FOREWORD AND ACKNOWLEDGMENTS

The development of this program implementation plan is the result of considerable effort by several individuals. Chapter 3 of Part II on Coal Gasification was prepared primarily by the staff of the Materials Science Division of Argonne National Laboratory under the leadership of W. A. Ellingson. The remainder of the document was prepared by the staff of the Fossil Energy Materials Program, Metals and Ceramics Division, Oak Ridge National Laboratory. Guidance for the preparation of this plan was provided by E. E. Hoffman, Department of Energy Oak Ridge Operations, and by M. I. Singer and F. M. Glaser, Department of Energy Fossil Energy Office of Technical Coordination.

FOSSIL ENERGY MATERIALS PROGRAM IMPLEMENTATION PLAN
FOR FISCAL YEARS 1987 THROUGH 1991*

Compiled by
R. R. Judkins and P. T. Carlson

ABSTRACT

This program implementation plan for the Department of Energy Advanced Research and Technology Development (AR&TD) Fossil Energy Materials Program reviews the technical issues and the materials research and development needs of fossil energy technologies. The status and plans for research and development activities in the AR&TD Fossil Energy Materials Program to meet those needs are presented. Detailed information about these plans is provided for FY 1987 through FY 1989, and long-range plans are described for FY 1990 and FY 1991.

*Research sponsored by the U.S. Department of Energy, AR&TD Fossil Energy Materials Program [DOE/FE AA 15 10 10 0, Work Breakdown Structure Element ORNL-4(A)] under contract DE-AC05-84OR21400 with Martin Marietta Energy Systems, Inc.

PART I
INTRODUCTION

1. INTRODUCTION

1.1 PROGRAM DESCRIPTION AND OBJECTIVES

This implementation plan for the Department of Energy Advanced Research and Technology Development (AR&TD) Fossil Energy Materials Program was prepared in cooperation with the U.S. Department of Energy (DOE) Oak Ridge Operations (ORO) Office and the DOE Fossil Energy Office of Technical Coordination. It describes the program objectives, organization, and responsibilities of the various participants on the program. In particular, details of planned activities for FY 1987, FY 1988, and FY 1989 and an indication of anticipated activities through FY 1991 are presented.

The goal of the AR&TD Fossil Energy Materials Program is to develop a fundamental understanding of materials and their performance in fossil energy systems. The scope of the program encompasses all fossil energy systems, and materials research projects address the needs of these systems. Work on this Program is divided among four research thrust areas: structural ceramics, alloy development and mechanical properties, corrosion and erosion of alloys, and technology assessments and technology transfer.

The structural ceramics research thrust area focuses on ceramic composites and includes research on chemically vapor deposited ceramic matrix-ceramic fiber composites, whisker reinforced ceramic composites, and advanced fiber-reinforced composites.

Alloy development and mechanical properties research presently addresses alloys for advanced steam cycle systems, and a new class of intermetallic compounds (iron-nickel aluminides) which may be used in many high-temperature applications.

Research on corrosion and erosion of alloys places emphasis on understanding the formation and properties of protective oxide scales on alloys, and on fundamental studies of erosion of alloys and the fluid dynamics of fossil energy systems.

The technology assessment activities assist in maintaining an awareness of the technical issues and research needs of emerging fossil energy

technologies, whereas the transfer of the technology developed on this program is an important responsibility of the entire fossil energy community.

National and government laboratories, universities, and industrial research centers are conducting independent, yet complementary, research in these four research thrust areas as participants in the AR&TD Fossil Energy Materials Program. These concerted research efforts will lead to an understanding of the performance of materials in fossil energy systems, and this understanding will permit materials to be specified for these applications with more assurance of acceptable performance.

Materials research and development for specific fossil energy technologies are funded by various DOE offices having specific materials requirements for those technologies. The intent is that this program be consistent with the emphasis of DOE on long-range generic research to address the needs of evolving fossil energy technologies. An indication of which long-range generic research tasks of the AR&TD Fossil Energy Materials Program support the needs of these fossil energy technologies is given in Table I.1. In many areas, the generic research of the program contributes to the understanding of materials problems in several fossil energy technologies.

Management of the program has been decentralized to DOE-ORO, with the Oak Ridge National Laboratory (ORNL) as technical support contractor. A substantial portion of the work on the AR&TD Fossil Energy Materials Program is performed by participating subcontractor organizations. All subcontractor work is technically monitored by program staff members at ORNL and at Argonne National Laboratory (ANL).

The program is organized according to a work breakdown structure (WBS) with Level 1 elements that correspond to the materials research thrust areas described above. A schematic summary of this organization is provided in Fig. I.1. In this Plan, relevant materials research and development needs of fossil energy technologies are identified in Part II. Descriptions of ongoing and planned research by the research thrust areas to address these needs are presented in Part III.

^aDesignations of the research tasks of the AR&TD Fossil Energy Materials Program are listed vertically according to research thrust area, and the fossil energy technology areas are listed horizontally. The X-symbols indicate those technology areas supported by research in the different thrust areas.

Tables in each chapter of Part III, Current and Planned Projects in the AR&TD Fossil Energy Materials Program, present funding levels for each project. The funding distribution for FY 1987 reflects the activities planned for that year; for subsequent years, the distribution reflects our assessment of research and development needs for the DOE Fossil Energy Materials Program. These needs included those identified by an assessment of fossil energy materials needs,¹ from research and development proposals, from discussions with individuals and organizations interested in fossil energy materials development, and from a series of technology base reviews conducted annually by the DOE Fossil Energy Office of Technical Coordination. In addition, the AR&TD Fossil Energy Materials Program interacts with other DOE research programs, such as the Materials Science Program of the Office of Basic Energy Sciences (BES), through participation in the activities of the Energy Materials Coordinating Committee (EMaCC). One activity of EMaCC of particular importance in contributing to close coordination among programs is the annual technical report, the most recent issue of which covers research activities during FY 1985 (ref. 2). Numerous other interactions occur between the Fossil Energy Materials Program and other DOE programs to ensure that the goals of the program are consistent with the needs of fossil energy technologies. Finally, to maintain an awareness of current research needs, the program management staff and principal investigators in the AR&TD Fossil Energy Materials Program routinely receive news bulletins from various programs and organizations on subjects such as welding, erosion, structural ceramics, sulfur attack, and other areas of interest. We expect this program implementation plan to be revised annually, and industrial and other research organizations are invited to offer suggestions for future revisions.

PART II

MATERIALS RESEARCH AND DEVELOPMENT NEEDS

OF FOSSIL ENERGY TECHNOLOGIES

1. INTRODUCTION

Part II covers a spectrum of fossil energy technologies and the technical issues relating to the materials of construction. Other technical issues related to coal liquefaction, coal gasification, structural ceramics for heat engines and heat recovery, combustion systems, fuel cells, coal preparation, magnetohydrodynamics, oil shale, technology assessment, and technology transfer are discussed.

2. COAL LIQUEFACTION

2.1 TECHNOLOGY STATUS AND MATERIALS NEEDS

For several years direct coal liquefaction processes have been under development by private industry with support from DOE. These development activities have included the operation of four major pilot plants: the SRC-I plant in Wilsonville, Alabama (1974-present); the SRC-II/I plant in Fort Lewis, Washington (1974-1981); the Exxon Donor Solvent plant in Baytown, Texas (1980-1982); and the H-Coal plant in Catlettsburg, Kentucky (1980-1982). Only the Wilsonville plant remains in operation. The principal processes are described in a previous program plan.¹ Although the processes differ in detail, similar systems may be considered for identifying materials research and development needs. For this discussion, the direct liquefaction processes will be divided into the following major process areas: coal and slurry preparation, preheater and reactor system, pressure letdown and separation system, and fractionation system.

The research and development program described in Part III is based almost entirely on the needs of direct coal liquefaction plants of the types mentioned above. However, there are materials needs for advanced processes which are currently at a bench-scale level of development. Many of the current and planned activities in the AR&TD Materials Program are appropriate for advanced processes. These include the areas of erosion, corrosion, and erosion-corrosion. Present pressure vessel materials projects are being phased out, since the technology has advanced to the point that it can be pursued by private industry. Thus, as the plans described in Part III suggest, research and development on pressure vessels will be discontinued.

2.1.1 Coal and Slurry Preparation System

The main materials problems in the slurry preparation system of liquefaction process development units (PDUs) and pilot plants are due to wear, erosion, and corrosion of the various components and are fairly well understood. In recent years, however, several changes have been introduced into component designs, materials selection, and process stream flow

characteristics. It is not altogether certain that all the materials technology now maturing around pilot plant experience can be extended to larger scale plants without some degree of trial and error. Some materials substitutions can also be expected. Strong tough alloys are needed for coal-crushing equipment. Wear can be reduced by hardfacing critical areas. Selection of erosion-resistant piping materials in the slurry preparation system is not a significant problem if the design, sizing, and construction are adequate. Erosion-corrosion problems may increase with increasing slurry mixing temperatures. Pump and valve designs are critical, and new hardfacing alloys may be needed in these components to achieve satisfactory life. Piping and vessel materials that hold the recycle slurry must be selected to accommodate the erosive and corrosive species that will be present, such as coal ash, hydrogen sulfide, and chlorides. Lining of critical vessels will be necessary in many cases.

Specific areas needing attention include erosion at low particle velocities (0.9–6 m/s) with liquid carriers typical of the slurries actually present. Chemical effects of coal liquids need to be studied more extensively. Effects of reaction products have been determined for only simple systems to date. Development of improved hardfacing materials and coatings and methods of applying these materials as liners are needed to extend slurry pump life. The use of inserts, liners, and coatings of erosion-resistant materials of compatible thermal expansion characteristics to slurry pump construction materials needs to be explored. Additional effort is required to characterize and understand the combined effects of mechanical wear and corrosion.

Nondestructive testing methods such as ultrasonic testing and eddy-current techniques for thickness determination and ultrasonic and infrared techniques to confirm bonding integrity should be investigated and developed for hardfacing in pumps, valves, and other components subjected to erosion.

2.1.2 Preheater and Reactor System

The high-pressure high-temperature hydrogenation section of coal liquefaction plants presents many problems from an economic and reliability point of view. The preheater coils, dissolver, and high-pressure

separators will be designed to the rules of the *ASME Boiler and Pressure Vessel Code*, and the designs will incorporate sections of the American Petroleum Institute (API) codes where needed. Considerations that must be addressed in the design of these systems include pressure, temperature, fabrication techniques, welding procedures, steel composition, temperature cycling, and partial pressures of hydrogen and hydrogen sulfide.

Potential failure modes that can affect materials selection include aging embrittlement, hydrogen attack, hydrogen embrittlement, sulfidation, erosion, stress rupture, creep-fatigue, chloride attack, polythionic acid attack, naphthenic acid attack, stress corrosion cracking, thermal fatigue, and dissimilar-metal weld cracking.

In recent years, the AR&TD Fossil Energy Materials Program has conducted extensive research relative to pressure vessel steels for coal liquefaction (and gasification). The research projects included work on alloy development, fabrication, welding, mechanical properties, and environmental effects. Because the work on pressure vessel steels has been highly successful in the identification and development of new alloys, it has been concluded that industry can continue this work. The work, therefore, is being phased out of the AR&TD Fossil Energy Materials Program.

2.1.3 Pressure Letdown and Separation System

Materials problems in the pressure letdown and separation area include both erosion and corrosion. Erosion due to the handling of coal upstream from the reactor and ash solids downstream was anticipated as a major materials problem in solvent refined coal (SRC) pilot plants, and experience in these plants has borne out the adverse effects of erosion on the operation of pumps and letdown valves in these processes. Projects to optimize materials selections for these applications are needed.

Erosion is a special problem in the pressure letdown valves, where selection of an appropriate trim material has been difficult. Letdown valve trim failures at the H-Coal Pilot Plant indicate a need for valve trim evaluation and fabrication programs. To date, commercially available materials that have shown the best performance in letdown valves are cemented tungsten carbides with cobalt or cobalt-chromium binders. The PDUs and pilot plants have reported significant variations in the

performance of a given grade or type from a given manufacturer. In addition to the basic materials limitations, the standard trim component designs for all available commercial letdown valves have proved inadequate for the extreme service conditions in processes for the direct liquefaction of coal. In general, design and component assembly process revisions have been made by each PDU and pilot plant to modify its sizes and types of valves to improve their reliability. To date, such specific modifications have been reasonably successful in that the pilot plants have been able to improve letdown valve performance to the point that process development could proceed.

The maximum service life achieved for letdown valve trim has been several thousand hours at the Wilsonville Advanced Coal Liquefaction Research and Development Facility, but in most cases the service life was limited to 300 to 400 h. Of the two larger pilot plants previously operated, the H-Coal Pilot Plant at Catlettsburg, Kentucky, experienced serious valve problems, whereas the Exxon Coal Liquefaction Plant at Baytown, Texas, completed operations with no serious letdown valve failures. Based on the Exxon experience, the desired life between required maintenance or replacement of about one year of operation (8000 to 10,000 h) can be achieved.

Stress corrosion cracking has been observed in the separation system which was caused by both chloride and polythionic acid. Cracking has often been observed in the heat-affected zone around welds but also was found in the cladding in separation vessels at the Fort Lewis, Washington, Solvent Refined Coal Pilot Plant.

Erosion is a potential problem in the vacuum distillation units and in the initial atmospheric distillation units of the Exxon Donor Solvent and SRC-II systems. Specific materials problems in the separations systems involving both liquid-gas and solid-liquid separations are not well defined. Both corrosion and erosion-corrosion, as well as gas phase corrosion, have been observed in pilot plant liquid operations.

2.1.4 Fractionation System

Erosion of materials in the fractionation area of coal liquefaction systems is minimized by the absence of solids in most of the liquid streams. However, process designers thought that the liquids being

handled were similar enough to those in petroleum refineries that the technology associated with refinery operation would be sufficient to handle any problems encountered. Unfortunately, in the two SRC pilot plants (the H-Coal Pilot Plant and the Exxon Coal Liquefaction Pilot Plant) severe corrosion was observed, which was not explained by petroleum refinery technology. The most severe corrosion was found in the 220 to 260°C range in fractionation columns used to separate the filter wash solvent from a heavier liquid sometimes used as the recycle solvent. Corrosion is characterized by selective removal of iron from exposed alloys and is proportional to the chlorine content of the coal feed. Mechanisms for chlorine transport, concentration in the columns, and corrosion of the columns have now been developed. The formation of corrosive species and their transport as well as the corrosion process have been explained and duplicated in laboratory simulations. Methods for control of fractionator corrosion were proposed and tested on a limited basis in pilot plant operation. This completed activity was highly successful. The ORNL activity was complemented by activities at the Southwest Research Institute [an AR&TD Fossil Energy Materials Program project funded through The Metal Properties Council, Inc. (now The Materials Properties Council, Inc.)], the Institute of Mining and Minerals Research of the University of Kentucky, the International Coal Refining Company, and the coal liquefaction pilot plants. On the basis of the results of these activities, plant designers should now be able to incorporate and test various control measures in plant systems.

3. COAL GASIFICATION

3.1 TECHNOLOGY STATUS AND MATERIALS NEEDS

The several coal gasification processes currently under development for use in the United States are described in the program plan for FY 1981 (ref. 1). Although these processes differ considerably in detail and mode of operation, many features or process areas are common. Throughout this section, reference is made to low-, medium-, and high-Btu gas. Low-Btu ($3\text{--}5\text{ MJ/m}^3$) gas is made by gasifying coal with air and steam. To produce medium-Btu gas ($10\text{--}20\text{ MJ/m}^3$), coal is gasified with oxygen and steam. High-Btu (40 MJ/m^3) gas is produced by the catalytic methanation of the CO and H_2 in medium-Btu gas. In the discussions that follow, the gasification systems are divided into several common process areas, namely, coal preparation and feed systems, gasification pressure vessels, refractories for gasifiers, metal gasifier internals, gasifier heat exchangers, and gas cleanup and shift converter.

3.1.1 Coal Preparation and Feed Systems

Coal is fed into gasifiers as either a dry solid or a slurry with water or other liquid. Depending on the coal conversion process, several stages may be necessary to prepare the coal for injection. The equipment used in these stages includes storage hoppers; transport lines; pretreatment vessels; lock-hopper systems; and coal slurry feed systems, including slurry pumps, slurry feed lines, and slurry driers. Most of these components are exposed to fairly low temperatures ($<100^\circ\text{C}$) and to benign environments typically consisting of slurries mixed with water, oil, or inert gases at pressures up to 10 MPa. Some components, however, encounter severe service conditions. For example, mild oxidation of coal to destroy its caking qualities is carried out in vessels heated to 425°C in an oxygen atmosphere, and parts of the lock-hopper valve system that are close to the gasification reactors may be subjected to temperatures up to 425°C and pressures up to 11 MPa. The pretreatment unit generally consists of a vessel with a thermocouple assembly. The normal operating conditions for this unit are 400 to 425°C ; atmospheric pressure; coal, steam, and either air or O_2 reactants; and environments of

gas containing C_nH_{2n+2} , H_2 , CO , N_2 , H_2O , and CO_2 , with some H_2S . Even at these more severe conditions, materials-related problems are not expected under normal operating conditions. Materials now in use in the pretreatment units of pilot plants appear to be adequate; refractory-lined carbon steel shells should be suitable for commercial application up to $425^\circ C$. In the Hygas Pilot Plant, a type 304 stainless steel (ASTM A 312) pretreatment vessel was in use up to $650^\circ C$.

In some gasifiers, particularly high-pressure entrained-flow gasifiers, the char feed burner nozzle is exposed to high-temperature, high-velocity, erosive, and corrosive environments and is subject to thermal fatigue, which can be critical to performance.

The major materials-related problems with lock-hopper valves are abrasion and erosion of the balls and seats, which result in the inability to seal against the pressurized feed. Erosion is caused by impingement of solids passing through the open valve and by leakage across the sealing elements after the valve has been closed and a pressure differential created.²⁻⁴ Improved materials are needed for development of valves having satisfactory lifetimes at temperatures above $427^\circ C$ under conditions of erosive and abrasive wear.

Hoppers made of carbon steel appear to be quite adequate. Carbon steel components may be hardfaced to improve wear resistance. The use of materials such as Stellite 3, Stellite 6B (a Cr-Ni-B-Co alloy), and high-chromium white irons for ball and seat applications has improved component lives considerably. At present, high-chromium white iron alloys such as ASTM white cast iron with 28% chromium and 2.8% carbon (which showed more than 40 times the abrasion resistance of mild steel in bench-scale wear tests), type 440C stainless steel with a plasma coating of chromium oxide or tungsten carbide, and Graph-Air tool steels appear to be the most promising for this application.⁵ These alloys could prove to be more economical than cobalt-base alloys such as Stellites 3 and 6B, which are much more expensive.

In a slurry feed system, the components of interest include coal slurry storage vessels, slurry tanks, mixing and feed discharge pumps, driers and preheaters, and feed lines. Temperatures and pressures are

fairly low in most parts of the system; however, components between the discharge pump and gasifier may encounter temperatures and pressures as high as 425°C and 7 MPa, respectively. Slurry flow rates in the system normally range between 3 and 9 m/s. The environment in the system is usually not corrosive except when effluent gas is circulated to preheat the slurry before it is pumped into the gasifier. This gas may be corrosive because of such constituents as residual sulfur compounds and trace elements from coal. High pressure and temperature in some parts of the system, together with corrosive flue gas and, possibly, moisture associated with chemicals leached from the feedstock, tend to accelerate materials degradation through a combined action of erosion and corrosion.

The high-pressure slurry feed system brings coal up from atmospheric pressure to slightly above gasifier pressure, allowing the coal to be fed into the gasifier by gravity flow. Centrifugal pumps are generally used for low-pressure (≤ 4 -MPa) applications, whereas for higher pressure operations positive-displacement reciprocating pumps are required.⁶⁻⁹

Slurry pumps are subject to erosion from coal particles moving at high velocities. The discharge velocities across the valves of high-pressure pumps range from 3 to 9 m/s. The vanes of impeller pumps move through the slurry at a high velocity and are subject to a spectrum of velocities and effective angles of particle incidence, but the surfaces of the surrounding pump housing constrain and direct the flow. In addition to erosion and corrosion, the pumps may have to withstand impact, shock loading, fatigue stress, and so forth. Several cases of erosion failures in pump components ranging from impellers to casings have been reported in pilot plant operations.¹⁰

Abrasion or wear of pump parts is governed by the size of the solid particles, slurry concentration, velocity of flow, impingement angles, and so forth. If the impact is essentially normal to the surface, softer pump materials are selected; if the impact angle is relatively small with flow almost parallel to the surface, harder materials are selected. Parts of cast iron with Stellite hardfacing should perform satisfactorily under conditions of solid-particle impact.¹¹ Pumps with carbon or low-alloy casings, erosion-resistant impellers, and internal linings of 27% chromium high-carbon cast iron (HC-250) should also perform

adequately. Materials suitable for high-pressure pumps include forged 12% chromium stainless steel for casings, type 440C stainless steel for impeller blades, and tungsten carbide for balls and seats of associated valves. In addition to use of the best available materials for slurry feed pump parts, one should consider the use of disposable parts and liners and localized application of multilayered metallic and ceramic coatings, where possible, in high-wear areas.

Coal slurry feed lines are subject to both erosion and corrosion. The fluid flow in a typical slurry feed line is turbulent to maintain the particulates in suspension. This turbulent motion, however, causes severe erosion in pipe joints, elbows, valves, and at other locations where the flow is perturbed. Misalignments at joints and other manufacturing defects also contribute to increased erosion in the feed lines. The slurry feed line should be designed for an optimum velocity high enough to prevent particle drag but low enough to prevent excessive friction and damaging particle impingement.

Carbon steel for low-temperature ($<100^{\circ}\text{C}$) feed lines and austenitic stainless steels, such as types 347 and 316, for higher-temperature (up to 540°C) applications should perform satisfactorily. Hardfaced inserts must be considered where the flow changes direction. Erosion in 90° elbows has been reduced by replacing the elbow with a tee containing a blocked branch. Abrasive particles collect in the blocked branch and provide an abrasion-resistant layer over the most critical area of the line. The use of a blocked tee also permits the line to be opened periodically for inspection and maintenance. As with slurry pumps, slurry lines need to be examined closely, and materials programs to address erosion need to be initiated.

Unwelded alloy 800 appears to be a suitable material for the pre-heater coils under normal operation; types 304 and 316 stainless steel should perform equally well. Because the first few coils of the heater remain much cooler than those near the fired end, consideration should be given to the use of low-alloy 2.25Cr-1Mo steel for the low-temperature section of the coil, followed by types 304 and 316 coil segments as the temperature increases.^{12,13}

3.1.2 Gasification Pressure Vessels

The specific pressure, temperature, and train capacity needed to make a given gasification process economical have a major influence on the selection of the pressure vessel material and construction methods, and there are literally a hundred or more gasification schemes.¹⁴ These range in operating pressure from near atmospheric to more than 9.3 MPa. Gas temperatures vary from 650 to 1650°C, and coal input train capacities for current designs range from 725 to 2500 tons/d (ref. 15), although the capacity will probably center around 900 to 1000 tons/d. As a result of the wide diversity in the operating parameters, it is virtually impossible to define a set of operating parameters that can be used to develop a conceptual gasifier pressure vessel design for materials selection and performance evaluation. Without such a design, it is difficult to quantify the economic impact of alternative pressure vessel alloys and construction methods.

In his description of the construction of coal conversion vessels, Hicklen¹⁶ narrows the choice of gasifier pressure vessel materials to five alloys identified in Table II.1. The A 516-70 is often described as a carbon-manganese (C-Mn) or carbon-silicon (C-Si) steel and would be selected when wall thickness does not exceed 75 mm (3 in.). The SA-302-C and SA-533-B steels, on the other hand, are identified as prime candidates for vessels that see service to 370°C or for vessels whose wall thicknesses range from 50 to 250 mm (2-10 in.). Both steels contain 0.5% Ni for hardenability and 0.5% Mo for strength and resistance to hydrogen attack. These steels are often mentioned in connection with gasifier pressure vessel service.¹⁵ Both have excellent strength to 371°C. The fourth and fifth steels listed in Table II.1 are the low-alloy SA-387, grade 22, class 2, and SA-387, grade 21, class 2, chromium-molybdenum steels: 2.25Cr-1Mo and 3Cr-1Mo. These are popular pressure vessel steels in the petrochemical and petroleum industries because of their good strength properties ranging from 370 to 480°C. The chromium imparts resistance to oxidation and hydrogen attack, and the molybdenum imparts high-temperature strength. For gasifier applications, these steels as currently approved in the Code for pressure vessel application are of less interest than are the A 302-C and A 533-B, class 1, steels because of the lower allowable

Table II.1 Candidate plate steels for pressure vessels with wall thickness requirements of greater than 0.1 m

^dCurrent practice normally limits the specification to this thickness.

stresses at temperatures up to 370°C. However, both of these low-alloy steels can be heat treated to produce much higher strength.^{17,18} For example, the quenched and tempered A 542 version of 2.25Cr-1Mo has four higher strength classes.

The economic savings that would accrue from the use of an advanced steel would be many times the cost to the government for the development and code qualification of such a material. This conclusion is drawn from a study of assessment reports written from 1975 to 1982, which include requirements for high-Btu gasification processes. These reports reflect the opinions and technical judgments of people representing material producers, vessel fabricators, architect engineers, vessel users, code bodies, and research funding agencies.¹⁷⁻²⁶

The need for a high-strength low-alloy steel for hydrogen service ranging from 316 to 538°C is recognized by the technical community, and several approaches have been taken to meet this need. One approach, supported by the American Petroleum Institute (API) and The Materials Properties Council, Inc. (MPC), is to upgrade the 2.25Cr-1Mo steel by restricting the composition and introducing heat treatments (accelerated cooling, lower tempering temperatures) to improve short-time properties.²⁷ Another approach, taken by several industrial laboratories, such as U.S. Steel,²⁸ Climax Molybdenum,²⁹ and Japan Steel Works,³⁰ is to include microalloying additions (V, Ti, and B) in a restricted-chemistry version of 2.25Cr-1Mo steel or 3Cr-1Mo steel to improve the heat-treating response and long-time strength properties. The first approach represents a near-term minimum-expense solution to the problem and has been formulated into a program by Subcommittee 1 of MPC. Clearly, DOE has little or no justification for developing a similar program. Action on the second approach has been deferred by industry on the basis that it will take a longer time and require more money to reach the ultimate objective of a code-qualified alloy with higher allowable design stresses and improved corrosion resistance. The development program on the microalloyed steel fits well within the mission of DOE in advancing the technology of coal conversion. Such a program has higher potential, in terms of applicability, than does the MPC program. Development of the microalloyed steel has a somewhat higher risk, so near-term returns are unlikely.

Development by DOE of a 3Cr-1.5Mo-0.1V alloy to the point that a Code case for low-temperature applications could be made should provide the needed confidence by industry to ensure the continued development, incorporation into the ASME Code, and use of the alloy for its broad range of applications. Quite importantly, the steel developed would offer a domestic alternative to foreign-produced alloys.

3.1.3 Refractories for Gasifiers

Gasifier refractories can be divided into low- and high-temperature applications. Low-temperature applications are those below about 1100°C, in which coal ash is still in solid form and does not react with the refractory liner of the gasifier. Degradation mechanisms are mainly gaseous corrosion and erosion by particulates. In addition to applications in dry-ash and agglomerating ash gasifiers, such refractories are useful in pressurized fluidized-bed combustors, process heaters, cyclones, and associated piping. With cooling, low-temperature refractories can be substituted for refractories normally used in high-temperature applications (e.g., water-cooled refractory liners in high-temperature entrained gasifiers). High-temperature applications generally involve temperatures above about 1250°C, at which coal ash is molten and reacts with the refractory liner. The main degradation mechanisms are (1) corrosion-erosion by molten slag and (2) damage caused by thermally induced mechanical stress. Typical applications are in slagging gasifiers and combustors. Refractories for molten-salt gasifiers may also be classified with this group, although temperatures are much lower (about 980°C), and no molten slag is present.

Refractories for low-temperature applications can generally be modeled after those used in the petrochemical industry.^{31,32} Refractory concretes, both dense and insulating types, are standard materials in that industry. Results from extensive testing and evaluation programs to select the most suitable refractories for these applications have indicated that suitable low-cost materials are available commercially.³³

Refractory service conditions in slagging gasifiers are much more severe than the conditions in dry-ash gasifiers because of the higher temperatures in slagging gasifiers and the corrosiveness of the slag. In the early 1970s slagging gasifier technology was severely limited by lack of

suitable refractories. Therefore, a DOE program was initiated at Argonne National Laboratory (ANL) to identify the refractory-bond systems best suitable for slagging gasifier applications.

Refractory experience in blast furnaces³⁴ served as a guide for refractory applications in slagging gasifiers. However, the atmosphere in a gasifier contains considerable sulfur and, most important, is more oxidizing. Consequently, the slag generally does not contain metallic iron, but may contain appreciable quantities (as high as 25%) of iron oxide. Therefore, successful performance in a blast furnace does not guarantee adequate performance in a gasifier. Thermodynamically, none of the currently available refractories are stable in the presence of typical coal slags. Therefore, the approach to ensure satisfactory operation is to modify refractory composition and structure, slag composition (through the addition of fluxing agents to the coal), and/or operating conditions to promote the formation of protective layers and/or to alter the kinetics of the refractory slag corrosion reactions.

One approach, and still the only viable method for operating at temperatures above 1600°C, is to cool extensively by using water walls coated with a thin, sacrificial refractory lining. This approach has limited practical application because the large heat loss drastically reduces the overall efficiency of the gasification system. For gasifiers operating at lower temperatures (1400–1600°C), the essentially qualitative laboratory corrosion tests at Argonne indicated that thick refractory linings (with or without water cooling) of chromium-base refractories should be satisfactory in many applications.³⁵⁻⁴²

In particular, a fused cast microchromite (a chromia-magnesia spinel containing 75–80 wt % Cr_2O_3) was quite resistant to slag attack in laboratory tests. More recently, a number of refractory material suppliers, at least some of whom were encouraged by these laboratory results, developed sintered bricks of similar composition. Subsequent quantitative work at Argonne confirmed the superiority of the microchromite refractories, and the laboratory results are supported by actual gasifier service.⁴³⁻⁴⁶

The early work on the fused cast material indicated that while the microchromite had superior corrosion resistance, its resistance to thermal

shock and/or thermal-stress-induced fracture was unsatisfactory. Thermal-shock damage testing undertaken in a separate program at ANL confirmed that many of the picrochromite bricks then commercially available were in fact lower in thermal-shock damage resistance than many alumina-based refractories.⁴⁷ Further research at ANL showed that thermal-shock damage resistance could be improved by microstructural alterations that improved fracture toughness.⁴⁸ One composition, which includes about 17% ZrO_2 , was demonstrated to have about five times the fracture toughness of pure magnesium chromite.

In addition to the work on picrochromite, tests at ANL (which were again confirmed by limited plant data) indicate that (at least in acidic slags) solid solution refractories of the composition 75% Cr_2O_3 -25% Al_2O_3 have slag corrosion resistance comparable to that of the picrochromites.⁴⁵ Also, these materials appear to possess superior thermal-mechanical properties.⁴⁷

Because some types of slagging coal gasification systems can operate at rather low temperatures (1400-1500°C) without a significant loss in efficiency, and because the corrosion rates of the refractories generally decrease as temperature decreases, the limiting factor in operating at relatively low temperatures in these processes is often the plugging of the slag tap hole. Because plugging of this hole is directly related to the flow properties of the slag, the criterion of maintaining the viscosity of the slag at less than 25 Pa·s (generally accepted as the point at which slag starts to flow under its own weight) may govern the selection of the process temperature, particularly in first-generation gasifiers. The viscosity data necessary to run experiments at selected viscosities and thus determine the effect of viscosity on refractory material wastage was not available at the start of this program. Therefore, the data were developed in a separate program at ANL.⁴⁹⁻⁵¹ Data developed at ANL have demonstrated that slag temperature is a much more important variable than slag viscosity in controlling refractory material corrosion. Thus, the use of fluxes (e.g., CaO or dolomite) to produce adequately low slag viscosities at temperatures sufficiently low to assure satisfactory operating life of refractories is a viable method of operation.⁴⁵

The environments found in dry-ash gasifiers (temperatures < 1200°C) are significantly less demanding of refractory materials than are those of slagging gasifiers. To date, no critical problems have been identified from pilot plant exposures. Laboratory tests have shown that existing low-cost intermediate alumina products may give satisfactory service; however, some questions remain. Results of research at Babcock & Wilcox indicated that the use of metal-fiber-reinforced monolithic linings results in less cracking during heatup. However, laboratory tests at the Virginia Polytechnic Institute indicated that carbon monoxide disintegration can occur in metal-fiber-reinforced monolithics as well as in materials with as little as 0.1% metallic iron. Thus, further research may be needed to characterize carbon monoxide disintegration, especially in metal-fiber-containing refractories. Also, the mechanical properties, in particular the high-temperature creep of metal-fiber monolithics, need to be characterized. Long-duration exposures of promising candidate concretes are needed to identify optimal materials and potential refractory material problems caused by upset conditions.

Refractory linings for gasifier transfer lines need attention. Available refractories have undergone a limited number of tests under conditions of flow and entrained-particle content typical of gasifiers. Most testing was under more severe conditions, so present units may be over-designed. A test program should be considered to identify a material with optimal insulating value and resistance to erosion.

3.1.4 Metal Gasifier Internals

In contrast to the design situation for vessels and piping, no code or standard exists for vessel internals and long-life external components, especially for service in corrosive-erosive environments at elevated temperatures.

Natesan⁵² has published reviews of corrosion behavior of materials in high-Btu coal gasifier environments as well as in low- and medium-Btu environments.^{53,54} These reviews clearly establish that sulfidation is the major mode of material attack in these systems and that a viable alloy should develop protective surface oxide scales during the service life of the component.

Results from a recently completed program administered by the MPC show that several commercially available alloys exhibit acceptable corrosion rates of about 0.6 mm/year (24 mils/year) based on 10,000-h exposures. However, the corrosion experiments were conducted at oxygen partial pressures of $\geq 10^3$ times the threshold for oxide formation. The available data have been analyzed in detail to establish a criterion for alloy composition with minimum corrosion rate.⁵⁵ On the basis of the combined criteria for Fe:Cr ratios in the range 1.6 to 2.0 and an Ni:Cr ratio of about 1.0, the following alloy compositions have acceptable metal loss rates: 25 to 28 wt % Cr, 25 to 28 wt % Ni, and 50 to 44 wt % Fe. Alloys such as Incoloy 800 and type 310 stainless steel fall on either side of this range. The analysis indicates that the calculated compositional range for Fe, Cr, and Ni can be used as a base to develop optimized alloys with minor alloying additions that improve scale adhesion, self-healing, and resistance to thermal cycling, and thereby provide acceptable corrosion performance in coal gasification atmospheres.

Metallic materials for internal members in a gasification system must operate under environmental conditions that have strongly deleterious effects on mechanical properties. The rupture strength of the best of these materials is quite low in the temperature range (800–1000°C) that typifies most second-generation gasification processes. The gasification environment may result in even lower levels of stress-rupture strength. Wells and coworkers reported 27 to 86% losses in stress-rupture life as a consequence of testing various metallic materials in high-Btu gasification environments rather than in air.⁵⁶ Their test specimens failed in 100 to 300 h at 815°C at stresses from 36 to 90 MPa. These short rupture times conflict with the desired useful life of 20,000 h (2.3 years) for commercial applications.

The effects of mixed-gas environments on mechanical properties are primarily determined at a fixed oxygen and sulfur activity in the gas phase. Although the uniaxial tensile data for several alloys preexposed to complex gas mixtures showed a loss in strength and tensile ductility, the residual properties are generally adequate for the internal components.⁵⁷⁻⁵⁹ However, the data are based on 1000-h preexposure times,

and the effect of longer exposure times was not established. The results of uniaxial and biaxial stress-rupture tests showed a loss in the 1000-h rupture strength of the materials preexposed to mixed-gas environments. Recently, Natesan showed that if the test environment is such that the alloy can develop a protective oxide scale (i.e., the oxygen partial pressure is above the threshold partial pressure needed for oxide formation), then the creep properties of the materials are not significantly affected.⁶⁰ This effect of test environment has been confirmed by experiments in air, low- p_{O_2} , and oxygen-sulfur atmospheres with p_{O_2} greater than $p_{O_2}(\text{threshold})$. On the other hand, if the test environment is such that p_{O_2} is less than $p_{O_2}(\text{threshold})$, then the alloy exhibits significant sulfidation and substantial degradation in the creep properties, with significantly lower rupture life and rupture strain. On the basis of the morphological features of creep-tested specimens, it was concluded that the breakdown or cracking of the protective oxide scale (i.e., mechanical properties of the scales) may determine the degree to which the oxygen-sulfur environment degrades the creep properties of the material. The mechanical testing effort is expected to continue into low-chromium heat exchanger materials with and without surface coatings.

Coal gasification environments generally contain particulates such as char and ash, which can interact both chemically and physically with materials of construction of various components. Char, derived from coal, is a major ingredient in any gasification scheme. The reactivity of chars can vary widely, depending on the coal from which the char was derived and processing conditions. In general, chars have high carbon contents and may contain appreciable amounts of sulfur and mineral matter. The corrosion behavior of materials used in elevated-temperature regions of the gasifiers can be affected by (1) the deposition of char and ash particles on the components, which thereby prevents the development of continuous protective oxide scales, and (2) the gasification of sulfur in the char to H_2S , which alters the mixed-gas chemistry to higher sulfur potentials in the vicinity of the component materials.

Very limited work is being conducted to evaluate the role of particulates on the corrosion behavior of materials.^{61,62} The meager data now available show that the presence of particulates such as char can

alter the mode of attack from oxidation to sulfidation. Furthermore, the corrosion rates at elevated test pressures in particle-laden gases were significantly greater than those in atmospheric pressure tests. In the selection of an alloy for use in internal components of coal gasification systems, the available results dictate that the char effect be considered, especially when the sulfur content of the char is high. To reduce the corrosion rates to acceptable levels, the alloy selected should develop protective oxide scales even in the presence of one to two orders of magnitude higher sulfur potential (caused by sulfur in the char) than in the gas phase.

Sulfidation is the major type of corrosion in environments that prevail in coal gasification systems. Therefore, it is essential that the alloys develop a protective oxide scale during the service life of the component. It should also be recognized that various ongoing corrosion programs involve evaluation of commercial materials, but that very little work is being conducted to modify or tailor alloys for application in coal conversion systems. Research activities in the areas of alloy composition modification, alloy coatings, alloy claddings, and weld overlays should be conducted for development of materials that resist corrosion and erosion when exposed to coal gasifier environments.

Significant additional work is required to establish the mechanisms of scale formation, adhesion and plasticity of the scales, and transport properties of cations (such as Cr, Fe, and Ni) and anions (such as O, S, and C) in and across the scale. Most alloys tested in a mixed-gas environment exhibit breakaway or accelerated corrosion at some stage of exposure, depending on temperature and partial pressures of sulfur and oxygen in the environment. It is imperative that alloys selected for application in coal conversion systems not exhibit breakaway corrosion during the service life of the component. However, very little is known about the mechanisms that cause accelerated corrosion. Additional work is required in this area so that the contents of minor alloying additions can be optimized judiciously.

Most long-term kinetic work has been conducted with commercial alloys, primarily in environments with fixed oxygen and sulfur partial pressures. Without a substantial understanding of the corrosion processes

that occur in these environments, it is difficult to extrapolate and predict the corrosion rate for a given alloy under various practical conditions from the kinetic information obtained at a fixed gas composition. Several investigators have observed breakaway corrosion of alloys exposed to multicomponent gas environments. It has been established that sulfur in the gas environment accelerates the outward migration of base metal elements such as iron and nickel through the oxide scale leading to sulfidation at the external gas-scale interface. Significant additional research is required to develop predictive capability for onset of breakaway processes so that alloy modification can be approached systematically. It is also essential to develop a fundamental understanding of the role of chlorine in the gas phase on the corrosion of metallic materials of interest in moderate- to high-temperature components for coal gasification systems.

Experimental programs are needed to determine the fundamental aspects of the corrosion of materials exposed to particle-laden gas environments. The corrosion rates of materials are substantially greater at higher pressures if the experiments are conducted in particle-laden mixed-gas environments. Therefore, it is necessary to establish the influence of high pressures on the erosion parameters, such as particle velocity, to develop a better understanding of material behavior under corrosive-erosive conditions.

The effects of mixed-gas environments on mechanical properties must be known to establish the design and performance requirements of various components in a coal gasification system. Substantial additional work is needed to determine the long-term creep properties and to develop creep correlations that are useful to component designers.

Programs should be supported to design alloys that resist corrosion in complex gas atmospheres. Previous and ongoing programs have shown that the usefulness of conventional off-the-shelf engineering materials as internal members of a gasification plant is limited. Greater emphasis must be placed on novel design approaches that minimize the number of internal components and on alternative materials to achieve the desired lifetimes for the internal components. Avenues that involve alloy modification (composition, second-phase particles, etc.) and surface modification (duplex tubes, coatings, and weld overlays) should be supported at

reasonable funding levels over a long period of time. The results from such programs not only will have a large impact on component performance but may be the only approach that can make these gasification schemes viable.

Studies of surface modification to improve lifetimes of internal components should have attendant studies for nondestructive testing (ultrasonics and eddy current) of the initial and interim surface conditions.

3.1.5 Heat Exchangers

Heat exchangers and waste heat boilers are generally absent from pilot plant systems but are essential in larger demonstration- and commercial-size gasification units to increase the process efficiency and to reduce the plant operating cost. Heat exchangers are an integral part of both dry-ash and slagging gasification processes. The raw gas outlet temperatures can range from about 1000°C or below in the dry-ash process to as high as 1400°C in slagging concepts. The so-called second-generation processes will produce raw gas rich in carbon monoxide and hydrogen; as a result, the inlet gas to the heat exchangers and waste heat boilers will have fairly low oxygen partial pressures and moderate to high sulfur partial pressures, depending on the coal feedstock.

Very little design information is available for the heat exchangers and waste heat boilers considered for various processes. A 150-ton/d demonstration plant based on a Texaco gasification process has been in operation since 1978 at the Ruhrchemie petrochemical plant in Oberhausen, Federal Republic of Germany. A 150 ton/d plant for NH₃ production, also based on a Texaco process, is in operation at Muscle Shoals, Alabama. A Texaco gasifier is also used in Southern California Edison's 100-MW(e) combined-cycle generating plant near Barstow, California. All these have heat exchangers or waste heat boilers operating with metal temperatures as high as possible.

Another process of considerable interest is the Shell-Koppers, a high-pressure entrained-flow process that has its origin in the atmospheric-pressure Koppers-Totzek technology. This process has reached pilot plant stage with the construction of a 150-ton/d unit at Harburg, Federal Republic of Germany. The process schematic shows waste heat boilers upstream of the cyclones. On the other hand, the Saarberg-Otto

entrained low-Btu gasifier scheme shows waste heat boilers downstream of the cyclones. It is clear that the particle loading of the inlet gas stream will largely depend on the process concept, the raw-gas outlet temperature, and the hot-gas cleanup technology available. Even with sophisticated hot-gas cleanup systems, slag and particulate carryovers to the extent of 10% with particle sizes of 5 μm or less are expected.

Only limited technical information is available to predict material performance (lifetime, corrosion rates) in these heat exchangers and waste heat boilers. A substantial amount of corrosion information in the range 400 to 700°C in simulated low- and medium-Btu gasification atmospheres is required for judicious materials selection in these applications. The results developed thus far show that the presence of heat flux can accelerate the corrosion scale development and thus lead to a significant increase in scale thicknesses, especially at high gas temperatures.⁶³ Further data are needed to identify the roles of critical variables such as metal and gas temperatures and gas chemistry on corrosion rates, and to establish the process variable envelopes for several commercial materials to be used in heat exchangers and waste heat boilers.

As pointed out, structural ceramic materials may have potential for use as heat exchanger components at temperatures greater than 650°C, where problems are encountered with metallic components. Results of corrosion studies on silicon carbide ceramic heat exchanger tubes indicate that this material may be useful at temperatures up to at least 1000°C in a clean, nonslagging environment.⁶⁴⁻⁶⁷ At higher temperatures, or in the presence of slag, degradation of mechanical strength is observed. The iron oxide component of coal slags was found to react with the silicon carbide to form a low-melting phase which penetrates and causes weakening of the ceramic grain boundaries. Further studies could be carried out to determine the potential lifetime of these materials in the 1000°C temperature region. The design, fabrication, and application of structural ceramic components is described further in Chapter 4, Structural Ceramics for Heat Engines and Heat Recovery.

3.1.6 Gas Cleanup System and Shift Converter

Coal-derived gaseous fuels leave most gasifiers at high temperature and pressure. These fuels are laden with chemical impurities (such as

H₂S, NH₃, H₂S, COS, HCN, oil, tar acids, and chlorides) and entrained solids (such as char, ash, and unburned coal). The raw product gas must be purified for several reasons, the most important of which are (1) to prevent entrained solids from interfering with operations downstream of the gasifier that produce high-Btu gas, (2) to increase life expectancy of downstream equipment and reduce equipment downtime, (3) to protect sensitive downstream catalysts, (4) to minimize erosion of hot turbine parts, and (5) to comply with air-pollution standards and with purity standards for pipeline distribution. Gas cleanup may be accomplished through either low- or high-temperature methods; only the latter are discussed here.

A major problem encountered in hot purification processes is erosion of high-efficiency solids removal equipment (i.e., cyclones and filters). Materials problems in the hot-gas solids separation step include erosion, deposition, and corrosion in the gasifier overhead lines and cyclones.

In coal conversion processes, construction materials are subjected to the synergistic effects of erosion and corrosion at both low and high temperatures and at high pressures. In the absence of corrosion, the material removal rate is controlled by ductile or brittle erosion. If corrosion also occurs, erosion of the corrosion product rather than the substrate will occur, and the rate of erosion of the corrosion product can be greater or less than that of the substrate.

4. STRUCTURAL CERAMICS FOR HEAT ENGINES AND HEAT RECOVERY

4.1 TECHNOLOGY STATUS AND MATERIALS NEEDS

Structural ceramics are of interest in fossil energy systems, particularly for use in heat engines and heat recovery devices, because of their ability to withstand high temperatures and corrosive-erosive environments. The term structural ceramic as used in this text describes a ceramic material to be employed under conditions in which the maximum working stress is an appreciable fraction of the average measured fracture stress for the material. We have chosen this definition to designate a structural ceramic as a material with ability to maintain its mechanical, physical, and dimensional stability under stress and various environmental conditions rather than a more arbitrary definition based on less relevant characteristics such as melting point. Interest in ceramic materials for potential applications in fossil energy systems focuses primarily on high-temperature environments. Most anticipated fossil energy applications for this type of material involve temperatures above 1100°C.

Presently, this plan almost exclusively addresses structural ceramics for heat engine and heat recovery applications because of the high temperatures typical of these systems. However, for certain applications, nonceramic alloy development and evaluation also need to be addressed. Collaboration with industrial organizations knowledgeable about these systems will be undertaken to assess the needs for nonceramic materials.

4.1.1 Heat Engines

Stationary heat engines for the production of power are an important application for coal and coal-derived fuels, and they represent significant materials problems not always encountered in engines that use petroleum fuels or natural gas. In particular, corrosion of engine materials by ash particles (or, if the ash is molten, by slags) and gaseous combustion products and erosion of surfaces by ash particles are unique problems for heat engine materials when coal-derived fuels are used. Gas turbine and diesel engines are the primary engine types for use in fossil systems. Heated air and combustion gases from coal burned in a

pressurized fluidized-bed combustor, gases from intermediate- or low-Btu gasifiers, and coal-derived fuels (liquids and solids) may all be used in gas turbine systems.

Potential improvements in the efficiency of gas turbine systems for producing electricity from coal or other fossil fuels by use of structural ceramics for selected components have been known for some time. Efforts to use ceramics in gas turbines were first formalized in the United States by the National Advisory Committee for Aeronautics [now National Aeronautics and Space Administration (NASA)] in the 1950s and later in a program undertaken in the early 1970s and funded by the Defense Advanced Research Projects Agency (DARPA) of the Department of Defense (DOD). During the DARPA program it became obvious that the available structural ceramics of the 1971 period were not adequate for use in gas turbines, but great strides were made in developing the methodology for design with brittle materials.

Some potential benefits anticipated with the use of uncooled ceramic turbines having turbine-inlet temperatures above about 1370°C were reported in October 1976 by the Committee on the Use of Ceramics in Industrial Gas Turbines.¹ This committee concluded that turbine-inlet temperatures of 1370°C and above could increase the efficiency of a combined-cycle power plant by 2 to 3% to a net efficiency of over 50%, because the conversion efficiency of a gas turbine is roughly proportional to the absolute turbine-inlet temperatures if the pressure ratio is held constant. This is a very significant increase, which could ultimately have a major national impact on fuel consumption. The conclusions of this committee were fairly similar to those reached in 1975 by the National Materials Advisory Board,² which are still relevant today. The high-temperature combustion and hot walls of the combustor are of particular importance for lower-rank coal fuels, which will burn more completely and with lower emissions in the high-temperature radiant combustor.

For example, both of the advanced ceramic gas turbine (AGT) efforts currently being funded within the DOE Conservation Program have high turbine inlet temperatures as a principal goal. This program includes two major ceramic gas turbine efforts identified as the AGT 101 and

AGT 100 engines. The AGT 101 engine being developed for vehicular propulsion by the Garrett-Ford team has as its final configuration (Mod II) an all-ceramic structure capable of a 1370°C turbine inlet temperature. The AGT 100 engine, also being developed for vehicular propulsion by the Allison Gas Turbine-Pontiac team, has the major goal of demonstrating a final engine configuration capable of operating with a turbine inlet temperature of 1288°C . Alternative fuels capability is also an important goal of the AGT programs. The potential advantages of high turbine inlet temperatures in providing higher turbine engine efficiencies and alternative fuels capability for the AGT type engines (~ 70 kW) also apply to larger turbines of interest for cogeneration and utility application (5-100 MW).

In Japan the Agency of Industrial Science and Technology (AIST) has been conducting a large-scale seven-year program to demonstrate a 100-MW AGT with a combined plant efficiency greater than 50%. This program is part of the "Moonlight" project, which began in 1978. The AGT is a large stationary gas turbine that drives an electrical power generator and includes exhaust heat recovery to drive a steam turbine power generator. The turbine input temperature is 1300°C . This program has included ceramic materials development; however, the available structural ceramics during the period of performance for this project were not adequate for large turbine components, and cooled superalloy components are being used in the demonstration. The AIST and the parent Ministry of International Trade and Industry consider structural ("fine") ceramics to be a very high-priority development task in Japan, and they continue to fund and to promote aggressively ceramic development for heat engine application.

Silicon carbide (SiC) and silicon nitride (Si_3N_4) are the primary candidates for use in the AGT because of their high-temperature strength and oxidation resistance. Corrosion and erosion by particulate and gaseous combustion products of coal represent a unique requirement for turbines fired directly with fossil fuels. The principal developmental requirement for these materials in gas turbine applications is mechanical reliability at 1300 to 1400°C in corrosive and erosive atmospheres. Development of the required mechanical reliability can be realized only by

a balanced effort that addresses the undesirable creation of flaws in raw materials and component processing; characterization of the behavior of flaws as a function of stress, environment, temperature, and time; and the design of components by use of realistic statistical descriptions of flaw populations and strength behavior.

A variety of ceramic materials have been and are still being investigated in various DOE and DOD programs for application at high stress and high temperatures in both heat engines and heat exchangers. These include ceramics wherein the major phase is silicon carbide, silicon nitride, silicon-aluminum oxynitrides, and others, but most work on national programs has been performed on silicon-carbide and silicon nitride. To address the materials research problems adequately in the area of structural ceramics and to attain significant results within the next five years, the expected available AR&TD Fossil Energy Materials Program tasks will initially be focused primarily on SiC-base ceramics for several reasons. In past work on employing structural ceramics in heat engines and heat exchangers, the data clearly show that both dense SiC and siliconized SiC ceramics have considerable potential as high-temperature engineering materials. In addition, several industrial firms manufacture these SiC-base ceramics, and it is reasonable to expect positive results from this program to be transferred to at least some of the firms and thereby to generate industrial sources of improved SiC ceramics for future fossil energy systems. Potentially competing materials are Si_3N_4 -base ceramics and related ceramics, primarily because of desirable high-temperature properties of this material and the large amount of research conducted on it in previous DOD and in current DOE heat engine programs. Other structural ceramics such as the sialons (e.g., the Si-Al-O-N system), which are related to the Si_3N_4 ceramics, or toughened ceramics (e.g., SiC-fiber-reinforced ceramics and transformation-toughened systems) are also considered as candidate materials with excellent potential and will be factored into the program as it progresses.

To overcome brittle fracture characteristics while still taking advantage of excellent high-temperature properties, the structural ceramic materials technology program should include ceramic-matrix composite

systems for possible applications in gas turbines.³ (A ceramic-matrix composite as discussed here is defined as a material having a continuous homogeneous ceramic phase, reinforced with at least one other phase, which may or may not be continuous. The added phases may be either particulate or fibrous and may be ceramic or possibly metallic.) Available data suggest that the dispersed phases in ceramic-matrix composites greatly increase the fracture energy (toughness) and effectively arrest catastrophic crack propagation in the brittle major phase when the secondary phase has the correct mechanical and geometric properties. Toughness must be improved without degrading the fracture strength for the improvements to be usable.

Diesel engines are the other heat engine alternative for combustion of fossil fuels. Coal slurries or coal gases can be burned in diesel engines for power generation. Erosion, corrosion, and wear of the cylinder, piston, rings, and valves by ash from coal represent significant materials problems. Ceramic coatings on cast-iron components or monolithic ceramics may be necessary for the wear resistance required in the combustion chamber. High-temperature ($\sim 1000^{\circ}\text{C}$) radiant uncooled combustion chamber components will be required to achieve acceptable ignition delay, combustion efficiency, and gaseous emissions when coal or coal-derived fuels are used. The requirement of uncooled high-temperature combustion chamber materials that are resistant to corrosion and erosion by ash particles and gaseous products restricts the materials of construction to ceramics. High-temperature "adiabatic" engines introduce other materials problems not otherwise encountered. High-temperature lubrication and tribology requirements are not well defined, but low friction is obviously important and also limits materials selection to ceramics. Cyclic fatigue of materials at elevated temperatures could possibly be a problem, but it is not well-characterized or understood.

Adiabatic diesel engines for transportation are being developed by DOD and by DOE Conservation and Renewable Energy. The Army Tank Command is developing uncooled engines for tanks and other armored vehicles to eliminate vulnerable cooling systems. The DOE Office of Vehicles and Engines Research and Development is developing adiabatic diesel components

in the Heavy Duty Transport Program for fuel conservation. The high-temperature exhaust is used for turbocharging and turbocompounding, that is, expanding the exhaust through a gas turbine geared to the diesel engine's crankshaft.

Zirconia is a promising material for the transportation applications of adiabatic diesels. Zirconia has a coefficient of thermal expansion (CTE) that matches the CTE of cast iron fairly closely. The compatibility of CTE makes substitution of zirconia into conventional engines attractive. Zirconia is also a very good thermal insulator for a structural ceramic. Plasma-sprayed zirconia on cast iron makes an excellent thermal barrier. Partially stabilized zirconia (PSZ) is very strong and relatively tough. The critical question for PSZ is whether or not the time-dependent behavior at operating temperatures in the engine will be adequate.

A new program entitled Ceramic Technology for Advanced Heat Engines was initiated by the DOE Office of Transportation Systems under the Assistant Secretary for Conservation and Renewable Energy in FY 1983 as part of a major new DOE effort. In addition, a major program initiative in structural ceramic technology has been undertaken by NASA, and this program is the responsibility of the NASA Lewis Research Center. The DOE program, a generic structural ceramic materials program, has the purpose of developing the industrial technology base needed for the AGT and adiabatic diesel engines for transportation. The NASA program is limited to turbine applications for aeronautics and is also generic.

Many of the structural ceramic work objectives to be conducted in the DOE and NASA programs are common to the needs and objectives of the Fossil Energy Materials Program.

4.1.2 Heat Recovery

The technology for transferring heat from one working fluid to another, such as gases, through a metallic heat exchanger is well established. Materials for metallic heat exchangers in combustion systems are discussed in Chap. 5.

Structural ceramics in heat exchangers for heat recovery are of interest only at temperatures high enough and in environments hostile

enough that available alloys are unsuitable because of their lack of the mechanical strength or the corrosion resistance required. There are two potential applications for ceramic heat exchangers in fossil energy systems. In one, the heat exchanger is used to transfer heat from a fossil-fuel-firing process to a high-pressure working fluid such as helium for use in a closed-cycle Brayton system or to air or nitrogen for use in an open-cycle Brayton or possibly some other similar system. The second application uses the heat exchanger (recuperator) to recover heat from hot waste gases by preheating combustion air, batch materials, or process reactants or for some similar purpose.

Outside the AR&TD program, materials research and development on the high-temperature high-pressure unit outside the AR&TD program has been sponsored primarily by the Electric Power Research Institute (EPRI) in a recent Coal-Fired Prototype High-Temperature Continuous Flow Heat Exchanger Program. Results of that program provided considerable understanding of structural ceramics technology relevant to advanced heat exchangers, including tube-to-tube and tube-to-header joining needs. The heat exchanger design consisted of tubular inlet and outlet headers joined by U-tubes, which are the heat transfer surfaces.^{4,5} Results from this program clearly indicated significant potential for ceramic heat exchangers for high-temperature applications. The design in the EPRI program focused exclusively on a tube-and-header with folded cross flow because of the energy flux requirements and the need to ensure that the coal slag on the hot face did not adversely foul the heat exchanger during service. Availability of candidate structural ceramics in a limited number of shapes was also a significant factor in determining several aspects of these early designs.

The research and development on ceramic heat exchangers for waste heat recovery has been conducted under both government and private sponsorship. Two earlier demonstration programs on recuperative ceramic heat exchangers were funded by the Office of Industrial Applications and Commercialization of DOE (INDUS-DOE). Two program efforts on tubular ceramic recuperators, supported by the Industrial Conservation Program through the Idaho Operations Office of DOE, are under way with industrial

contractors. Specifically, the Babcock & Wilcox and the Garrett-AiResearch program efforts are directed to heat recovery from steel soaking pits and aluminum remelt furnaces. Both programs will use ceramic recuperators in the high-temperature regions of the burner ducts. The design phase of the recuperators is complete, and they are currently under construction. In addition, substantial efforts on ceramic recuperators are being supported by the Gas Research Institute. A program on materials for waste heat utilization is also under way at ORNL, supported by the DOE Industrial Conservation Program. Two other programs, the Ceramic Heat Exchangers for High-Temperature Fossil Fuel Combustion Environments Program at ORNL and the Ceramic Joining Project at the Solar Division of International Harvester, were initiated by the DOE Office of Fossil Fuel Utilization and were managed by Pittsburgh Energy Technology Center in the Heat Exchanger Technology Program. Both of these programs are complete.

The two programs supported by INDUS-DOE involved the demonstration of much smaller ceramic recuperators on process heat furnaces. The GTE Sylvania program had the objective of demonstrating extended-surface honeycomb ceramic heat exchangers on five different types of production furnaces. This program is complete. A major program objective was to demonstrate the viability of the honeycomb type made of magnesium aluminum silicate or other ceramic material operating in a cross-flow mode with waste gas inlet temperatures of 1300°C and above with an effectiveness exceeding 50%.

The second INDUS contractor, TerraTek, Inc., had the major objective of demonstrating a very high-temperature ceramic heat exchanger capable of operating on a commercial glass-melting furnace or similar relatively dirty industrial hot waste gas source. Materials screening tests and selection were a part of this program. Limited evaluations were completed under this contract.

Of the 14 programs previously active in the Heat Exchanger Technology Program (HETP) sponsored by DOE Fossil Energy as listed in the May 1978 *Heat Exchanger Technology Program Newsletter*,⁶ five were directly oriented to ceramic heat exchanger technology, and a sixth was oriented to heat transfer enhancement.

HETP and Industrial Conservation have sponsored the major DOE programs oriented to technology development of ceramic heat exchangers, with the exceptions of work at the Solar Division of International Harvester funded by the AR&TD Fossil Energy Materials Program, a Surface Gasification Materials Program project at Argonne National Laboratory (ANL subcontracted part of this work to Solar), and two solar energy programs. The AR&TD project at Solar resulted in successful assembly of an SiC ceramic heat exchanger during FY 1980, followed by successful high-temperature and leakage tests. Work involving coal combustion studies continued with EPRI support.

The use of structural ceramics in heat exchangers is anticipated to be less demanding than that in gas turbines, because in general the stress levels in these components will be lower and because more design latitude may be available in a heat exchanger than in the rotors and stators of a turbine. However, practical ceramic heat exchangers for fossil energy systems will typically be very large.

An understanding of the mechanical behavior of silicon carbide and silicon nitride ceramics at elevated temperatures in the presence of stress and atmospheric exposure conditions appropriate to the end use (hot gas exposure from clean and dirty fuels) is needed. Evaluation of the oxidation and corrosion properties of SiC and Si₃N₄ under high-temperature service conditions is also needed, as is an orderly sequence of ceramic heat exchanger module testing in aggressive fossil-fuel-fired environments to identify limitations in corrosion and joint durability. Testing should include materials exposed to actual fossil fuel combustion, rather than to simulated conditions, and should also include tube-and-header and possibly honeycomb designs.

Relationships between the powder properties, impurities, fabrication processes, etc. and the final mechanical properties of silicon and silicon carbide ceramics are poorly understood. This lack of understanding limits a realistic assessment of the potential of silicon nitride and silicon carbide ceramics as fossil energy system components. Near-net-shape fabrication of these ceramics is critically important for economic reasons; therefore, the potential for fabricating high-density

high-strength silicon-base ceramics by cheaper or simpler, novel techniques and from lower cost starting materials should be determined.

Unlike metals, ceramics generally cannot be procured in standard sizes and then cut, joined, and assembled by the end user. Frequently, the ceramic part must be fabricated to its final or near final shape. The inability to join silicon carbide and silicon nitride ceramic shapes reliably once the parts have been densified is a serious impediment to the design of large assemblies such as heat exchangers. Furthermore, results from the AGT and later DARPA programs indicate that undesirable bonding can occur at ceramic-ceramic or ceramic-metal joints in a structure designed for a free mechanical interface. Such bonding problems can result in high stresses and fracture in the ceramic joints during system cooldown. Joining and sealing of structural ceramics for high-temperature service is particularly important for heat exchanger applications. Mechanical compression seals for tube-to-header joints may be a desirable design choice if leakage can be maintained sufficiently low under service conditions. Alternatively, solid material joints or brazed joints must withstand multiple thermal and stress cycles in aggressive environments. Joint repair capability in the field (and possibly field fabrication of large tube-and-header ceramic heat exchangers) is very desirable for maintenance.

A general drawback to the use of structural ceramics is the lack of a data base of key material properties as a function of temperature and time in reactive environments. Data must be developed for a consistent set of well-defined specimens and materials. This deficiency has resulted in a lack of property-material specifications for structural ceramic applications where moderate or high stresses are experienced at high temperature. The only substantial effort of this type has been supported at IIT Research Institute by the U.S. Air Force and others.

Work is needed to identify the potential and limitations of cellular ceramic heat exchangers for large fossil energy systems. If fouling and leakage can be controlled adequately in highly contaminated combustion gas environments, this design offers great potential for providing relatively small, low-cost, high-performance heat exchangers. Several candidate

materials should be evaluated for fabricability, leakage, and durability by means of module firing tests with coal, synthetic fuels, and residual oils. Such heat exchangers may have particular promise if advanced indirectly fired gas turbine systems with isolative heat exchangers and multiple fuel burners are attractive for the system's performance or economics.

4.1.3 Nondestructive Testing

Nondestructive examination (NDE) techniques for materials characterization and flaw detection can have a large cost impact if applied to green-state ceramic bodies before densification. Correlation of flaw data (size, type, and location) and characterization (density distribution, porosity distribution, binder/plasticizer distribution, elastic modulus variation, etc.) should lead to better failure prediction models. Nondestructive examination methods may also be used to inspect raw powders before each processing step to identify which step is introducing flaws. Characterization of microstructure (grain size, porosity, free silicon content) can also be related to processing parameters as well as component performance and may lead to better predictions of lifetime. However, the NDE effort should be directed not only to green-state specimens but to densified specimens as well. Also, laboratory specimens and actual components used in heat engines and heat recovery systems (e.g., turbine blades, piston caps, valve covers, valve wear plates, and heat exchanger tubes) should be studied by NDE together with a rather comprehensive fracture behavior effort. The type of defects to be detected by NDE is dependent upon whether the ceramic material is a monolithic material or a composite material, whether surface or bulk body is the most important, and whether the material is in a green or densified state.

The allowable load on structural ceramics is controlled by the stress necessary to propagate a suitably oriented and sized flaw to critical size. This critical flaw size may be as small as 10 μm , which is about two orders of magnitude smaller than those for metals, and special techniques must be developed to detect such small flaws. Most ceramic materials are subject to slow crack growth. In principle, the probability of failure can be predicted if the temperature, stress, and atmosphere are

known; if the material is adequately characterized; and if the type and size of existing flaws are known. If it can be established that flaws are smaller than a determined critical size and that the material properties and slow crack growth behavior are known, component life can be assured. The resolution and speed of such NDE measurements must be improved. Component reliability must ultimately be assured by developing controlled processes for fabricating components and by keeping the manufacturing process in control. Nondestructive examination is an integral element of such a quality program and is preferable in terms of efficiency, cost, and quality to a program that depends on mass inspection and rejection of significant numbers of components.

4.1.3.1 Densified Ceramics

Process-induced defects, such as inadequate binder distribution or lack of uniform green density, embody themselves in the final product. Other flaws to be detected typically include high- and low-density inclusions, cracks, and large voids. In composite ceramics made with random-length random-oriented fibers (whiskers), typical flaws to be detected include whisker clusters, whisker stratification, and inclusions. In both monolithic and composite ceramics, where large loads are carried, measurement of residual stress levels in densified parts are also desirable.

The best technical NDE approach for the ceramic material depends on whether the material is a composite or a monolithic, if surface or whole-body flaws are most important, and if the material is in the densified or green-body state. Application of ultrasonic techniques to densified ceramics allows higher frequencies (>200 MHz) than those allowable for green-state ceramics. Higher frequencies provide shorter wavelengths for improved spatial resolution, which is necessary for detecting critically sized flaws in the whole body.

Use of focused acoustic transducers with appropriate signal processing should allow complete through-the-body flaw detection (and characterization) such that only selected planes in a body could be interrogated.⁷ Exactly what the spatial resolution capability will be is yet to be determined. Special highly focused transducers may allow very high spatial resolution in the 25 μm range for specific types of defects.

Radiographic techniques (X- and gamma-ray computed tomography, X- and gamma-ray contact and projection, real-time, and film with image processing) also hold potential for interrogating densified ceramic bodies. It has been known for some time that low-kV radiographic imaging techniques are best for low-density materials.⁸ Ellingson⁹ has shown that for green-state ceramics, X-ray heat voltages less than 50 kV (photon energies ~20 keV) can be used, but for densified, reasonable-sized specimens with high-atomic-number material, up to 1-MeV photon energies are necessary for penetration. Highly tailored radiographic techniques do appear to hold promise for inspecting ceramic materials.

Computed tomography (CT)¹⁰⁻¹⁴ can detect low- and high-density inclusions and cracks in the 25- to 50- μ m range in quite large bodies, and it can map density distributions. The energy levels needed for CT imaging depends on the composition of the ceramics, the thickness, and the state (green or densified). An important attribute of CT is that it provides a method to interrogate the entire ceramic body in a noncontacting way and provides almost immediate images on which to base decisions. It remains to define the limits of operation for flaw detection and characterization and to reduce the cost of implementation.

Contact or projection radiographic imaging has strong potential for application to ceramics. Its drawback is that no through-thickness spatial information is provided. Thus, a high-density inclusion may be detected, but the method does not allow the location (within the thickness dimension) in the body to be determined. For thin parts, location in the thickness may not be important, and thus the image may be immediately useful. Analysis of X-ray images by digital image processing techniques will allow isodensity maps to be obtained as well as enhancement of low-contrast defects such as silicon inclusions in silicon-based ceramics.

Surface acoustic waves may be useful for detection of surface flaws, such as machining-induced cracks, by looking at backscattering. Backscattering may also be useful for characterizing surface finish (i.e., machining-induced roughness).

Small-angle neutron scattering, a new NDE technique, may be used to detect micropores and/or residual stresses. In general, studies must be carried out to establish the correlation between results of the various NDE studies.

4.1.3.2 Green-State Ceramics

For green-state ceramics, it is desirable not only to detect flaws such as agglomerates, inclusions (Fe, Si, etc.), voids, and cracks, but to characterize the specimens for density distribution, binder content and distribution, and porosity distribution. The delicate nature of green-state bodies implies that noncontacting methods be used. In addition, full-volume interrogation is necessary because it is not sufficient to look only at surface flaws.

In contrast to densified materials, where all chemical additives (binders, plasticizers, and sintering aids) have been burned out, green-state ceramic bodies still contain these additives. Further, it is usually considered that the distribution of these additives affects the distribution of the mechanical properties within the ceramic part. Thus, in addition to acoustic and radiographic techniques discussed earlier for densified ceramics, chemically sensitive NDE methods such as nuclear magnetic resonance (NMR) may have potential for application. Full-body mapping of porosity, distribution of carbon-containing binders/plasticizers, and perhaps silicon distribution in siliconized Si_3N_4 may be possible.¹⁵ For mapping of porosity, dopants that are compatible with the additives but that have nuclear spins (i.e., the nuclei are detectable by NMR) may allow mapping of porosity. Perhaps green-body characterization is where NDE could offer the highest payoff in ceramic processing.

Present techniques most widely employed by industry for NDE of ceramics are X-ray radiography and fluorescent dye penetrant testing. These techniques provide a relatively coarse resolution of discontinuities (density variations, pores, cracks, inclusions, etc.). However, as noted earlier, efforts are under way to advance NDE techniques for structural ceramics. The techniques being studied include advanced acoustic methods (including focused transducers and signal processing), X- and gamma-ray tomography, X- and gamma-ray radiography with digital image processing, NMR imaging, surface acoustic wave testing, small-angle neutron scattering, and overload proof testing. No single technique is expected to serve as a universal flaw detection and characterization method. Several techniques will be required to assess ceramic components thoroughly and

cost-effectively in the green and densified states. Most of these techniques are currently being evaluated by the AR&TD Fossil Energy Materials Program and have application to heat recovery systems as well as heat engines.

Future studies should focus on selected structural ceramic specimens (SiC , Si_3N_4 , ZrO_2 , and Al_2O_3), including samples in the green state. Samples should have variations in shape as well as variations in microstructure (grain size, grain distribution) and flaws (seeded inclusions, cracks, and pores).

Work on ceramics should include establishing the ability to characterize green-state bodies. This ability would affect not only ceramic process development but flaw detection as well. Variations in ceramic specimen parameters relative to flaw detection should be used to predict fracture behavior in laboratory specimens (tensile and flexure stress modes), and the relationship between flaw detection and failure needs to be established.

Fracture mechanics analyses and microstructural evaluation should be carried out to identify flaws most likely to limit component life so the NDE effort can focus on the most important areas. Studies must be carried out to correlate NDE results with fracture behavior to establish the utility of the NDE techniques. Tests must be performed on samples with controlled flaw populations to determine the effect of flaws on failure probability distribution.

A significant effort should be developed to evaluate CT, acoustic, and NMR imaging for ceramics in the green and densified state, and to correlate the data with fracture behavior. Cracks, porosity, and density variations are all potentially detectable with these advanced sophisticated methods. In addition to CT scanning, advanced NMR imaging systems for materials should be evaluated.

5. COMBUSTION SYSTEMS

5.1 TECHNOLOGY STATUS AND MATERIALS NEEDS

5.1.1 Fluidized-Bed Combustion

The combustion of coal in a fluidized bed of crushed limestone or other sulfur sorbent offers a more energy-efficient approach for sulfur capture than is currently attainable with other more conventional combustion processes. When coal is burned in a fluidized bed, the bed temperature must be kept below about 950°C to prevent ash agglomeration. In fact, efficient removal of sulfur will probably limit the bed temperature to below 900°C; these relatively low combustion temperatures also limit NO_x emissions. The heat of combustion may be transferred to in-bed and above-bed tubes carrying water, steam, or air, or it may be removed by increasing the air flow to greater than that required for stoichiometric combustion. In the latter application, the bed is normally pressurized, and the combustion gases are expanded through a gas turbine. Although the tube temperatures of the in-bed heat exchangers vary greatly with choice of coolant, the heat exchanger concepts are alike in their requirements for uncooled support members, coal ports, ash lines, and other components that can operate at temperatures approximately equal to the bed temperature.

Materials requirements for fluidized-bed combustors (FBCs) have been addressed in several design studies.¹⁻³ All components contacted by the fluidized bed — heat exchanger tubes and supports, air distributor plate, coal and limestone feed nozzles, side walls, bed-drain hardware, and instrumentation — must satisfy operating requirements that are unique in terms of past operating experience for coal combustion systems. Design parameters, such as location of coal feed ports and air fluidizing velocities, strongly affect materials performance, and the compromises that can ultimately be achieved between design and materials requirements will be a major factor in establishing the feasibility of FBC concepts. Additional challenges to the designer are problems of creep and fatigue arising from imposed loads and vibrations. Not unique, but also of concern, are problems with dissimilar-metal welds.

Fireside corrosion of superheaters in conventional pulverized-coal-fired boilers is due to the deposition of ash-containing alkali sulfates on the metal. Sulfate-containing coatings are also formed on heat-exchanger and other metallic surfaces immersed in fluidized-bed combustors using limestone as a sulfur sorbent above approximately 400°C. In this case, the coatings are predominantly CaSO_4 , which remains solid even at the maximum bed temperature. Nevertheless, chemical interaction between these coatings and the underlying metal-metal oxide substrate is a major factor in the corrosion of FBC materials. Also of importance is the distribution of air, coal, and combustion gas within the bed. Determinations of the oxygen fugacity of the bed by solid electrolyte probes responsive to oxygen anion activities show rapidly fluctuating oxygen pressures at any given point in the bed, the pressures reaching apparent levels as low as 10^{-10} Pa, implying that transient reducing conditions exist in the vicinity of burning coal particles.

In addition to corrosion, the in-bed and freeboard heat exchanger components may also be subject to erosion. In practice the local gas velocities in the freeboard (above-bed) area of an FBC are comparable to those in conventional coal-burning systems. Thus, although the particle size and density are much higher in the FBC, problems with erosion in the freeboard region appear to be more conventional than those in the bed. Erosion patterns in the in-bed regions of fluidized beds have been of two general types. In the first type, tube surfaces and water-walls operating at temperatures lower than approximately 300°C in some (but not all) fluidized beds have suffered rapid erosive and abrasive wear. The eroded surfaces appear highly polished, exhibiting no oxide films, sulfate, or char coatings. The second type of erosion has been manifested at higher temperatures (400-600°C) where the under surfaces of heat exchanger tubes have sometimes exhibited much higher wall losses than the mating upper surfaces. The latter form of erosion appears to be associated with an erosive effect on CaSO_4 deposits and/or underlying oxide films. Neither form of erosion has been observed for heat resisting (austenitic) alloys operating at 800°C or above, where relatively thick, wear-resistant oxide films are formed. Three factors that appear important in effecting

in-bed erosion are: (1) the feedstock characteristics such as chemical composition, particle size and size distribution, and hardness; (2) the operating conditions such as fluidizing velocity, temperature, and pressure; and (3) the mechanical design of the combustor including the tube bundle dimensions of tube diameter and pitch, the distance from air distributor and coal and limestone introduction points, and the materials of construction of tubes and support hangers. The complex interaction of these variables determines the nature of fluidization, the combustion gas composition, the possible formation of protective deposits or excessive corrosion, and, finally, the rate of erosion.

A recent overview of FBC erosion⁴ indicated that several additional (to those discussed above) mechanisms may operate in FBCs, although not at all times or in all units, including the following: groups of particles moving against tubes under the influence of gas bubbles and solids in the vicinity of the group of particles; fast-moving particles in the wake of rising bubbles; large, though slowly moving, particles with high kinetic energy; particles thrown into metal surfaces by the action of bubbles collapsing; particles accelerated into in-bed components under the influence of in-bed jets associated with coal and limestone feedports, limestone recirculation ports, and air streams used to keep bed drains clear of obstructions; and particles trapped within and moving with large-scale flow patterns in the fluidized bed. Bed design parameters, particularly the nominal fluidizing velocity, the design of the air distributor and lower bed plenum, and bed depth are fundamentally important in controlling erosion.

In general, combatting in-bed erosion through material upgrading and coating has not been as effective as have controlling local particle velocities and using spoilers for disrupting adverse solids flow patterns.

Erosion problems of still another form are encountered when the combustion gases from the FBC are expanded through a gas turbine. A substantial amount of work has dealt with gas turbines ingesting dusty air and with the recovery of energy from fluidized-bed catalyst regeneration units by expanding the product gas through turbines. All this work indicates that even moderate concentrations of 5- μ m particulates can be very damaging at the high velocities in the engine. Because these erosion

problems cannot be solved by materials selection only, design solutions must also be sought. The magnitude of the erosion problem is strongly influenced by the degree of hot-gas cleanup that can be realized and by the detailed aerodynamics of the turbine. The former strongly influences the particulate concentration, and the latter controls particle velocities and temperatures in multistage gas turbines. Solution of the coupled hot-gas cleanup and gas turbine erosion problem is probably the most difficult technological problem facing the pressurized fluidized-bed combustion (PFBC) system.

Erosion and deposition (fouling) have generally limited the lives of coal-fired gas turbines. However, at longer times or higher temperatures, hot corrosion of gas turbine components appears to be a significant threat.⁵ After entering the turbine, the PFBC gases are cooled by expansion in the turbine and by contact with cooled metal parts or with the boundary layer surrounding them. Alkali sulfates can then condense on the metal surfaces. Thus, the selection of the metal temperatures controls not only the rate of the corrosion reactions but also the rate of deposition of corrodent on the surface. Although the alkali vapor concentrations produced in a PFBC are in most cases lower than those encountered in pulverized-coal combustion systems, the flux of alkali salts in the gas turbine will be substantially greater than that regarded as acceptable for current engines using distillate fuels. Temperature is critically important, and there is now strong evidence that corrosion of PFBC turbine components will be even more severe in the range 600 to 750°C than at higher temperatures. However, some alloys and claddings are clearly less susceptible to this type of attack than are others, and the choice of an adequate turbine protection scheme (material and surface temperature) is not yet clear.

Given the complexity of materials degradation processes in fluidized beds (e.g., erosion, corrosion, and erosion/corrosion), it is not surprising that the wastage rates reported for specific heat exchanger materials have differed by orders of magnitude among the various in-bed materials studies conducted to date.⁶⁻⁸ However, the pattern of materials behavior has become more predictable as specific degradation mechanisms have been better identified. For example, at service temperatures of

800°C and above, candidate materials have narrowed to austenitic stainless steels (including Alloy 800), and the degradation of these materials is controlled by classic oxidation/sulfidation mechanisms. The major concern with these materials is breakaway oxidation, which is associated with a critical distribution of internal sulfides near the oxide-metal interface. Still to be determined is the role of CaSO_4 deposits in the corrosion processes and the transport mechanisms of sulfur through the oxide film. Under steam boiler conditions (600°C and below), degradation of candidate heat exchanger materials has been negligible except where erosion has accelerated the normal oxidation processes or abraded unoxidized tube surfaces.

Although laboratory corrosion and erosion tests are extremely useful in establishing the environmental and temperature conditions under which a given degradation mechanism can operate, it is still necessary to relate these laboratory test results to fluidized bed design parameters (excess air and SO_2 in the flue gas, bed temperature, superficial velocity, sorbent-fuel ratio, coal and sorbent feed size, etc.) Such comparisons require the exposure of materials in an FBC dedicated to materials testing, where the corrosion performance of heat exchanger and turbine materials can be correlated with bed design and operating parameters. During FY 1985 an \$8 million in-bed materials test program was completed under the sponsorship of Energy, Mines, and Resources (EMR) Canada. The test was conducted for a total of 10,000 h in a 1- × 1-m atmospheric fluidized-bed combustor owned and operated by the Nova Scotia Power Corporation. Materials data from this test are being made available to the United States through the Physical Metallurgy Research Laboratories, a technical arm of EMR. In addition, the Morgantown Energy Technology Center has solicited proposals for an in-bed materials testing program to investigate the effects of operating and design parameters on tube metal wastage in FBCs. These programs constitute an important adjunct to the AR&TD Fossil Energy Materials Program and are reflected in the current and proposed test programs for FBC materials studies.

Laboratory experiments under carefully controlled conditions are being conducted to understand the mechanisms and microstructural conditions that lead to breakaway oxidation at 593 to 850°C. Recent studies

on heat exchanger materials exposed at 1140°C to an alternating high- p_{O_2} /low- p_{O_2} atmosphere with a cycle time of 10 or 100 h showed that the materials need a sustained exposure for times greater than 10 h to low- p_{O_2} atmosphere to initiate sulfidation attack.⁹ It has also been established that a combination of $CaSO_4$ or CaO deposits and the presence of low- p_{O_2} in the gas phase can lead to initiation of sulfidation in high-chromium alloys.¹⁰ Tests at lower temperatures should be conducted to establish the conditions under which erosion will affect the mechanical integrity of oxide films and $CaSO_4$ deposits. Laboratory tests are also required to identify the mechanisms of low temperature hot corrosion of turbine alloys and coatings in simulated PFB flue gas environments.

The materials requirements for certain hot-gas cleanup systems, such as cyclones, do not seem particularly difficult to meet, although candidate materials should be subjected to long-term testing. However, more advanced hot-gas cleanup systems (e.g., ionic conducting materials) are under development; their materials requirements must be determined, and successful materials performance must be demonstrated.

A current problem in steam generators is that oxide scale spalls from reheater and superheater tube surfaces and partially obstructs passages or damages turbines. Conditions of high heat flux, such as in liquid-metal heat exchangers, increase the extent of spallation.¹¹ Because the heat fluxes of FBC in-bed steam generators will be higher than those in current fossil-fired generators, the problem of spallation could be accentuated. A program should be initiated to determine the effect of the heat fluxes in FBC steam generators on oxide spallation. If the effect is significant, the benefits of chromizing or substituting more oxidation-resistant materials should be evaluated.

Dissimilar-metal joints between ferritic and austenitic boiler tubes are currently made with high-nickel filler metal. Such joints may not be suitable for applications that locate the joints within the fluidized-bed region of atmospheric FBCs (AFBCs), because such high-nickel alloys are susceptible to catastrophic sulfidation corrosion. The performance of joints made by existing methods must be related to operating temperatures and local bed conditions in AFBCs, and, if necessary, alternative joining methods and materials must be explored.

Nondestructive techniques (ultrasonic and eddy current) for in-service inspection should be developed and applied for tubing, dissimilar-metal welds, and other components.

5.1.2 Conventional Combustion

Relative to combustion systems, the two central objectives of the DOE Office of Fossil Energy are (1) substitution of coal (or coal-liquid mixtures) for oil and natural gas in utility and industrial boilers and (2) extension of the reserves of oil and gas by improving the reliability and efficiency of boilers and furnaces.

Replacement of oil and natural gas by pulverized coal or coal-liquid mixtures in industrial and utility boilers requires solutions to several technical problems. The principal problems are those of fly-ash fouling, slagging, corrosion, and erosion of boiler tubes and other components in conventional combustors. These problems are caused in part by the mineral matter present in the feed coal and the transformation and reactivity of the mineral matter during and following combustion. An adequate understanding of the mechanisms responsible for the chemical and physical reactions seen with the use of coal or coal-liquid mixtures is needed. Tube wastage in conventional pulverized-coal boilers is caused primarily by the corrosive reactions that occur at high temperatures between the impurities contained in the coal and the metal tube surfaces. Low-temperature corrosion is due mainly to attack by sulfur-containing acids. In addition to the development of more corrosion-resistant materials for boiler components, better coal cleaning techniques (as discussed in Chap. 1) will result in the removal of a large amount of the ash and sulfur from the feed coal and, thereby, reduce the problems caused by these materials. In addition to providing a better quality coal for pulverized-coal combustion, improvement of feed coal quality is an important step in the preparation of coal-liquid slurries for combustion in retrofitted oil or gas combustors. The prime problems encountered when oil- or gas-fired boilers are retrofitted to burn coal or coal-liquid slurries are corrosion, erosion, and wear of the burner nozzle. Again, proper coal cleaning will reduce this problem somewhat; however, burners will need to be redesigned to atomize the injected slurries into the

combustion zone properly. The coal-liquid mixtures most successful to date have been coal-water mixtures.¹²⁻¹³ Currently coal-oil mixtures are not economically attractive compared with oil, and recent studies showed that considerable loss of power-generating capacity could be expected when coal-oil mixtures are used in oil-fired boilers.¹² Slurry production also requires the addition of chemicals that cause a different type of fouling problem, and this area will need to be addressed as well before coal-water mixtures will replace oil or gas. However, the use of slurries resulted in NO_x emissions 100 to 200 ppm lower than those occurring when pulverized coal of the same quality was burned.¹³

Among the current materials limitations that the Electric Power Research Institute (EPRI) has singled out as particularly significant to electrical utilities are the corrosion fatigue of steam turbine rotors and blades and the oxide spalling of superheater materials, which causes erosive impingement on turbine blades.¹⁴ The attainment of higher efficiencies in the steam-Rankine power cycle demands materials with improved fireside and steam corrosion resistance at 600 to 700°C. Higher efficiencies are thus achievable by the substitution of more highly alloyed metals for present-day boiler materials, albeit with a significant increase in plant capital costs. The development of oxidation- and sulfidation-resistant coatings to upgrade existing boiler materials may be a more cost-effective means of achieving the needed temperature increases.

Failure of dissimilar-metal welded joints in steam generators has become a major factor affecting the reliability of utility steam boilers.¹⁵ Superheaters and reheaters delivering steam at 540°C commonly employ austenitic stainless steels for higher temperature regions and ferritic steels for lower temperature regions. Although these tubes can be joined with a variety of welding approaches, cracks are characteristically encountered in the ferritic material adjacent to the weld interface or in the heat-affected zone. Of 54 utilities responding to a survey by the Steam Power Panel of the American Society for Testing and Materials, American Society of Mechanical Engineers, and The Metal Properties Council, 20 reported dissimilar-metal weld failures.¹⁵ These failures involve 60 units of a total of 320 and were not attributable to poor welding techniques. Because none of the techniques now used for

joining stainless steel and ferritic tubes has resolved the cracking problem, the development of an improved type of dissimilar-metal weld is a major requirement for increasing the reliability of steam power plants.

The effluent emission standards imposed by the Environmental Protection Agency on fossil-fueled power plants require the removal of SO_2 from the stack gases of plants burning high-sulfur coals and fuel oils. The most common method for SO_2 removal is wet scrubbing. Typically the stack gas is quenched by water immersion and is then passed upward through a spray tower in which a neutralizing material, such as limestone or MgO is contacted with the gas to capture sulfur-bearing species. Wet scrubbers can use a variety of liquids, ranging from seawater to both acidic and alkaline chemicals. As these liquids contact the flue gas, the absorption of SO_2 and SO_3 lowers the pH and increases corrosion. Chloride ions introduced by the coal, scrubber water, or sorbent also exacerbate the corrosion problem, especially where closed-loop recirculating water systems are used. The relatively low temperature of the combustion gas as it leaves the scrubber also poses a serious dewpoint corrosion problem (condensation of acids) in stack and blower sections downstream from the scrubber.

Corrosion problems experienced to date in the operation of pollution control equipment have been sufficient to warrant upgrading to more corrosion-resistant alloys to reduce downtime and repair.¹⁶ Corrosion testing and field surveillance will be required to verify that the performance improvement in the upgraded materials is cost beneficial.

As noted above, the EPRI has instituted a materials development program to improve the reliability of steam turbine rotors and blades. Advances in turbine material performance require commensurate improvements in steam supply components. Duplex materials such as corrosion-resistant claddings on austenitic stainless steels, when retrofitted into existing steam generators, have proved very cost-effective in reducing fireside corrosion under current boiler operating conditions.¹⁷ The claddings used in the latter application are generically similar to those being developed for gasifier applications. Accordingly, coating and cladding developments for gasifier applications should be extended to cover potential coal-fired

boiler applications at temperatures of 600°C and higher. Nondestructive techniques, including eddy-current, ultrasonic, and infrared methods, are needed to accommodate the cladding developments.

6. FUEL CELLS

6.1 TECHNOLOGY STATUS AND MATERIALS NEEDS

A fuel cell is an electrochemical device that converts the chemical energy of a fuel and oxidant into electrical energy in a highly efficient manner. Once in operation, a fuel cell will continue to operate to convert chemical energy to electrical energy as long as both fuel and oxidant are supplied to the electrodes. A typical fuel cell consists of two electrodes and an electrolyte (either solid or liquid), which is an ionic conductor in intimate contact with each electrode. The electrolyte is a nonporous barrier which separates fuel and oxidant, whereas the electrodes are porous to facilitate transport of the fuel and oxidant to the reaction surfaces. The fuel is generally hydrogen or natural gas and is introduced at one electrode, whereas the oxidant (typically oxygen or air) is supplied to the other electrode. Reaction surfaces are the interfaces between each of the electrodes and the electrolyte. Oxidation of the fuel at the one electrode provides electrons to the external circuit; the reduction of oxygen (or air) at the other electrode uses electrons from the external circuit. Through the above process, a fuel cell can produce dc electricity on the order of hundreds of amperes per square foot of electrode area and voltages of about 1 V. Voltage levels can be increased by connecting a number of individual fuel cells in series. This configuration is referred to as a fuel cell stack.

The five principal types of fuel cells, categorized according to the type of electrolyte used, are phosphoric acid, molten carbonate, solid oxide, alkaline, and solid polymer electrolyte. The phosphoric acid, molten carbonate, and solid oxide fuel cells have applications primarily in the commercial and industrial areas, while the alkaline and solid polymer electrolyte fuel cells are used mainly for space, military, and transportation applications. Consequently, the latter group falls outside the scope of the AR&TD Fossil Energy Materials Program. In addition, the technological advances for the phosphoric acid fuel cell over the past ten years have been significant and have brought this technology very near to commercialization. Materials research that addresses this technology would therefore be inappropriate for a long-range generic research

program such as the AR&TD Fossil Energy Materials Program. Consequently, the following discussion addresses only materials research needs for molten carbonate and solid oxide fuel cells.

6.1.1 Molten Carbonate Fuel Cells

The molten carbonate fuel cell (MCFC) operates from 600 to 700°C. It consists of a porous nickel anode, a porous nickel oxide cathode, an electrolyte structure that separates the anode and cathode and conducts only ionic current between them, and anode and cathode current collectors that may also serve as bipolar cell-separator sheets for stacks of cells.¹ The individual cells within a stack are maintained in physical contact by mechanical loading. The anode and cathode gases are sealed in the stack by the capillary action of a wet seal at the edges of the stack at the junction of the current collector and electrolyte structure.

The nickel anode sheet is typically about 0.8 mm thick and contains an additive of from 2 to 10 at. % Cr_2O_3 or Al_2O_3 . Additions of these oxides strengthen the anode and stabilize the nickel against in-situ sintering (coarsening). The nickel oxide cathode is a 0.4-mm-thick sheet containing about 3 at. % lithium that increases the electronic conductivity of the nickel oxide. Both the anode and cathode are porous. The cathode is a dual-porosity structure in which the fine pores ($<1\text{ }\mu\text{m}$) become filled with electrolyte to provide catalytic surfaces and ionic conductance paths, and the large pores ($10\text{ }\mu\text{m}$) remain unfilled to provide access of the gas to the cathode. Likewise, the anode is fabricated with $5\text{-}\mu\text{m}$ pores to permit gas access.

The electrolyte structure (matrix), sandwiched between the electrodes, is a composite structure of about 40 wt % of inert particulate matrix material, currently LiAlO_2 , and 60 wt % of a mixture of alkali carbonates. The binary alkali carbonate mixture commonly used is 62 mol % Li_2CO_3 -38 mol % K_2CO_3 , which becomes a molten ionic conductor above 490°C. The resistance of the electrolyte matrix is directly related to its thickness; therefore, the thinnest matrix possible is preferred. The thickness currently used is about 0.5 mm for matrices up to 0.1 m^2 in area.

The anode and cathode current collectors (common bipolar sheets in stacks) are generally constructed of type 316 stainless steel; however,

this material corrodes in the anode environment and, therefore, is usually protected on the anode side with a nickel layer. A more corrosion-resistant bipolar sheet is needed.

The principal materials problems with the MCFC are dissolution of the nickel oxide cathode, interface corrosion, corrosion of the anode and cathode current collectors, electrolyte loss, and sulfur tolerance of materials.

Dissolution of the lithiated nickel oxide cathode material in the presence of the carbonate salt is a serious problem at the high pressures (up to 1 MPa) proposed for large MCFC plants. (The potential result is the loss of mechanical and electrical stability and subsequent failure of the fuel cell.) Nickel oxide dissolves as a result of concentration-driven mass transport in which nickel ions in equilibrium at the cathode diffuse toward the anode, where under the reducing conditions they precipitate as metal. Under the fuel cell cathode conditions, nickel oxide dissolves according to the reaction $\text{NiO} = \text{Ni}^{2+} + \text{O}^{2-}$, where the oxide activity is fixed by the equilibrium between the electrolyte and the partial pressure of CO_2 in the oxidant, $\text{CO}_3^{2-} = \text{CO}_2 + \text{O}^{2-}$. Thus, solubility at the cathode is proportional to the CO_2 partial pressure and, therefore, is greater for pressurized cells. If the fuel cell is operated under high pressures, that is, under high partial pressure of CO_2 , additional nickel dissolves in the carbonate melt as Ni^{2+} , which subsequently diffuses toward the anode. In accelerated tests cell failures from cathode dissolution make it unlikely that the goal life of 40,000 h can be reached with cells operating at high pressures of CO_2 . Cell failures occurred by shorting as a result of nickel deposition in the electrolyte matrix.

Interface corrosion was a problem in the wet seal area in which the metallic cell separator contacts the electrolyte tile to form sealed compartments for the fuel and oxidant gases of the MCFC. Depending on the blanket gas composition, electrical potential gradients within the wet seal can give rise to possible galvanic corrosion problems, especially at the anode. Aluminizing these surfaces has proved effective for controlling this problem through formation of an inert insulating layer of LiAlO_2 on the separator sheet surface.

The separator sheet (also called a bipolar plate) maintains the electrodes in intimate contact with the electrolyte structure and provides a path for current to or from the electrodes. Thus, the terms "separator sheet" and "current collector" are synonymous in the following discussion. Corrosion of these components in the active area of the cell can cause cell degradation through contamination of the electrodes and electrolyte by the corrosion products. Typically, a salt layer on the electrode and current collector initiates the corrosion process. In addition, the growth of a corrosion product scale on the current collectors can cause excessive cell resistance. The most significant corrosion problem for the current collectors, however, is the possibility of through-corrosion allowing parasitic mixing of fuel and oxidant. The successful operation of an MCFC current collector depends on the formation of a protective oxide scale; however, the scale must be thin, electrically conducting, and mechanically stable. Alternative materials and cladding materials have been examined for use as current collectors, but economic considerations limit the choices. Finally, the material chosen for the current collectors must resist oxidation by the oxidant gases. The corrosion of current collectors is a problem that must be solved before long-term service with MCFCs is possible.

Electrolyte losses due to evaporation, seepage, or corrosion processes are also life-limiting factors in MCFCs. These losses, which result in decreases in the electrolyte conductivity, increased electrolyte structure porosity, and diffusion of reactants across the cell, cause a decrease in cell voltage and efficiency.^{2,3} A possible problem with electrolyte matrices is crystal growth of LiAlO_2 during cell operation, which might result in unacceptable changes in the distribution of interstice sizes in the matrix and, consequently, in a decrease in cell performance.^{4,5}

It is generally acknowledged that even ppm levels of sulfur in the fuel may cause an unacceptable loss of cell voltage. For example, voltage losses of tens of millivolts have been observed in various laboratory- and bench-scale fuel cells when using fuel gases containing 1 to 10 ppm of H_2S . Performance loss due to the presence of sulfur in the fuel and

oxidant gases occurs primarily at the anode. Potentially, cost benefit may be derived by replacing the nickel anode with a more sulfur-tolerant material. Development of sulfur tolerant materials for MCFCs is thus desirable.

6.1.2 Solid Oxide Fuel Cells

The solid oxide fuel cell (SOFC) operates between 900 and 1100°C. The MCFC configuration is that of planar electrode and electrolyte sheets held in mechanical contact, but the configuration of the SOFC is typically that of a laminated cylindrical tube. The laminates, from the inner to outer diameter of the tube, consist of (1) a porous support tube of calcia-stabilized zirconia, (2) an air electrode (cathode) of strontium-doped lanthanum manganite, (3) an electrolyte of yttria-stabilized zirconia, and (4) a fuel electrode (anode) consisting of a cermet of cobalt or nickel metal with stabilized zirconia. In addition, an interconnection contact consisting of magnesium-doped lanthanum chromite is laminated to the air electrode and provides the electrical path between individual cells in a stack. During operation, oxygen (or air) is passed through the SOFC cylinder, while the fuel gas, generally hydrogen, is passed over the outer surface.⁶⁻¹³

The materials in a SOFC must (1) be stable in an oxidizing and/or reducing environment, (2) be chemically compatible with other materials in the cell at both the operating temperatures and higher fabrication temperatures, (3) have high electrical conductivities, and (4) have similar coefficients of thermal expansion to avoid delamination of the layers comprising the cell. The last criterion is particularly important because the process conditions cannot be selected independently for the fabrication of each component of an SOFC. Because the fabrication of an SOFC consists of progressive lamination, the sintering temperature of each successive layer must be lower than that of the preceding porous layer to avoid altering the characteristics of the previously deposited layers.⁹⁻¹¹

The principal materials needs of SOFCs are (1) the development of a higher conductivity cathode material and (2) improvement in the sulfidation resistance of the fuel electrode (anode). The relatively low conductivity of the cathode material coupled with the long current path in

the plane of the cathode results in the cathode being the principal component responsible for voltage losses due to internal resistance in an SOFC. In addition, the low conductivity of the cathode results in a non-uniform distribution of current around the circumference of the cell and through the electrolyte. An improved cathode material should have an electronic conductivity greater than $75 (\Omega \cdot \text{cm})^{-1}$ at 1000°C , which is the conductivity of the currently used cathode material, strontium-doped lanthanum chromite.⁹ Cell performance can be significantly improved through the development of higher conductivity cathode materials; however, the alternative materials must also satisfy the other three criteria mentioned above. First, the cathode materials must be stable in an oxidizing environment at temperatures of cell operation ($900\text{--}1100^\circ\text{C}$) as well as of cell fabrication ($1100\text{--}1500^\circ\text{C}$). Second, the alternative materials must be compatible with the other cell components so that interdiffusion and chemical interactions at the interfaces are kept to a minimum, both for operating and fabrication conditions. Third, the alternative cathode material should have a coefficient of thermal expansion of about $1.0 \times 10^{-5}^\circ\text{C}^{-1}$ to avoid delamination of the ceramic layers during fabrication and thermal cycling during operation.⁶

Development of anodes with increased sulfidation resistance is also needed. Experimentally, solid oxide materials are much more tolerant of sulfur than are the materials in other fuel cells. For example, approximately 800 h of operation at 50 vppm hydrogen sulfide have been observed with a nickel anode. After an initial voltage drop of about 5%, no further deleterious effects were noted. Furthermore, the initial performance loss was recovered at the end of the test, when sulfur-free fuel was reintroduced. However, much more data on sulfur tolerance are needed. A fundamental understanding of the effect of sulfur on fuel cell performance is required. Anode materials with even higher tolerances for sulfur are desired for more efficient operation. Furthermore, an increase in sulfidation resistance would reduce the already minimal gas cleanup requirements and allow the use of more energy efficient hot-gas cleanup methods in combined coal gasification-SOFC plants. In addition, improving the sulfur tolerance would allow the direct use of liquid fuels such as diesel fuel (0.5 wt % sulfur).

7. COAL PREPARATION

7.1 TECHNOLOGY STATUS AND MATERIALS NEEDS

The recent increased emphasis on the efficient and cost-effective combustion of coal and on the environmentally acceptable use of pulverized coal and coal-liquid slurries has increased the importance of proper cleaning and preparation of the feed coal. The performance and efficiency of combustion facilities depend strongly on coal quality. Inorganic mineral matter in the feed coal, which transforms and reacts during the combustion process, can be found in both the coal slag and fly ash waste products. The resultant slag and ash generally have highly deleterious erosive and corrosive effects on the components of a combustion facility. Particular problems of erosion, corrosion, slagging, and fouling during combustion are discussed in more detail in Chap. 5, Combustion Systems. The presence of mineral matter also results in erosion of coal-handling and coal preparation equipment. These problems are most economically addressed with adequate coal-cleaning techniques to reduce the ash and sulfur levels. In addition to pulverized coal, coal-water slurries are becoming increasingly more interesting as fuel for conventional combustors. Coal-water slurries typically contain 65 to 75% pulverized coal and 25 to 35% water. An important factor in the preparation of such slurries is the use of ultrafine, ultraclean coal, and this need has resulted in the development of advanced physicochemical cleaning methods for the removal of ash and sulfur. To produce coal-water slurries, the coal is ground 5 to 10 times finer than conventional pulverized coal and cleaned to 1 to 3% ash content and 0.5 to 1% sulfur content. Finally, the need to address the question of acid rain, which may result from the combustion of high-sulfur coal, has increased the interest in advanced coal-cleaning techniques. The use of coal-water slurries may contribute to the reduction of sulfur oxides in the atmosphere in light of the requirement for ultraclean coals for the slurries.

The principal objective of any coal preparation process is to remove the mineral impurities, and the methods currently used commercially are derived largely from the separation of impurities based on the differences

in specific gravity of the various coal constituents. These are generally referred to as gravity separation processes and typically use mechanical separators such as jigs, tables, and cyclones. Another commercial method used is froth flotation, which uses the differences in surface properties of the coal and its mineral matter to clean the coal physically. Physical cleaning or beneficiation extracts the coarser forms of mineral matter, including pyritic sulfur; however, none of the organic sulfur is removed. As the coal particle size decreases below 0.5 mm, gravity separation methods are ineffective in removing sufficient quantities of sulfur and mineral impurities. Techniques that can be employed for cleaning coal that has been pulverized to fine or ultrafine particle sizes are (1) selective coalescence, (2) heavy-liquid cycloning, and (3) froth flotation.¹

Materials problems encountered with gravity separation processes are primarily from erosion of pipes, chutes, cyclones, and screens. The problems of erosion and wear in physical coal preparation systems arise essentially from the constituents of the coal. For example, a high-ash coal containing significant quantities of hard minerals (e.g., quartz and chert) and other inorganic matter will be more erosive than will a low-ash coal. Pipe erosion occurs primarily in elbow locations, and quite often the simplest approach to eliminating the problem is to design and build a facility on the basis of experience. Areas subject to excessive wear are identified in practice, and problems are usually overcome by removing the eroded area and redesigning the elbow to include a blind tee. The blind tee initially catches the solids, which then become the impingement surface. Chute wear is minimized through the use of armor plate (hardened steel surfaces). Protective coatings could possibly be developed and plasma sprayed onto the critical surfaces of gravity separation cyclones to reduce erosive wear in these devices. Screen wear occurs at the site of product impingement, and operators minimize it by periodically rotating the screen locations. Screen wear can be dramatically reduced by use of rubber-coated screens; however, these screens cost considerably more than uncoated screens. In addition, rubber coating of screens reduces their capacity.

Theoretically, a high percentage of the ash and inorganic sulfur could be removed from the coal by physical cleaning methods; however, total sulfur reduction is limited by the concentration of organic sulfur in the coal. To reduce the organic sulfur and, thereby, the total sulfur content beyond the levels possible with physical cleaning, chemical coal cleaning methods are employed. Chemical coal cleaning methods have demonstrated the ability to remove greater than 90% of the total sulfur from various coals. In addition, an acid wash following desulfurization can remove about 95 to 98% of the ash in the coal.¹ Removal of ash and sulfur to these levels represents a significant step in mitigating acid rain through the reduction of SO_x emissions from coal combustion. As a result of the increasing need for cleaner coals with the lowest possible ash and sulfur levels and their expanded use, more advanced chemical coal cleaning techniques are being developed. Because of the severity of these advanced chemical cleaning techniques (corrosive fluids at high temperatures and pressures), materials selection is of utmost importance.

As discussed above, coal-water slurries are of considerable interest as fuels for conventional combustors. In fact, the ease of handling slurries in the same fashion as that for liquid fuels has resulted in slurries being considered as replacements for pulverized coal for combustion. Advanced cleaning techniques such as those mentioned above can produce ultrafine pulverized coals with about 1% ash. Ultrafine pulverized coals are extremely difficult to feed into the combustion zone in the dry state; consequently, the use of coal-water slurries (containing ultraclean coal) will result in more efficient combustion. The principal materials problems in both slurry production and slurry use arise from the often caustic nature of the chemical additives present in the slurries (to impede agglomeration) as well as from the erosive attack of the ash and other inorganic matter still present in the coal. Corrosion, erosion, and wear of slurry mixers, pumps, transport pipes, and feed systems for transport of the slurry, either during the production process or to the combustor, result in significant materials problems. The corrosive and erosive nature of the slurry due to entrained ash particles and hard minerals is accentuated by degradation processes within the slurry itself

such as changes in viscosity, pH, and particle size. The latter problem arises when insufficient mixing allows the individual coal particles in the slurry to agglomerate. Research programs need to continue to address the problems of erosive-corrosive attack of key components of slurry production equipment if this technology is to remain economically competitive with pulverized-coal use.

A potential rival of conventional coal transportation is the proposed use of slurry pipelines.^{2,3} Erosion and wear problems for this transportation system are expected to be similar to those experienced in slurry production processes. Pumps and mixing systems will be needed at various positions of the pipeline to maintain the flow of a uniform unagglomerated slurry. Erosion and corrosion will need to be reduced through the choice of proper materials or the application of coatings and claddings on conventional materials. Research activities on mechanisms of corrosion and erosion will greatly assist the ability to address these materials problems satisfactorily.

In addition to the effects that proper coal preparation will have on either pulverized-coal-fired or coal-slurry-fired combustion systems, the substantial reduction or the virtual elimination of ash, sulfur, and chlorine in the feedstock for coal conversion systems would dramatically temper the materials technology needs for these systems. These systems are discussed in Chap. 2, Coal Liquefaction, and in Chap. 3, Coal Gasification.

In summary, most of the materials problems of coal preparation are due to corrosion, erosion, and wear. Projects on the AR&TD Fossil Energy Materials Program which address these problems are discussed in Part III. These materials problems should continue to be assessed by the AR&TD Fossil Energy Materials Program to better understand the corrosion and erosion problems and to identify the research needed to solve these problems. The results from several projects on the AR&TD Fossil Energy Materials Program, which address problems of erosion and corrosion in coal liquefaction and coal combustion environments, have contributed significantly to understanding erosion and corrosion mechanisms that occur in coal preparation systems. Furthermore, we will coordinate our efforts with the

research supported by the Coal Preparation Program of the DOE Fossil Energy Office of Clean Coal, Combustion, and Conversion Systems to ensure that the research projects initiated by the AR&TD Fossil Energy Materials Program are consistent with the current materials needs of this technology.

8. MAGNETOHYDRODYNAMICS

8.1 TECHNOLOGY STATUS AND MATERIALS NEEDS

Magnetohydrodynamic (MHD) power generation is the direct conversion of heat to electricity by passage of a high-temperature high-velocity electrically conducting fluid through a magnetic field. The principle of MHD power generation is the interaction of a partially ionized coal combustion gas with a transverse (to the fluid flow direction) magnetic field to induce an electric field within the fluid. Potassium carbonate injected into the combustion region provides the needed electrical conductivity of the fluid. Electrodes collect the current, and electric power can be supplied through an inverter to a power grid.

The major government MHD test facilities in the United States are located at the University of Tennessee Space Institute (UTSI) near Tullahoma, Tennessee, and at the Component Development and Integration Facility (CDIF) in Butte, Montana. The UTSI Coal-Fired Flow Facility was constructed to provide development testing of components simulating the complete MHD steam system. The CDIF was established to evaluate the performance of MHD components and systems, to compare performance of different designs, and to provide a basis for scaleup of MHD system designs.

The materials research, development, and evaluation needs for MHD components are considerable. These needs include metals and ceramics for channel electrodes, ceramics for electrode insulators and channel side walls, ceramics for a regenerative air heater for preheating combustion air, high-temperature metal alloys for a recuperative air preheater, and metals and refractories for the steam bottoming plant. These needs are being addressed primarily by the MHD program in the DOE Fossil Energy Office of Advanced Energy Conversion Systems and managed by the Pittsburgh Energy Technology Center (PETC). Although no MHD materials research is presently in progress on the AR&TD Fossil Energy Materials Program, an MHD project¹ at the National Bureau of Standards (NBS) was funded by the AR&TD Fossil Energy Materials Program in FY 1981. The objective of the project was to determine the dimensional stability of refractory materials for

MHD regenerative heat exchangers by measurement of properties such as yield strength, creep strength, and microstructural instability under both cyclic and static exposures to elevated temperatures.

Several materials projects, supported by the MHD program in the DOE Fossil Energy Office of Clean Coal, Combustion, and Conversion Systems, have contributed to an improved understanding of materials behavior in MHD systems.

One such project² at the Westinghouse Electric Corporation on MHD electrode development, completed in September 1982, consisted of laboratory screening tests to provide data on electrochemical stability and anode arc erosion resistance for selected electrode material candidates, engineering tests of preferred electrode designs under simulated MHD operating conditions, and preparation and fabrication of electrode materials. The emphasis was to evaluate metal electrode materials suitable as alternatives to platinum as an anode material. Several materials including chromium, E-Brite 26-1, Inconel 601, and type 330 stainless steel which showed favorable resistance to electrochemical corrosion by slags were evaluated in engineering tests.

In another project³ at Avco Everett Research Laboratory, various designs of metal electrodes were evaluated during MHD channel tests. Electrode wear was found to be caused by several corrosion and erosion mechanisms, with electrochemical attack and arcing being the more important. Electrodes made of copper capped with platinum in areas of high electrode stress and nonnickel-bearing stainless steels performed well throughout 1300 h of channel testing at Avco and are currently in use at CDIF.

The primary objective of a project⁴ at Fluidyne Engineering Company was to evaluate and select materials for use in the directly fired high-temperature MHD air heaters for MHD power plants. Long-term tests with fusion-cast magnesia-35% alumina cored brick and a spinel castable hot liner indicated that those materials are suitable for this application. A calcium-aluminate-bonded fused-grain spinel with 4 wt % stainless steel fibers showed only minimal degradation in a test valve system. A high-chromia fused cast refractory also appears to have promise for some MHD refractory applications.

At the NBS, work⁵ on MHD seed-slag interactions addressed, among other things, the corrosion of alloys in downstream components of MHD systems. The corrosion portion of the program included the development of test methods for assessing relative corrosion resistance of alloys, screening of alloys under some simulated downstream conditions, and evaluation of screened alloys to determine the applicability of certain alloys to downstream components.

A second study⁶ at the NBS on creep and other properties of refractories resulted in data on the high-temperature compressive creep of refractories for use in MHD air preheaters. In addition, the refractories were ranked for creep resistance at 1400 to 1600°C. Of several materials tested, an excess magnesia spinel refractory material (X-317) had the lowest creep and was most stable under the test conditions.

The corrosion of a wide variety of commercial refractories was studied at Argonne National Laboratory (ANL) under reducing conditions at 1500°C in the presence of mixtures of coal-ash slag and potassium seed.⁷ For several refractories, the results appeared quite promising with a fused cast-chromia-spinel refractory material exhibiting superior corrosion resistance.

A second project⁸ at ANL was concerned with the evaluation of materials for the MHD steam bottoming plant and the corrosion behavior of selected ASME-coded boiler materials exposed to simulated MHD combustion atmospheres for about 500 h at gas temperatures in the range 825 to 875°C. The data, in general, indicated that high-chromium iron-base alloys such as type 310 stainless steel and Incoloy 800 are suitable for steam heaters with tube temperatures above 475°C. Low-chromium alloys appeared to be suitable for service below 425°C.

During FY 1984, the national MHD program was redirected to conduct only that testing necessary to obtain design data for a retrofit plant by the end of this decade. This plant would be assembled by integrating an MHD topping cycle into an existing coal-fired power plant.

9. OIL SHALE

9.1 TECHNOLOGY STATUS AND MATERIALS NEEDS

Oil shale is one of the energy resources being developed to satisfy the U.S. midterm energy requirements. The western Green River shale formation in Utah, Colorado, and Wyoming is the primary source of oil shale in this country. The two major methods of production being pursued are surface and in-situ retorting and materials requirements. The two methods differ in significant ways.

Some of the materials research and development needs that may be appropriate for funding as part of the AR&TD Fossil Energy Materials Program are addressed. Oil shale retorting processes, however, are nearing commercialization, and some of the identified materials research and development needs are more appropriately addressed by the oil shale industry. The needed areas of research that are appropriate for AR&TD Fossil Energy Materials Program sponsorship will, for the most part, be based on industry's experience and its identification of specific materials problems.

Because of the tremendous quantity of rock that must be mined, transported, and handled (each ton of rock contains only 91 to 182 L of recoverable product) in aboveground retorting, more abrasion-resistant low-alloy steels may be required in the future. The need for longer-life mining components, such as rock-cutting heads, may also require materials development. The refractories available for a variety of elevated-temperature processes appear to be satisfactory for lining aboveground crucibles. The ability of the refractories to withstand the abrasion or combined corrosion and abrasion of the shale may become a problem. The effects of heating and cooling cycles and severe climatic changes during inactive periods may also limit refractory material life. Corrosion of metals in hot retorting environments is a problem that should be addressed. Tumbling abrasion tests are directly applicable to a rotating-kiln retort and could be extended to other equipment items. High-temperature erosion by shale particulates should also be investigated.

Because of the quantity of fairly large-diameter piping that will be needed in in-situ retorts for injection and recovery wells, economics dictates that the lowest-cost low-alloy steels be used. In some systems, these pipes may pass through the retort, and their ability to withstand the corrosive environments of the retort for the required times is a problem. Protective coatings, such as aluminizing on carbon steels and on low-alloy steels, may solve this problem. In some retort designs, these pipes will not encounter the hot corrosive environment.

In vertical retorts, the thermowells can be more than 300 m long and must pass through the combustion and burned-out zones to carry their critical temperature measurements to the surface. The corrosion of their metal sheaths, which occurs because of the presence of oxygen and sulfur at 1000°C and even higher, can severely limit thermowell life. Temperatures high enough to cause severe attack may be maintained for periods ranging from many hours near 1000°C to days at over 800°C. The creep strength of thermowell sheaths must be sufficient to protect the internal components from the forces of shifting rock during the retorting operation. The development and demonstration of successful indirect chemical methods of monitoring retort zones may have eliminated the need for thermowells and materials research associated with these thermowells.

Maintaining reliable functioning of sump pumps to drive the products from the bottom of retorts to the surface can be a problem. The corrosion potential of the liquids and gases being pumped has not been well defined and may adversely affect the recovery piping and its control valves as well as the pumps. The fluid temperatures in these components will be about 250°C. Shale dust entrained in the oil may result in accelerated wear of pump components.

The uncertainty of future development of oil shale retorting processes makes it difficult to identify positively those materials research and development programs that should be undertaken. Whether both above-ground and in-situ retorting will become commercial is not clear. Some unresolved materials requirements of aboveground retorting were identified. Research and development to support more generic energy-supply materials requirements, such as those in mining and coal conversion, may be applicable to some of these needs.

The additional requirements of in-situ retorts are difficult to predict this early in the development and utilization of the process. The one-time use of the piping and other components in underground retorts may permit the use of already available materials, primarily those that are used in the oil-drilling industry. The thermowell problem is currently definable, but even here it is expected that, after the retort development period is over, retorts could be operated according to procedures established during the development without the need to monitor combustion zones. At this time more experience appears to be necessary, particularly in actual underground operations, before additional specific materials research and development programs can be defined. However, as improved alloy coatings are developed to reduce corrosion losses in the retort, attendant nondestructive testing development including ultrasonic and eddy-current methods should be accomplished to ensure adequate integrity.

Considering the magnitude and near-term timing of commercial oil shale processing, a materials review and/or a materials needs assessment for surface retorting is indicated. If generic materials needs are identified, support of research addressing these needs by the AR&TD Fossil Energy Materials Program would be indicated.

10. TECHNOLOGY ASSESSMENT AND TECHNOLOGY TRANSFER

10.1 TECHNOLOGY ASSESSMENT

One of the more important responsibilities of the AR&TD Fossil Energy Materials Program is to be aware of technical issues and research and development needs of both established and emerging fossil energy systems. The assessment of materials problems and needed research to solve those problems in a wide variety of fossil energy technologies is the foundation of an active and relevant research program. The AR&TD Fossil Energy Materials Program fulfills this responsibility by use of technology assessments of materials needs in fossil energy systems.

One such assessment was performed in FY 1980 to identify materials problems in a variety of fossil energy systems.¹ Background information relative to the various technologies is given, and materials research needed to improve the viability and economics of fossil energy processes is discussed. The assessment is presented on the basis of materials-related disciplines that affect fossil energy materials development. These disciplines include design-materials interface, materials fabrication technology, corrosion and materials compatibility, wear phenomena, ceramic materials, and nondestructive testing. The needs of these various disciplines are correlated with the emerging fossil energy technologies that require materials consideration.

A second assessment was completed in late FY 1982 to identify and quantify the critical (strategic) materials requirements for a generic direct coal liquefaction facility.² It was performed as an engineering estimate of materials requirements based on engineering and technical data for this type of synthetic fuel facility.

A third assessment was completed in FY 1985 to determine the status of materials technology for advanced-steam-cycle pulverized-coal plants and to identify materials research and development that would permit the design, construction, and reliable operation of more efficient power plants.³ A pulverized-coal power plant employing an advanced steam cycle to improve the overall plant efficiency was defined. The proposed system was analyzed with existing computer codes to determine the net efficiencies achievable

with various steam conditions (e.g., at temperatures between 593 and 650°C and pressures between 28 and 34 MPa). Through consultation with boiler and turbine-generator manufacturers, the ability of existing materials to meet the requirements for advanced steam cycles was determined. Materials research and development needs and areas of research that will provide the greatest payback in terms of improved efficiency and plant availability were identified. A report³ documenting the findings and recommendations resulting from the study has been published. Prior to publication, a draft of the report was sent to boiler manufacturers, turbine-generator manufacturers, and the Electric Power Research Institute (EPRI) for their review and comment.

10.2 TECHNOLOGY TRANSFER

The transfer of technology to interested parties is aided by a bi-monthly newsletter, *Materials and Components in Fossil Energy Applications*. This project (WBS element BCL-4), conducted for the AR&TD Fossil Energy Materials Program by the Battelle Columbus Laboratories (BCL), provides for the collection, evaluation, and dissemination of information pertinent to the use of materials and components in fossil energy applications. The program at BCL has been very effective for information and technology transfer and is expected to continue.

To provide a more effective distribution of information gained on this AR&TD Fossil Energy Materials Program, consolidated quarterly reports on the progress of the program were initiated in FY 1981 and have continued.⁴ The consolidated quarterly reports cover the progress of all activities conducted on the program. Each report is divided into sections and chapters, with each section describing projects related to a particular fossil energy technology.

An important consideration of the AR&TD Fossil Energy Materials Program is to ensure that others in the fossil energy community, as well as in the overall research community, are knowledgeable of the reports and publications that result from each of the research projects on the Program. To facilitate this awareness and to encourage transfer of the technology developed on the Program, the AR&TD Fossil Energy Materials

Program published in FY 1986 a bibliography of publications by past and current participants on the Program.⁵

Ad hoc meetings on current materials problems related to corrosion and erosion have been sponsored jointly by the AR&TD Fossil Energy Materials Program, the Office of Coal Processing, and the SRC/H-Coal Projects Office. Meetings on the subject of corrosion in liquefaction plant fractionation columns were held at Oak Ridge, Tennessee; Baytown, Texas; Lexington, Kentucky; and Birmingham, Alabama. These meetings brought together those parties directly involved in the study of materials problems for coal liquefaction in forums specifically designed for the transfer of information.

The Department of Energy, Electric Power Research Institute, Gas Research Institute, and National Bureau of Standards sponsor conferences on Materials for Coal Conversion and Utilization.⁶ Seven of these conferences have been held, and they have been very effective in the transfer and exchange of information from the sponsors' programs. Proceedings of these conferences are published, making this information readily available.

PART III
CURRENT AND PLANNED PROJECTS
IN THE AR&TD FOSSIL ENERGY MATERIALS PROGRAM

1. STRUCTURAL CERAMICS

1.1 RESEARCH OBJECTIVES

The objective of this research area is to study the relationships between the chemical composition, microstructure, and properties of structural ceramics and fiber-reinforced ceramics used in fossil energy systems. This area also includes work on nondestructive examination of ceramics and on electrochemical behavior and phase chemistry of oxides for solid oxide fuel cells.

Materials such as silicon carbide (SiC) or silicon nitride (Si_3N_4) offer the potential of higher strength, lower creep, and greater oxidation resistance above 1000°C than do available engineering alloys, but they have the disadvantage of having large variations in strength (low Weibull modulus) and relatively low fracture toughness compared with alloys. Their mechanical behavior is determined by flaw sensitivity and brittle behavior. Flaws may be pores, inclusions, grain boundaries, large grains, or other microstructural irregularities. Flaws introduced from the starting materials or from material processing and fabrication cannot be mitigated by microplasticity as they would be in ductile materials. Thus, the characterization of the starting materials and the processing technology are critical. The populations of flaws must be treated statistically in the design of components. For example, the strength of components made from the same material depends on component volume (and the probability of a critical flaw). Subcritical flaws may grow under stress and, in aggressive environments, may become critical and thus cause failure. The time-dependent behavior of brittle materials must be understood and considered in design. An understanding of the mechanisms responsible for strengthening and toughening will provide the basis for the development of whisker- or fiber-reinforced ceramic composites with improved properties for high-temperature fossil energy systems.

Current and planned research projects in this thrust area are described in the following section and are listed in Table III.1 at the end of the section.

1.2 SUMMARIES OF CURRENT AND PLANNED RESEARCH

ORNL-1(A), "Fabrication of Fiber-Reinforced Composites by CVD Infiltration," Oak Ridge National Laboratory. The purpose of this task is to develop a ceramic composite having high fracture resistance and strength yet retaining the typical ceramic attributes of refractoriness and high resistance to abrasion and corrosion. The desired fracture toughness and strength are on the order of $20 \text{ MPa} \cdot \text{m}^{1/2}$ and 500 MPa, respectively. In addition, a practical process for fabricating simple or complex shapes is desired. The ceramic fiber-ceramic matrix composites are fabricated by infiltrating low-density fiber structures with gases which deposit as solid phases on and between the fibers to form the matrix of the composite. The goal is to demonstrate that a ceramic composite can be prepared from materials of high interest to the fossil energy community. Our earlier assessment identified SiC fibers and matrices of SiC and Si_3N_4 as being most promising. Effects of fiber dimensions, geometry, packing density, binder type and concentrations, and other processing variables are evaluated experimentally.

Initial experimental efforts focused on the use of a vacuum-forming molding process to form a low-density fiber bed suitable for gas infiltration. Once the fiber bed was formed, dried, and heat treated, the matrix of the composite was formed by chemical vapor deposition (CVD) in a high-temperature furnace. A novel scheme (patent applied for) of forcing the coating gases to flow *through* the fiber bed was tested in an attempt to increase the deposition rate over rates normally obtained when the deposition gases flow across the fiber bed with simple diffusion used to infiltrate. In addition, depending on the deposition reaction, a vacuum may or may not be used to assist the flow of gases through the fibrous parts. Important variables of the CVD process, such as temperature, gas composition, flow rate, and pressure, are systematically altered to maximize matrix density and to obtain a microstructure consistent with the goal of fabrication of high-toughness, high-strength ceramic composites. A statistically designed experiment is being conducted to determine the effects of these process variables on properties of the composites.

The room temperature flexure strength and the stress-strain curve are currently determined in four-point flexure. The notched beam technique is used to measure the fracture toughness of the composite. However, the strength and fracture toughness values determined by these techniques may not be valid for fibrous composites, and other measurement techniques are being explored. Direct tensile measurements are being evaluated for these composites.

ORNL-1(B), "Characterization of Fiber-CVD Matrix Interfacial Bonds,"
Oak Ridge National Laboratory. The purpose of this task is to optimize the strength and toughness of fiber-reinforced ceramic composites by tailoring the strength of the bonds between the fiber and the matrix. Methods must first be developed to characterize the fiber-matrix bond strengths in fiber-reinforced ceramic composite systems. Coating or pretreatment processes can then be utilized to tailor the fiber-matrix bonding within various composite systems and to optimize the strength and toughness of the composite.

The principal goal of this project is to demonstrate that the interfacial bond between Nicalon fibers and various ceramic matrices can be measured and controlled for optimization of mechanical properties such as strength and toughness. The technical approach to be followed during this project includes four tasks: (1) develop interface characterization techniques, (2) develop bond strength measurement techniques, (3) determine candidate overcoat compositions and develop or contract for overcoating of fibers, and (4) characterize composites and correlate fiber-matrix bonding with strength and strain tolerance. Techniques will be developed to investigate the interfacial region and determine whether intermediate layers are present and how they affect the bond strength and resulting strain tolerance of the composite.

Mechanical properties of fiber-reinforced composites are controlled not only by the strength and modulus of the fibers and matrices, but also by the strength of the bond between the fibers and the matrix. Methods will be developed to determine the bond strength in fiber-reinforced composite systems or at least to determine the relative bond strength of one fiber-matrix system as compared to another.

B&W/ORNL-1, "Transfer of CVD Infiltration Technology to Industry,"
Babcock & Wilcox and Oak Ridge National Laboratory. The purpose of this task is to transfer to industry the technology developed in WBS element ORNL-1(A) for fabricating ceramic fiber-ceramic matrix composites by the CVD infiltration process. An agreement was established between ORNL and the Babcock and Wilcox Company (B&W) to collaborate in the further development of this technology. ORNL and B&W are developing and characterizing fiber-reinforced ceramic composites with improved fracture toughness. The development of useful composite materials requires (1) the development of higher density ceramic fiber preforms and (2) rapid, low-cost methods of infiltrating the fibrous preforms with a ceramic matrix. Babcock and Wilcox is developing the higher density ceramic fiber preforms at its Lynchburg, Virginia, facility. With the assistance of a B&W researcher working part-time at ORNL, ORNL is infiltrating the preforms by using the CVD process. New CVD apparatus and tooling are being developed as part of this joint effort and are being tested by the B&W assignee at ORNL. The materials being investigated include silicon-carbide and aluminum-oxide fibers, and CVD infiltration matrices of silicon carbide and silicon nitride. Oak Ridge National Laboratory is evaluating composite microstructures by optical microscopy, and B&W is performing additional characterization by determining mechanical properties.

GT-1(A), "Modeling of Fibrous Preforms for CVD Infiltration," Georgia
Institute of Technology. The purpose of this project is to conduct a theoretical and experimental program to develop an analytical model for the fabrication and infiltration of fibrous preforms. CVD has demonstrated considerable promise as a technique for fabrication of fiber-reinforced ceramic composites. Unidirectional and cloth-reinforced composites of SiC fibers in a SiC matrix have shown good strength and exceptional strain tolerance. However, results have been inconsistent with the fabrication of randomly oriented short-fiber composites. A critical problem has been the inability to consistently fabricate fibrous preforms with both high fiber loading and a permeability suitable for infiltration. A better understanding of the fundamental parameters controlling preform fabrication and CVD infiltration of such preforms is needed to guide further

development. The analytical model predicts (1) preform structure (density, porosity, fiber orientation, etc.) based on fabrication technique and fundamental fiber parameters (diameter, aspect ratio, etc.) and (2) permeation and heat conduction through the preform structure and, thus, predicts CVD infiltration performance. Initially, the model was developed for preforms containing only one type of fiber, but has been extended to mixed fiber and fiber-particle blends.

GT-1, "Development of Advanced Fiber-Reinforced Ceramics," Georgia Institute of Technology. The purpose of this work is to conduct a theoretical and experimental program to identify new compositions and processing methods to improve the physical and mechanical properties of selected fiber-reinforced ceramics. The ceramic matrix material studied in the first year was amorphous "fused" silica or modified silica glass, and the focus was on the development of fiber-reinforced silica. Parameters studied included (1) differences in elastic modulus between matrix and fiber, (2) differences in thermal expansion, (3) nature of interfacial bond, (4) densification of matrix, (5) nature of fiber fracture-pull-out, (6) fiber diameter and fiber length-to-diameter ratio, (7) fiber loading, and (8) fiber dispersion and orientation. In addition, a model based on the information generated in the experimental phase of the program is being developed. Work is also directed at the improvement of the physical and mechanical properties of sintered and reaction-bonded fiber-reinforced silicon nitride.

PNL-1, "Advanced Ceramic Matrix-Ceramic Fiber Composites," Pacific Northwest Laboratory. The purpose of this research is to improve the properties of ceramic fiber-ceramic matrix (ceramic-ceramic) composites for fossil energy systems by controlling the fiber-matrix interface. The approach is to: (1) develop a basic understanding of fiber-matrix interfaces; (2) relate this understanding to the composite materials, properties, structures, processes, and environments; and (3) apply this knowledge to modify or control the fiber-matrix interface.

This research will initially investigate the microstructure, crystal structure, and chemical interactions of fiber-matrix interfaces and relate these interfacial characteristics to the materials, properties, process

histories, and service environments of the bulk composite. This work will emphasize silicon carbide and silicon nitride composites. With this knowledge, modifications will be made to the matrix, the fiber, or the composite fabrication process to control the fiber-matrix interface and the composite properties. Studies will initially include the most promising ceramic-ceramic composites now being developed for fossil energy systems.

LANL-1, "Short Fiber Reinforced Structural Ceramics," Los Alamos National Laboratory. The purpose of this project is to investigate the utility of whisker reinforcement technology for producing structural ceramic composites of improved strength and fracture toughness. The project consists of two technical tasks. The first is to optimize a whisker growth process to produce alpha-phase silicon nitride (α -Si₃N₄) whiskers and beta-phase silicon carbide (β -SiC) whiskers of uniform size and optimum strength and in quantities suitable for composite use. The second task will involve determining the contribution of the whiskers to fracture strength and toughness in selected ceramic-matrix composites.

INEL-1(B), "Joining of Silicon Carbide Reinforced Ceramics," Idaho National Engineering Laboratory. The purpose of this project is to identify and develop techniques for joining composite materials reinforced with silicon carbide fibers. Primary emphasis is on composite materials with either a silicon nitride or a silicon carbide matrix; lesser emphasis is placed on silica reinforced with silicon carbide fibers. The work is investigating oxynitride and oxide glass joining materials, and joining techniques that promote the devitrification of these materials to produce glass-ceramics and joints that are both strong and tough. Joining of composite matrix materials is being studied, and the resulting information will be applied to the joining of the fiber-reinforced composites. Joining material, surface preparation, heat treatments, methods of binder application, joining technique, and joint configuration are being considered during joint design and fabrication. Microstructural examination of the joints is conducted to investigate wetting, microstructure, mass transfer, and process parameter effects. Limited mechanical testing of joints will be conducted. Thermal cycling and service environment scoping tests will be performed for selected composite joints. Practical joining techniques

must be developed to fully realize the advantages of ceramic composite materials reinforced with silicon carbide fibers. Successful joining methods will permit the design and use of complex component shapes and the integration of component parts into larger structures.

ANL-1(C), "Study of Fracture Stress and Fracture Toughness Behavior of Fiber-Reinforced Ceramic Composites," Argonne National Laboratory.

The goal of this project is to establish acceptable mechanical property evaluation methods for fiber-reinforced composites, with particular emphasis on fracture stress and fracture toughness measurements. Fracture toughness is currently considered a property of major importance for monolithic materials, yet its significance with respect to composites with multiple phases has yet to be resolved. The influence of chemical composition, microstructure, and fiber-matrix interaction on these mechanical properties will be investigated.

SC(U)-1, "Investigation of the Mechanical Properties of CVD Infiltrated Ceramic Composite Tubular Components," contractor to be determined. The purpose of this project is to develop an understanding of the long-term performance of CVD infiltrated ceramic composite components. Comprehensive mechanical properties tests of composite components such as tubes, plates, shells, and beams subjected to static and cyclic multiaxial loading at elevated temperatures over various time periods will be conducted.

INEL-1(A), "Nondestructive Evaluation of Advanced Ceramic Composite Materials," Idaho National Engineering Laboratory. The purpose of this project is to develop an effective capability for nondestructive evaluation of ceramic-fiber-reinforced ceramic composites. The response of selected samples of sintered composite materials consisting of SiC fibers in SiC and silicon nitride matrices to both ultrasonic and radiographic techniques is being investigated. Experimental techniques and signal processing algorithms will be developed for (1) characterizing acoustic properties and sample morphology, including fiber size and distribution and the degree of bonding of the fibers to the matrix, (2) detecting flaws including cracks, porosity, fiber clusters, and bonding anomalies, and (3) detecting flaws in joints. The nondestructive evaluation (NDE) techniques developed in this project will result in more effective and extensive use of advanced ceramic composite materials in fossil energy applications.

ANL-1(A), "Development of Nondestructive Evaluation Techniques for Structural Ceramics," Argonne National Laboratory. The purposes of this project are to (1) evaluate and develop effective NDE techniques (mainly acoustic and radiographic techniques) for detecting flaws and characterizing structural ceramics (green state and densified); (2) establish the types and characteristics of flaws that can be found by such techniques; and (3) determine correlations between detected flaws, characterizations, and fracture behavior of the ceramics. The NDE techniques will be applied primarily to monolithic ceramics to detect porosity, cracking (surface and internal), inclusions, and density variations. Green-state specimens are being emphasized at present, but densified samples are included in the experimental program. This task is coordinated with WBS elements ANL-1(B), INEL-1(A), and PNL-1.

ANL-1(B), "Effect of Flaws on the Fracture Behavior of Structural Ceramics," Argonne National Laboratory. The purpose of this work is to (1) establish correlations between the composition, microstructure, and mechanical properties of structural ceramics (Si_3N_4 and SiC) with well-defined flaws, and (2) provide information that will be used to relate mechanical properties to NDE results obtained in WBS element ANL-1(A). The work will include fabricating specimens of Si_3N_4 and SiC with controlled flaws and measuring their mechanical properties (fracture stress, fracture toughness, and elastic modulus). Subsequently, microstructures of the fracture surface will be evaluated in order to locate the critical flaws. The results of the evaluation of mechanical properties and microstructure will be used together with the results of WBS element ANL-1(A) in a joint effort to correlate fracture behavior with flaws. Information obtained from these studies will help control processing of structural ceramics to improve mechanical properties. Furthermore, correlation of mechanical properties with NDE results will provide additional information that will help verify the ability of NDE to detect failure-initiating flaws. Knowledge of failure-initiating flaws is needed to help better define the flaws to be detected by NDE in WBS element ANL-1(A).

NBS-1, "Structural Reliability and Damage Tolerance of Ceramic Composites for High-Temperature Applications," National Bureau of Standards. The objective of this study is to determine the critical factors that influence the high strength and thermal shock resistance of ceramic composite materials. The activities of the program are grouped under two major subtasks, each designed to develop the key data, associated test methods, and predictive models that assist in the determination of the mechanical and microstructural behavior. The subtasks for this effort are:

- (1) study of interfacial and microstructural composite properties, and
- (2) investigation of high-temperature damage modes and failure mechanisms.

ACX-1, "Assessment of the Causes of Failure of Ceramic Filters for Hot-Gas Cleanup in Fossil Energy Systems and Determination of Materials Research and Development Needs," Acurex Corporation. The purpose of this project is to determine the principal causes of failure of ceramic filters used for removal of fine particulates from high-temperature, high-pressure gas streams in coal conversion and utilization systems such as fluidized-bed combustors, direct coal-fired gas turbines, and coal gasification systems. As part of this project, current practices in design and engineering of ceramic filters will be identified, and current uses for such filters in industrial and utility applications similar to those in the fossil energy systems will be described. Material failure experience will be examined, and causes of failure of ceramic filters will be determined through conversations with manufacturers and users and through laboratory failure analyses. Materials research and development that would improve the reliability of these filters and design features of current filters that contribute to materials failure will be identified.

SC(I,U)-1, "Development and Evaluation of Ceramic Filters for Hot Gas Cleanup," contractor to be determined. This work, which will be initiated in FY 1988, will address the development of ceramic filters for use in systems requiring particulate removal from hot gas streams. It is anticipated that the project will be defined in large measure from the results of project ACX-1.

UKCRE-1, "Investigation of the Mechanisms of Failure of Ceramic Materials for Hot Gas Filtration," United Kingdom Coal Research Establishment. High-temperature ceramic filters used for removing particulates from gas streams have been under evaluation at the United Kingdom

Coal Research Establishment (UKCRE). These filters, also called "candles," have been tested at 950°C in gasification atmospheres. Cracks at the point of attachment to the manifold have not only been a drawback to the application of this specific ceramic design, but they also represent a phenomenon generic to most rigid ceramic filters. No detailed phenomenological explanation of the failure has been determined. This task is a cooperative project of the DOE AR&TD Fossil Energy Materials Program and the UKCRE to develop an understanding of the mechanisms of failure of ceramic hot-gas filtration materials and, thereby, provide a basis for material and system improvements.

2. ALLOY DEVELOPMENT AND MECHANICAL PROPERTIES

2.1 RESEARCH OBJECTIVES

The objective of research in this thrust area is to understand the chemical and physical metallurgy that affects the high-temperature mechanical properties, as well as welding and joining, of high-temperature alloys used as structural materials in coal conversion and utilization systems. Work in this area will include studies of mechanical properties, weldability and fabricability of materials ranging from advanced austenitic steels to ordered intermetallic alloys. The research in this area will provide the needed background for the development of high-strength, structural alloys for high-temperature applications in coal gasification and coal combustion systems. This thrust area also includes projects near completion on pressure vessel materials for coal liquefaction applications.

Research projects are described in the following section and are listed in Table III.2 at the end of the section. As was noted above, and as will be obvious from the following descriptions, the emphasis in previous years on pressure vessel materials will be replaced by emphasis on high-temperature structural alloys for wider applications.

2.2 SUMMARIES OF CURRENT AND PLANNED RESEARCH

2.2.1 Pressure Vessel Materials

UCB-2, "Study of Damage Mechanisms in Coal Conversion Atmospheres Affecting the Fatigue and Creep Rupture Properties of Cr-Mo Steels,"
University of California, Berkeley. The purpose of this project is to evaluate the effects of high-temperature service in adverse environments on the metallurgical properties (particularly on fatigue crack propagation and creep rupture properties) of weld metal and heat-affected zone (HAZ) regions in thick-section weldments of 3Cr-Mo steels. The overall objective is to develop techniques for modifying the microstructures (in the HAZ and base plate) resulting from welding in order to provide adequate resistance to environmentally induced damage while at the same time maintaining other desired mechanical properties.

Microstructures in the base metal, HAZ, and weld will be fully characterized in terms of microconstituents and phases. Damage in the form of

microcavities or methane bubbles, situated in areas expected to be high-damage areas resulting from extended environmental exposure (e.g., to high-pressure, high-temperature hydrogen) and from welding, will be introduced. Fatigue crack growth characterization studies of weldments will be carried out to determine the influence of metallurgical features and environment on the fatigue crack growth rate from near-threshold to near-instability. Creep rupture testing will be done in order to investigate the influence of damage mechanisms in weldments that are time dependent in their effect on microstructure/mechanical property relationships.

UTN-2, "Transformation, Metallurgical Response, and Behavior of the Weld Fusion Zone and HAZ in Cr-Mo Steels," University of Tennessee.

Continuous cooling transformation diagrams were developed for several chromium-molybdenum (Cr-Mo) alloys. The heat-affected zone (HAZ) and autogenously welded fusion zone microstructures of gas tungsten arc (GTA) welds were metallurgically characterized. The cold cracking tendency of the weld and HAZ regions are being determined as well as the effect of postweld heat treatment on the HAZ properties, microstructure, and cracking tendencies. Some weldments are being creep-rupture tested. Materials include 2.25Cr-1Mo, 3Cr-1.5Mo-V, and 9Cr-1Mo-V-Nb steels.

UCSB-2, "Analysis of Hydrogen Attack on Pressure Vessel Steels," University of California, Santa Barbara. The initial objectives of this program have been achieved, and physical models that describe the initiation and development of methane damage in carbon steel, C-Mn-Si steels, 2.25Cr-1Mo steel, and weldments have been developed. Nelson diagrams have been predicted and appear to be reasonably consistent with available data. Additional work is in progress to refine the analyses and to confirm the adequacy of the basic thermodynamic information available in the literature. The model has been particularly useful in establishing the relative importance of microconstituents, deformation mechanisms, and fracture mechanisms to the hydrogen attack process. In this sense it will guide the development of modified low-alloy steels for optimum resistance to hydrogen attack. In FY 1985 significant progress was made in examining the role that stress and plastic strain transients play in the hydrogen attack phenomena. Such information is vital because the current design

rules for hydrogen service restrict the use of Nelson curves to situations in which the stresses do not exceed the primary stress intensities provided in the *ASME Boiler and Pressure Vessel Code*.

WEC-2, "Evaluation of 3Cr-1.5Mo Steel in a Simulated Coal Conversion Environment," Westinghouse Electric Corporation. The purpose of this work is to develop a fracture mechanics characterization of candidate materials for coal gasification pressure vessels. The apparatus being used for the fracture characterization has unique capabilities for in-situ testing of steels in high-pressure high-temperature H_2 - H_2S environments. The study is complemented by a physical metallurgical evaluation of the various degradation processes observed in the basic characterization. This effort focuses primarily on the simulated environmental properties of a candidate material (3Cr-1.5Mo-V steel) for use in pressure vessel construction for coal gasification processes. The environments and conditions to which the steel will be exposed are (1) a mixture of gases including H_2 and about 1% max H_2S and (2) 10.4 MPa pressure at 315°C. This is a laboratory simulation of the coal gasification environment, which, in addition, includes CO - CO_2 and H_2 - H_2O . Because the selected steel will ultimately be welded, the following metallurgical considerations must also be evaluated: (1) weldability of the base metal, (2) weld metal composition, and (3) heat-affected zone (HAZ). Thus, it will eventually be necessary to test base metal, weld metal, and the HAZ to ensure reliability. The current work includes the base plate metal only.

2.2.2 Superheater and Reheater Materials

ORNL-2(B), "Development and Microstructural Evaluation of Advanced Austenitic Alloys," Oak Ridge National Laboratory. Alloys based on modifications to four groups of alloys will be developed on the basis of attributes required for advanced steam cycle superheater service. The four alloy groups to be studied include modified type 316 stainless steel, modified type 310 stainless steel, modified high nickel (alloy 800H) steels, and aluminum-containing steels. The bases for the alloy design include long-term strength and stability. Strength is developed by control of chemical composition, and stability is assured by suppression of intermetallic and other embrittling phases by the addition of elements that promote austenitic stabilization. Added strength is achieved through the precipitation of

fine carbides, nitrides, or phosphides that stabilize dislocation networks, prevent grain boundary migration, and resist coarsening during long service under constant and varying load conditions. Metallurgical tools used in these studies include optical microscopy, electron microscopy, and micro-hardness measurements.

SC(I)-2(A), "Production of Test Heats of Candidate Alloys for Superheaters and Reheaters for Advanced Steam Cycles," contractor to be determined. This task will involve the production of test heats (up to 40 compositions) of alloys developed or selected by ORNL for evaluation as superheater and reheater materials. Standard melting practices or modifications thereof based on the requirements of the particular alloys will be used. The test ingots will be shipped to ORNL for evaluation. Procurement of the materials will be by competitive bidding by commercial suppliers. Since several suppliers are likely to be involved, we have not designated a specific supplier in the WBS element nomenclature.

ORNL-2(C), "Evaluation of Mechanical Properties of Advanced Austenitic Alloys," Oak Ridge National Laboratory. Creep-rupture data on alloys developed in ORNL-2(B) are being gathered in the temperature range 600 to 760°C for times from 10 to 10,000 h. The effects of mechanical and thermal cycles will be examined, and results from testing will be used to establish cumulative damage models. Multiaxial stress testing, notched-bar stress-rupture testing, and creep crack-growth testing will be undertaken for constant and variable load conditions to verify cumulative damage models.

CU-2, "Mechanical Properties and Microstructural Stability of Advanced Steam Cycle Materials," Cornell University. The purpose of this project is to rank the strengths and metallurgical stabilities of advanced steam cycle superheater alloys at temperatures ranging from 650 to 760°C. Mechanical testing of the steels consists of relaxation experiments (~24 h duration each) that cover stresses producing deformation rates from about 10^{-3} to 10^{-9} /s. The precipitate or dislocation microstructure of the steels in the grain boundary and matrix regions is being studied to determine the role of strain-time history on the stability of the microstructure. The relaxation data will be correlated with constant-load creep data provided by Oak Ridge National Laboratory [ORNL-2(C)] and analyzed in terms of deformation mechanisms to determine relative contributions of grain

boundary and matrix deformations. The most promising alloys from the screening test will be included in relaxation tests at 700°C to determine optimum heat treatments for strength and metallurgical stability.

SC(I)-2(E), "Effect of Microalloying Additions on High-Temperature Strength of Candidate Alloys for Advanced Steam Cycle Superheaters and Reheaters," contractor to be determined. This project will be directed to understanding the performance (and thus the effect of microalloying additions) of advanced austenitic alloys under temperature and load cycling conditions that could be experienced in advanced steam cycle superheaters and reheaters. This project will be complementary to ORNL-2(C), but it will extend the range of testing to conditions more representative of actual steam cycles. Multiaxial stress testing, bend testing, creep testing, and crack initiation and growth testing will be performed. Data from these tests will be used in project ORNL-2(C) to further verify the cumulative damage models.

SC(I)-2(B), "Production of Small Heats of Tubing," contractor to be determined. Based on the production and evaluation of the initial candidate alloys in ORNL-2(B), -2(C), and -2(D), the number of compositions will be reduced to sixteen in the four alloy groups. These alloys will be produced as small heats and will be formed into tubular shapes for evaluation. These tubes will be submitted to ORNL and will be evaluated for mechanical properties and phase stability. Surface protection methods for fireside and steamside corrosion will also be investigated.

SC(I)-2(C), "Production of Full-Size Tubing of Candidate Alloys," contractor to be determined. On the basis of evaluation of the small heats of tubing in SC(I)-2(A), the number of candidate alloys will be reduced to four alloys in two alloy groups. An industrial subcontractor will be selected to produce tubing by current commercial techniques. This tubing will also be delivered to ORNL and evaluated for the advanced steam cycle application.

ORNL-2(D), "Weldability Studies of Advanced Austenitic Alloys," Oak Ridge National Laboratory. Evaluation of the weldability of the alloys developed in ORNL-2(B) includes a specialized technique on a device called a Sigmajig, which evaluates the hot cracking tendency of the weldments. Ranking of alloys is by the extent of cracking as a function of

applied load and plate thickness. Weldments in the alloys produced as tubing will be evaluated against requirements of the ASME BPV Code Sections I and IX, which involve bend testing, tensile testing, and metallography. Additional evaluation will be based on vareststraint and circular groove tests. Other tests not required by the Code may be identified during the course of this work, and those tests will be included as appropriate. The development of a suitable filler metal is an important part of this work. ORNL will work with university and industrial subcontractors [SC(I,U)-2(C)] in this development.

SC(I,U)-2(C), "Joining Techniques for Candidate Alloys for Superheaters and Reheaters for Advanced Steam Cycles," contractor to be determined. The complete development of alloys for advanced steam cycle superheaters and reheaters will include the development of reliable filler metals and welding techniques, as well as the establishment of appropriate welding parameters. We will initiate a collaborative industry-university project in FY 1987 to develop these joining techniques.

SC(I,U)-2(A), "Fireside Corrosion Tests of Candidate Superheater Tube Alloys, Coatings, and Claddings," contractor to be determined. Molten coal ash corrosion is probably the most critical materials concern for superheaters and reheaters in the advanced steam cycle plants. Laboratory tests of candidate alloys (with coatings and claddings) in environments that simulate the fireside environment of superheater and reheater tubes will be conducted. Tests of the superior candidate alloys may also be conducted in operating units or test furnaces. Our approach will be to fund this activity as a supplemental part of the Electric Power Research Institute (EPRI) Phase 1 test program, which will be conducted at lower temperatures. We anticipate a usual metal temperature of about 700°C whereas the EPRI Phase 1 program would involve usual metal temperatures of about 590°C.

HEDL-2, "Application of Coatings to Candidate Superheater Alloys by the Electrospark Deposition Coating Process," Hanford Engineering Development Laboratory. The purpose of this task is to examine the use of the electrospark deposition coating process for the application of corrosion-resistant coatings to candidate superheater alloys. As coating materials are identified [SC(I)-2(D)] and tested [SC(I,U)-2(A)], the use of electrospark deposition as an application technique for these coatings will be investigated.

SC(I)-2(D), "Surface Treatments of Tubing for Fireside Corrosion Protection," contractor to be determined. Selected surface treatments, developed for the candidate alloys in this project, will be tested in the project SC(I,U)-2(A) to determine their ability to provide resistance to corrosion on the steamside and in the fireside environment of advanced steam cycle systems. Alternative techniques including coatings (e.g., chromizing), claddings, and coextrusions will be investigated and demonstrated.

SC(I,U)-2(B), "Steamside Corrosion Tests of Candidate Superheater Tube Alloys," contractor to be determined. Steam corrosion of superheater tubes in the advanced steam cycle systems is a critical problem because of the more rapid formation of scale at the higher temperatures. Exfoliation of the scale is the principal concern because of the damage to turbines that can result due to erosion. This project will involve laboratory tests of the candidate alloys and coating materials in the steam environment. This project, as well as project SC(I,U)-2(A), will provide information for the investigation of surface treatment techniques [SC(I)-2(D)].

UI-2, "Development of a Design Methodology for High-Temperature Cyclic Application of Materials which Experience Cyclic Softening," University of Illinois. The objective of this project is to develop a design methodology for high-temperature cyclic conditions, taking into account the effects of strain softening. Since the problem of cyclic softening is generic to a wide class of medium- to high-strength low alloy steels, it is not the main purpose of this investigation to examine specific characteristics of any one steel but to investigate the general behavior of components subject to the cyclic softening phenomenon.

The specific objectives of the project are: (1) the development of simplified methods of component analysis to evaluate overall and local effects of cyclic softening on time-dependent deformations, (2) the development of an improved understanding of the mechanisms of interaction between intermittent cyclic stresses and reduction of resistance to creep deformation, (3) an evaluation of the possible effects of cyclic softening on the initiation and propagation of defects, (4) an evaluation of the possible effects of cyclic softening on the procedure for determining allowable design stresses for high-temperature design, and (5) provision of

input into the material effort to extend life in existing power plants by examining the relation between material damage parameters and component performance criteria, for possible use in remnant life assessment.

2.2.3 Aluminides

ORNL-2(A), "Development of Iron and Nickel Aluminides," Oak Ridge National Laboratory. New improved alloys are needed for high-temperature components in severe environments for applications such as coal-fired gas turbines or diesel engines, fluidized bed combustors, coal gasification systems, and fuel cells. The purpose of this task is to design and test materials that will possess good mechanical properties at elevated temperatures and that will develop protective Al_2O_3 layers to prevent sulfidation attack. Aluminides based on the pseudobinary systems Ni_3Al - Fe_3Al and NiAl - FeAl form the basis for development of materials with the required properties. Success in development of iron and nickel aluminides as structural materials could substantially improve the performance and reliability of advanced fossil energy systems.

The development of iron and nickel aluminides for critical components in coal combustion and conversion systems is based on determining phase relationships and understanding the structure-property relationships that determine the oxidation-sulfidation behavior, the mechanical properties, and the fabricability and weldability of the alloys. A knowledge of the physical metallurgy of the alloy systems involved as well as the source of the grain-boundary embrittlement and the oxide/sulfide formation is required. Compositional control by macro- and microalloying and microstructural control by processing treatments are used to optimize the desirable properties.

The initial approach of this task is to develop aluminides based on the pseudobinary system Ni_3Al - Fe_3Al . Iron is macroalloyed to Ni_3Al for solid solution hardening at elevated temperatures and for corrosion resistance in sulfidizing environments. Boron and other elements are employed for controlling the chemistry and cohesion of grain boundaries. The development of aluminides will also be extended to the FeAl - NiAl system, which contains 50 at. % Al for better oxidation and corrosion resistance.

Welding studies concentrate on two areas: evaluating weldability and developing an understanding of the factors controlling weldability. Part of the goal of this project is to assess the effects of alloy composition and welding process variables on weldability by using both the electron-beam and gas-tungsten-arc processes to make autogeneous welds. This work is done mainly with thin sheet material (typically 0.7 mm thick), but thicker material will also be used when available.

The more basic work is subdivided into microstructural characterization and high-temperature mechanical testing. The microstructural work is aimed at characterizing fusion zone microstructures in terms of phase identification, distribution, and composition as well as microsegregation behavior. The high-temperature mechanical testing is used to determine the ductility and strength of alloys as a function of temperature. This information will be used to help evaluate weldability and fabricability and to help identify factors controlling cracking phenomena in aluminides. An attempt will also be made to incorporate a computer model of thermal stress analysis into this work.

INEL-2(A), "Consolidation of Rapidly Solidified Aluminide Metal Powders," Idaho National Engineering Laboratory. The purpose of this project is to determine the most effective means of, and associated parameters for, consolidating rapidly solidified nickel-iron aluminide powders. Three consolidation techniques will be explored for the rapid solidification process (RSP) powders: hot extrusion (baseline), hot isostatic pressing (HIP), and dynamic (i.e., explosive) methods. The investigation of these consolidation techniques will emphasize the influence of pressure, temperature, and time on RSP structures. Structure/property assessments will be performed on the consolidated materials. In particular, thermal stability, mechanical properties, and oxidation response will be determined. The RSP aluminide powders and extrusions will be obtained from outside sources. Limited atomization investigations will be performed at the Idaho National Engineering Laboratory to establish RSP parameters for the aluminide powders. Compositions of the aluminide powders will be based on Oak Ridge National Laboratory's assessment and initially will involve Ni-80, Fe-10, Al-10, B-0.02 (all in wt %), with and without microalloying additions, such as hafnium.

CSM-2, "Investigation of the Weldability of Ductile Aluminides,"
Colorado School of Mines. The purpose of this project is to study the weldability of nickel-iron aluminides. The major thrust of the project is to determine the role of microstructure in the intergranular cracking of aluminides, with special emphasis on weld cracking susceptibility. This project is a cooperative effort of Oak Ridge National Laboratory (ORNL) and Colorado School of Mines (CSM) and is being conducted as a PhD thesis project by a CSM student working at CSM and at ORNL.

INEL-2(B), "Joining of Advanced Aluminides," Idaho National
Engineering Laboratory. The objective of this project is to investigate weldability problems limiting the use of aluminides in welded structures. Weldability effects of minor alloying elements, process and process variable effects, solidification mechanics, filler material development, and extension to heavier sections are included.

2.2.4 New Techniques

RDA-2, "Evaluation of the Feasibility of Pressure Quenching to Produce Hard Metastable Materials," R&D Associates, Inc. The purpose of this work is to design, build, and test a novel high-pressure press system to explore the scientific possibilities of pressure quenching of materials, that is, the retention at ambient conditions of metastable material phases normally observed only under extremely high pressures. The device will be capable of exerting pressures up to 6 GPa on small specimens of solids at room temperature and of releasing the pressure so rapidly (about 10 μ s or less) that the high-pressure phases will be retained. It is anticipated that new materials will result from specific experiments on selected materials undertaken to demonstrate the capability of producing such materials.

3. CORROSION AND EROSION OF ALLOYS

3.1 RESEARCH OBJECTIVES

Because of the mineral ash, sulfur, and chlorine content of coal, the heat exchanger and heat recovery components in coal utilization and coal conversion systems are subject to severe corrosion. These components include syngas coolers in coal gasification systems, superheaters and reheaters in pulverized-coal boilers, superheaters in industrial coal-fired boilers, heat exchangers in fluidized-bed combustors, and heat exchangers in hot-gas cleanup systems or steam-bottoming cycles associated with direct coal-fired heat engines.

Since sulfide scales are not protective, the alloys used in heat exchangers in coal utilization and coal conversion systems depend on the formation of oxide scales to provide protection against catastrophic corrosion by oxygen or sulfur-bearing gases. In the temperature range of interest, only Al_2O_3 and Cr_2O_3 scales provide significant protection. However, even in alloys that initially form protective Al_2O_3 or Cr_2O_3 scales, the scale eventually breaks down as a result of penetration of sulfur, chlorine, or cation species through the scale, cracking of the scale due to thermal or mechanical (including growth) stresses, loss of adhesion of the scale to the substrate, or a combination of those mechanisms.

The purpose of this part of this thrust area is to provide a generic development plan to understand the key factors that affect nucleation and growth of protective oxide scales and the mechanisms by which the scales degrade in sulfur-bearing atmospheres. The primary objective is to identify alloy modifications and surface treatments that will improve the mechanical performance and chemical integrity of oxide scales in the environments characteristic of coal combustion and coal conversion processes.

Another objective of this research thrust area is to investigate the mechanisms of erosion and wear of alloys and cermets used in fossil energy systems. An improved understanding of erosion mechanisms will provide the basis for the development of alloys and cermets that possess significantly improved erosion resistance. The research in progress and that planned is designed to lead to this better understanding of erosion processes.

Research efforts include studies of erosion behavior of alloys and cermets under conditions representative of coal preparation, coal liquefaction, coal gasification, coal combustion, and coal-fired heat engines.

This thrust area also includes research and development activities near completion on materials for molten carbonate fuel cell (MCFC) systems. An important part of the involvement of the AR&TD Fossil Energy Materials Program in this research area has been coordination with independent but related fuel cell activities sponsored by the Fuel Cells Program in the DOE Fossil Energy Office of Advanced Energy Conversion Systems. Such awareness of other programs ensures that the long-range goals of the AR&TD Fossil Energy Materials Program fuel cells effort are consistent with the needs of the technology and compatible with work elsewhere. The principal problems with MCFCs are dissolution of the nickel oxide cathode, interface corrosion, corrosion of the anode and cathode current collectors, and electrolyte loss. The AR&TD Fossil Energy Materials Program has addressed the problems of corrosion mechanisms of anode and cathode current collectors in MCFCs.

Finally, this thrust area includes work recently completed on the mechanical behavior of refractories for coal gasification systems. Some related work [SC(I,U)-4] based on this effort is described in Chapter 4.

Research and development activities for this thrust area are described in the following section and are listed in Table III.3.

3.2 SUMMARIES OF CURRENT AND PLANNED RESEARCH

3.2.1 Corrosion of Alloys

BCL-3, CWR-3, and UES-3, "Investigation of the Effects of Microalloy Constituents, Surface Treatment, and Oxidation Conditions on the Development and Breakdown of Protective Oxide Scales in Mixed Oxidant Gases for Coal-Related Applications," Battelle-Columbus Laboratories, Case Western Reserve University, and Universal Energy Systems. A 36-month experimental research project was initiated in FY 1986 to investigate the chemical and metallurgical factors that control the nucleation, growth, and eventual breakdown of protective oxide scales on Al_2O_3 - and Cr_2O_3 -forming alloys or coatings in coal-related environments. The objective is to

improve the corrosion resistance of heat exchanger materials by enhancing the mechanical properties and chemical passivity of corrosion-product scales based on alumina or chromia. The project will address the following effects pertaining to the development and breakdown of protective oxide scales: (1) microalloy constituents, (2) method of incorporating microalloy constituents, (3) surface pretreatment, and (4) oxidation conditions. This project will involve complementary and collaborative efforts by the three identified subcontractors.

ORNL-3(A), "Investigation of Corrosion-Resistant Oxide Scales on Iron-Based Alloys in Mixed Gas Environments," Oak Ridge National Laboratory.

The purpose of this task is to develop protective oxide scales on Cr_2O_3 - and Al_2O_3 -forming iron-based alloys in mixed oxidant (O_2 , SO_2 , H_2S , H_2O) environments for coal-related applications at 600 to 800°C. Specific objectives include (1) the development of protective oxide scales by modifying oxide chemistry and microstructure to reduce the transport of sulfur through the scale; (2) the formation of a sulfur-diffusion barrier (e.g., SiO_2 layer) under or above the protective oxide scale to minimize the sulfur attack; (3) the study of the effects of alloy chemistry, oxide morphology, and temperature on the breakdown of protective oxide scales; and (4) the examination of methods to limit internal sulfidation.

ANL-3(A), "Corrosion and Mechanical Properties of Alloys for Internals and Heat Exchangers in Mixed-Gas Environments," Argonne National Laboratory. The purposes of this task are to (1) develop corrosion information in the temperature range 400 to 750°C in mixed-gas atmospheres containing O, S, and Cl by use of internally cooled tube specimens of selected commercial materials; (2) evaluate mechanisms of the formation and breakaway behavior of protective scales on base metals and weldments exposed to atmospheres containing O, S, and Cl; (3) experimentally evaluate the uniaxial creep rupture behavior of selected high-chromium alloys and weldments exposed to complex gas mixtures; (4) establish the synergistic effects of stress and environment on the materials behavior; (5) develop corrosion rate expressions on the basis of experimental data for long-term extrapolation to component design lives; and (6) correlate the creep properties such as rupture life, rupture strain, and minimum creep rate with the chemistry of exposure environment, temperature, and alloy chemistry.

Work being conducted under this task provides a basic understanding of the corrosion behavior of commercial and model alloys after exposure to multicomponent gas mixtures. The information on scale thickness, intergranular penetration, and morphological changes developed in this task provides a rational basis for the extrapolation of corrosion rates as a function of temperature, alloy composition, and chemistry of the gas environment. Corrosion experiments in mixed-gas atmospheres using a thermogravimetric technique are being conducted on selected commercial high-chromium alloys and on model alloys fabricated with compositional variations to establish the role of different alloying elements on the mechanisms of scale development and adhesion and on breakaway phenomena leading to scale failure. The project on heat exchanger materials involves development of corrosion information in the low- and medium-Btu gasification atmospheres. The experiments are conducted with internally cooled tube specimens of selected commercial materials and some commercial coatings. The critical variables, such as gas temperature and metal temperature, are independently controlled in the ranges of interest in practical systems. The gas temperatures will range from 850 to 1100°C, a range that encompasses the raw gas outlet temperatures of dry ash and slagging gasifier types. The results from this program will establish the process variable envelopes for various commercial materials for use in heat exchanger applications. Incoloy 800H plates welded with low-nickel filler metals have been fabricated, and they will be examined for their corrosion resistance in mixed-gas atmospheres. Nickel aluminides and iron-nickel aluminides developed at ORNL will be examined for their sulfur resistance by using thermal gravimetric analysis and post-exposure analysis of specimens.

ANL-3(B), "Corrosion of Alloys in FBC Systems," Argonne National Laboratory. This work involves laboratory studies of the formation mechanisms and corrosion effects of CaSO_4 coatings on in-bed heat exchanger surfaces. More specifically, the purposes of this task are (1) to study experimentally the high-temperature corrosion behavior of iron- and nickel-base alloys and weldments with low-nickel filler metals in simulated combustion gas environments with a wide range of oxygen and sulfur potentials; (2) to study deposit-induced corrosion behavior of coated and uncoated heat exchanger and gas turbine materials after exposure to multicomponent gas

environments; (3) to evaluate the sulfidation and oxidation resistance of ORNL-developed nickel aluminides and iron-nickel aluminides in simulated FBC atmospheres with and without deposits; and (4) to develop corrosion rate expressions, based on experimental data, for long-term extrapolation to component design lives.

PITT-3, "Investigation of Corrosion Mechanisms of Coal Combustion Products on Alloys and Coatings," University of Pittsburgh. The objective of this research project is to investigate the formation and breakdown of protective oxide scales in mixed oxidant gases. The results of this research will support the development of improved heat exchanger materials for applications in (1) heat recovery systems for coal conversion plants (particularly gasification) and (2) coal-fired industrial and utility boilers. The materials used in this study will be model alloys selected for their ability to form single oxides of chromium, aluminum, and silicon. The temperature range of interest is 500 to 700°C, and the test environments contain mixed oxidants (O_2 , CO_2 , SO_2 , H_2S , and Cl_2). Specific objectives include determination of the effect of surface pretreatment and preoxidation on the structure and properties of oxide scales, and the correlation of these treatments and the resulting structures and properties with the breakdown of the scales in mixed oxidant gases. Loss of scale protection by mechanical means (cracking, spalling, etc.) and by transport of corroding species (S and Cl) are considered.

GE-3, "A Mechanistic Study of Low-Temperature Corrosion of Materials in the Coal Combustion Environment," General Electric Company. The purpose of this work is to develop a mechanistic understanding of low-temperature corrosion of materials exposed to environments characteristic of coal combustion. Specific tasks include (1) studies of the corrosion morphology and interface chemistry on selected specimens after exposure to coal contaminants; (2) thermochemical calculations to establish the range of conditions for stability of the alloy phases, corrosion products, and chemical compounds formed; and (3) specific laboratory tests to correlate the experimental results with predictions from the thermochemical calculations. Specimens are characterized with scanning electron microscopy, electron microprobe analysis, and X-ray diffraction. Reference alloys include IN-738, FeCrAlY-coated IN-738, RT-22-coated IN-738, and two

different CoCrAlY coatings on IN-738. The thermochemical calculations include (1) the minimum partial pressure of SO_3 required to form a K_2SO_4 - CoSO_4 liquid and an Na_2SO_4 - K_2SO_4 - CoSO_4 liquid, and (2) the thermochemistry of low-temperature attack of iron- and aluminum-rich coatings in the coal combustion environment. Laboratory test results will be correlated with thermochemical calculations and phase stability plots.

ORNL-3(D), "Mechanical Properties of Oxide Films and Correlation with Metal Oxide Interface," Oak Ridge National Laboratory. During a one-year assignment in the United Kingdom, a researcher from the Oak Ridge National Laboratory will conduct joint high-temperature gas-metal reaction studies with researchers at Harwell Laboratory's Materials Development and Metallurgy and Metals Physics Division. The mechanical behavior of oxide films will be investigated and correlated with the chemical and physical changes occurring near the metal/oxide interface. In addition, the dynamic embrittlement of Ni_3Al in air will be examined with the use of a Harwell-developed model for stress-driven segregation of impurities to crack tips at elevated temperatures. The latter portion of the research will support research being conducted under WBS element ORNL-2(A) on iron and nickel aluminides.

OSU-3, "Investigation of the Elastic Properties of Oxide Films and Adhesion of Oxides to Metal Substrates," Ohio State University. The purpose of this project is to study the elastic properties of oxide films on metal substrates and to examine their adhesion properties. A dynamic resonance device has been designed and built for the study of elastic and anelastic behavior of thin films on metals. The approach is to measure both the elastic properties of Al_2O_3 as it forms on Pt, Pt-Al, Ni-Al, and (Fe,Ni)-Al alloys, of Al_2O_3 deposited by chemical vapor deposition on platinum substrates, and the adhesive strength of the film-substrate composites. The microstructure and modes of failure of the Al_2O_3 films as they are subjected to thermal cycling will be related to the ability of the film to deform plastically and the manner in which the elastic-plastic behavior is influenced by platinum solution in the scale. The data from this study can form the beginning of the ability to modify the mechanical properties of an oxide-substrate composite and, thus, develop a truly protective oxide film.

3.2.2 Erosion of Alloys

LBL-3, "Studies of Materials Erosion in Coal Conversion and Utilization Systems," Lawrence Berkeley Laboratory. The erosion of material surfaces by small solid particles carried in gas and liquid carriers is being investigated. The materials are tested over a range of conditions that simulate portions of the operating environments of containment surfaces in coal gasification, liquefaction, and fluidized bed combustion processes. The effects of the materials properties, microstructures, and compositions on their erosion behavior are determined. The effects of elevated temperature corrosion in combination with the erosion are studied to determine the mechanisms and rates of the combined surface degradation modes.

ORNL-3(B), "Mechanisms of Erosion-Corrosion in Coal Combustion Environments," Oak Ridge National Laboratory. The purpose of this task is to perform a fundamental study of the erosion, corrosion, and erosion-corrosion of alloys in coal combustion environments by in-situ observation of a surface after being subjected to erodent particles in a stream of corrosive gas. The goal is to improve our understanding of the fundamental nature of erosion, corrosion, and erosion-corrosion. The basic feature of this study is the impingement of erodent particles on alloy surfaces that may be exposed to corrosive gas environments. Degradation of the alloys will be monitored by a scanning electron microscope equipped with a hot-stage test chamber. Single or multiple particle effects will be determined as well as the effects of temperature, corrosive medium, and characteristics (size, mass, hardness, and angle of impingement) of eroding particles.

UCIN-3, "Study of Particle Rebound Characteristics and Material Erosion at High Temperature," University of Cincinnati. The purpose of this effort is to investigate the erosion processes and fluid mechanics phenomena that occur in fluidized-bed combustors, coal-fired boilers, cyclones, pumps, turbines, valves, and other coal conversion systems. The overall objective is to develop a quantitative model that will facilitate the prediction of erosion in systems operating in particle-laden environments. The experimental study of the impact and rebound characteristics are being performed with selected solid particles, including Al_2O_3 and

SiO₂, with sizes from 5 to 200 μm. The target materials are selected according to present and anticipated materials needs of coal conversion systems. Candidate materials include stainless steel, INCO 718, Ti 6-4, and 2024 Al.

UND-3, "Correlation of Materials Structure with Flow Characteristics of Erosive Particles," University of Notre Dame. From FY 1982 through FY 1986, a project [UND-3(A)] sponsored by the AR&TD Fossil Energy Materials Program at the University of Notre Dame (UND) involved the study of the effects of the microstructure of alloys on their erosion behavior. This new project, to be initiated in FY 1986, will emphasize the correlation of materials structure with flow characteristics of erosive particles. The work to be performed will be closely related to, and coordinated with, the study of particle rebound characteristics and material erosion being performed at the University of Cincinnati (UCIN-3).

UCB-3, "Investigation of Fluid Dynamic Behavior of Erosive Particulates in Gas Streams," University of California, Berkeley. The purpose of this investigation is to improve the understanding of erosion processes in gas streams. To fully understand erosion processes caused by particles entrained in gas streams, the fluid dynamic behavior of the particulates must be understood. Laboratory experiments have generally focused on erosive particles interacting with materials under carefully controlled flow conditions (particle velocity and impact angle). This project should aid attempts to correlate the results of the carefully controlled laboratory experiments with the experience of plant systems.

SC(I,U)-3(A), "Flow Characteristics of Particles in a Simulated Coal-Fired Gas Turbine System," contractor to be determined. This work is scheduled to begin in FY 1988 and will provide a determination of the flow characteristics of particles in simulated coal-fired gas turbines. The tests will examine the effects of particle sizes and loadings in gas streams at temperatures characteristic of coal-fired systems subjected to cleanup by cyclone separators. The purpose of these tests is to determine the manner in which particles behave in these gas streams and, thus, obtain insight into the likely erosion modes. The need for additional cleanup and the need for development of materials to withstand erosion in such systems should be indicated by these tests. This work will benefit from the

information gained in the study of the fluid dynamic behavior of particulates in gas streams being conducted at the University of California, Berkeley (UCB-3).

SC(I,U)-3(B), "Investigation of the Mechanisms of Erosion and Corrosion of Materials During Combustion of Coal-Liquid Slurries," contractor to be determined. An investigation of the mechanisms responsible for erosion and corrosion of boiler tubes and components in oil- or gas-fired boilers that have been retrofitted to burn coal slurries is proposed for initiation in FY 1988. A bench-scale experiment may be designed to measure the extent of fly-ash erosion and corrosion of materials that are the current choices for construction of boiler tubes and related components. The results of this effort will provide input to the selection of materials used in conventional fossil-fired systems as well as information regarding necessary design changes to reduce the effect of fly-ash corrosion-erosion. Furthermore, an increased understanding of the mechanisms responsible for the corrosion reactions in the combustion zone and the relation of such mechanisms to the coal slurry quality and characteristics will improve the ultimate effectiveness of the combustion of coal-liquid mixtures.

NBS-3, "Mechanisms of Galling and Abrasive Wear," National Bureau of Standards. This work addresses the mechanical and chemical effects experienced in closure regions of valves in coal conversion systems. The purpose of this project, which began at the National Bureau of Standards in FY 1983, is to develop an understanding of the wear mechanisms of materials associated with valves. It includes theoretical considerations of chemical reactions and effects of the working media on valve closure materials. Measurements are also being performed to determine the static and kinetic coefficients of friction of the various combinations of test materials.

3.2.3 Fuel Cells

ORNL-3(C), "Investigation of the Mechanisms of Molten Salt Corrosion of Candidate Materials for Molten Carbonate Fuel Cells," Oak Ridge National Laboratory. The purpose of this task is to define and study the mechanisms controlling the corrosion of anode and cathode current collector

materials in molten carbonate fuel cells (MCFCs). Important objectives include (1) the identification of the reaction products formed between carbonate salt and iron and chromium under oxidizing (cathode side) and reducing (anode side) conditions; and (2) the measurement of the solubilities of structural metal oxides in the carbonate salt under acidic (cathodic) and basic (anodic) conditions. Differential thermal analysis/thermogravimetric analysis (DTA/TGA) studies are conducted to evaluate reactions between selected structural metals (Fe and Cr) and molten carbonate salts. Aliquots of finely divided metal are loaded in gold capsules containing granular $\text{Li}_2\text{CO}_3\text{-K}_2\text{CO}_3$, and DTA/TGA of the mixtures is performed up to 700°C under controlled gas atmospheres. Thermal analysis is used to establish the melting points and identity of any molten reaction products.

The relative solubilities of structural metal oxides (Cr_2O_3 and Fe_3O_4) are determined in carbonate salt under oxidizing ($\text{air} + \text{CO}_2$) and reducing ($\text{H}_2 + \text{CO}$) gas conditions. By using a reference electrode developed on this project, the oxidizing potential of the salt under a given gas atmosphere is measured in terms of the oxygen ion concentration (O^{2-}), and the saturation concentration of the structural metal oxide at that oxygen ion concentration is recorded by atomic absorption analysis of a melt sample. Potentiometric techniques are used to continuously measure the oxygen ion concentration (oxidizing potential) of the salt under the different gas atmospheres.

The corrosion processes which occur between selected stainless steels and carbonate salt are being investigated. These results will be combined with the information that has already been gathered on reactions between chromium and iron and carbonate salt to understand the behavior of typical materials of construction in operating fuel cells. This work will be completed in FY 1987.

4. TECHNOLOGY ASSESSMENT AND TECHNOLOGY TRANSFER

4.1 INTRODUCTION

The purpose of the technology assessment activity of the AR&TD Fossil Energy Materials Program is to maintain an awareness of the technical issues and research and development needs of established and emerging fossil energy technologies. Specifically, the performance of the assessments of materials problems and needed research to solve those problems in a wide variety of fossil energy technologies is an important part of the AR&TD Fossil Energy Materials Program.

In addition to technology assessments, the transfer of technology developed on the AR&TD Fossil Energy Materials Program to others in the fossil energy community is an important responsibility and serious commitment of the Program.

The activities specifically associated with technology assessment and technology transfer are described in the following section and are listed in Table III.4 at the end of the section. It should be noted that technology assessment and transfer play important roles in all the research projects described in the preceding chapters.

4.2 SUMMARIES OF CURRENT AND PLANNED ACTIVITIES

4.2.1 Technology Assessment

SC(I)-4(A), "Assessment of Materials Needs for Coal-Fired Heat Engines," contractor to be determined. The objective of this project is to identify the specific materials requirements for coal-fired heat engines, to assess the state of technology for materials to meet those requirements, and to identify the primary areas in which materials research and development is required.

SC(I)-4(B), "Assessment of Alloy Needs for Heat Engines and Heat Recovery," contractor to be determined. The objective of this project is to identify applications in heat engine and heat recovery systems which are best suited for the use of high-temperature alloys rather than structural ceramics. The project will also assess the ability of currently available materials to meet these needs and will identify needed research and development on new and/or improved alloys.

SOR-4, "Reference Book on Performance of Materials in Coal Liquefaction Environments," G. Sorell. Through the auspices of The Materials Properties Council, Inc. (MPC), several government, industrial, and university organizations are contributing information and data on materials performance in coal liquefaction environments for inclusion in a reference book. Such a book is not only desirable but is sorely needed as an archival reference to the great body of information developed over the past several years. A consultant (G. Sorell) will collect information (chapters of the book) from the various authors, edit the submitted information, and compile it into a single reference source for subsequent publication.

4.2.2 Technology Transfer

BCL-4, "Materials and Components in Fossil Energy Applications Newsletter," Battelle Columbus Laboratories. This newsletter communicates experience and test results related to fossil energy materials and components to those organizations involved in the development of fossil energy systems. The newsletter is issued by the DOE Oak Ridge Operations and is distributed bimonthly to about 2500 domestic and foreign subscribers.

ORNL-4(C), "Coal Conversion and Utilization Plant Support Services," Oak Ridge National Laboratory. This project provides support to the staffs of operating coal conversion and utilization facilities in the areas of materials selection, evaluation, testing, on-site examination, and analysis of failed components. In addition to providing a valuable service to the operators of these facilities, these services assure that the Fossil Energy Materials Program staff is kept abreast of the materials problems that are encountered. Thus, there is an ongoing assessment of materials research needs based on actual operating experience, as well as an active technology exchange.

The Fossil Energy Materials Program staff collaborates with plant operators to identify needed materials testing and works with plant staff to develop a test program. This may include the placement of materials test specimens in selected vessels at the plants. Metallurgical examinations of failed and selected components are also made when needed and requested. The components are removed by plant staff members and shipped to ORNL for examination and analysis. Extensive use is made of optical

microscopy, scanning electron microscopy, nondestructive examination, and other metallurgical techniques, which are not usually available at the plant sites.

SC(I,U)-4, "Transfer of Refractory Technology to Industry," contractor to be determined. The purpose of this effort is to transfer to industry the technology developed by the Massachusetts Institute of Technology (MIT) to predict the thermomechanical stresses that occur in refractory-lined vessels during heat-up and cool-down, as well as during steady-state and transient operations. The computer model was developed by the AR&TD Fossil Energy Materials Program for understanding and predicting the behavior of refractory linings in gasification vessels. The model is able to predict the behavior of specific refractory materials in other high-temperature systems as well, such as blast furnaces in the steel industry. To facilitate the usability of the model, user-friendly software will be developed through a joint venture with industry. In addition to the prediction of the behavior of specific refractory materials, the software will include special features to model joint behavior and the refractory material spalling process. To ensure that the physical properties information on refractories is kept current, testing of additional refractory materials will be pursued, and the database will be updated in conjunction with the software developed.

174-203. DOE, TECHNICAL INFORMATION CENTER, P.O. Box 62, Oak Ridge,
TN 37831

For distribution by microfiche as shown in DOE/TIC-4500,
Distribution Categories UC-102 (Coal Preparation), UC-103
(Fluidized Bed Combustion), UC-106 (Gas Stream Cleanup),
UC-108 (Coal Liquefaction), UC-109 (Coal Gasification),
UC-110 (Fuel Cells), UC-111 (Heat Engines), UC-112
(Magnetohydrodynamics), and UC-114 (Coal Based Materials
and Components).
