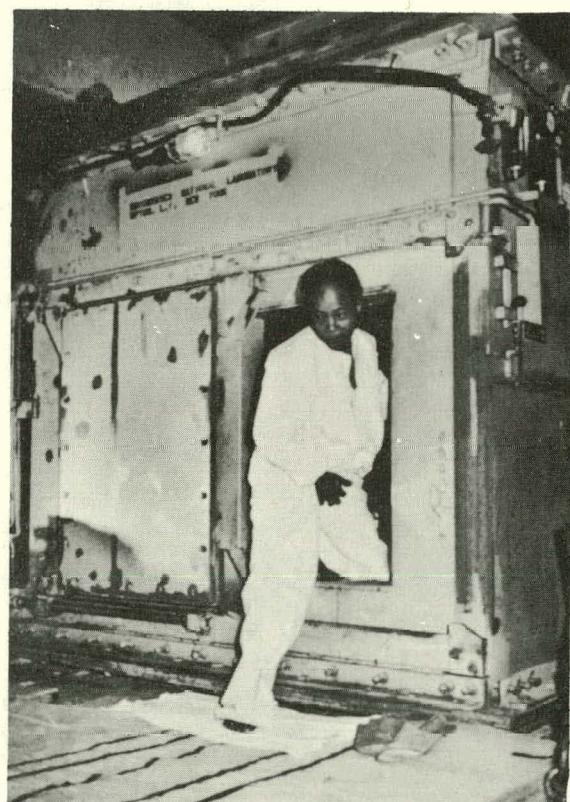

Figure 54. Marshallese subject leaving the counting room through the pneumatically-driven sliding door.

tronic equipment (Figure 52). The air conditioning and dehumidification were of considerable value in maintaining the stability of the instruments in the tropical climate.

The subjects were ferried out to the ship, and, before being counted, showered and donned paper coveralls and slippers in order to minimize the possibility of counting external contamination from the island environment on their bodies and clothing. The subjects were seated on a folded hospital cot and placed in a standard, fixed position under the detector, as shown in Figure 53. Figure 54 shows a Marshallese subject leaving the counting room through the pneumatically-driven sliding door.

The counting geometry employed in the portable counter is identical to that used in the permanent whole-body counter at BNL, which makes possible the cross calibration of the two units.¹³ The efficiency and precision of the portable counter for the various isotopes are presented in Table 16. The values obtained are very similar to those for the whole-body counter at BNL.

The background observed in the Marshall Islands counting room in the range 100 kev to 2 Mev was 1796 cpm (counts per minute), a value somewhat higher than the average background level observed at BNL (1400 cpm). The increased background count in the Marshall Islands was chiefly in the very low energy range and probably

can be explained in terms of the thinner shielding in the portable counter and the omission of Pb lining for the ceiling of the counting room. To some extent the thinner shielding was compensated for by the shielding provided by the water under and around the ship.

Since difficulties had been experienced in identifying small photopeaks of various isotopes deposited in the Marshallese in the presence of relatively large amounts of Cs¹³⁷ and Zn⁶⁵, the counting time was increased for a number of subjects over that used in previous years. In addition, a larger crystal detector was substituted for the 5-in. detector formerly used. The majority of the subjects were counted for 10 min, and a large number were counted for 30 min.

An 8×4-in. NaI (Tl) crystal (Harshaw) detector was placed above the patient at a distance of 19 in. (see Figure 53). Pulses from three 3-in. photomultiplier tubes were fed into a Nuclear Data 256-channel transistorized pulse-height analyzer (Model 120). The analyzer fed the data directly to an IBM typewriter and simultaneously to a Tally paper punch unit, Model 420. Provision is made in this analyzer for transferring spectra recorded on paper tapes into the memory of the analyzer so that calibration spectra can be compared with the incoming data when desired.

The data recorded on the punched paper tapes were transferred to IBM cards and thence to the

*For 70-kg phantom in standard counting geometry,

$$P = \frac{\sqrt{(R_c/t_c) + (R_b/t_b)}}{C.F.}$$

where R_c = Sample plus background counting rate (cpm), R_b = background counting rate (cpm), t_c = sample plus background counting time (min), and t_b = background counting time (min).

**Average Marshallese adult male.

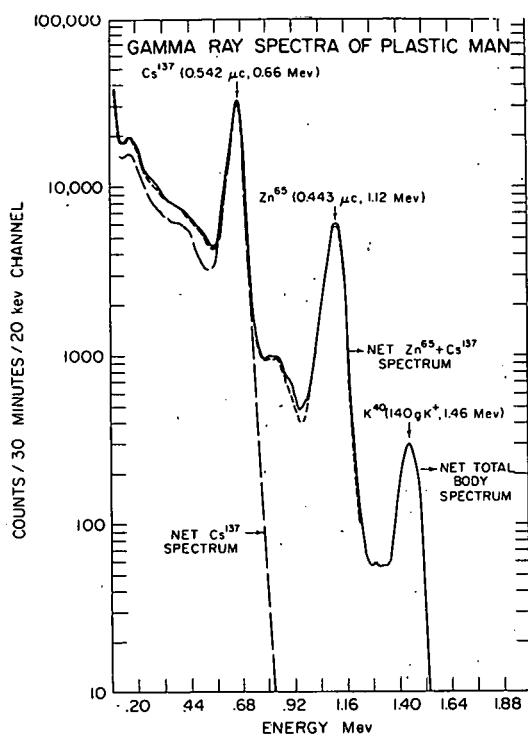

Figure 55. Gamma spectrum of the calibration phantom containing Cs^{137} , Zn^{65} , and K^{40} in the approximate range found in Marshallese subjects. The dotted lines indicate the results of spectral stripping of the higher energy photopeaks.

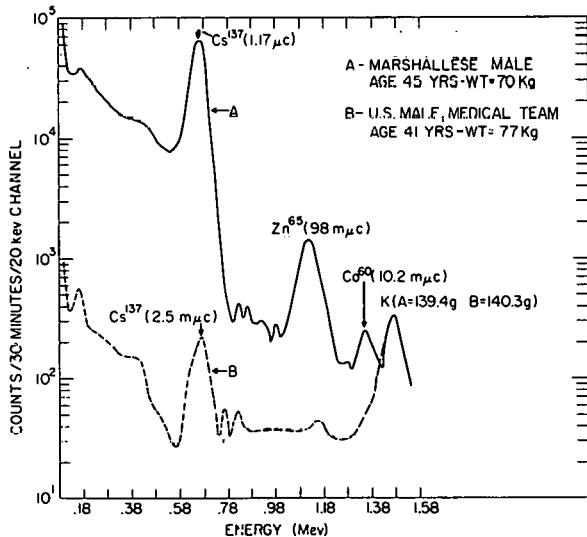

Figure 56. Spectrum of typical Marshallese adult male compared with that of member of the U.S. medical team.

magnetic tape of a 704 computer. The task of "spectral stripping" was carried out on the computer with a FORTRAN program. In this operation the spectrum of each individual isotope is removed from the total spectrum obtained for the subject, which represents the combination of the contributions from all the isotopes deposited in that subject.

Spectra for each of the individual isotopes quantitated in this study were obtained with the use of an Alderson phantom (REMCAL). Solutions of known concentration of each radionuclide were placed in the phantom to approximate the effects of tissue absorption and scatter. The spectrum of the phantom for each of the isotopes was obtained under conditions of counting geometry identical with that used in counting the subjects. By this technique it was possible to simulate quite closely with the phantom the multicomponent spectra of the Marshallese. A representative Marshallese spectrum obtained by adding K , Cs^{137} , and Zn^{65} at average levels (as determined in the medical study of 1959) to the phantom is shown in Figure 55. The K , Cs^{137} , and Zn^{65} were distributed homogeneously throughout the phantom, while Co^{60} was placed in the liver only.

Analyses of the complex spectra were performed by subtracting the calibrated pulse-height spectrum for each gamma emitter to be quantified. Although these spectra are obtained ideally from a subject of identical build, an approximation is obtained with the use of the plastic phantom. Computation was carried out by an IBM-704 computer. Starting with the highest energy photopeak, that of K^{40} (after correction for background and normalization of the K^{40} photopeak to that of the subject), the computer performs a channel-by-channel subtraction of the normalized K^{40} spectrum. In a similar manner, the normalized spectra for Zn^{65} , Co^{60} , and Cs^{137} were subtracted from the total spectrum (see Figure 55).

Individual 24-hr urine specimens were collected and one pooled urine sample of 20 liters. The radiochemical procedure for the Sr^{90} analysis has been described previously.⁴

RESULTS

A spectrum for an average Marshallese adult male, obtained in the 1961 study, is shown in Figure 56, with the spectrum of a member of the U.S. medical team of about the same body weight

*Standard error of mean.

and age included for comparison. Almost identical amounts of the radionuclide K⁴⁰ are noted along with large differences in the Cs¹³⁷ and Zn⁶⁵ levels between the two subjects. The summary of the average levels of Cs¹³⁷, Zn⁶⁵, K⁴⁰, and Co⁶⁰ determined in 1961 for both the exposed and the non-exposed Marshallese, according to age and sex, is presented in Table 17. The frequency distribution of values in various groups is shown in Figure 57. Appendix 7 contains the individual values for each subject.

Cesium-137

The mean value for all groups for body burden of Cs¹³⁷ was 13.7 m μ C/kg body weight. Although

the mean levels of the exposed are slightly higher than those of the unexposed groups, the two do not differ significantly. Variation within any group is large, as can be seen from Figure 57 and from the value of the standard error. As expressed here in terms of body weight, Cs¹³⁷ body burdens in the groups aged >16 and <16 years do not differ significantly. The mean levels of Cs¹³⁷ in females tend to be somewhat lower than in males, but the difference does not appear significant (Figure 57).

Zinc-65

Zn⁶⁵ body burdens per kg body weight appear to be somewhat lower in the younger population group, but again the differences are not statisti-

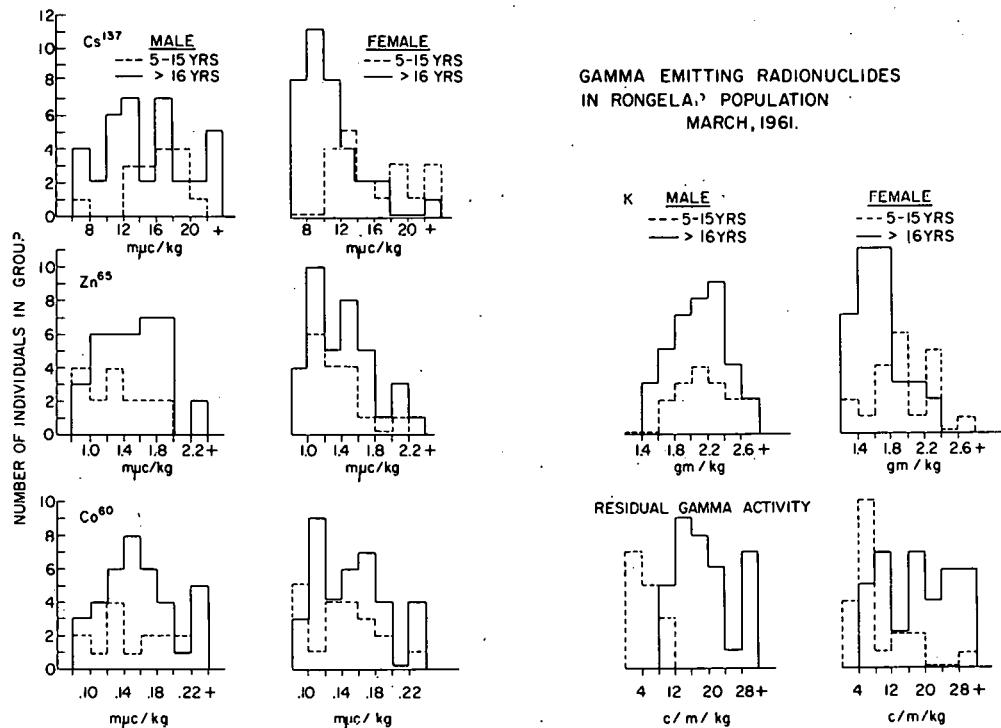

Figure 57. Frequency distribution of levels of radionuclides in various Marshallese groups.

cally significant. Also, females tend to have values lower than those found in the corresponding male group (Figure 57). No significant difference between the Zn⁶⁵ concentrations in the exposed and unexposed groups could be determined. The percent variation within each group was approximately the same as in the case of Cs¹³⁷.

Potassium-40

The mean K concentrations for the younger groups were consistently higher than those for the corresponding adult groups. The male adult group averaged 2.13 g/kg body weight and the female adult group 1.63.

Cobalt-60

Analyses of the residual spectra obtained after subtraction of the three above-mentioned photo-peaks revealed the presence of a fourth photopeak, Co⁶⁰. The levels of Co⁶⁰ were quite low (mean = 0.148 mμC/kg), but were nevertheless readily detectable. No significant differences between the Co⁶⁰ levels in the exposed and unexposed groups, or on the basis of age or sex, were observed.

Total Residual Gamma Activity

The total residual gamma activity levels present after subtraction of the above four spectra are also shown in Table 17. The activity in cpm/kg has no absolute significance, but is of value in indicating, first, that there is some activity left, and, second, the nature of its distribution by groups. Members of the adult group have considerably higher levels of residual activity per unit body weight than do members of the juvenile group. No significant differences were observed, however, on the basis of sex, or between the exposed and nonexposed groups.

Radiochemical Analysis for Strontium-90

The estimated 1961 Sr⁹⁰ mean urinary excretion in the Rongelap inhabitants was $7.2 \pm 0.4 \mu\mu\text{C/l}$; this represents a 14% increase over the 1959 value ($6.3 \mu\mu\text{C/l}$). This value is based on the results of analysis of a pooled 20.8-liter sample collected from the adult population (see Table 18). This Sr⁹⁰ urinary excretion expressed in terms of urinary calcium is $50.6 \pm 3.9 \mu\mu\text{C/g Ca}$. These values give

an estimated body burden of 6.9 m μ C as compared to 6.0 m μ C estimated in 1959.

Wide variation was found in the individual "24-hour" urine samples collected and analyzed individually (Table 18). The average Sr⁹⁰ excreted was 159 $\mu\mu$ C Sr⁹⁰/g Ca for the children as compared to 30.9 for the mean adult population. Adult women appeared to have higher Sr⁹⁰/Ca ratios than men. However, in terms of urinary Sr⁹⁰ ($\mu\mu$ C/l), the value was 2.3 for women compared to 4.5 for men. This difference was similar to that observed in 1959. With the small sample size and the wide spread in values in any single group, it is not possible to detect any significant difference between the exposed and unexposed Rongelap groups.

Two coconut crabs were brought back from the survey and analyzed for Sr⁹⁰. One from Rongelap Island had a level of 1140 (± 12) $\mu\mu$ C Sr⁹⁰/g Ca, and one from the more heavily exposed island of Eniaetok, 8 miles north, had a level of 3900 (± 23) $\mu\mu$ C Sr⁹⁰/g Ca. These values were about half those found in these crabs in the early years after the fallout.

One 3-month fetus, the product of a miscarriage in a Rongelap woman, was also analyzed and showed a level of 25 (± 20) $\mu\mu$ C Sr⁹⁰/g Ca. However, the sample was so small that the results are of little significance.*

Figure 58 shows the levels of radionuclides in the Rongelap people at various times after exposure, based on radiochemical urine analyses and spectrographic determinations.

DISCUSSION

It is interesting that no significant differences were observed in the body burdens of the four gamma-emitting radioisotopes measured in the 1961 whole-body spectrographic study between the groups of Marshallese exposed to fallout in the 1954 accident and unexposed groups who have been living in the same environment for the last 4 years. The original contamination of these gamma emitters in the exposed population has already been eliminated, and what is observed in this study is the radioactivity derived from the slightly contaminated environment.

*We wish to thank Mr. E.P. Hardy, Jr., Health and Safety Laboratory, New York Operations Office, AEC, for carrying out these Sr⁹⁰ analyses.

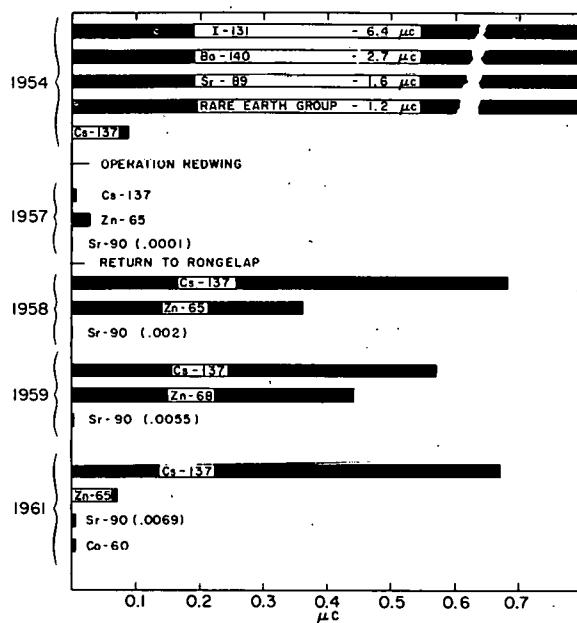

Figure 58. Estimated body burden of isotopes in Rongelap people at various times since 1954. Values obtained either by gamma spectroscopy or by radiochemical urine analyses.

The levels of radioactive contamination appeared to be about the same for juveniles as for adults, for men as for women. Factors of age and sex apparently do not influence significantly the deposition of these radionuclides. Wide variations in the level of contamination appear among individuals of all groups, as might be expected when the source of the contamination is via ingestion. Even with a fairly limited diet, individual tastes may dictate great differences in the food consumed.

As for the time course of the contamination in the population as a whole, it is necessary to consider each radioisotope individually, as to source of supply and discrimination of the soil, plant and animal life, and the human body for each isotope.

The mean Cs^{137} body burden of the Rongelap adult males is $14.7 \text{ m}\mu\text{C/kg}$ as compared to $14.1 \text{ m}\mu\text{C/kg}$ in 1959. Thus, no significant change has occurred in the past 2 years. These Cs^{137} body burdens of the Marshallese result from the relatively high dietary intake through foodstuffs produced in the Marshallese environment. They reflect the level of residual fallout on the island, and also the higher uptake and retention of Cs^{137} by food plants grown in a K-deficient soil. It appears that the body burden of Cs^{137} has reached an approximate equilib-

rium with the levels of Cs^{137} in the diet (although this is a difficult point to ascertain). The uniformity of the $\text{Cs}^{137}/\text{g K}$ in the entire Marshallese population suggests that the Cs^{137} level, like the K^{40} level, is proportional to the lean body weight.

The mean Cs^{137} body burden of the Rongelap adult males ($14.7 \text{ m}\mu\text{C/kg}$) was 300 times the mean of that of the medical team carrying out the study (0.048). The level of Cs^{137} in the world-wide population in July 1961 appears to have declined from the maximum level observed in 1959. The average value for Cs^{137} measured in BNL personnel, for example, declined from $59 \text{ }\mu\mu\text{C/g K}$ in June 1960 to 30 in December 1961. The body burdens of the Marshallese will, of course, also be affected by this world-wide fallout as well as by the fallout released in the series of tests carried out by the USSR in October 1961. As the accumulation is gradual both in the environment, as world-wide fallout settles out, and in the human body, via the ingestive route, it will be a number of months before a clear picture emerges. However, after the moratorium of 3 years, during which time the Cs^{137} levels had an opportunity to stabilize, it will be clear what the direct results are of that particular series of tests.

The mean Zn^{65} concentration per kg body weight of the Marshallese does not differ significantly between the exposed and unexposed groups, nor does it differ on the basis of sex or age. However, the mean was generally slightly higher among adults than in juveniles, and higher among adult males than adult females. In the period 1959-1961 the value of Zn^{65} body burden dropped by a factor of 6. The value of Zn^{65} in male adult Marshallese dropped from $9.9 \text{ m}\mu\text{C/kg}$ body weight in 1959 to $1.51 \text{ m}\mu\text{C/kg}$ in 1961. No clear reason emerges as the basis for this drop, although it is possible that dietary variation may be responsible. It is known that the source of Zn^{65} in these people is from fish, which selectively concentrate this element. Therefore, it is possible that the decrease in Zn^{65} levels noted may be due to the fact that the people are eating more canned meats in place of fresh fish. If the Zn^{65} intake in the diet had decreased radically during that period, the observed fall in the level of internally-deposited Zn^{65} would be consistent with the effective half-life of Zn^{65} , which is ≈ 120 days.¹⁴ The evidence that could be obtained on this subject is insufficient to make any conclusive statement, however.

Although levels of Zn^{65} body burdens equivalent to those found in the Marshallese (1.51 $m\mu C/kg$ body weight) have been observed in certain BNL reactor workers,¹⁵ the values in the Rongelap population were about 100 times those measured in the members of the medical team. The mean level of Zn^{65} in the medical team was 0.015 $m\mu C/kg$ body weight, just slightly higher than the precision of the counter, and therefore not statistically significant (Table 17).

The K content of the adult Marshallese male averages 2.12 g/kg, compared to the mean for the medical team of 1.72. The average K of a large group of male employees at BNL is 1.84 g/kg body weight.¹⁵ The higher value for the Marshallese males reflects their well-developed musculature and low fat content, as the value of K is proportional to the lean body mass. Thus, the K values for the Marshallese females are generally lower, in the range 1.52 to 1.71 g/kg body weight. As expected, the K concentrations measured in the children are somewhat higher than those of the adults, particularly among females.

A new and very interesting finding of this study was the determination of the presence of Co^{60} in the Marshallese population. The mean level is fairly uniform, about $\frac{1}{6}$ of the Zn^{65} level, but the spread in values in any one group is large. There is a fairly consistent correlation between the Zn^{65} and the Co^{60} values, which could very well reflect their common origin in the fish, snails, and clams of the Marshallese diet. The induced activity, Co^{60} , had not been detected previously in this population because its very low level was masked by the relatively large peaks of the other radionuclides in the relatively short counting periods hitherto used. It was to reveal just such secondary levels that the longer counting period and larger detector were adopted for the 1961 study.

The residual gamma activity in the spectra remaining after the subtraction of the major components indicates that there are some residual radionuclides present in quantities not sufficient for identification via their photopeaks. The adult groups all had approximately the same level of residual activity, while the juveniles had 25 to 50% of the adult levels. The residual activity values in the adult groups were at least 10 times the mean observed in the U.S. medical team. Unfortunately whole-body counting techniques have not been developed for external beta counting of the very

important fission product Sr^{90} . Its levels can only be estimated from data obtained by radiochemical analysis of urine. Undoubtedly the bremsstrahlung resulting from the Sr^{90} body burdens in the Marshallese contributes to the residual activity noted above.

A study of the levels of body burdens of the several gamma-emitting radionuclides in the Marshallese people indicates how the fission products move through the environment and accumulate in man. Further, the biological turnover rate of these radionuclides in human beings can be estimated. The survey made with the portable whole-body counter has been invaluable in monitoring the levels of internal contamination of gamma emitters in this population. The experience gained in this study should be of value in future surveys among other populations.

Summary and Conclusions

In March 1961, a medical survey was carried out on the Marshallese people of Rongelap Atoll who had been accidentally exposed to fallout radiation 7 years previously. The medical team consisted of 10 medical specialists from the United States and 8 from the Trust Territory of the Pacific Islands. A total of 267 Rongelap people were examined, most of them on Rongelap Island and some at Kwajalein and Majuro Atolls. Of this number, 76 were in the exposed group; 28 were children of exposed parents; and 163 were adults and children from the comparison population not exposed to fallout. The Trust Territory ship *Roque* was used to transport and house the team and in addition housed, in its cargo hold, the 21-ton steel room with its electronic equipment for carrying out spectrographic analyses.

Prior to the survey, at Rongelap a village meeting held with representatives of the medical team revealed that the people were still concerned and had some misconceptions about certain conditions that they felt were related to fallout such as fish poisoning and a sickness from eating arrowroot flour. The true nature of these maladies was explained to them. Some dissatisfaction was also expressed about the continued ban on eating coconut crabs, but the people were assured that regular analyses for radioactivity would be run on the crabs and they would be notified as soon as the crabs were considered safe for consumption.

A review of the medical status of the people during the previous year revealed that few major illnesses had occurred and no epidemics of infectious diseases. No illnesses were reported in the exposed group which might be related to radiation exposure. No deaths had occurred except in two infants. One baby born of unexposed parents died of a congenital malformation (anencephaly). Only a few miscarriages had occurred and the incidence was no greater in the exposed women than in the unexposed. Thus, the suggestive trend of increased number of miscarriages and stillbirths in the exposed women reported for previous years was not apparent during the past two years.

Physical examinations showed no acute illnesses present nor any diseases which could be directly associated with radiation effects. The incidence of various diseases was generally the same in the exposed and unexposed groups. It was noted that several of the older people, particularly in the exposed group, were becoming quite feeble and helpless.

Residual skin changes in areas previously showing lesions from fallout were present with certainty in about 10 people. The changes noted were principally atrophy, scarring, and pigment aberrations. None of these cases showed any evidence of chronic radiation dermatitis or malignant change. The appearance of pigmented maculae and moles in previously irradiated areas of the skin was more common this year than noted in the past, it is believed. However, these pigmented lesions appeared quite benign. They will be scrutinized closely on future surveys. The incidence of diabetes in both exposed and unexposed people appeared to be higher than found in the United States.

Dental examinations revealed a high incidence of caries in the younger people and periodontitis in the older people. No difference was noted between the exposed and unexposed group in regard to dental findings.

Careful examinations for the detection of such late effects of radiation as cancer and leukemia revealed no evidence of these malignancies in any of the people, exposed or unexposed.

Growth and development data from 1958 through 1960 were reviewed for the children. These data revealed a distinct tendency for the exposed boys of ages <12 to be shorter than the unexposed males of comparable chronological ages. This was

prominent in the boys exposed before 6 years of age, and most marked in those exposed at 12 to 18 months. A similar but less distinct trend was noted for body weight among the exposed boys. These trends were not noted among the exposed girls. However, skeletal maturation studies (roentgenograms of left hand and wrist) showed trends suggestive of inferior skeletal maturation in both male and female exposed children compared with unexposed children, although the differences did not reach the level of statistical significance. A high degree of correlation was found between retardation in skeletal age and inferiority in statural growth. Of specific interest was the group of children now 8 years old who had been exposed to fallout at ages 12 to 18 months; this group showed the most marked retardation in physical and skeletal growth.

Similar studies comparing growth and development in children of exposed parents and in children of unexposed parents showed that the male offspring of exposed parents were smaller in stature at all ages than those of unexposed parents. The most marked differences occurred at 1, 3, and 4 years of age, and in those born <2 years after the fallout.

In order to investigate the possible effect of radiation in inducing premature aging, various criteria were measured or estimated during physical examinations (visual acuity, accommodation, arcus senilis, graying of hair, balding, skin looseness, skin elasticity, senile skin changes, blood pressure, peripheral arteriosclerosis, and neuromuscular function). No apparent effect of radiation was noted, since measurements were not greatly different in the exposed and unexposed age groups and were similar to the measurements previously reported.⁷ However, the study is of interest with regard to the measurement of biological aging, since the various criteria showed definite age dependent trends, and, by combining the scores on a percentage basis, an over-all biological age score was determined.

Slit-lamp observations for cataracts were not carried out on this survey, but previous surveys had shown no evidence of induced opacities of the lens.

Genetic studies have not been specifically conducted. Examinations of children of exposed parents have revealed little in the way of congenital anomalies. One baby born of an exposed

mother was diagnosed as having congenital heart disease and died several months after birth. The suggestive evidence of increased miscarriages and stillbirths in the exposed women during the first few years after exposure might be related to irradiation of the germ plasm. The finding that male children of exposed parents were shorter in stature than children of the same age of unexposed parents may have some genetic significance, but further studies would be necessary to substantiate such a conclusion.

Hematological studies showed that certain peripheral blood elements in the more heavily exposed Rongelap group continued to show slightly lower levels than in the unexposed comparison population, suggesting a persistent irradiation effect on hemopoietic function. Examination of the data by age and sex groups showed that neutrophil and platelet levels among the exposed were consistently below the unexposed levels, and that exposed males aged 7 to 15 years and exposed persons, both males and females, aged >40 showed the most difference from their controls. The exposed males and females of ages 15 to 40 showed less difference, with even higher levels of some elements than the unexposed groups of the same ages. The platelet levels, however, were consistently lower in all age groups in both sexes. It was noted also that male children of exposed parents had somewhat lower levels of neutrophils, lymphocytes, and platelets than children of unexposed parents.

The Rongelap population as a whole continued to show slightly lower erythropoietic function than found generally in Americans, the explanation for which is not clear. Though iron deficiency does not appear to be a problem in view of generally normal serum iron levels, some other type of nutritional deficiency may be responsible. The high incidence of eosinophilia may be partly related to chronic fungus infection of the skin and intestinal parasitism, but other causes, not immediately obvious, may be involved.

The "portable" whole-body counter was used to obtain the gamma spectra of 110 Marshallese, half of whom had been exposed to the fallout in 1954. No significant difference in body burdens of the gamma-emitting radioisotopes was observed between the Marshallese exposed to fallout in 1954 and those of the comparison population living in the same environment for the past 4 years.

The levels of internal contamination per unit weight appeared to be about the same for juveniles as for adults, male and female. Wide variations in levels of contamination in any group were found, apparently due to differences in diet and metabolism. The mean Cs¹³⁷ body burden in adult males was 14.7 $\mu\mu\text{C}/\text{kg}$, which is not significantly different from the mean value of a similar group obtained 2 years ago; it was 300 times that of the medical team, who were measured at the same time for comparison. The Zn⁶⁵ level in adult males (1.51 $\mu\mu\text{C}/\text{kg}$) dropped to 17% of the mean value measured 2 years ago. With a larger detector and a longer counting time than previously employed, it was possible to identify and quantify Co⁶⁰ for the first time in these people; the mean level of Co⁶⁰ was about 11% of the Zn⁶⁵ level. A small amount of residual activity was still present after the subtraction of K⁴⁰ and the above radionuclides from the total spectrum. The mean level of urinary excretion of Sr⁹⁰ was 7.2 $\mu\mu\text{C}/\text{l}$ or 14% higher than measured in the 1959 medical survey.

Though the acute effects of radiation exposure in the Marshallese have largely subsided, it is possible that certain late or delayed effects may occur. Some late effects have already been observed in the Japanese, such as an increased incidence of leukemia and possibly other malignancies and also development of cataracts. Still other late effects have been observed in irradiated animals. It is unlikely that such abnormalities will develop in the relatively small Rongelap population and, should they develop, the incidence should be quite low. Nevertheless, it is extremely important that further surveys be conducted to detect subtle changes associated with the development of such abnormalities so that they can be documented and therapeutic procedures instituted whenever possible. The examinations show some findings which persist in the exposed people, and these need to be carefully followed. These include incomplete recovery of certain blood elements to levels found in the unexposed people, retardation of growth and development in some of the irradiated children, and pigmented changes at the sites of radiation burns of the skin.

Recognizing the importance of these surveys, the Trust Territory of the Pacific Islands and the U.S. Atomic Energy Commission have agreed that annual medical surveys of the Marshallese people exposed to fallout in 1954 should continue indefinitely.

Acknowledgments

The cooperation of many agencies and persons was necessary to carry out these surveys successfully. The authors are deeply grateful to many individuals, too numerous to name, for valuable assistance.

Many officials of the Atomic Energy Commission, particularly Dr. Charles L. Dunham, Dr. H.D. Bruner, and many of their staff of the Division of Biology and Medicine, were most helpful in the coordination of arrangements with various governmental agencies and in supporting these surveys in every possible way.

We are grateful to the officials of the Department of the Interior and particularly to the officials of the Trust Territory of the Pacific Islands, for their support and assistance in carrying out the surveys. Particularly helpful were Mr. Maynard Neas, District Administrator for the Marshall Islands, and his assistant, Mr. William White, and Mr. R. J. Umhoefer; also Dr. A. Hicking, Dr. John Iaman, and Mrs. Ruth Martin of the Marshall Islands Memorial Hospital. The officers and crew of the Trust Territory ship *Roque* were most helpful.

At Brookhaven National Laboratory contributions were made by many individuals in many departments including Medical, Instrumentation and Health Physics, Photography and Graphic Arts, the Shipping section, and others. We are grateful to the following people for their support and advice: Dr. Leland J. Haworth, Director; Dr. Lee E. Farr, Chairman of the Medical Department, and others in this department including Drs. D.D. Van Slyke, E.P. Cronkite, V.P. Bond, J.S. Robertson, R.A. Love, L.K. Dahl, G.C. Cottias, and Mr. W.A. Finn, Mr. W.J. Walsh, Mr. Clyde Sipe, and Mrs. L.M. Tassinari. We wish to thank Miss R.H. Straub for carrying out radiochemical analyses on the urine. In the Instrumentation and Health Physics Department, Dr. J.B.H. Kuper, Chairman, and Drs. R.L. Chase and W. Higinbotham gave invaluable assistance in assembling and testing complex electronic equipment.

As in the past, the Department of Defense, particularly the Department of the Navy, contributed most vitally to the mission. The Pacific Missile Range Facilities at both Kwajalein and Eniwetok were of great assistance in furnishing necessary

air lifts and loading of medical supplies and equipment.

We are grateful to Drs. W.W. Fennel and W.S. Shippey of the Texas Transport Company Hospital at Kwajalein for their willing assistance.

At Eniwetok, we greatly appreciate the splendid assistance of Mr. Thomas Hardison and others of the Holmes and Narver Construction Co. in handling and storing of equipment.
