## ABSTRACT

The work on Phase II of this project focused on the occurrences of geopressures in Appalachia and selected California basins. In the former region, where geopressures have been observed, the pressure gradients for the most part were only slightly above normal as in the case of the Oriskany formation of Devonian age; this unit was also characterized by extremely high salinity. The one notable exception was in the Rome trough of West Virginia where Cambrian beds at depths below 10,000 feet display very high geopressures, approaching the lithostatic gradient, and the waters are only moderately saline. Though the geothermal gradient throughout Appalachian is relatively low, even in the Rome trough, the pressure, temperature and salinity values in this area indicate that the methane content of the Cambrian formation waters is in the range of 30-35 SCF/barrel.

The two California areas researched included the contiguous Sacramento and San Joaquin Valleys. In the first, geopressures have been principally encountered in the Forbes formation of Cretaceous age, often at very shallow depths. Further the formation waters are invariably characterized by very low salinity, far below the salinity of normal sea water, while the geothermal gradient is apparently higher in geopressured than in normally pressured zones. In the San Joaquin Valley, geopressures are particularly noteworthy in at least two formations of Miocene age at depths generally greater than those of the Forbes. The formation waters are likewise low in salinity; however, the geothermal gradient, especially in the geopressured zones on the west side of the valley, can be extremely high, up to twice as much as the normal temperature gradient. In view of these conditions, it is estimated that in the western San Joaquin Valley the methane content of geopressured formation waters will range from 30 to 40 SCF/barrel while in the Sacramento Valley, the methane content is estimated to be 20-25 SCF/barrel.

## 1. INTRODUCTION

The work in Phase I amply demonstrated that the occurrence of geopressures is not an isolated phenomenon confined strictly to the Gulf Coast, but rather can be found in numerous onshore and offshore sedimentary basins throughout the United States. This bodes well for the extension of current development efforts in the Gulf Coast to other areas since the occurrence of methane in formation waters is, in part, a function of pressure. It has long been recognized, according to Weeks (1958), "One fact which requires little contemplation to appreciate is the truly immense quantity of hydrocarbons that abound in the sedimentary basins in the form of gas dissolved in water outside the accumulation in gas pools, gas caps over oil pools, and dissolved in the oil of oil pools themselves (and) there seems to be no reason to assume that formation waters of basins generally over the world carry less gas per barrel than the average of the many areas and sands investigated by the authors." From a practical standpoint, the quantity of methane dissolved in formation waters is directly related to pressure and temperature and inversely related to the salinity of such waters. Thus, there may be situations in overpressured oil and gas zones where there is little or no formation water, but where present, they will assuredly contain varying quantities of dissolved methane.

In view of the results attained in the Phase I work, it was decided that the Phase II project should focus on two areas, namely California and Appalachia. The former was chosen since conditions in several basins were favorable (at least from a preliminary basis) for the occurrence of dissolved methane based on high pressures, relatively high temperatures, and significantly low salinities. The latter region was selected for study for geographic balance, proximity to markets and the potential for important quantities of dissolved methane in formation waters of deep Cambrian sediments.

As there is a paucity of readily available written material on geopressures in either of these two regions, the major effort during this phase was focused on obtaining additional published papers together with documents, reports, and well descriptions from state geological agencies, private companies, and individuals. The following individuals and organizations were particularly cooperative:

## 2. APPALACHIA

### 2.1 GENERAL

The Appalachian basin has classically been considered to be composed of those Paleozoic sediments lying between the Blue Ridge Mountains on the east and the crests of the Cincinnati-Findley arches and Nashville dome on the west extending from the Canadian border southward to Alabama where it is overlapped by Cretaceous rocks. However, seismic work conducted a few years ago indicates that the Appalachian province should be extended 60-100 miles eastward, an area termed the Eastern Overthrust Belt, in which the older Blue Ridge crystalline rocks are overlying younger Paleozoic formations. Current drilling activities in the eastern panhandle of West Virginia and elsewhere tend to confirm the existence of the overthrust area.

The stratigraphic sequence of sediments in terms of the major oil/gas producing zones which will be cited in this discussion are listed in Table 1.

### 2.2 CHARACTERISTICS OF GEOPRESSURING

For the most part, the sediments of the Appalachian basin aside from several noteworthy exceptions, tend to be either normally pressured or abnormally underpressured. As shown in Table 2, overpressuring was only noted in the Oriskany and Huntersville (primarily of lower Devonian age) and the Onondaga (of middle Devonian age). One reason advanced for the abnormally low pressures is that lenticular reservoirs closely associated with shales have undergone erosion which caused a reduction in the fluid pressure in the pore space of shales that was transmitted to the closely associated reservoir beds (Russell, 1972).

The occurrence of abnormally high pressures indicates the presence of permeability barriers between the outcrop of the reservoir and the

(1) Russell, 1972

location of the high fluid pressures. This phenomenon is buttressed by the fact that the Oriskany formation, in both West Virginia and Pennsylvania, is characterized by very high salinities and only rare instances of low salinities as shown in Tables 3 and 4. (It should be noted that Tables 3 and 4 have been prepared without reference to overpressuring, but as described elsewhere in this report, known overpressured Oriskany zones, with only one exception, are likewise marked by extremely high salinities.) Evidently, these barriers have severely limited the invasion of fresh meteoric waters. In fact, since many of the salinity values are considerably higher than sea water (35,000 ppm), it strongly suggests that these Devonian beds have received significant quantities of saline water from the underlying Silurian salt beds.

It should also be noted, as set forth in Table 3, that the geothermal gradient is relatively low in the Oriskany formation in the Appalachian basin. Aside from an occasional extremely high and/or very low gradient the bulk of the readings are in the range of 1.5 to 1.7<sup>°</sup>F/100'. Similar values obtained for deep wells into the Cambrian (described further in this part of the report) confirm the general low temperature regime of the region.

As indicated in Table 2, there is an apparent correlation between the deformation the rocks have undergone and the pressure gradient. For example, in the Oriskany-Onondaga sequence in the strongly folded areas of north and north-central Pennsylvania, the pressure gradient is 0.050 higher than in nearby relatively deformed regions to the west. Of the many determinations in the former, 20 were above 0.6, 6 above 0.7 and 1 above 0.8 while in the slightly deformed area, only 3 were above 0.6 and none were higher than 0.7 (Russell, 1972).

### 2.3 SPECIFIC OCCURRENCES

The following section comprises a description of various specific occurrences and their salient characteristics in various formations of

Paleozoic age in the Appalachian basin. The location, on a county basis is shown in the accompanying state maps.

### 2.3.1 Pennsylvania (Figure 1)

One of the noteworthy gas fields in Appalachia that is characterized by very high pressures is the Leidy field in Clinton County, Pennsylvania. Discovered in the early 1950's, this field and the nearby South Leidy field, both of which produced from the Oriskany formation, have been depleted and are currently used for gas storage by Consolidated Gas Supply Corporation. The pressure gradient in virtually all of the wells listed below, for which data was available, exceeds the normal pressure gradient in the area.

#### Pressure Gradient of Selected Wells in the Oriskany Formation in the Leidy Field\*

\*Enright and Ingham, 1951

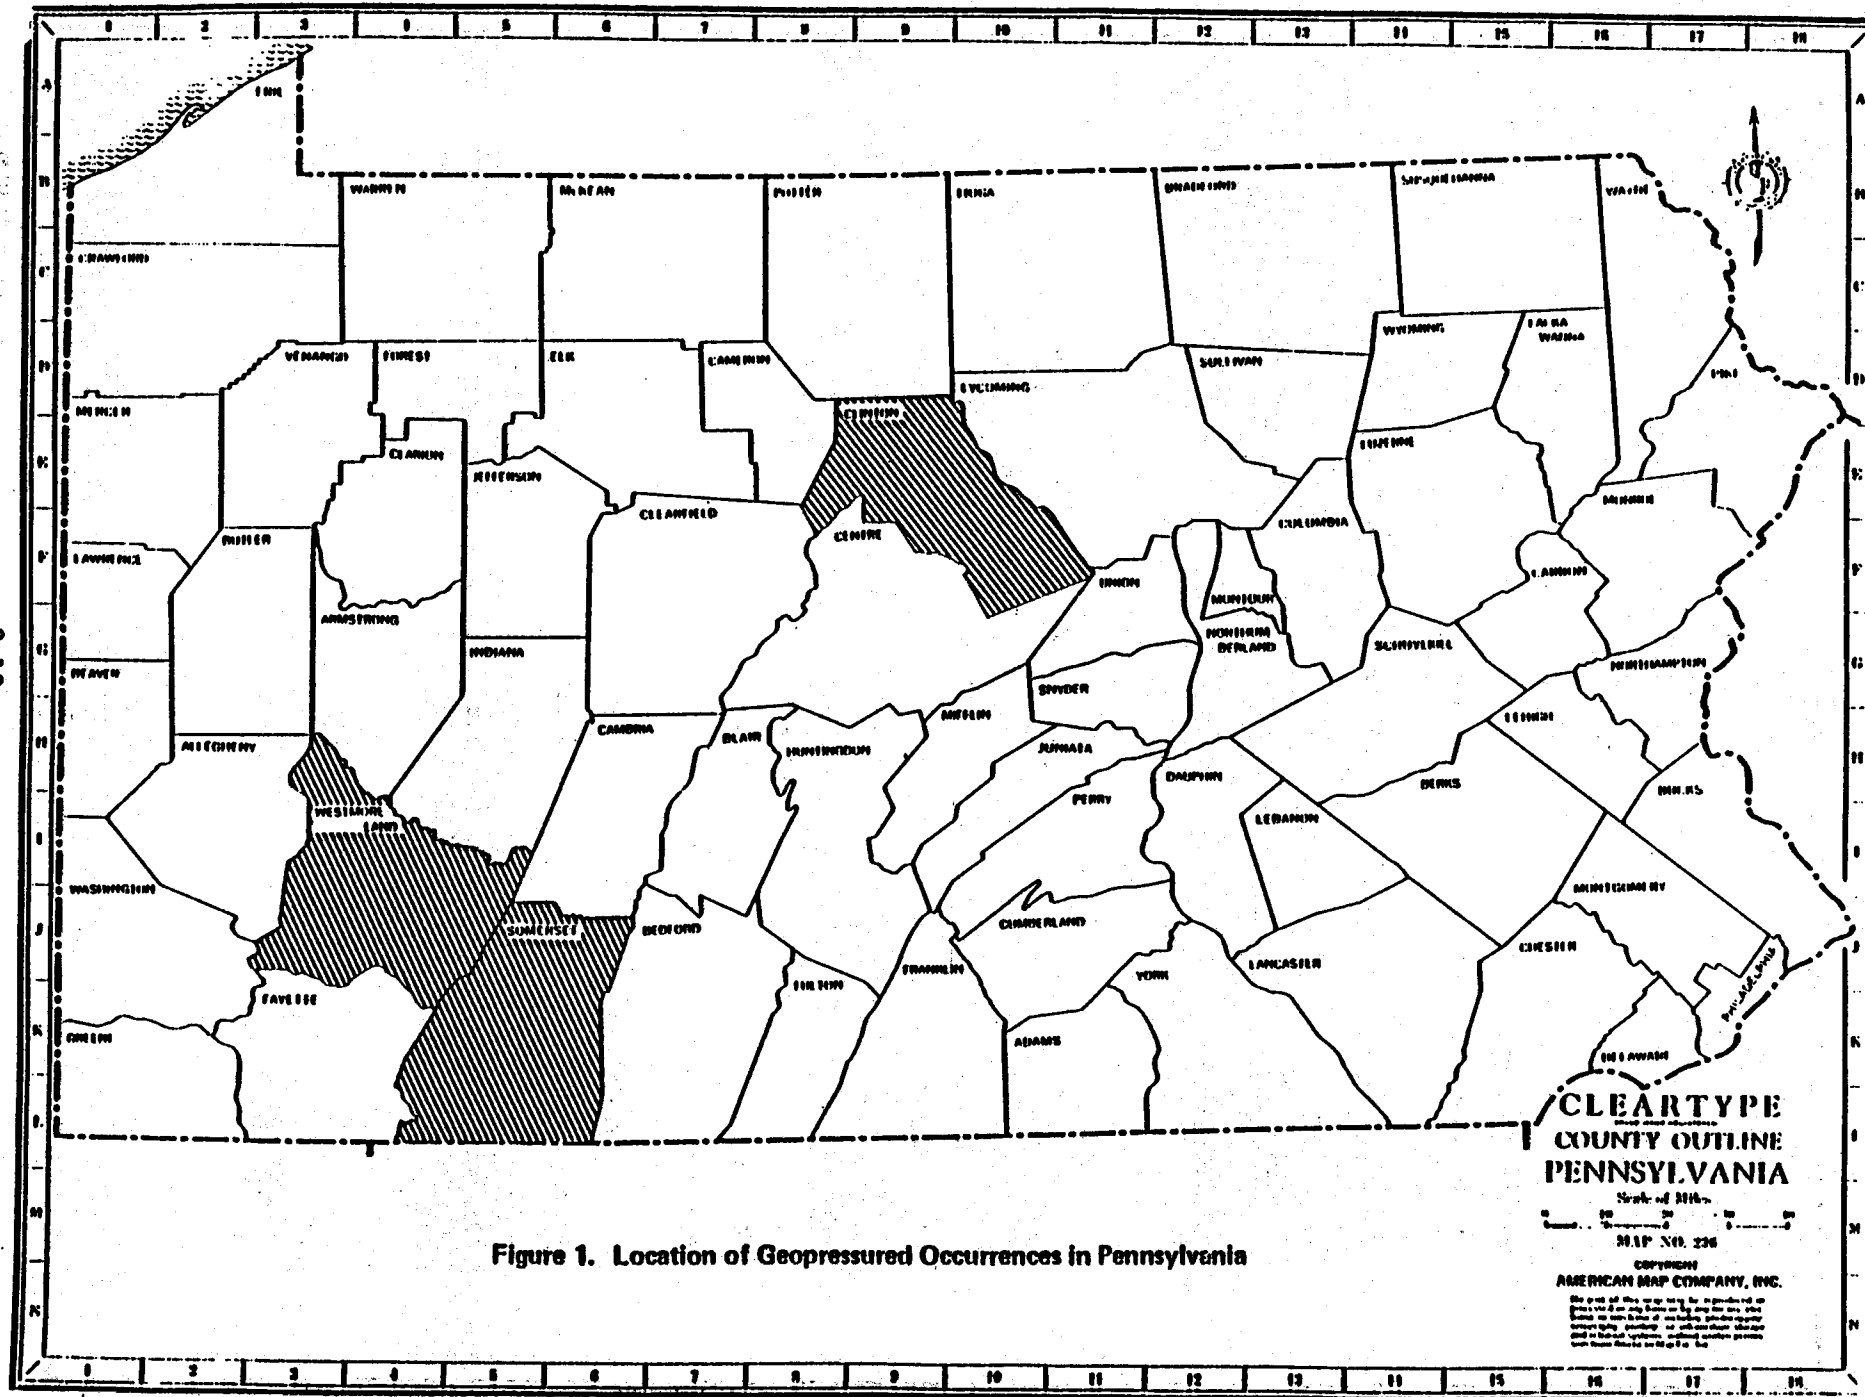

Figure 1. Location of Geopressed Occurrences in Pennsylvania

The salinity of the Oriskany in the Leidy field is apparently rather low in contrast to the analyses of this formation elsewhere in the state as shown in Table 4. The following tabulation of Oriskany waters from the Leidy area is derived from data furnished by Consolidated Gas Supply Corporation (Cross, 1980).

Water Analyses from Wells in the Leidy Field Area

| Leidy North      | 351                      | 626                     | 977   |
| "                | 398                      | 687                     | 1080  |

The Leidy /South Leidy fields located in north central Pennsylvania, where the formations are relatively more deformed than those farther west, essentially confirms the relationship between deformation and high fluid pressure gradients. The low salinities present are anomalous by contrast to those normally found in the Oriskany, but it is probable that the folding in the region had permitted the introduction of meteoric waters and a consequent freshening.

Several wells drilled to a depth of 7000-9000' in western Pennsylvania encountered overpressuring in the Oriskany formation. In five (5) wells drilled by Peoples Gas Company in Westmoreland County, the results were as follows (Tatlock, 1980) :

| <u>Well #</u> | <u>Depth<br/>(ft)</u> | <u>Pressure<br/>(psi)</u> | <u>Gradient<br/>(psi/ft)</u> | <u>Total Solids in ppm*</u> |
|---------------|-----------------------|---------------------------|------------------------------|-----------------------------|
| 4736          | 7899                  | 4347                      | .550                         | 149,769                     |
| 4387          | 7933                  | 4250                      | .536                         | 144,829                     |
| 4388          | 7701                  | 4350                      | .552                         | 181,019                     |
| 4365          | 7739                  | 4372                      | .565                         | 154,783                     |
| 4092          | 7476                  | 4100                      | .548                         | 323,253                     |

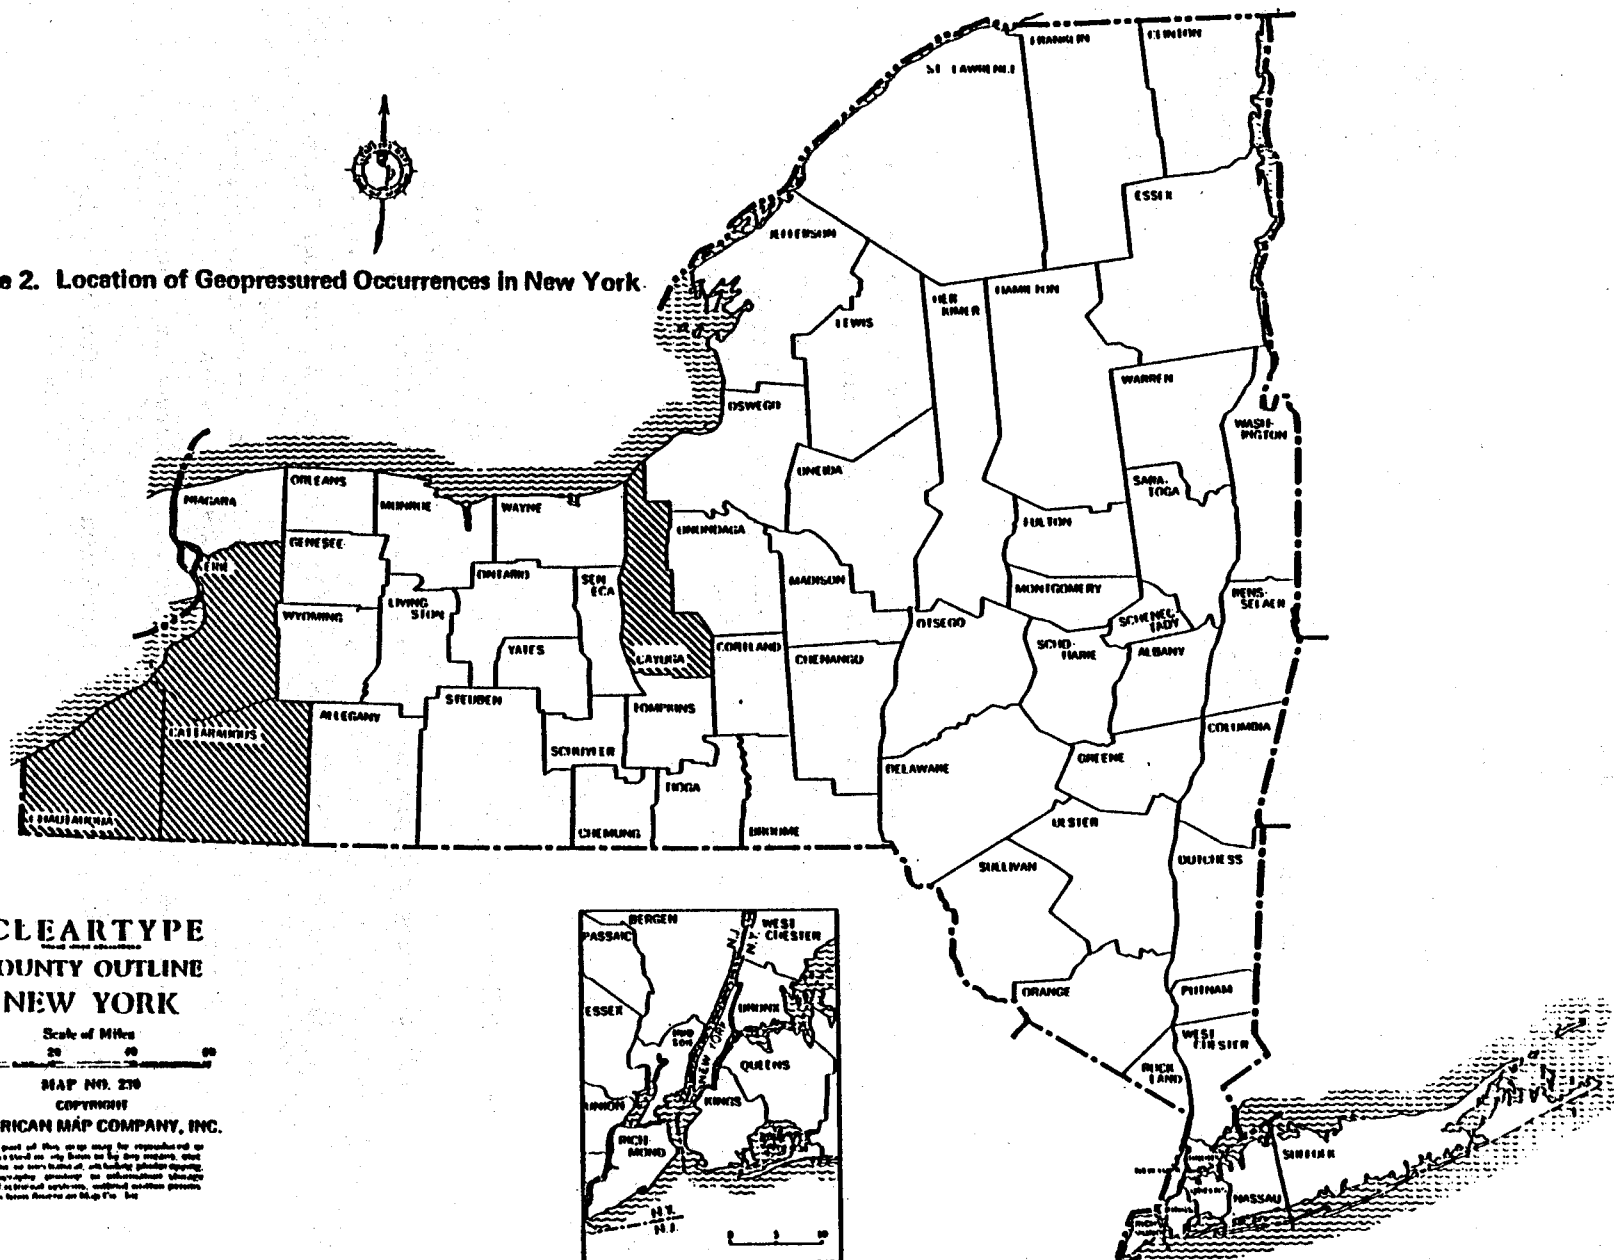

(\*A complete chemical analysis is available for each listed well)

The pressure gradients found here are within the range anticipated for the slightly deformed area of Pennsylvania.

Numerous Oriskany wells have been recently drilled in Somerset County through a joint effort of UGI and Amoco. Several selected wells show slight overpressuring, with pressure gradients ranging from 0.456 to 0.493 psi/ft. None of these wells initially produced water but it is anticipated, based in part on experience, that formation water incursion will shortly occur (Kelley, 1980).

#### 2.3.2 New York (Figure 2)

Slight to notable overpressuring has been reported from several wells in New York as set forth in the tabulation below. Aside from the occurrence in Cayuga County, all of them are localized in the extreme western part of the state and, other than in Cattaraugus County, are found in either Silurian or Ordovician formations or both. The lithostatic-plus pressure in the Chautauqua County well is extremely unusual given the rather shallow depth and may reflect a measurement or reporting error.

#### 2.3.3 Tennessee

One area of overpressuring has been reported from the eastern part of the state where the Petroleum Development Corporation drilled several shallow wells (1700-1800' depths) into the Fort Payne limestone (upper Mississippian) and encountered oil-bearing zones, with little or no water, that have pressure gradients ranging from .510 to .620 psi/ft (Jenkins, 1980).

#### 2.3.4 West Virginia (Figure 3)

##### 2.3.4.1 Previous Citations

Overpressuring has previously been reported in Phase I in the following areas:

- In the Oriskany in the Sissonville Gas field in Kanawha, Jackson Putnam Counties
- In Cambrian formations in deep wells in the Rome trough drilled in Calhoun, Jackson, Lincoln, and Mingo Counties
- In a test well in Devonian shales at Morgantown in Monongalia County
- In Reedsville/Utica/Trenton formation (upper Ordovician) in southern West Virginia

- In the Eastern Overthrust Belt in Ordovician formations in Mineral County, slight overpressuring encountered at a depth of about 12,000' - believed to reflect relict overpresurring associated with thrust faulting
- In the Oriskany in the Gladys field in Randolph and Pocahontas Counties.

#### 2.3.4.2 Rome Trough

Abnormally high pressures such as those found in California and the Gulf Coast have only been observed in the Appalachian basin in the Cambrian formations of the Rome trough. The latter is a subsurface graben-like depression which extends from eastern Kentucky-southern West Virginia into southwestern Pennsylvania. The configuration of this basin is indicated in Figure 4, an isopachous map which indicates a thickness of over 8000' of the lower Cambrian section. The general stratigraphic sequence of Silurian and older formations is shown in Figure 5. A description of the various wells, all of which were drilled during the mid-1970's, is presented below.

- o McCoy #1 Well, Jackson County, WV (Brown, 1980)

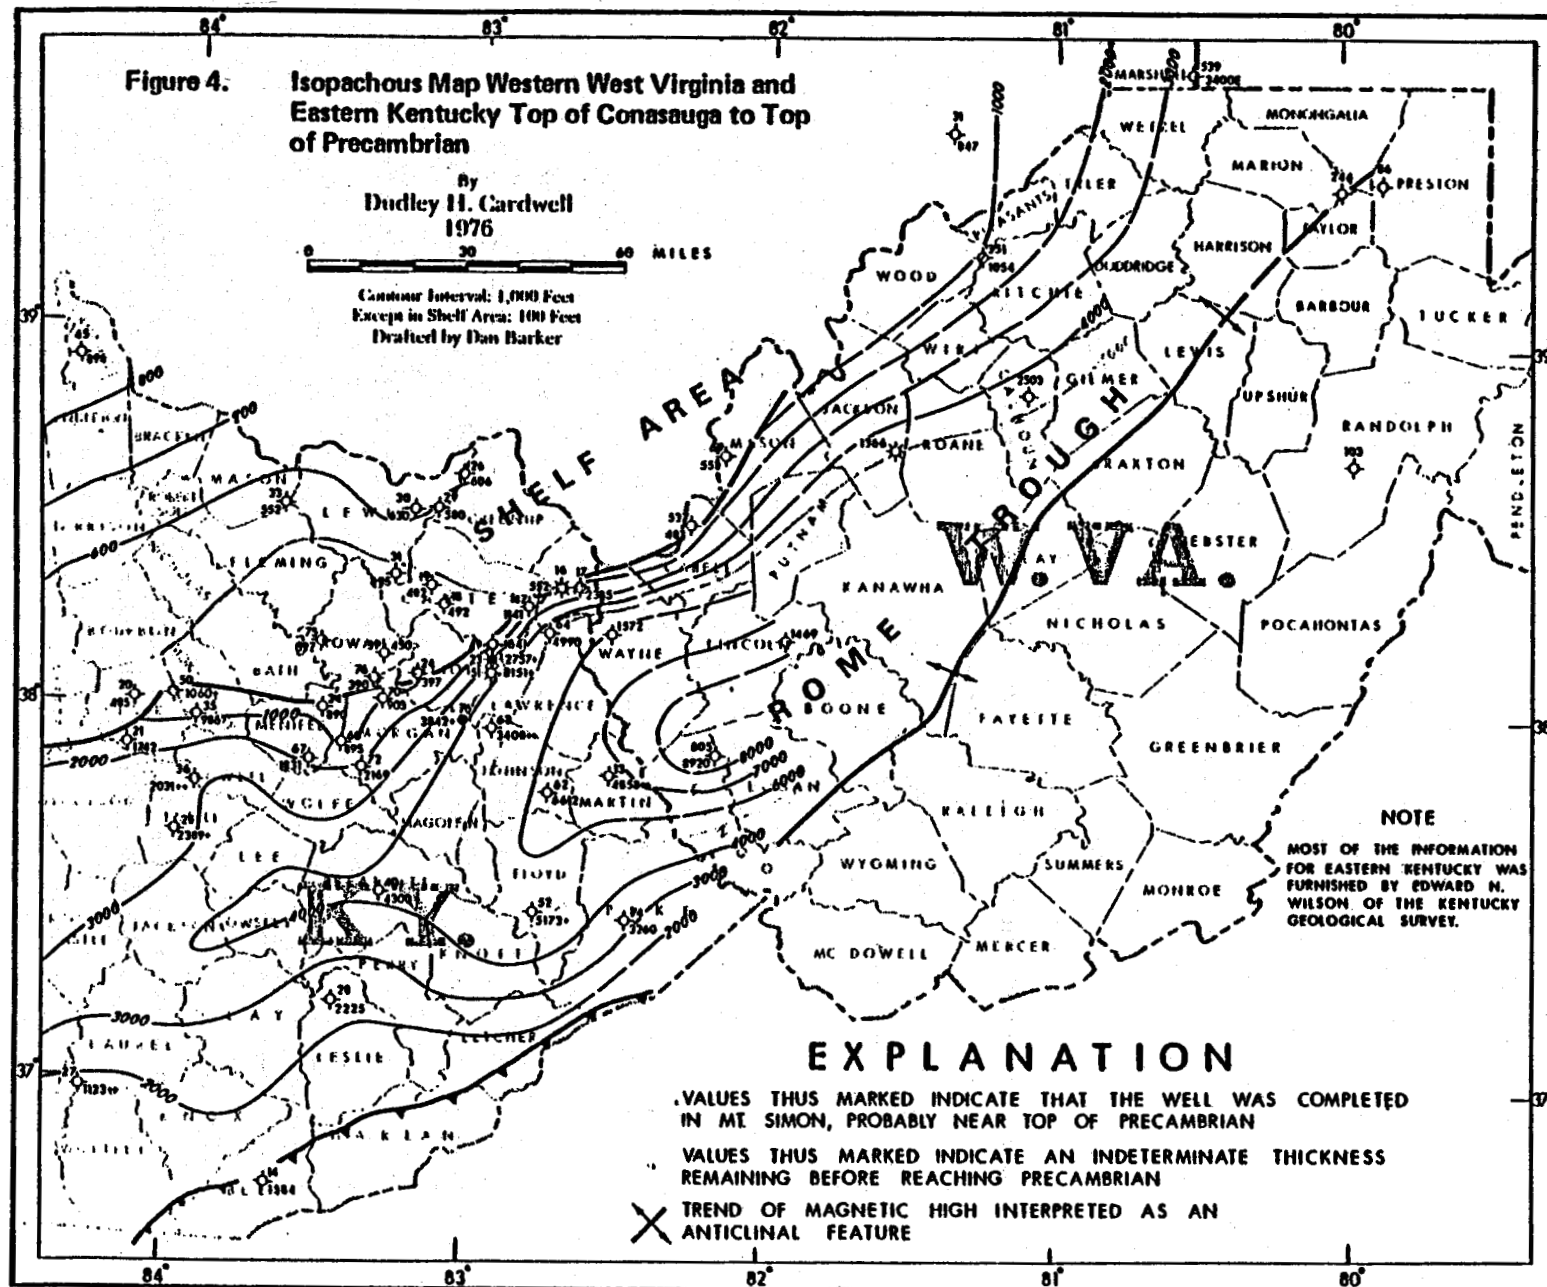

This well reached a total depth of 17,689' and encountered high overpressuring in the Upper Elbrook section of the Rome formation. The shut-in pressures and pressure gradients for several drill stem tests are as follows:

This well produced water and gas for a limited period from a pay zone at 14380-14384'. The water from this zone, which occurred above the gas, is characterized by relatively low salinity, i.e. 53,000 ppm of total dissolved solids. The initial output on a test basis was 5000 Mcf/day together with considerable water, but a cutback in gas production did not result in a reduction in water output. It was never determined whether or not this was free gas or gas dissolved in water. The well was plugged shortly after these tests were conducted.

o McCormick well drilled in Lincoln County, WV in 1974 encountered overpressuring in the Rome formation as indicated by the change in mud weights, as follows (Brown, 1980).

|                  |   |
|------------------|---|
| Depth of 12,091' | - mud weight increased from 9.9 to 11.2 to 13.0 ppg |
| 12,124'          | - increase from 13.3 to 13.5 to 13.7 ppg            |
| 12,900'          | - increase of mud weight to 16.9-17.0 ppg           |
| 13,300'          | - increase of 18.0 ppg                              |
| 13,600'          | - mud weight remained at 18.0 ppg                   |
| 19,124 (TD)      | - mud weight remained at 18.0 ppg                   |

Two drill stem tests were performed - zone at 12,184' indicated a flow of 100 Mcf/day of gas and water, the latter with a salinity of 27,000 ppm of total dissolved solids; a second test at 19,124' had a flow of 3000 Mcf/day of gas but without water.

- o Well 9674-T, Mingo County, WV (Brown, 1980)

This well drilled into basement rock, encountered at 19,527', penetrated the top of the Rome formation at 10,840'. A seismic survey made before drilling indicated two abnormally high pressure zones at 10,900 to 11,300' and from 16,900 to 19,600'. A plot of the calibrated velocity log also indicated abnormal pressure at 10,800 and possibly in three other zones at 10,500 to 12,700'; 14,250 to 15,000'; and 16,500 to 19,537'. Abnormal pressure was encountered during drilling at 13,057' where a mud weight of 18.1 ppg was employed, i.e. equivalent to a pressure gradient of 0.94 psi/ft as compared to a normal gradient of 0.465. One of the drill stem tests was from 13,057 and below and had non-commercial shows of gas and accompanying water, the latter with a relatively low salinity of 45,000 ppm total dissolved solids.

The Ordovician and Cambrian section encountered in this well was as follows (Cardwell, 1977):

|                 |        |                     |
|-----------------|--------|---------------------|
| Elevation       | 958'   | Total Depth 19,600' |
| Depth to Top of |        |                     |
| Martinsburg     | -4427  |                     |
| Trenton         | -5005  |                     |
| Black River     | -5650  |                     |
| Wells Creek     | -6802  | Ordovician          |
| St. Peter       | -7536  |                     |
| Beekmantown     | -7564  |                     |
| Rose Run        | -8342  |                     |
| Copper Ridge    | -8492  |                     |
| Rome            | -9692  | Cambrian            |
| Mount Simon     | -18292 |                     |
| Pre-Cambrian    | -18612 |                     |

- o The Gainer-Lee well drilled in Calhoun County to a total depth of 20,222 into the Pre-Cambrian is reported to have encountered overpressuring in Ordovician and Cambrian formations similar to that found in the Mingo County well. The salinity of Cambrian formation waters was approximately 53,000 ppm total dissolved solids.

- o The bottom hole temperatures in these deep Cambrian wells ranged from 258°F in the Mingo County well to 270°F in the Jackson County well for a temperature gradient of 1.6 to 1.8°F/100'. This is fairly representative of the relatively low temperature conditions in the Appalachian basin (Brown, 1980).
- o A fourth well drilled in the Kentucky part of the Rome Trough encountered the Rome formation at a depth of about 10,000' but no further information was available.
- o In 1981, a new well in Jackson County offsetting the McCoy well is planned (Brown, 1980) and in view of the interesting results of the original, this would be an excellent well for future monitoring and study.

#### 2.3.4.3 Extension of Rome Trough

Based on work by Wagner (1976) it is highly likely that the Rome trough extends further northward into western Pennsylvania and western New York. In this region, an upper Cambrian sandstone called the Olin sandstone (as much as 300' thick and more) has been deposited in an elongated basin some 50 miles wide. This entire section is characterized by various stratigraphic changes which strongly suggests that contemporaneous or growth faulting was active along the western edge of the depression throughout the Cambrian. A structure contour map, Figure 6, indicating the form, depth and position of the basin in southwestern Pennsylvania strongly suggests that this basin is apparently the northward extension of the Rome trough. Further, the Olin sandstone appears to be correlative with the Conasauga and part of the upper Rome formation in West Virginia (Cardwell, 1977).

**Figure 6. Structure Contours on Precambrian Basement in Southwestern Pennsylvania Indicating the Projection of Growth Faults to Basement (Wagner, 1980)**

There was no pressure data available for the Cambrian wells in western Pennsylvania but given the general association of growth faults and abnormally high pressures and the occurrence of the latter in the Rome trough in West Virginia, it is highly probable that future deep drilling will likewise encounter overpressuring.

#### 2.4 SUMMARY

It is apparent from the foregoing that the Appalachian basin is generally an area of normal to abnormally low pressures. Even where abnormally high pressures and even superpressures are encountered, as in the Oriskany (Devonian) and Rome (Cambrian) formations, respectively, the salinities are generally too high (as in the former) or the temperatures are too low (as in the latter) to expect significant quantities of dissolved methane in the formation waters. Moreover, it is not uncommon in either case to encounter high pressure gas zones with little or no water. The only area in the Appalachian basin which holds any promise insofar as the recovery of methane from geopressured waters is concerned, would be the Rome trough. Operating on the premise that dissolved methane is present and based on the solubility relationship as a function of temperature and pressure (Culberson and McKetta, 1951) and subsequently modified by others to account for salinity, it can be estimated that the methane content of these Cambrian waters is approximately 30-35 standard cubic feet (SCF) per barrel of water.

It is accordingly suggested that future drilling in this area be closely monitored, and should a given well (such as the proposed Columbia well previously mentioned) provide meaningful results, then consideration ought to be given to testing under DOE's Wells of Opportunity Program. The monitoring of recently planned drilling activities in the Appalachian basins through the various state geological agencies and selected private monitoring groups does not indicate the contemplation of any other deep wells in the region.

### 3. CALIFORNIA

#### 3.1 Great Valley

Geopressures have been previously reported in Phase I in various parts of the state, the Great Valley including the Sacramento and San Joaquin Valleys, Coast Ranges, and the Ventura, Santa Barbara, Los Angeles and Eel River basins and their offshore extensions. For the most part, the occurrences outside the Great Valley are isolated and lack consistency. Therefore, for purposes of this report, the principal focus will be on the Sacramento and San Joaquin Valleys though limited data on these other areas, in addition to that cited in the earlier work, will be presented.

From a geologic perspective, the Great Valley with an average width of about 50 miles, occupies the central part of the state extending from near the Oregon border to Bakersfield, a distance of approximately 450 miles. As shown in the geologic map of central and northern California, Figure 7, the floor of the valley is underlain by Tertiary-Quaternary sediments flanked on the west by a thick assemblage of older Jurassic-Cretaceous sediments; these in turn underlie the valley floor. Further west are the Coast Ranges comprised of a complex of Franciscan rocks while to the east, the valley is flanked by a suite of Jurassic-Cretaceous intrusive rocks comprising the Sierra Nevadas. The latter highland area is believed to be the major source of detritus for the relatively thick accumulation of sediments in the valley.

Geologically and structurally, as shown in Figure 8, the Great Valley may be considered an elongated northwest-trending asymmetric structural trough which has accumulated an enormous thickness of sediments ranging in age from the Jurassic to the Recent. This

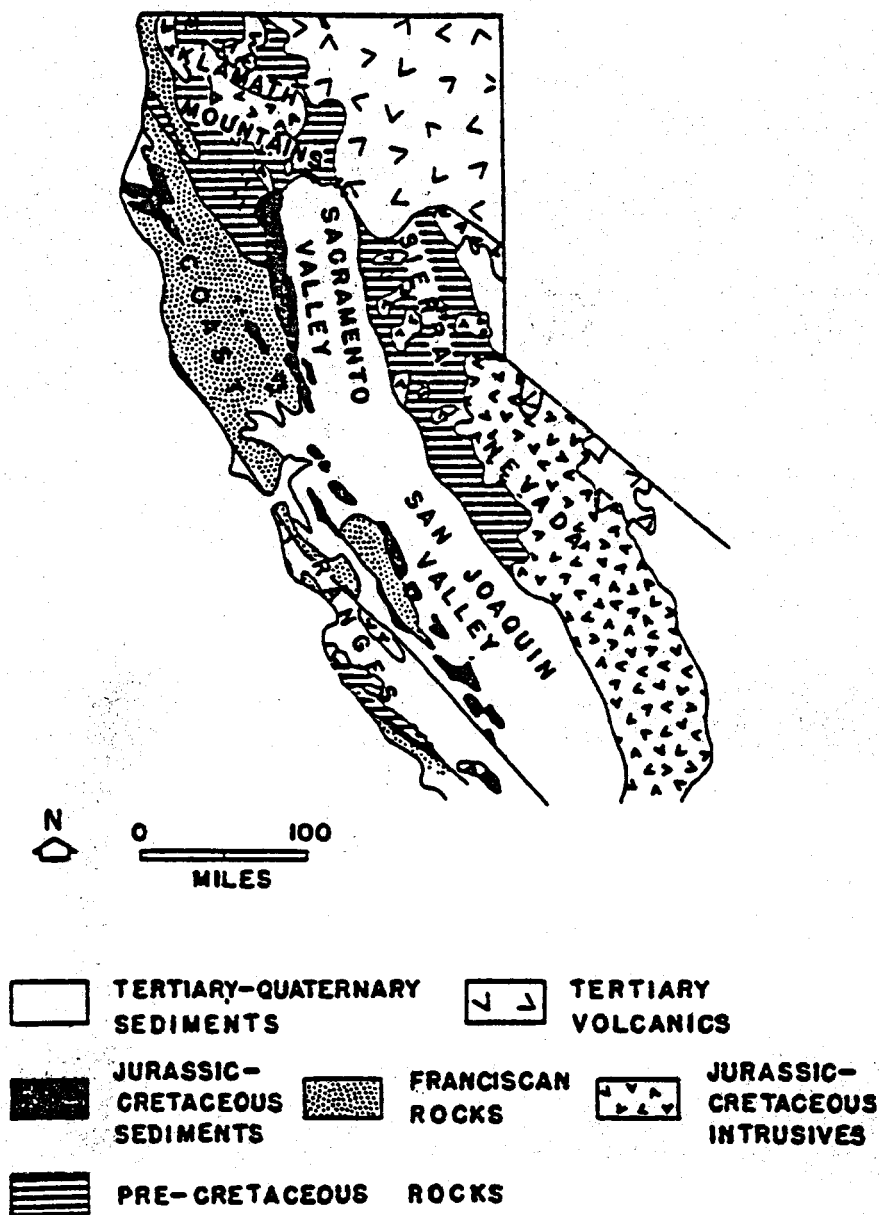

Figure 7. Generalized Geologic Map of Northern and Central California (Chuber, 1962)

**Figure 8. Regional Tectonic Elements of the Great Valley of California**

asymmetric geosyncline, with the axis along the western flank, is bounded on the east by the long relatively stable shelf of the Sierra Nevada and on the west by an abbreviated flank in which the basin sediments have been upturned. The basin has a regional southward tilt and the Stockton arch is generally considered to be the boundary between the Sacramento Valley and the San Joaquin Valley.

In terms of stratigraphy, the rock sequences in the two valleys are quite different. The Sacramento Valley is characterized by a thick section of Mesozoic rocks, topped by a relatively thin layer of Paleocene and Eocene sediments. The Mesozoic sequence is thickest along the west side of the Sacramento Valley suggesting that the maximum deposition, believed to be 60,000' at a minimum (Hackel, 1966) occurred somewhat west of the present structural trough. By contrast, the San Joaquin Valley is underlain by a relatively thinner assemblage of Mesozoic sediments which is overlain by a relatively thick sequence of Tertiary sediments (of Paleocene to Pliocene in age) approximately 15-20,000' thick north of the Bakersfield arch and about 30,000' thick south of the arch. The thickest accumulation was along the western edge of the southern part of the San Joaquin basin, close to the present position of the structural low. The relationship between the two basins in terms of type and accumulation of sediments is shown in Figure 9, an isopachous map depicting the thickness of the Mesozoic and Cenozoic sediments in the Great Valley.

### 3.2 Other Occurrences Outside Great Valley

Other fields outside the Great Valley have isolated reports of geopressures. In addition to the Ventura Avenue Oil field in the Ventura basin and occurrences in the Coast Ranges and elsewhere (including the offshore) which were cited in Phase I, the following overpressured occurrences have been noted.

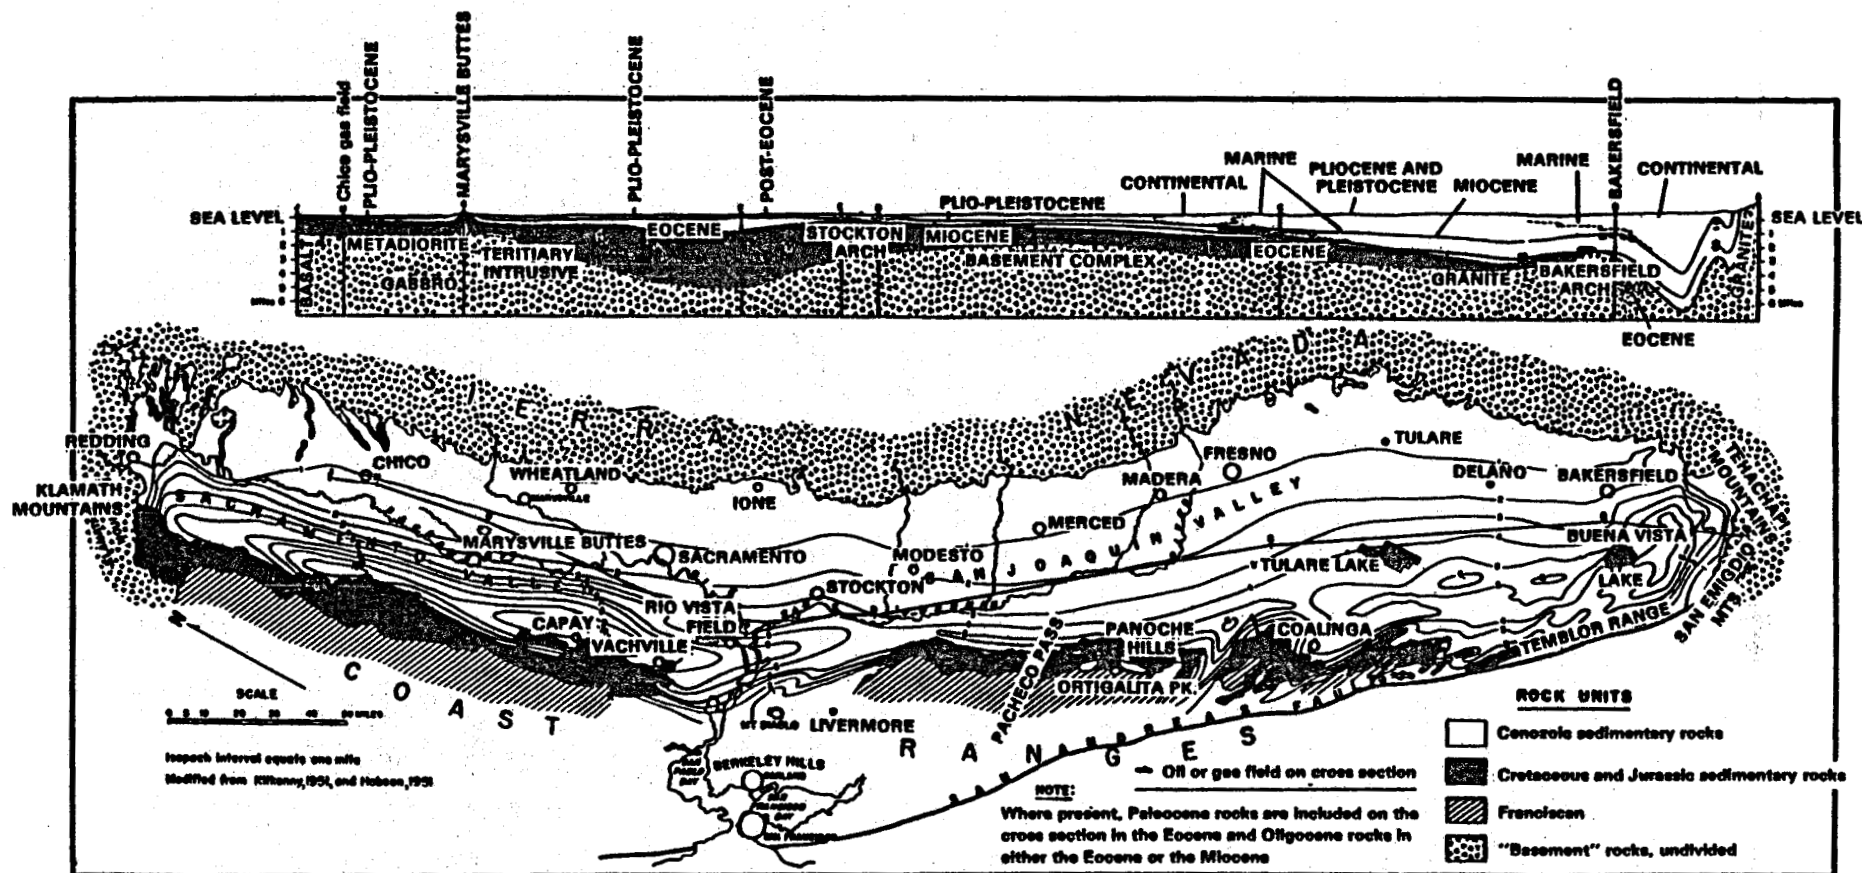

Figure 9. Map of Central California Showing Thickness of Sedimentary Rocks in the Great Valley (Repenning, 1960)

- 1) Goleta Gas Field, Santa Barbara County (Cal. Div. Oil & Gas Vol. II, 1973)  
The Vaqueros formation (lower Miocene) at a depth of 3950' had an original pressure of 1910 psi (.483 psi/ft. pressure gradient) and salinity of 342-5135ppm.
- 2) San Ardo Oil Field, Main Area Monterey County (Cal. Div. Oil & Gas, Vol. II, 1973)  
The Santa Margarita formation (above the Monterey formation) at depths of 1500-2000' has sand pressures that exceed normal hydrostatic pressure.
- 3) Long Beach Oil Field, Los Angeles County (Ingram, 1968)  
During the early stages of development, gas under very high pressure in the lower Wilbur zone (top of lower Pliocene Repetto formation) at an average depth of 2500' and fairly limited in areal extent, was the apparent cause of several spectacular blowouts.
- 4) Pimental Canyon Gas Area of Vallecitos Oil Field, San Benito County (Cal. Div. Oil & Gas, 1973)  
Yokut formation (lower Eocene) at a depth of 2500' displays a salinity of 1113 ppm and a pressure of 1200 psi for a pressure gradient of .480 psi/ft.
- 5) Tompkins Hill Oil Field, Humboldt County (RIE, T3N)  
This field, with productive intervals in the Pico-Repetto formation (Pliocene) is characterized by numerous high pressure gas zones. The following is a list of pressures and salinities for selected wells (Saunders, 1980):

| <u>Well</u>      | <u>Prod.</u><br><u>Interval</u><br><u>(ft)</u> | <u>Total</u><br><u>Dissolved</u><br><u>Solids</u><br><u>(ppm)</u> | <u>Orig.</u><br><u>Shut-In</u><br><u>Pressure</u><br><u>(psi)</u> | <u>Calc.</u><br><u>Pressure</u><br><u>Gradient</u><br><u>(psi/ft)</u> |

### 3.3 Sacramento Valley

#### 3.3.1 General

In order to track the various formations and their relative age and juxtaposition as they will be discussed in this report, the stratigraphic column for this region is depicted in Figure 10. The locations of the various fields in the Sacramento Valley is shown on two maps - Figure 11A for the northern part and Figure 11B for the southern part.

#### 3.3.2 Geopressure Characteristics

The Sacramento Valley is essentially a dry gas area in which numerous gas fields have been developed for more than fifty years. Fortunately for the purposes of this report, the California Division of Oil and Gas which maintains records on all oil and gas fields in the state, publishes pressure and salinity data in addition to other information, on all gas fields; however, there is no formalized system for

Figure 10. Stratigraphic Column — Sacramento Valley

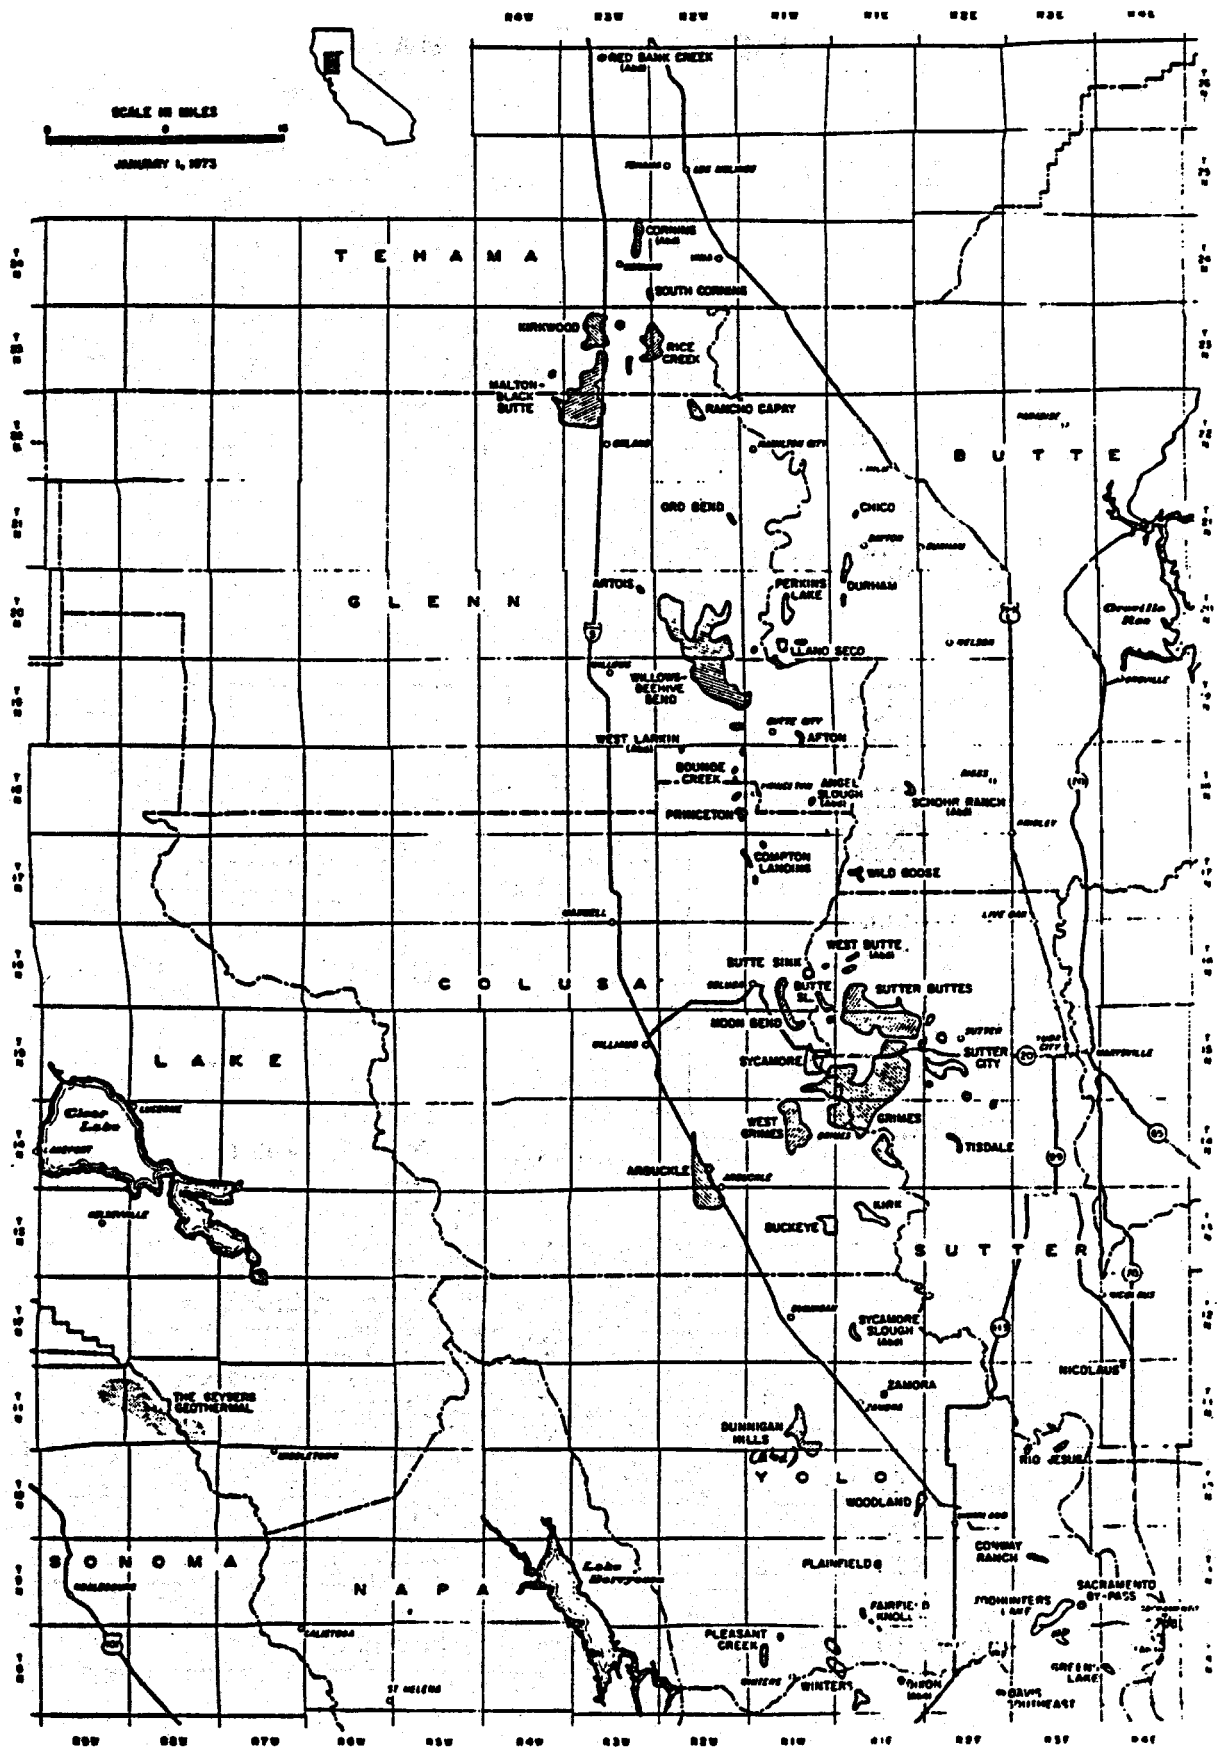

Figure 11A. Location of Fields in Northern Part of Sacramento Valley

reporting pressure data for oil fields even though many of them produce gas. Consequently, there was no difficulty in determining which fields and formations in the Sacramento Valley were overpressured, unlike the San Joaquin Valley, essentially an oil province, where pressure data needs to be obtained from a variety of sources.

Table 5 indicates the geopressured field and formations therein, together with salinity values, depths, ages, and calculated pressure gradients for the Sacramento Valley and northern San Joaquin Valley.

From a review of Table 5, it is apparent that the Forbes formation is ubiquitously overpressured and often superpressured throughout the Sacramento Valley unrelated to depth. For example, a) in the Malton Black Butte field, at a depth of 3250', the pressure gradient in the formation is .486 psi/ft; b) in the Moon Bend field, at 3270', the gradient is .795 psi/ft; and c) in Sutter Buttes field, at 2100', the gradient is .714. The overlying upper Cretaceous formations, such as the Kione, are only rarely overpressured, usually not in excess of .550 psi/ft. Similarly, the Paleocene and Eocene formations are only overpressured to a limited degree, rarely attaining the superpressures of the Forbes.

Geopressures in the Sacramento Valley are geographically oriented in that the abnormally high pressures/superpressures in the Forbes are generally localized along the west side of the valley while the moderate overpressures of the overlying younger formations are to be found along the eastern flank.

The Forbes formation is thickest on the western flank of the Sacramento Valley, e.g. 3000-5500' in the Grimes field, whereas to the east, it thins markedly, in part due to overlap. The Forbes, where productive, generally consists of interbedded dark gray claystones and siltstones and fine grained, gray, friable and lenticular sandstones.

NOTE

- 1) Unless otherwise indicated, all data is from California Division of Oil and Gas, California Oil and Gas Fields, Northern Area, Vol. 1, 1973 and Supplement, 1979.
- 2) Where listed in grains/gallon, values have been multiplied by 17.118 to obtain values in parts per million (ppm).
- 3) USS - unnamed sand stringers.
- 4) UMS - undifferentiated marine strata.
- 5) Only those fields and formations where the pressure gradient is at least .470 psi/ft have been listed.
- 6) California Division of Oil and Gas does not report pressures for oil fields; hence, data thereof must be acquired from other sources, namely selected annual reports of the California Division of Oil and Gas.

The Forbes is normally productive from stratigraphically-trapped lenticular sand bodies which are generally considered to be turbidites of a submarine fan facies reflecting deposition in a moderately deep marine environment many miles offshore. Generally, these occurrences are pod-like in shape and oriented in a northwest-southeast direction parallel to the regional tectonic trend. Individual sandstone lenses range in size from that present in a given well to dimensions ranging from 2-3 miles wide to more than 8 miles long. In the Malton field, for example, each lens has an areal extent of about 50 acres with a thickness of 1-40 feet (Hutchinson, 1981). Elsewhere, in the Grimes field, the thickness of individual sandstone beds varies between 8 to 60' (Weagant, 1972). The position and sedimentological character of the Forbes is in agreement with paleocurrent studies showing a consistent north to south trend throughout the late Cretaceous which indicates that the source was from the ancestral Klamath Mountains and that deposition was relatively uniform for a protracted time span (Ojakangas, 1968). A model indicating the nature and character of turbidite deposition during this period is depicted in Figure 12.

It has been pointed out by Lee (1980) that commercial gas production in the Forbes appears to be restricted to a particular fluid pressure gradient between .500 to .700 psi/ft. Further, it is apparent that such overpressure trends can be determined to indicate the position of entrapment mechanisms (for gas) in fault zones, stratigraphic pinchouts and other traps. In other words, the pressure can serve as an indicator of the barriers (and hence traps) that have resulted in the persistence of these abnormally high pressures.

The origin of the Forbes overpressures has been a subject of only limited study. It was previously discussed that the Forbes was probably deposited in the outer parts of a submarine fan, an area that generally has been subject to contemporaneous or growth faults caused by slumping that may have been enhanced by the tectonic instability of the region. A rather thick section of late Cretaceous and early Tertiary sediments

**Figure 12. Sedimentation Model for Upper Cretaceous Sediments in Sacramento Valley (Ojakangas, 1968)**

was deposited in the asymmetric Sacramento basin, the axis of which is close to the western margin. As deposition continued, sufficient sediments had accumulated to prevent the ongoing expulsion of water from the Forbes. Thus, the Forbes was now undercompacted and was supporting a part of the overburden. The Forbes at this point was most probably overpressured, but only moderately so. The superpressures noted were seemingly caused when the Sacramento depositional basin was uplifted and later subjected to erosion. Since the Forbes had retained its original pressure but was now at a shallow depth, higher than usual overpressures became the norm. The change from moderate overpressures to superpressures is depicted in Figure 13.

For illustrative purposes, a pressure gradient trend map for the Forbes, Figure 14, was prepared by Charles Lee, for the region between the Buckeye field in the south and the Malton-Black Butte field in the north which is the principal area of Forbes production in the Sacramento Valley. In general, the gradients increase from east to west reflecting the differential intensity of tectonism. It is interesting to note the obvious extremely high pressure (over .800 psi/ft) trend along the west flanks of the Willows-Beehive Bend and West Grimes fields. In the latter areas, gas production is lacking. For example, in the Willows-Beehive Bend field, Figure 15, production from the Forbes is obtained east of the fault where pressure ranges from normal to about .700 psi/ft; however, west of the fault on the downthrown side, where superpressures, in several instances approaching lithostatic, are present, production is lacking. This relationship between overpressures and production is further illustrated in Figure 16 which indicates that in the West Grimes field all commercial production with one exception occurs in the pressure gradient range of .500 to .700 psi/ft.

The detection of overpressures in the Forbes may be determined by various techniques. One involves drill stem tests, though few

STAGE I

STAGE II

Figure 13. Evolution of Superpressures in the Forbes Formation by Undercompaction and Uplift (Lee, 1980)

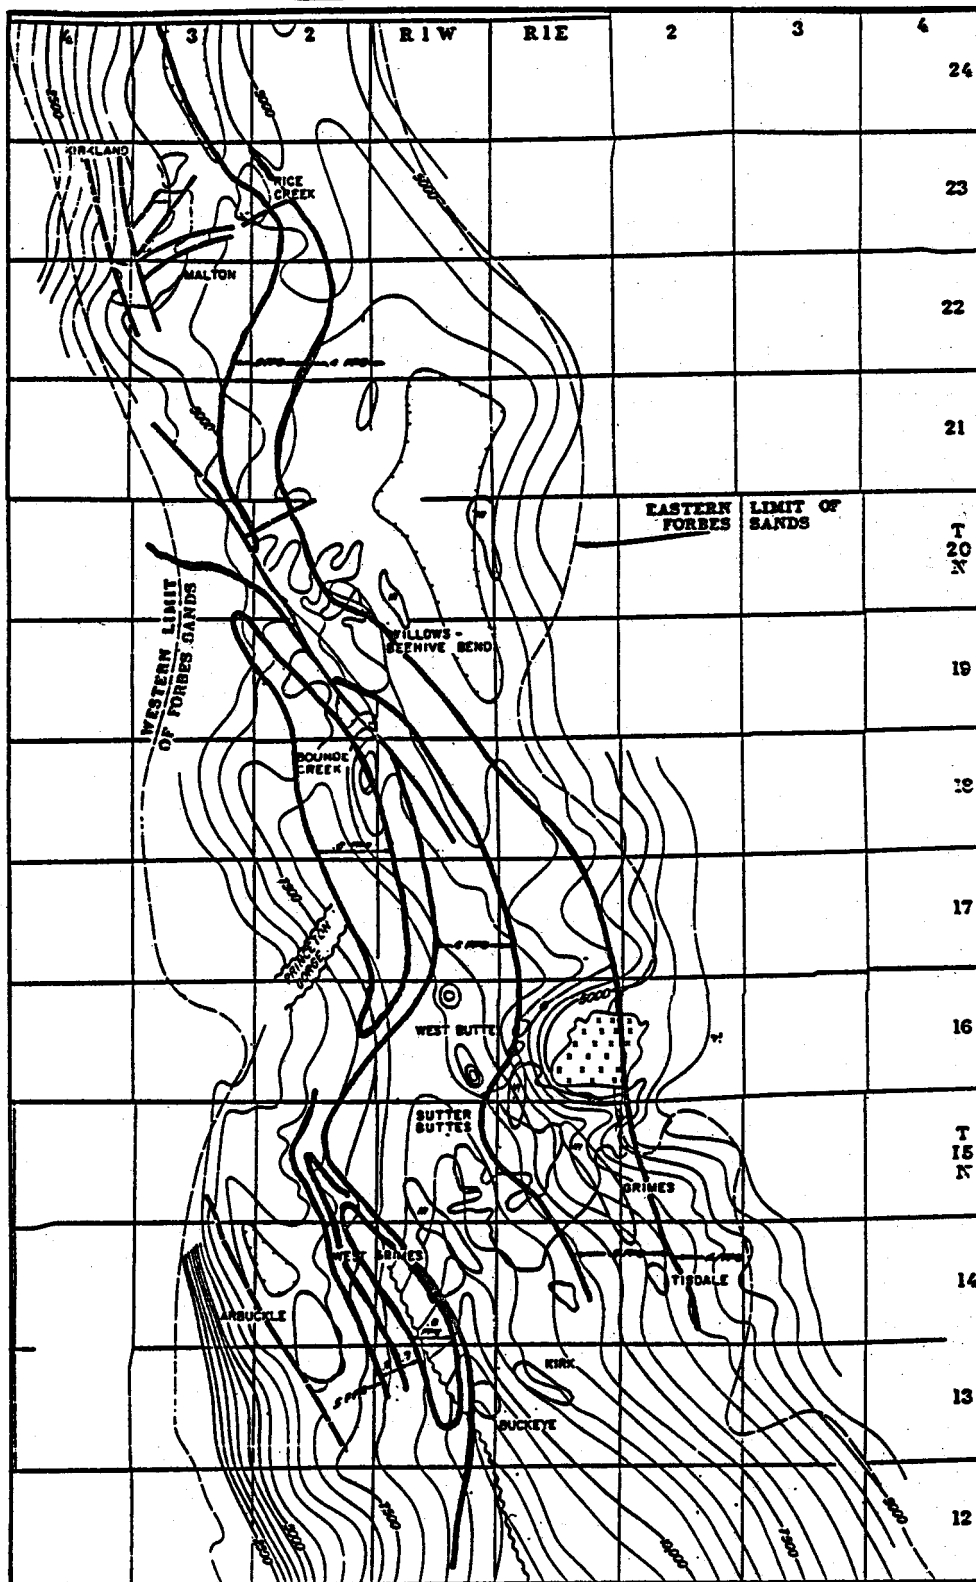

Figure 14. Pressure Gradient Trend Map in the Forbes Formation, Northern Sacramento Valley Showing Fluid Pressure Gradient (FPG) Corridors from .4 to .8 psi/ft. Structure Contours are on the Dobbins Shale (U. Cret.) Below the Forbes. See Figure 11A for Relative Location of Fields in Sacramento Valley (Lee, 1980)

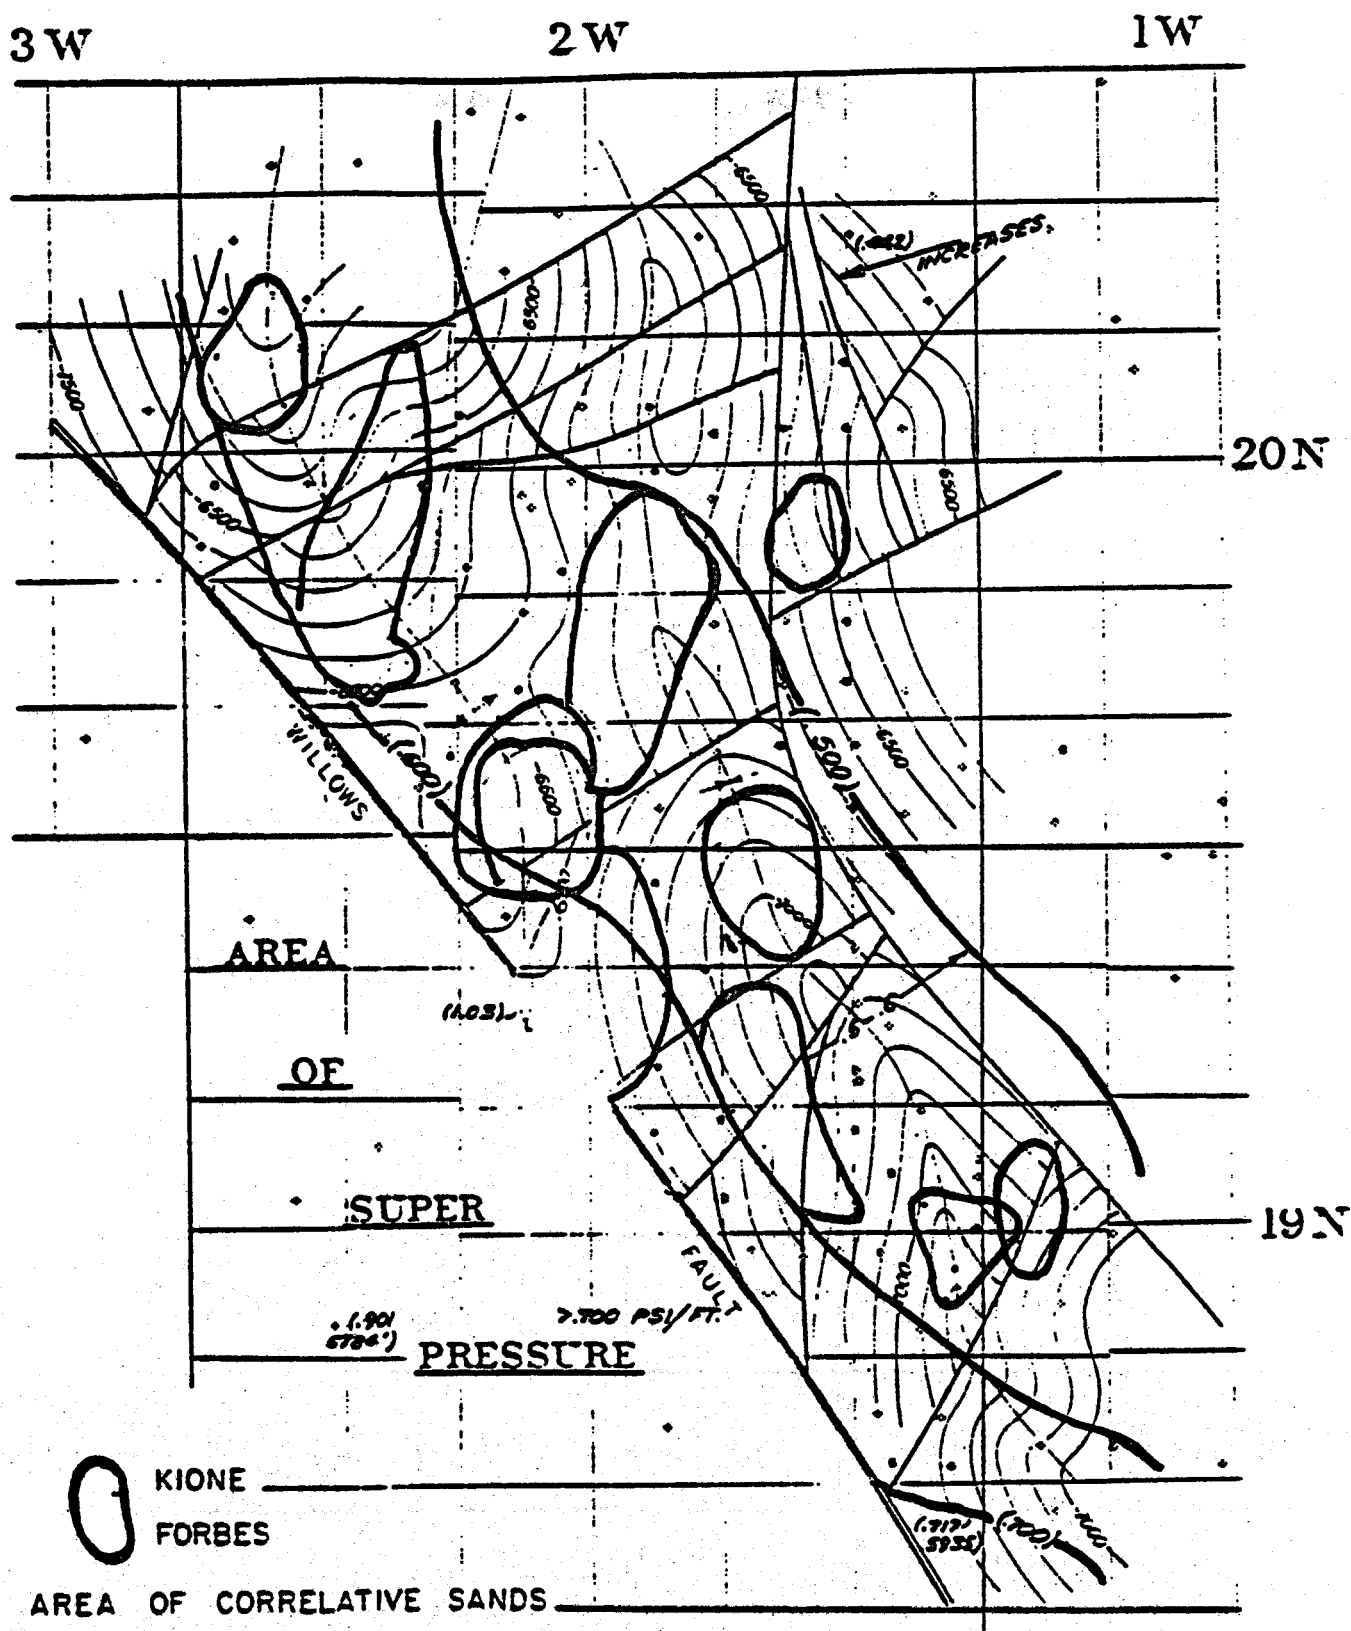

Figure 15. Relation of Production to Superpressures in the Forbes/Kione Formations in the Willows-Beehive Bend Gas Field, Northern Sacramento Valley. Structure Contours are on the Guinda Sand (U. Cret.) Below the Forbes (Lee, 1980)

Figure 16. Productivity vs. Pressure Gradient in West Grimes Field  
(Lee, 1980)

DST's are run in the formation. Static shut-in tubing pressure measurements can be extrapolated to bottom hole shut-in pressure but initial shut-in pressure data is required. A third method involves the use of mud weight data which are generally available, but given the tendency to drill in an overbalanced mode, they must be used with some discretion. It can be presumed that where mud weights greater than 110 lbs/cu.ft. are used, superpressures have undoubtedly been encountered. A final source of pressure information is from electrical logs involving the plotting of shale resistivities.

### 3.3.3 Specific Occurrences

#### 3.3.3.1 Fields

The following listing indicates the pressure gradients and/or salinities from known fields in the Sacramento Valley.

- 1) Moon Bend Gas field in Colusa County with production in the Forbes formation exhibits the following pressures (Saunders, 1980):

| <u>Well Number</u>   | <u>Prod.<br/>Internal<br/>(ft)</u> | <u>Orig.<br/>Shut-In<br/>Pres.<br/>(psi)</u> | <u>Pressure<br/>Gradient<br/>(psi/ft)</u> |
|----------------------|------------------------------------|--|---|
| Colusa UN 1 #1 Upper | 4561-4930                          | 2700   | .592-.548                                 |
| UN 1 #1 Lower        | 5561-5956                          | 3525   | .634-.592                                 |
| Colusa UN 2 #1       | 4452-4577                          | 2590   | .582-.566                                 |
| UN 2 #2              | 5184-5266                          | 2600   | .502-.594                                 |
| UN 2 #3              | 4979-5398                          | 2602   | .523-.482                                 |
| UN 2 #4              | 5065-5134                          | 2630   | .519-.512                                 |

#### 2) Colusa County

The attached charts, Figures 17, 18, and 19, are graphical representations of pressure gradients derived from mud weights as compared to drill stem tests for wells drilled into the Forbes formation in the Compton Landing, Arbuckle and Buckeye field.

| 5800                         | .620                  | .480                   | 6000                  | .590                  | —                      | 7800                 | .670                  | .520                   |
| 6900                         | .760                  | —                      | 6400                  | .620                  | .540                   | 8500                 | .760                  | .640                   |
| 7100                         | .810                  | —                      | 6900                  | .800                  | —                      | 8700                 | .810                  | .700                   |
| 8000                         | .900                  | .820                   | 7100                  | .850                  | .690                   | 9200                 | .900                  | .800                   |

3) Brentwood Field, Contra Costa County (Ditzler and Vaughan, 1968)

The producing reservoirs are characterized by slight overpressuring, e.g. a drill stem test in a well at a depth of 3550-3600' had an initial shut-in pressure of 1695 psi (.477 psi/ft).

3.3.3.2 Wildcat Wells

- 1) The following listing indicates representative pressure gradients (based on mud weights and/or drill stem tests) and/or salinities from two wildcat wells drilled into the Forbes in the Sacramento Valley (Lee, 1980):

Pressure Gradients (and Salinities) from Mud Weights  
and Drill Stem Tests in  
Selected Exploratory Wells in Colusa County

Well in Sec. 3, T14N, R2W  
(North of Arbuckle field)

| <u>Depth</u><br>(ft) | <u>Pres. Grad.</u><br><u>Based On</u> |

| 1200                 | .580                                  | .460       | —                        |
| 3000                 | .630                                  | .600       | —                        |
| 3700                 | .700                                  | .670       | 23000                    |
| 4000                 | .760                                  | .720       | 18000                    |
| 4400                 | .770                                  | .680       | 14000                    |
| 4900                 | .800                                  | .600       |                          |
| 5300                 | .810                                  | .650       |                          |
| 7300                 | .820                                  |            |                          |

- 2) Tenneco-Etchepare-Elliott #1 Well, Colusa County (Franklin & Mandel, 1981)

Located in the Maxwell area in Section 19, T17N, R3W, approximately 10 miles west of the Compton Landing Gas field and about 15 miles from the Willows-Beehive Bend Gas field.

This was a dry hole drilled in 1979 to 5300' T.D. designed to test the Forbes and Guinda formations and the total stratigraphic column penetrated was as follows:

|                           | <u>Depth</u> | <u>Subsea Datum</u> |
|---------------------------|--------------|---------------------|
| Base of Tehama fm         | 740' (est)   | -578                |
| Top Forbes fm             | 740' (est)   | -578                |
| Mid-Forbes Marker         | +2480'       | -2318               |
| "G" Marker-base of Forbes | 4313'        | -4151               |
| Top Guinda fm             | 4424'        | -4262               |
| Top Funks Shale           | 4962'        | -4800               |

Formation tests indicate notable overpressuring in the Forbes as indicated below:

| <u>Depth</u><br>(ft) | <u>Pressure</u><br>(psi) | <u>Pressure</u><br><u>Gradient</u><br>(psi/ft) |
|----------------------|--------------------------|--|
| 2180                 | 1345                     | .617   |
| 2209                 | 1392                     | .630   |
| 2243                 | 1445                     | .644   |
| 2268                 | 1487                     | .656   |
| 2504                 | 1713                     | .684   |
| 2792                 | 2475                     | .886   |
| 3787                 | 3178                     | .839   |

The mud weights used in the drilling of this well likewise convincingly demonstrated overpressuring in the Forbes as well as an underlying formation though it should be recognized that as a general practice, most operators in the Sacramento Valley tend to use over-balanced mud formulations. Therefore, as a general rule, when determining pressure gradients from mud weights, only those above .550 should be considered overpressured. The actual mud weights, depths and indicated pressure gradients (which are higher than the measured values) are as follows:

| <u>Mud Weight</u><br>(lbs/gal) | <u>Depth</u><br>(ft) | <u>Indicated</u><br><u>Pres. Gradient</u><br>(psi/ft) |
|--------------------------------|----------------------|---|
| 9.5                            | 850                  | .494  |
| 11.0                           | 1300                 | .572  |
| 11.1                           | 1650                 | .577  |
| 11.0                           | 1850                 | .572  |
| 11.2                           | 2050                 | .582  |
| 12.2                           | 2320                 | .634  |
| 13.3                           | 2450                 | .692  |
| 14.0                           | 2720                 | .728  |
| 17.4                           | 2765                 | .905  |
| 18.7                           | 2925                 | .972  |
| 19.8                           | 3350                 | 1.030   |
| 19.4                           | 3650                 | 1.009   |
| 18.8                           | 3950                 | .978  |
| 19.2                           | 4100                 | .998  |
| 19.0                           | 4700                 | .988  |
| 19.0                           | 5300                 | .988  |

A drill stem test at depths of 2714-95' recovered salt water with chloride content of 1500 to 2100 ppm. The bottom hole temperature was 124°F for a temperature gradient of 2.48°F/100 ft.

A nearby well, the West Azevedo #1, some 1½ miles southeast of the Elliott, in Section 29 penetrated a similar section but at about 1100 feet lower, it likewise encountered overpressuring in the Forbes but the maximum gradient was only .780 psi/ft.

### 3.4 San Joaquin Valley

#### 3.4.1 General

The stratigraphic succession and formation names used in this heavily developed region are shown in Figures 20A and 20B. As there has been extensive drilling into the Miocene and Oligocene beds, there is considerable stratigraphic control and detail available for these younger Tertiary formations for both the east and west side of the valley, in contrast to the underlying rock sequences. The locations of the various fields in the San Joaquin Valley are shown in Figures 21A, 21B, and 21C.

#### 3.4.2 Geopressure Characteristics

Geopressuring in the San Joaquin Valley is essentially present in the fields along the west side of the basin. One major area, previously discussed in Phase I, would be along the trend of the Kettleman Hills, a major structural feature that extends for about 100 miles in a southeasterly direction from the Coalinga region through the Kettleman North Dome, Middle Dome, and South Dome (latter believed continuous with the Lost Hills) and on to the area of the Semitropic and Button-

Figure 21C. Location of Fields in Southern San Joaquin Valley

willow fields. Within this belt, geopressures have been noted in upper Cretaceous sediments, the McAdams formation (upper Eocene), Leda sand (Oligocene), Temblor formation (lower Miocene), Stevens formation (upper Miocene), and occasionally in the overlying Etchegoin and San Joaquin sediments (Pliocene).

Slight to moderate geopressures have been reported from fields to the east and southeast such as in the Eocene and Oligocene formations of the Wheeler Ridge field cited in Phase I.

One of the problems associated with obtaining pressure data, whether through direct measurement, use of mud weights, and/or logs is that the California Division of Oil and Gas does not publish this information for oil fields, which predominate in the San Joaquin Valley. Consequently, the only way to acquire this data is to obtain access to the well files maintained by the Division (provided they have not been labeled proprietary by the operator involved, which is often the case) or to contact the operator directly for this purpose. In the former instance, the files are not always complete while in the latter case, files were often unavailable for proprietary or other reasons.

Within these limitations, considerable data on geopressured occurrences in the San Joaquin Valley has nevertheless been assembled. Table 6 is a listing of selected geopressured occurrences by field based on data, mostly from deep wells, that has been collected by A.L. Lorshbaugh, District Supervisor of the Bakersfield Office of the California Division of Oil and Gas. This list should not be considered complete but in conjunction with the descriptions of other specific occurrences gleaned from published material and other sources, it should provide a fairly comprehensive overview.

The San Joaquin Valley which has been continually subsiding from the mid-Tertiary to the Recent has been the site for the deposition

\* Lorshbaugh, 1981

Note: Since most operators in this region tend to overbalance mud formulations, only those pressure gradients of .550 psi/ft. and more are reported in this tabulation.

of thick off-shelf, deep-water marine clastic sediments throughout the Miocene and marine to continental beds since that time. The dominant source region through most of the Tertiary (till Miocene) has been the Sierra Nevada crystalline complex to the east; since late Miocene, the source terranes also included the highlands to the south and west (Webb, 1977). Based on paleontological and sedimentological characteristics, it is likely that most of the Miocene sediments including the Temblor (lower and middle Miocene) and Stevens sands were deposited in water depths in the range of 4000 to 6000'; hence, it is likely that these sands are turbidites.

There have been several recent studies of the Stevens sand, which is one of the major geopressed formations in the region. The most comprehensive study on the subject was authored by MacPherson (1977) and much of the data and analysis presented herein is from his paper.

The Stevens sand (upper Miocene) is a comprehensive nomenclature for over 5000' of deep marine interbedded sands and shales, the extensive lateral extent of which has been ascribed to the action of major coalescing submarine fans that emanated from various source areas. Essentially, four major cycles of turbidite deposition have been recognized in the Stevens, each of which is characterized by a relatively thick sand layer overlain by thinner shale members, the latter indicating periods of little or no sand supply. The turbidites within the Stevens sequence are apparently representative of the mid-fan facies of a submarine fan complex.

Two associated depositional processes have been recognized within this mid-fan area, namely contemporaneous or growth faulting and distributary channel transport. In terms of geopressed occurrences, the former phenomenon is most significant; it is believed to be caused by sedimentation accompanied by syndepositional faulting, in some respects analagous to that of the Gulf Coast. Similarities include a marked expansion of section on the downthrown side, reverse drag

or roll-over, and the presence of antithetic faults. A further similarity is that the growth faults migrate basinward and become progressively younger as new sediment wedges are accumulated. One dissimilarity, however, is that the principal or master fault plane in the Stevens appears to be nearly vertical and only moderately asymptotic to bedding planes with increasing depth.

It is generally held that conditions for growth faulting occur in a marine shelf environment where thick accumulations of sand are rapidly deposited over low-density shales with high water content. The increased pressure causes the formation of a glide plane similar to a slump block that has an arcuate plan shape and a concave upward cross-section. Ongoing lubrication of the glide or fault plane is furnished by the process of shale dewatering that results in a continual process of sliding and slumping. These conditions have apparently occurred in the Stevens, i.e. a thick, rapidly accumulating turbidite section deposited on a comparably thick sequence of underlying shales in which the growth faulting process was probably promoted by the incidence of periodic tremors. Given this set of depositional conditions and the rather recent geologic time frame, it is not surprising that abnormally high pressures have been encountered in many oil fields of the San Joaquin Valley.

### 3.4.3 Salinity of Formation Waters

#### 3.4.3.1 Northern Section - Fresno, Kings and Madera Counties

The analysis of oil field waters from this part of the San Joaquin is shown in Table 7. It is particularly interesting to note, especially in the Kettleman North Dome field, the differences in salinities between the Miocene and the underlying Eocene zones - the former salinities are considerably higher. This is the reverse of the commonly found condition where the salinity of subsurface waters increases with depth. This

variation is graphically illustrated for this field and the Guijarral Hills field in Figure 22.

This phenomenon in the Kettleman North Dome field has been further investigated by Kharaka and Berry (1974 and 1974A). In this field, the waters in the McAdams formation (Eocene), which has been termed "effluent-type" water by the authors, is believed to be associated with abnormally high pressures where a thick section of shales and siltstones are currently undergoing or have recently been subjected to compaction. The occurrence of this type of water, characterized by certain diagnostic chemical characteristics compared to waters from comparable geologic sections and depths, may be utilized for inferring the presence of geopressuring in underlying or adjacent sediments. This type of water is present in many other fields on the west side of the San Joaquin, as well as the Sacramento Valleys. Accordingly, even where direct pressure measurements are not readily available (e.g. the California Division of Oil and Gas does not record this information for oil fields), or where deeper zones have not yet been penetrated, their occurrence may be inferred from the presence of this type of formation water. Essentially, effluent-type waters, in contrast to other waters, have lower total dissolved solids and Ca/Na ratios and higher Li/Na,  $\text{NH}_3/\text{Na}$ , B/Cl,  $\text{HCO}_3/\text{Cl}$ , I/Cl, I/Br, and F/Cl ratios.

The producing sediments in the Kettleman North Dome field include five zones in the Temblor (Miocene) and two zones in the McAdams, upper and lower. The latter is underlain by a thick sequence of Mesozoic marine shales and siltstones estimated to be about 40,000' thick of which only 4000' has been penetrated. As shown below in Table 8 and illustrated in Figure 23, the original pressures in both the Miocene and Eocene sediments are only slightly above hydrostatic, but they approach lithostatic in the underlying Cretaceous rocks.

Note: In some cases the salinity content (ppm) has a higher apparent value than the total dissolved solids content (ppm). This technically is impossible; however, it probably represents the degree of accuracy in determining the various constituents.

1) Khareka and Berry, 1974

2) Khareka and Berry, 1974A

Previous discussion in Phase I and in the prior section on the Sacramento Valley indicated the role of tectonism in causing and maintaining these extremely high pressures. This is believed to have similarly occurred along the west side of the San Joaquin Valley which resulted in the squeezing out of large quantities of interstitial water from the Mesozoic shales and siltstones. The primary direction of flow of this water was upward and the first formation encountered in this field was the McAdams - the mixing and flushing of original McAdams water by water derived from the underlying sediments resulted in its total or near-total replacement. It should be noted that the salinity of water from these shaly zones tends to be much lower than sea water due to the high compaction pressure to which they have been subjected and the subsequent expulsion of much of this sea water.

#### 3.4.3.2 Southwestern Section

The salinities for the producing zones in the fields in the southwestern part of the San Joaquin Valley in Kern County essentially represent the structural extension of the fields cited above. Table 9, indicating the salinities for these southwestern fields, shows that the decrease in salinity with depth is likewise operative in this region. This is graphically presented for three fields in Figure 24, e.g. Elk Hills field with a decline in salinity from Pliocene to lower Miocene beds and the North Belridge field with a reduction in total dissolved solids from upper Miocene to Oligocene zones.

#### 3.4.3.3 Southeastern Section

The analyses of formation waters from the southeastern fields of San Joaquin Valley in Kern County is presented in Table 10. Unlike the other analyses, the waters in many of these fields display the more common phenomenon of increased salinity with increasing depth, as depicted in Figure 25 for several representative fields. This is to be anticipated in view of its relative distance from the locus of tectonic activity on the west side of the San Joaquin Valley.

NOTE: In some samples the salinity content (ppm) has a higher apparent value than the total dissolved solids content (ppm). This technically is impossible; however, it probably represents the degree of accuracy in determining the various constituents.

Figure 25. Graph Showing Salinity vs. Depth for Selected Fields in Southeastern San Joaquin Valley

### 3.4.4 Specific Occurrences

#### 3.4.4.1 Fields

##### Cal Canal Field (Pac. Petrol. Newsletter, 1977; Lorshbaugh, 1981)

Discovered in 1977, this field with productive intervals in the Stevens sands at depths of 11863'-12046' had an initial reservoir pressure of 7350 psi and initial reservoir temperature of 290°F for a pressure gradient of .619-.610 psi/ft. and a fairly high geothermal gradient of 2.44-2.41°F/100'. The salinity in one well producing from the Stevens zone at 11863-12046' was 22200 ppm.

##### Coalinga Oil Field (Kaplow, 1945)

High pressure gas zones have been reported from early-drilled wells penetrating the Temblor formation (lower Miocene) at depths ranging from 3000-4000'. The salinities were varied - ranging from 5133 ppm to 14,943 ppm.

##### East Coalinga Extension Oil Field (Kaplow, 1942)

The pressure in the Gatchell oil sands (lower Eocene) in the Gatchell Area (Coalinga Nose or Southeast Coalinga) were reportedly quite high, presumably in excess of the normal hydrostatic pressure. The average mid-sand pressure in this area was 3450 psi and the temperature was 198°F; in the Amerada Area to the northeast, the mid-sand pressure was 3740 psi and temperature 210°F.

##### South Coles Levee Oil Field, Kern County (Cal. Div. Oil & Gas, 1962)

The Steven at an average depth of 8800' is also overpressured, about .470-.500 psi/ft., but there is very little formation water.

##### Elk Hills Field, Kern County (Lorshbaugh, 1981)

The producing zones below the Carneros, i.e. below 9500' are superpressured, to the extent that in some cases it exceeds the lithostatic pressure.

Garrison City Gas Field, Kern County (Cal. Div. of Oil & Gas, 1973)

In this field, the Mulina zone of the Etchegoin formation (Pliocene) had an original shut-in pressure of 2240 psi at an average depth of 4500', for a pressure gradient of .498 psi/ft.

Gill Ranch Gas Field, Fresno County (Kharaka, 1980)

A well drilled in this field at Sec 16, T13S, R16E is reported to have encountered overpressures but no specific details are available.

Jerry Slough Oil Field, Kern County (Lorshbaugh, 1981)

This is a one-well field which attained a depth of 13,732 in the Stevens sands (upper Miocene) and production is from fractured shales within this zone at an average depth of 11,250'. The shut-in pressure at a depth of 11,700' was estimated to be 13,050 psi for a pressure gradient in excess of lithostatic, e.g. 1.12 psi/ft. Two water analyses from the interval 12,799-13,731' indicate the following salinities:

| <u>Cations</u><br>(ppm) | <u>Anions</u><br>(ppm) | <u>Total<br/>Dissolved Solids</u><br>(ppm) |
|-------------------------|------------------------|--|
| 12220.1                 | 17167.0                | 33840.3                                    |
| 24557.1                 | 27879.4                | 56927.2                                    |

Lost Hills Field, Kern County (Lorshbaugh, 1981)

A representative well completed in 1949 at the north end of the field penetrated the following formations:

| <u>Depth to Top of</u> | <u>Formation</u>         |
|------------------------|--------------------------|
| 820'                   | Etchegoin                |
| 2450                   | Reef Ridge Shale         |
| 3400                   | Main Cherts              |
| 5485                   | Temblor                  |
| 6047                   | Nonian-Nonionella Facies |
| 7512                   | Aqua Sand                |
| 9130                   | Kreyenhagen              |
| 9632                   | Belridge Sand            |
| 10386                  | Point of Rocks Sand      |

The mud weights used, depths, and indicated pressure gradients are as follows:

| <u>Depth</u><br>(ft) | <u>Mud Weight</u><br>(lb/cu.ft) | <u>Indicated</u><br><u>Pres. Grad.</u><br>(psi/ft) |
|----------------------|---------------------------------|--|
| 5000                 | 105                             | .729   |
| 6000                 | 106                             | .736   |
| 7700                 | 107                             | .743   |
| 8000                 | 106                             | .736   |
| 9000                 | 106                             | .736   |
| 9100                 | 108                             | .750   |

A formation test at the 5848-5888' interval had a shut-in pressure of 3700 psi for a pressure gradient of .633 psi/ft. (further demonstrating the tendency of operators to use over-balanced mud formulations in drilling activities in this region). The temperature ranged between 182-189°F at a depth of 4800' and 202-203°F at 5800' for an extremely high geothermal gradient of about 3.7°F/100'. The salinity of the formation waters at 5868-78' was 45,844 ppm total dissolved solids including a relatively high boron content of 62.1 ppm.

McKittrick Field, Kern County (Roger, 1917)

The waters in the sands immediately underlying the oil-bearing zones were reported to be under considerable pressure and at elevated temperatures.

Midway-Sunset Field, Kern County (Roger, 1917)

At depths of less than 100' below the oil zones, abundant supplies of heated water under very high pressure (presumably in excess of hydrostatic pressure) were reported. The temperature of several of these waters in the vicinity of oil sands in various fields along the west side of the San Joaquin Valley was 120-130°F at a depth of 3000-4000'.

Raisin City Oil Field, Fresno County (Cal. Div. Oil & Gas, 1954)

Specific data on pressures and depths are unavailable, but it has been reported that pressures are sufficiently high to necessitate the use of blowout prevention equipment.

Riverdale Oil Field, Fresno County, (Cal. Div. Oil & Gas, 1954)

The Zilch formation (middle Miocene), the continental equivalent of the marine Temblor, is considered to be slightly overpressured in which mud weights of 73 lbs/cu.ft. are considered appropriate.

Rosedale Oil Field, Kern County (Cal. Div. Oil & Gas, 1954)

The Stevens zone (upper Miocene) can likewise be considered to be slightly overpressured requiring the use of mud weights up to 75 lbs/cu.ft. The average temperature of the zone is 153°F.

Semitropic Field, Kern County (Lorshbaugh, 1981)

A well drilled in 1965 in Sec 24, T27S, R23E to a depth of 7700' was completed in the Randolph zone of the lower Etchegoin formation (lower Pliocene). The top of the zone was encountered at a depth of 7412'. The well was completed as an oil producer through four series of perforations between 7373-7600'. The shut-in pressure at 7450' was 7574 psi for a pressure gradient in excess of lithostatic, i.e. 1.017 psi/ft.; it was still building up at the time the well was completed. The geothermal gradient was high, i.e. 2.7°F/100'.

Tule Elk Oil Field, Kern County (Kohlbusch, 1977)

Located on the west side of the southern San Joaquin Valley, a 1966 well blew out in the San Joaquin formation at a depth of 3241' necessitating an increase in mud weight to 81 lbs/cu.ft. (equivalent to a pressure gradient of about .560 psi/ft.). The principal productive reservoir is the Stevens sand, at least 2000' of which has been penetrated. The formation is notably

overpressured and in some cases superpressured, in part believed to be due to gas entry from the overlying Reef Ridge shale; thus in some wells it is necessary to increase the mud weight from 85 lbs. to 122 lbs/cu.ft. (.847 psi/ft. gradient). The reservoir temperature at subsea datum of 8300' is 250°F.

Yowlumne Field, Kern County (Griffin, 1981)

Geopressured salt water zones have been encountered in the Reef Ridge formation overlying the Stevens sands.

3.4.4.2 Wildcat Wells

- 1) American Quasar Bravo #1-31 well in Sec. 31, T23S, R20E, in Kings County, 4-5 miles southeast of the abandoned Dudley Ridge Gas field (Van Matre, 1981)

This well, which was spudded in during 1977 and abandoned about two years later, was a deep test targeted for the Vaqueros formation at 18,300'. The deeper sediments penetrated in this well, which reached a total depth of 20,068' were as follows:

| <u>Depth to Top of</u> | <u>Formation</u>                   |
|------------------------|------------------------------------|
| 13,375                 | McClure (upper Miocene)            |
| 15,214                 | Temblor (middle and lower Miocene) |
| 17,890                 | Vaqueros (lower Miocene)           |
| 18,730                 | Tuney (Oligocene)                  |
| 18,820                 | Kreyenhagen (upper Eocene)         |

The representative mud weights at various depths were as follows:

| <u>Depth</u> | <u>Mud Weight</u><br>(ppg) | <u>Equiv.</u><br><u>Pres. Grad,</u><br>(psi/ft) |
|--------------|----------------------------|---|
| 6425         | 9.3                        | .467  |
| 13505        | 10.3                       | .517  |
| 15576        | 13.9                       | .697  |
| 17752        | 14.2                       | .713  |
| 18000        | 14.2                       | .713  |
| 18562        | 16.0                       | .803  |
| 18722        | 18.5                       | .929  |
| 18861        | 18.5                       | .929  |
| 19986        | 18.7                       | .939  |
| 20068 (TD)   | 18.8                       | .944  |

- 2) Great Basins Well #31X-10, Kern County located in the area of the North Buttonwillow field in Sec 10, T27S, R22E, (Franklin and Mandel, 1981). This was a dry hole drilled in 1972 to 21640' TD, the deepest well thus far drilled in California designed to test various formations. The total stratigraphic column penetrated was as follows:

| <u>Depth to</u><br><u>Top of Formation</u> | <u>Formation</u>              |
|--|-------------------------------|
| 2945                                       | San Joaquin clay              |
| 3275                                       | First Mya sand                |
| 6095                                       | Etchegoin shale               |
| 11970                                      | Reef Ridge shale              |
| 13300                                      | McClure shale (N marker)      |
| 14190                                      | McDonald shale                |
| 15420                                      | Round Mountain silt           |
| 16300                                      | Olcese sand                   |
| 17690                                      | Upper Santos shale            |
| 18203                                      | Vedder/Aqua sands             |
| 18668                                      | Lower Santos shale            |
| 18772                                      | Phacoides sand                |
| 19190                                      | Salt Creek shale              |
| 19650                                      | Tumey shale                   |
| 20050                                      | Kreyenhagen shale             |
| 20610                                      | Point of Rocks sand           |
| 20955                                      | Middle Eocene/Paleocene sands |

Based on obtained pressure data (e.g. 12,300 psi at 15,000' and recorded kick at 16086' with a pressure gradient of .905 psi), a sonic log pressure analysis indicated the following gradients in relation to the equivalent and actual mud weights (the latter indicative of the scope of overbalancing generally employed).

| <u>Depth</u> | <u>Computed<br/>Bottom-Hole<br/>Pressure<br/>(lbs)</u> | <u>Pressure<br/>Gradient<br/>(psi/ft)</u> | <u>Equivalent<br/>Mud Weights<br/>(lbs/cu.ft.)</u> | <u>Actual<br/>Mud Weights<br/>(lbs/cu.ft.)</u> |
|--------------|--|---|--|--|
| 6000         | 3000   | .500                                      | 70   | 81   |
| 6500         | 3400   | .524                                      | 75   | 80   |
| 7000         | 3600   | .520                                      | 73   | 81   |

| 14500        | 11300  | .778                                      | 112  | 124  |
| 15000        | 12300  | .820                                      | 118  | 125  |
| 15500        | 13400  | .865                                      | 125  | 124  |
| 16000        | 14200  | .890                                      | 127  | 125  |
| 16500        | 14900  | .905                                      | 130  | 137  |
| 17000        | 15400  | .905                                      | 130  | 136  |
| 17500        | 15900  | .910                                      | 131  | 136  |
| 18000        | 16400  | .910                                      | 131  | 136  |

In the depth range to 6000', the actual mud weights employed ranged from 74 to 78 lbs/cu.ft. while from 18000' to TD, they were approximately 132-134 lbs/cu.ft. The salinities throughout the section ranged from about 600 grains/gallon (10270ppm) to 200 g/g (4280ppm) in the first 15000' and declined to as low as 125g/g (2440 ppm) for the

balance of the column. The temperature readings which were recorded as shown below indicate an apparent declining temperature gradient with depth.

| <u>Depth</u> | <u>Temperature</u><br>(°F) | <u>Temp. Gradient</u><br>(°F/100') |
|--------------|----------------------------|------------------------------------|
| 5260         | 130                        | 2.47                               |
| 8215         | 140                        | 1.70                               |
| 10330        | 157                        | 1.52                               |
| 11930        | 160                        | 1.34                               |

### 3.5 SUMMARY

From the viewpoint of presumed methane content, the San Joaquin Valley is probably a more promising target area. Based on the relationship between methane solubility and temperature and pressure, and disregarding salinity which in this region is very low, the methane content in the Forbes formation in selected overpressured gas fields (such as the Grimes, West Grimes, Arbuckle, and Buckeye where the unit is at a depth of 7000-8000') is estimated to be about 20-25 SCF/barrel. The principal reason for these relatively low values is that geopressures in this formation occur at relatively shallow depths and thus, the absolute pressures are relatively low. Similarly, the geothermal gradient rarely exceeds 2.0°F/100' and the absolute temperatures at these depths are likewise relatively low.

By contrast, various fields on the west side of the San Joaquin Valley (such as Lost Hills, Kettleman Dome, Cal Canal, Belridge, Semitropic, and Jerry Slough) display comparable salinities and geopressured gradients, but much higher geothermal gradients, often over 2.5°F/100' and up to 3.7°F/100'. Under these conditions and the somewhat greater depths of occurrence of the overpressured Miocene formations, it is estimated that the methane content in this area will be between 30 to 40 SCF/barrel.

#### 4. DEEP WELLS IN GREAT VALLEY

The Munger Oilgram which is published several times a week provides detailed information on current California drilling activities. For the two-month period ending January 31, 1981, issues of this publication were examined and a listing made of all completed, planned, abandoned, proposed, and ongoing wells in the Sacramento and San Joaquin Valley. Listed in Table 11 are all of the above wells, 8000' or more in depth, by county, field, operator, well designation, depth, and status. The 8000' depth was selected since it indicated those wells which are most apt to penetrate moderately to highly geopressured zones though it is recognized that, as in the case of the Forbes formation in the Sacramento Valley, overpressures may be encountered at much shallower depths.

## 5. CONCLUSIONS AND RECOMMENDATIONS

From the vantage point of pressure, temperature, and salinity, the Forbes formation in the Sacramento Valley and the Stevens and Temblor formations in the San Joaquin Valley, all appear to be likely candidates for further study in terms of their potential for development of dissolved methane. In certain respects, these sediments, especially the geopressured Miocene formations in the San Joaquin Valley, compare as favorably or even more favorably than the reservoirs currently being studied and tested on the Gulf Coast, for the following reasons:

- o The salinities of all three formations are much lower than those in the Gulf Coast, usually less than 20,000 ppm and often less than 10,000 ppm, whereas the Gulf Coast is characterized by salinities that range from 20,000 to over 200,000 ppm (Kharaka and Berry, 1980).
- o The temperature gradients in the normally pressured zones of the Great Valley range from 1.0-1.5°F/100' up to 2.5°F/100', and up to twice as much in the geopressured zones, most notably on the west side of the San Joaquin Valley (Kharaka and Berry, 1980).
- o In the formations cited, the Forbes is invariably overpressured, in cases exceeding lithostatic, especially in those fields on the west side of the Sacramento Valley. The other two formations where overpressured, particularly on the west side of the San Joaquin Valley, have comparably high pressure gradients to be of considerable interest in view of the greater depth of occurrence of geopressuring.
- o In terms of depth, geopressured zones are noted in the Forbes, at depths as shallow as 2100' and extremely high pressure gradients are noted at depths in the 6000-8000' range. Geopressured zones in the San Joaquin Valley are also found at the latter depth and slightly deeper. By contrast, geopressured

zones can generally be anticipated in the Gulf Coast only at depths in excess of 10,000'.

The overriding issues of geopressured methane development that need to be resolved are that of methane content and reservoir producibility and longevity. These questions are currently being addressed by the several design wells being drilled and tested in Texas and Louisiana under DOE sponsorship and funding. In terms of methane content, it appears that in California, the San Joaquin Valley holds more promise than the Sacramento Valley, 1.5-2 times as much, but in neither case were any analyses available. It has been suggested that growth faulting has sharply limited the potential reservoir boundaries of the Tertiary sediments of the Gulf Coast and that similarly, the depositional nature of the California formations cited, i.e. turbidites deposited under deep-sea fan conditions, accompanied at times by similar contemporaneous faults, suggests that such (geopressured methane) reservoirs are likewise bound to be of limited extent. However, this cannot be determined at this time without much more detailed work involving the investigation of hundreds, if not thousands of logs, available cores, and drilling records to determine the lateral extent of these potential reservoirs and other salient characteristics.

In view of the favorable parameters attendant upon these California geopressured occurrences, particularly the western San Joaquin Valley, it is recommended that a study of the magnitude described be undertaken, similar to the work performed for the Gulf Coast to identify and pinpoint favorable "fairways" and site locations. Certainly, as a first step, there are many deep wells currently being drilled in the Great Valley (as shown in Table 11) and it would be useful if further specific data relevant to known geopressured fields and areas could be obtained.

In addition to the development of these geopressured waters for the recovery of methane (and secondarily for direct heating utilization or

possibly for exectricity generation) there are two other potential applications that merit further study:

- a) Given the low salinity of the California geopressured formation waters, in many cases approaching potability, and the inordinately high cost of irrigation water, consideration should be given to the feasibility of producing these waters, extracting the methane, and desalinating (and removing such objectionable elements as boron), the energy source for such operations might well be furnished by the recovered methane.
- b) These geopressured waters in California (as well as those of the Gulf Coast and elsewhere) might well have application as a source of heated waters in waterflooding operations in abandoned, depleted, or near-depleted fields and reservoirs with low to mid-gravity crude oil.

In the Appalachian basin, the only formation that holds any promise insofar as geopressured methane is concerned would be the upper Cambrian sediments in the Rome trough of western West Virginia, eastern Kentucky, and western Pennsylvania. The Oriskany formations can be essentially disregarded for this purpose in view of the slight to moderate overpressuring displayed, prevailing low geothermal gradient, and the general very high salinities. The upper Cambrian zones, on the other hand, are characterized by very high pressure gradients, close to lithostatic in cases, and relatively low salinities. The one negative factor, is the relatively low geothermal gradient. At this time, only a handful of wells have been drilled into this zone and the control is accordingly limited for assessing its areal extent. Therefore, as an initial step, it is recommended that more detailed studies be made of the data from the few Rome trough wells that have been drilled and to closely monitor the planned well that Columbia Gas will drill later this year.
