Executive Summary

The objective of this study is to present baseline employment and population forecasts for Benton, Franklin, and Yakima Counties. These forecasts will be used in the socioeconomic analysis portion of the New Production Reactor Environmental Impact Statement. Aggregate population figures for the three counties in the study area were developed for high- and low-growth scenarios for the study period 1990 through 2040. Age-sex distributions for the three counties during the study period are also presented.

The high and low scenarios were developed using high and low employment projections for the Hanford site. Hanford site employment figures were used as input for the HARC-REMI Economic and Demographic (HED) model to produce baseline employment forecasts for the three counties. These results, in turn, provided input to an integrated three-county demographic model.

This model, a fairly standard cohort-component model, formalizes the relationship between employment and migration by using migration to equilibrate differences in labor supply and demand.

In the resulting population estimates, age-sex distributions for 1981 show the relatively large work force age groups in Benton County while Yakima County reflects higher proportions of the population in the retirement ages. The 2040 forecasts for all three counties reflect the age effects of relatively constant and low fertility and increased longevity, as well as the cumulative effects of the migration assumptions in the model. By 2040 the baby boom population will be 75 years and older, contributing to the higher proportion of population in the upper end age group. The low scenario age composition effects are similar.

Acknowledgments

Several persons provided significant assistance in the preparation of this baseline report. Carlyn Orians and Lynn Miranda of Battelle HARC prepared the study area map. Paul Klarin provided research assistance to the project and helped prepare several data tables. Sarah Marsh and Mike Scott of Battelle PNL and Ed Liebow of Battelle HARC provided review comments, and Susan Stream and Terri Koval provided editorial and secretarial support.

1.0 INTRODUCTION

This report presents baseline employment and population forecasts for Benton, Franklin and Yakima Counties in Eastern Washington State. These counties account for most of the resident population lying within a fifty mile radius of a proposed New Production Reactor (NPR) facility on the Hanford Site. Figure 1 depicts the study area, the proposed NPR site and the areas in which the current population is predominantly settled. This baseline report presents current and projected future economic and demographic conditions in the vicinity of this proposed NPR site. It provides alternative baseline scenarios for the study area in the absence of the NPR facility.

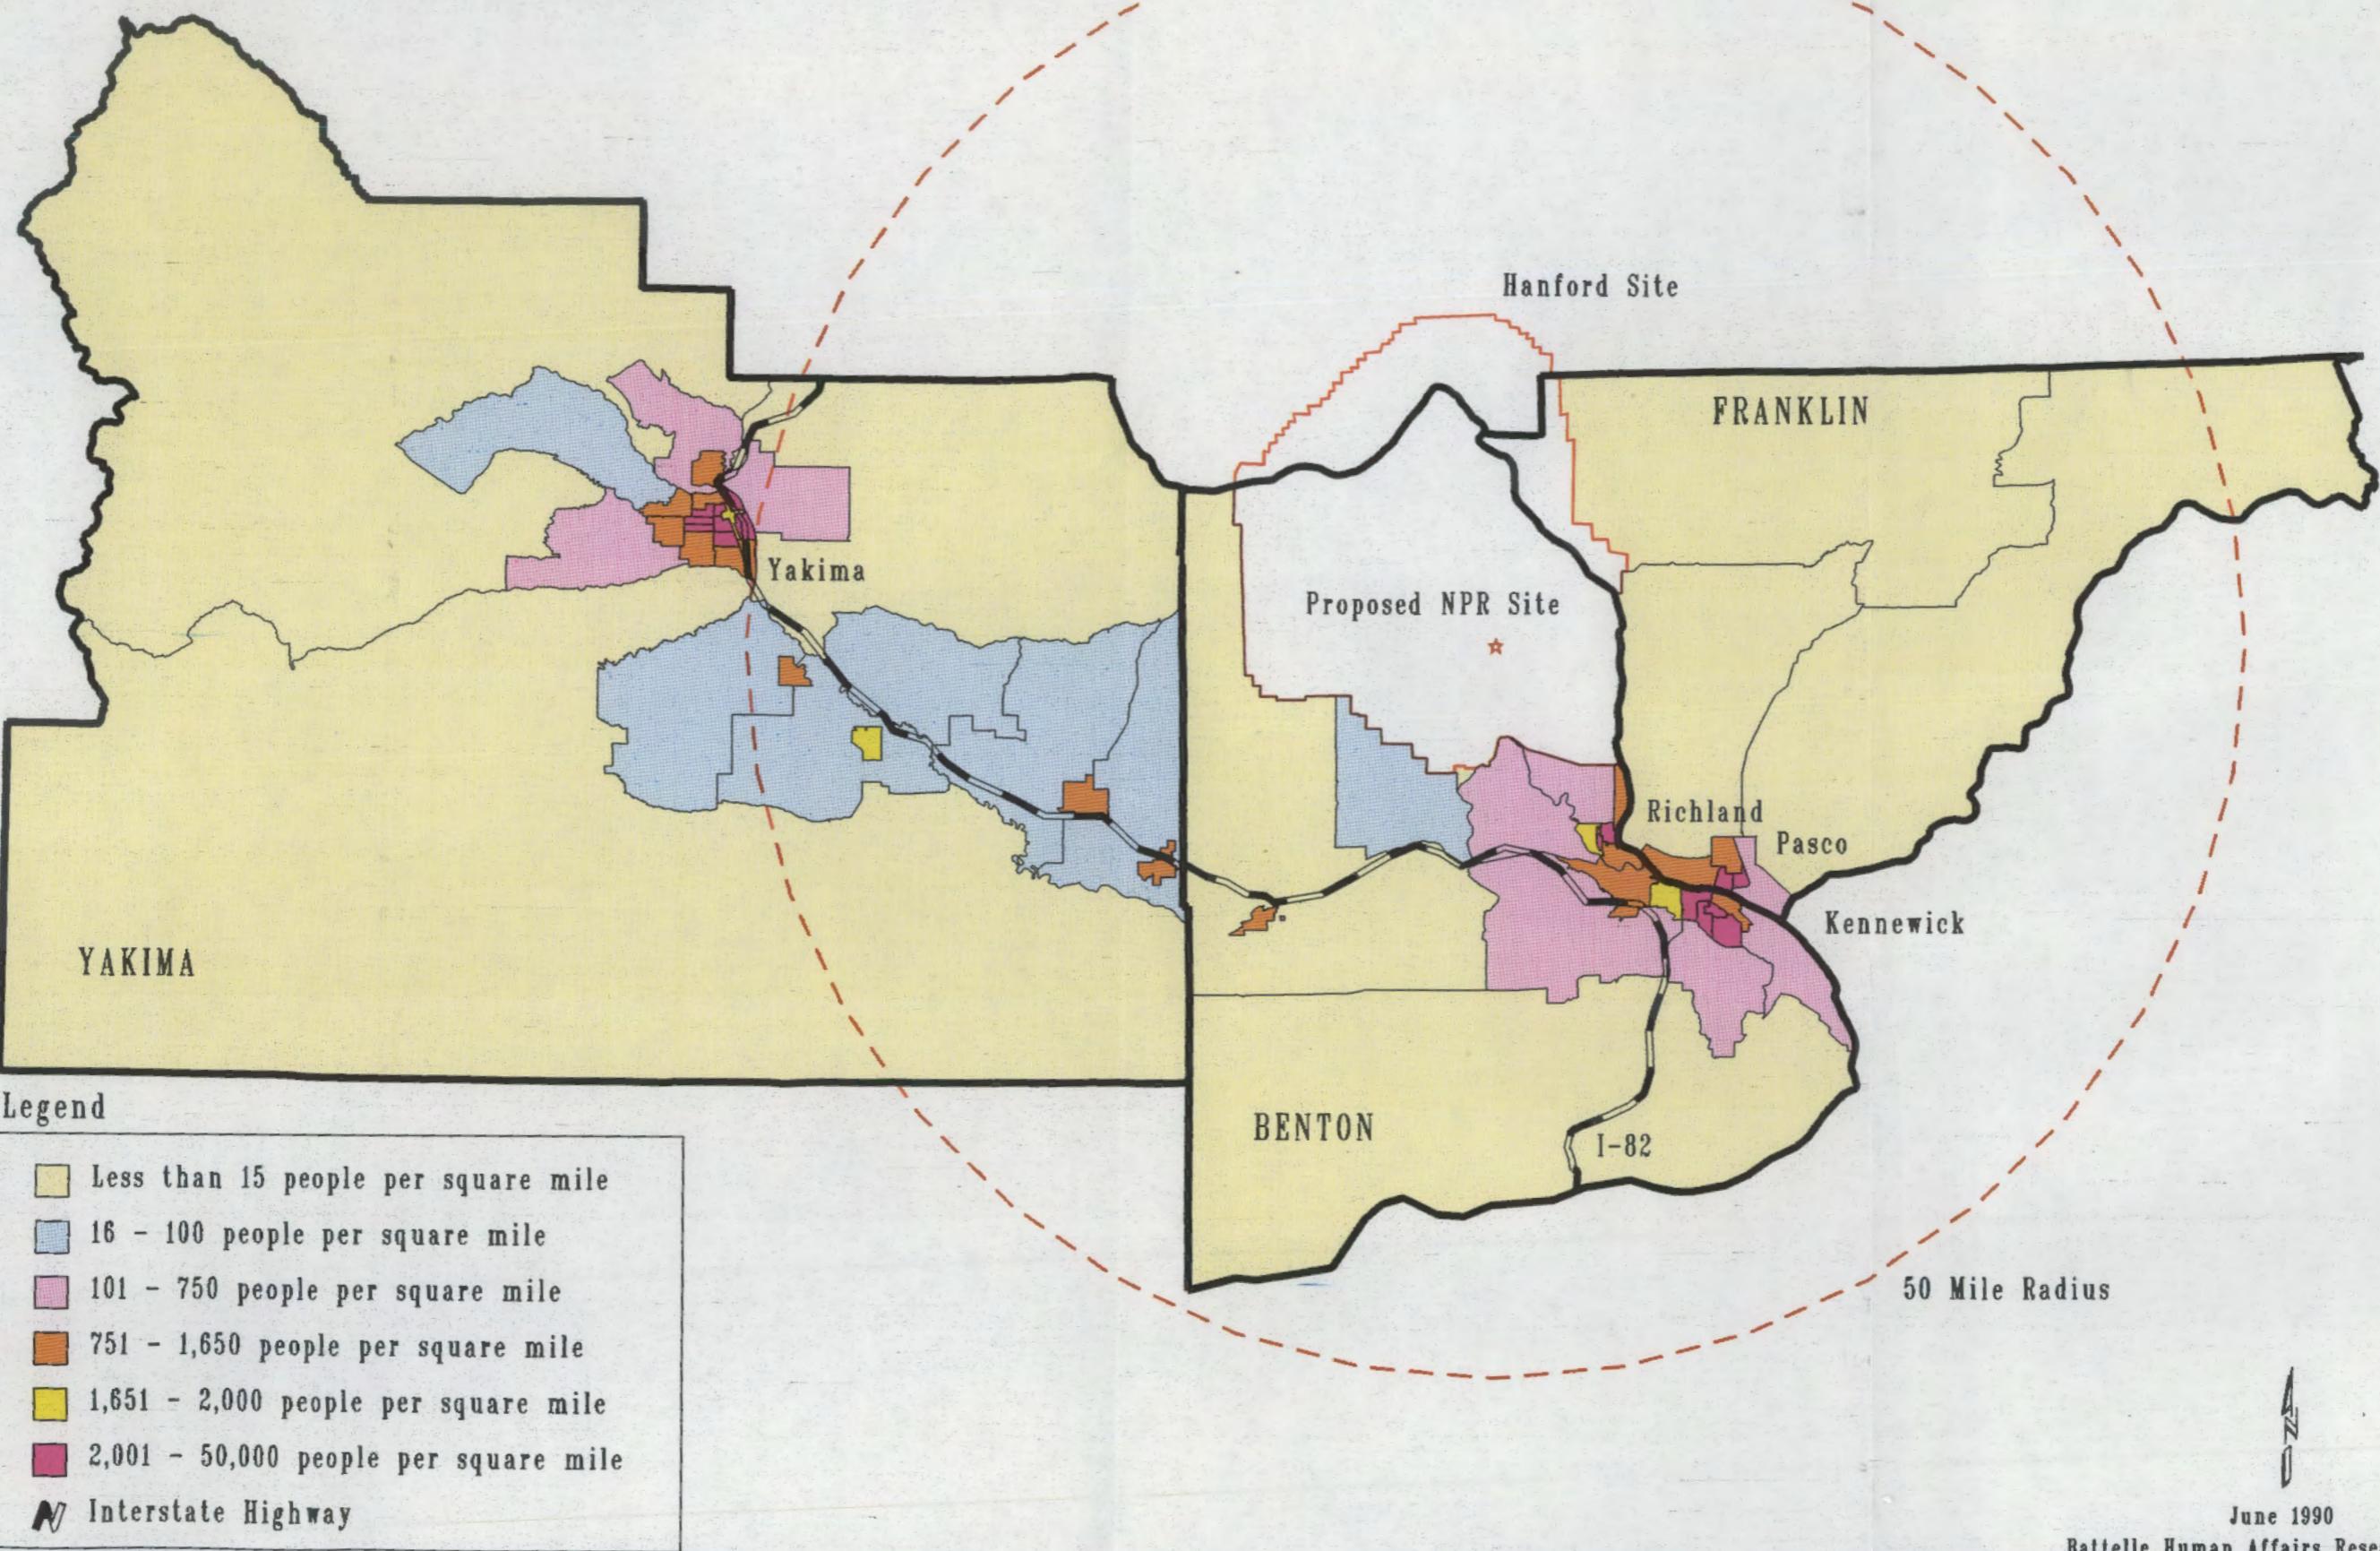

For the purposes of this baseline study, aggregate population figures are developed for the three counties in the study area. However, as the map shown in Figure 1 indicates, population is not at all uniformly distributed within this three county study area.¹ In addition portions of several other counties that fall within a fifty-mile radius of the proposed NPR site are not included in the study area. Topography, land use, and highway networks in this region dramatically have influenced population settlement patterns. Although the population density reflected in Figure 1 is based on the 1980 U.S. Census, this general distributional pattern is expected to persist for many years to come. Analysis of sub-county distributional patterns will be important for a complete understanding of the dose effects of potential releases from the proposed NPR site. Population characteristics also vary at the sub-county level. For example, portions of two Indian reservations fall within the 50-mile radius.

Two economic-demographic modeling systems were utilized to develop the employment forecasts and subsequently the demographic forecasts. This report discusses the models, methods and data that were used in this baseline study. Particular attention is paid to the key assumptions that were used in generating the forecasts. The first section of the report focuses on the economic and employment analysis, including labor force participation and commuting patterns in this region, and the second section focuses on the demographic analysis, including the population components of fertility, mortality and migration. The results are presented in tabular and graphic form, and the detailed demographic results of the baseline forecasts are included in an appendix.

The baseline population forecasts were generated using an integrated economic-demographic model. The concept underlying the model is that population changes are closely linked with economic trends. If employment in an area grows faster than its labor force, people will migrate to that area to fill the excess jobs. The HARC-REMI Economic and Demographic (HED) model was used in the generation of baseline employment forecasts, which in turn were inputs to an integrated three-county demographic model.

¹Figure 1 was created on Battelle HARC's ArcInfo Geographic Information System (GIS), utilizing the U.S. Bureau of the Census's TIGER file system and 1980 population data based on Census tracts.

Traditional demographic practice typically does not formalize the relation between migration, which strongly influences an area's population, and employment. While it is widely recognized that migration is driven largely by employment opportunity, many demographic models require that the user stipulate migration but do not formally quantify the relationship between migration and employment. Using a model designed for this study, employment forecasts are compared to the labor supply in the study area, and migration is used to equilibrate differences in labor supply and demand.

There are several uncertainties in forecasting over such a long time horizon, including future employment, vital rates (births and deaths), labor force participation rates (used to estimate labor force from age and sex structures), the age and sex structure of migrating populations, and commuting patterns. How each of these elements is addressed in this study is discussed below.

2.0 EMPLOYMENT FORECASTS

2.1 Baseline Forecasts

Two baseline (without the NPR) employment forecasts were generated for the study area. The reason for two forecasts is that there is a high level of uncertainty over future employment levels at Hanford.

The high and low forecasts were produced based on employment projections for Hanford provided by the Westinghouse Hanford Company (WHC)². However, since these forecasts only covered the period 1989-1995 (while the HED model forecasts to 2035), and did not include specific details by mission or by Standard Industrial Classification (SIC), the standard classification system used in employment research and in the HED model, a number of assumptions had to be developed to produce high and low forecasts. The procedures used to develop these forecasts are described below.

Employment forecasts were generated for Benton, Franklin, and Yakima counties using the HED model. The model produces detailed economic forecasts for the State of Washington, and for the combined Benton-Franklin County area, through the year 2035. The procedure for generating Yakima forecasts is discussed later. However, before the projections could be made, it was necessary to alter the HED model baseline forecasts to reflect the fact that the projected Hanford employment levels would represent a departure from historical trends. This adjustment was necessary because the forecasts of models with econometric components like HED assume that historical trends, in general, will continue into the future. In the case of Hanford employment, DOE forecasts do not call for a continuation of past trends, as is shown in Figure 2. Most Hanford employment has historically been classified as Miscellaneous Business Services or Chemicals Manufacturing, and until 1977, Hanford employment closely followed the combined employment in these two sectors.

²Memo from Larry Hafer to Sarah Marsh, Battelle PNL, November 10, 1989.

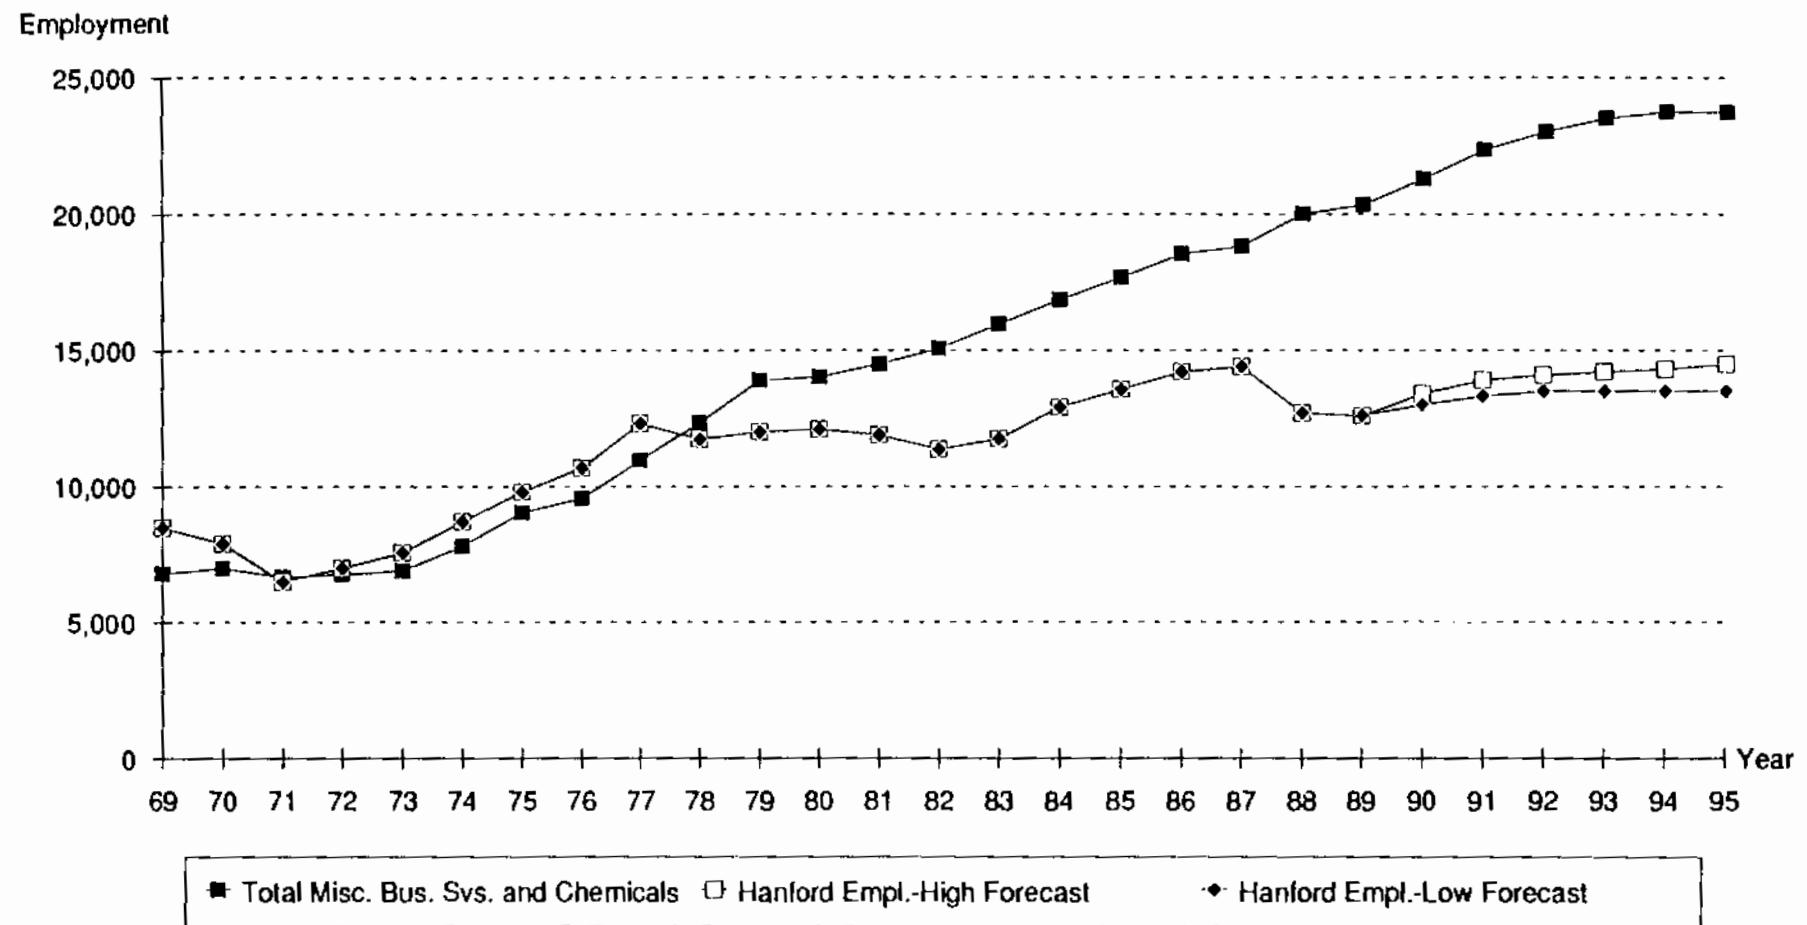

Figure 2. Sector Employment Comparison With Hanford Site Employment Scenarios: 1969-1995

After 1977, the Tri-Cities economy, particularly Business Services, experienced significant non-Hanford employment growth, but Hanford employment grew as well. After 1987 (the projection period for the HED model), however, Hanford employment fell, while the "default" HED projections, which assume continuation of past trends, show a continued increase in the Chemicals and Business Services sectors combined, and thus, in effect, assume a continuation of employment growth at Hanford. Since such growth is not expected, it was necessary to develop a way to adjust the HED forecasts to reflect the expected changes in Hanford employment.

First, however, it was necessary to use the 1989-1995 forecasts of Hanford employment provided by WHC to develop high and low scenarios out to the year 2035. In the case of the high forecast, it was assumed that the projected 1995 level of 14,500 represented not only near the historical maximum, but a reasonable high-side assumption. Although there are currently no Congressional initiatives that offer solid evidence that such a high level of employment is likely to persist, historically new missions have been instituted to replace older ones. It was assumed that about half the employment can be characterized as Miscellaneous Business Services, and half as Chemicals Manufacturing.

The low scenario was somewhat more difficult to construct, since it required assumptions regarding each of the missions currently in effect at the site. The general assumptions were a one percent annual increase in PNL's non-waste research efforts; a phase-out of nuclear energy and nuclear materials missions by the year 2000; and a rise in waste management employment to about 5,600, then a decline to zero over the years 2010 to 2020. The forecasts produced by these assumptions are tabulated in Table 1.

The next step was to estimate the level of Hanford employment implied by the default HED forecasts, so that this level could be adjusted according to the high and low Hanford employment forecasts. Since the HED model operates at the two-digit Standard Industrial Classification (SIC) level of detail, the implied level of Hanford employment had to be estimated at this level of disaggregation. This procedure assumed that the 1989 Hanford employment was evenly split between Chemicals and Miscellaneous Business Services, and that total Hanford employment would grow at the same rate as the rate projected for them by the HED model, adjusted by projecting the regressed share of total Hanford employment to Chemicals plus Miscellaneous Business Services employment over the 1980s (Hanford employment represented a declining proportion of total Chemicals and Miscellaneous Business Services over this period). Hanford Chemicals employment was assumed to follow the default HED projection for Chemicals Manufacturing, and Miscellaneous Business Services were estimated as the residual between total employment and Chemicals employment. The resulting implied Hanford projections are shown in Table 2.

Having estimated the implied level of Hanford employment, and established the high and low Hanford employment assumptions, the HED forecasts could readily be adjusted to produce consistency between the model forecasts and the high and low scenarios.

Since this study required individual county forecasts, additional analyses were undertaken to allocate HED's state and Benton-Franklin County employment forecasts to each of the three study area counties and extrapolate them to the year 2040. Historical employment data from the U.S. Bureau of Economic Analysis (BEA) are available for the years 1969-1987. These data include employment by major industry at the county level. The method used to develop forecasts for Benton and Franklin counties differed slightly from that used for Yakima County, but in both cases the historical BEA data and the HED model forecasts comprised the basic information used.

For Benton and Franklin counties, historical shares of employment by industry represented by Benton County were calculated as a proportion of total two-county employment. In most cases, a trend in Benton County's share was evident during the 1969-1987 period. Regression analysis was used to quantify trends in Benton County's share of the total employment. The regression time frame used was adjusted for some industries if unusual periods appeared in the historical data. For some industries, extrapolation of the trend over the entire 50-year forecast period resulted in projected shares over 100 percent, or shares which for other reasons appeared unreasonable; in these cases, the typical treatment was to hold the county's projected share at the level forecasted for the year 2000, or at some judgmentally arrived at maximum or minimum level, for the remainder of the forecast period. These projected shares of total two-county employment were then applied to the HED model projections for the combined Benton-Franklin County area to derive separate employment forecasts for the two counties.

For example, Benton County comprised 86.72 percent of total two-county employment in manufacturing in 1987; regression analysis indicated that Benton County's share was increasing on average by 0.85 percent over the 1969-1987 period. Thus, the county's 1988 share was projected to be 87.57 percent ($86.72\% + 0.85\%$). With a HED model forecast of two-county manufacturing employment of 11,308 in 1988 under the high employment scenario, Benton County was predicted to have manufacturing employment of 9,902 ($87.57\% \times 11,308$).³ However, extrapolating this regressed trend into the future quickly resulted in Benton County forecasts at over 100 percent of the two-county total. Therefore, the county's proportion was held constant at its 1991 level (90.12 percent) for the remainder of the projection period. The projected 2025-2035 trend in employment was then extrapolated linearly to the year 2040. All industry forecasts were summed to derive total employment projections for each year.

The procedure used for Yakima County was similar, but slightly different from that used for Benton and Franklin counties. The historical relationship between Yakima County employment and statewide employment was analyzed to derive year-to-year ratios of Yakima to statewide employment, for each industry, using BEA data. Regression analysis was used to derive the historical trend in those shares, and the trend was extrapolated to the year 2040. Yakima County employment forecasts were developed by applying those shares to the projected employment for Washington produced by the HED model. Both high and low scenario employment projections were developed for Yakima County because as Benton County employment changed under the high and low scenarios, so would employment in the rest of the state.

The resulting employment forecasts are shown in Table 3 and Figure 3.

2.2 Commuting Patterns

Commuting patterns are important in the projection model because it requires that employment projections be compared with labor force projections to produce "drivers" for migration. The employment forecasts discussed above are, like the data on which they are based, place-of-work estimates, but the labor force projections are on a place-of-residence basis. In order to compare the two, and thereby determine how much migration will be needed to create labor market equilibrium in each county, employment projections must be adjusted to a place-of-residence basis. This requires estimates of how many jobs in each county are held by residents of other counties.

³Washington State Employment Security Department (ESD) employment estimates for the combined Benton-Franklin County area show a 1987-1988 decline in total employment, caused primarily by a decline in Chemicals Manufacturing (ESD 1988 estimates are provisional). Thus, the procedure used for this report likely produced a 1988 "forecast" that is slightly on the high side. Further research should incorporate a method for using ESD estimates.

TABLE 3. COUNTY BASELINE EMPLOYMENT

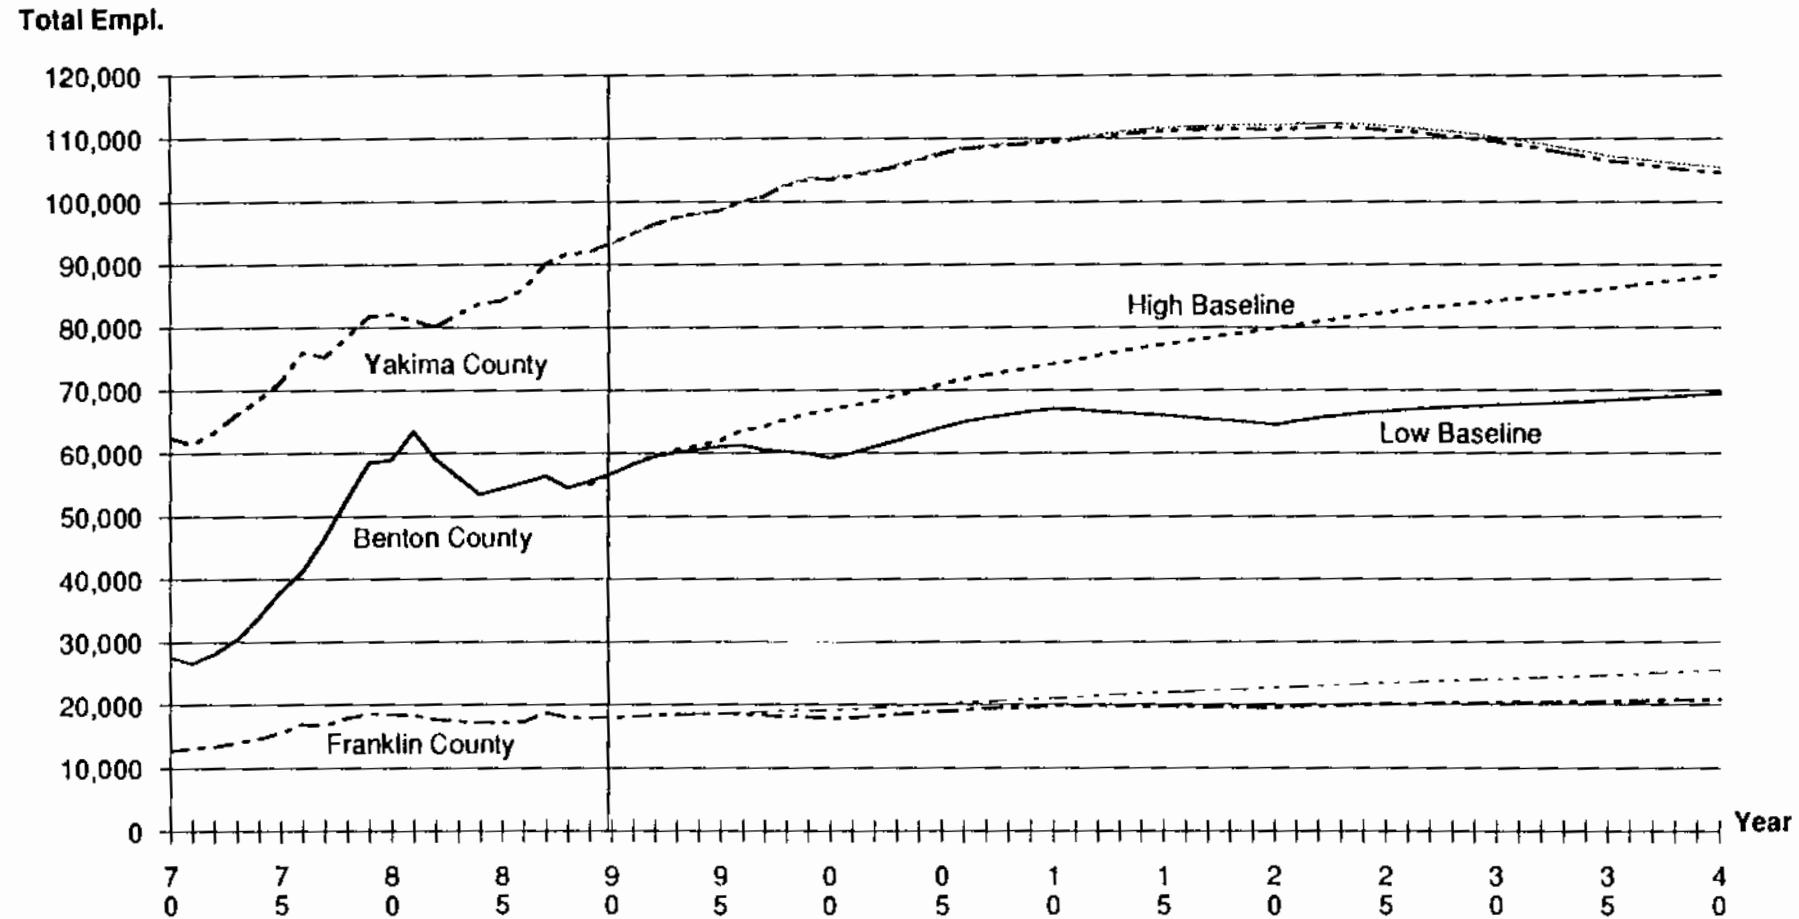

Figure 3. Historical and Projected Total Employment for Yakima, Benton and Franklin Counties (High and Low Scenarios): 1969-2040

Little is known about commuting patterns in the study area. The 1980 U.S. Census contains information on this subject, but changes in area employment and transportation improvements since that time have rendered those data obsolete. The 1980 Census data are shown in Table 4.

Table 4. 1980 Commuting Patterns*

Work at:	Reside in:			
	<u>Benton</u>	<u>Franklin</u>	<u>Yakima</u>	<u>Other</u>
<u>Benton</u>	83.11%	7.19%	6.02%	3.68%
<u>Franklin</u>	31.96	58.68	0.76	8.60
<u>Yakima</u>	0.96	0.00	97.00	2.04

*Source: U.S. Bureau of the Census

Two data sources can provide a basis for educated guesses about net commuting flows between the three study area counties: Survey data for the Hanford work force, and BEA income data, which include "residence adjustments" used to convert place-of-work earnings data to a place-of-residence basis.

Survey data indicate that as of November 1, 1986, approximately 7.5 percent of the \$505.5 million in wages and salaries paid to Hanford employees went to jobholders in Franklin County, 84.6 percent to people living in Benton County, 6.1 percent to people residing in Yakima County, and 1.8 percent to people who lived elsewhere (Scott, et. al., 1987). On the basis of number of jobs, rather than income, of the 14,652 jobs at the Hanford Site, 84.7 percent were held by Benton County residents, 7.5 percent by Franklin County residents, 6.3 percent in Yakima County, and 1.7 percent by people living elsewhere. Although non-Hanford workers in Benton County may not have the same residence patterns as Hanford workers, Hanford employment represented about 26 percent of total Benton County employment in 1986, and on an income basis, 39 percent of total earnings in Benton County.

The BEA income data (U.S. Department of Commerce, 1989) also contain some information useful to the conversion of place-of-work employment to place-of-residence employment. Figure 4 shows the time trend for Benton, Franklin, and Yakima counties in terms of percentage of the residence adjustments out of total place-of-work earnings. If the residence adjustment for a county is negative, it means that more income was earned in that county by residents of other counties than the income earned in other counties by residents of that county. Typically, the residence adjustment is a function of commuting patterns, and a negative adjustment means that on average more people commute into that county than out of it.

Benton County had a generally positive residence adjustment in the early 1970s, but it turned negative once significant construction activity began to occur at the WPPSS nuclear plants. The negative adjustments indicate that

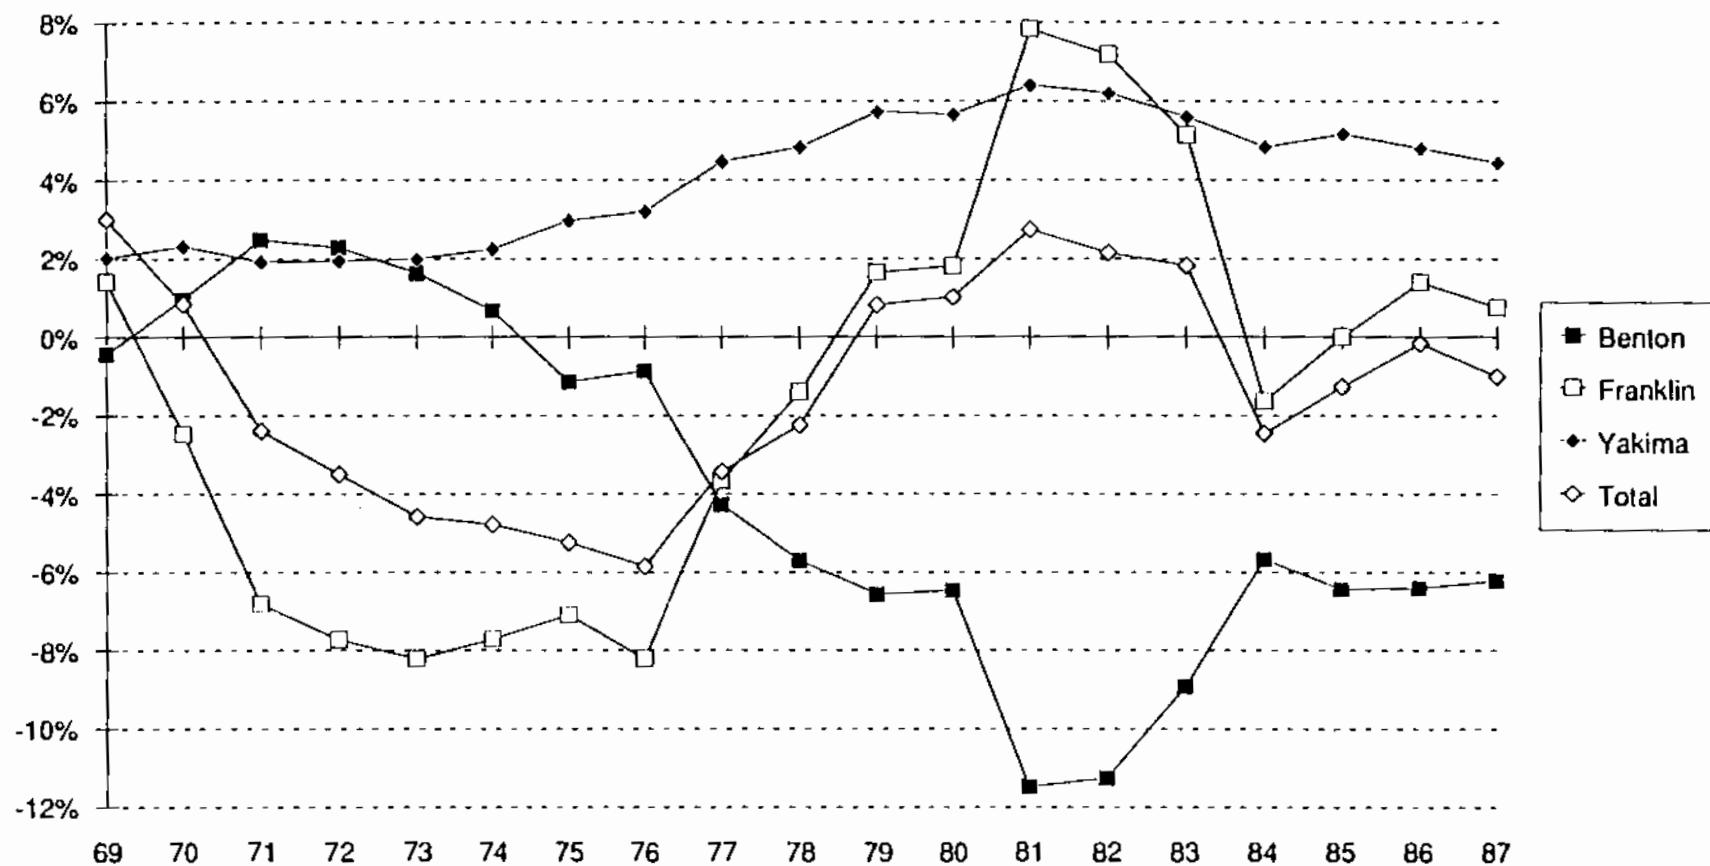

Figure 4. Residence Adjustments as a Percentage of Total Place-of-Work Earnings: Benton, Franklin, and Yakima Counties: 1969-1987

many workers either migrated temporarily to Hanford or commuted long distances to work there. After the rampdown of WPPSS construction in the early 1980s, including the termination of WNP-4 and the mothballing of WNP-1 in early 1982, the residence adjustment turned positive, and, as the county economy has recovered, the adjustment has stabilized at about minus 6 percent.

Franklin County's residence adjustment almost mirrors that of Benton County, with negative values in the 1970s, then positive values during most of the 1980s. In recent years the adjustment has been generally close to zero, but positive, indicating that in the net, the county's place-of-work employment approximately matches its place-of-residence employed population (i.e., commuting into Franklin County is about equal to commuting out of the county).

Yakima County's adjustment has been far less volatile than Benton's or Franklin's, ranging from plus 2 percent to plus 6 percent over the period from 1969 to 1987. This indicates that on balance, more people commute to other counties to work than the number of workers from other counties who commute into Yakima County for their jobs. In recent years the net adjustment has remained at about plus 5 percent.

Although the above information is not conclusive, since it indicates only net flows of income between counties rather than jobs, and those net flows probably involve counties other than the three study area counties, it is notable that the percentage of residence adjustments for the three counties typically add up to close to zero. Adjacent counties are all quite small, and therefore it seems reasonable to assume that the study area forms a fairly self-contained labor market area, and net out-flows from Benton County are equal to the sum of net in-flows to Franklin and Yakima counties. The "commuting matrix," if it is based on the most recent (1987) BEA data and information from the Hanford survey, would be as follows in Table 5.

Table 5. Percentage of Jobs Held by Residents

Work at:	Reside in:		
	Benton	Franklin	Yakima
Benton	85%	8%	6%
Franklin	6%	93%	0%
Yakima	1%	0%	98%

The reader may notice that the BEA and Hanford survey information, if interpreted as discussed above, only describes the first row of the matrix. However, other elements of the matrix can be filled in with some ease. First, it is doubtful that any noticeable commuting between Franklin and Yakima counties takes place due to the great distance involved (hence the zero entries in the matrix). Second, the constantly positive residence adjustment for Yakima

County, and negative one for Benton County, implies that very few Yakima County jobs are held by Benton County residents (one percent is the assumption used above). It has also been assumed that since the study area appears largely self-contained in terms of commuting flows, that only one percent of the jobs in any county are held by people living outside the study area (therefore, the rows all sum to 99 percent).

As a check on the reasonableness of these commuting estimates, an algorithm was developed to estimate year-by-year changes in the 1980 Census-based matrix cells for Benton and Franklin counties, based on the BEA data (the Yakima County commuting matrix was held constant, since the BEA data show that no appreciable changes occurred). The forecasts for 1987 are shown in Table 6. It appears evident that the estimates shown in Table 5 may be in error for Franklin County, but appear reasonable for Benton County.

Table 6. 1987 Commuting Matrix

Work at:	Reside in:			
	Benton	Franklin	Yakima	Other
<u>Benton</u>	83.14%	7.16%	6.02%	3.68%
<u>Franklin</u>	31.97%	57.80%	0.76%	9.47%
<u>Yakima</u>	0.96%	0.00%	97.00%	2.04%

The commuting matrix shown above and earlier from the U.S. Census, as well as the extrapolated matrices for the intervening years, were used to distribute jobholders among counties under each baseline scenario.

3.0 POPULATION FORECASTS

3.1 Linkage of Economic to Demographic Forecasts

Output from the HED economic model provides jobs by place of work. The demographic model is based on Census Bureau concepts, the relevant one being that population data are tabulated by place of residence. Thus, as discussed in Section 2.2, some workers enumerated in Franklin County have jobs in Benton County and vice-versa. The 1980 data on commuting (place of work, place of residence), unlike nearly all other published census data, are not adjusted for non-response. In the study area the non-response rate was around 10 percent. Numbers of non-respondents are tabulated by place of residence. Therefore, it was not possible to get a complete census count of people working in each of the three counties for comparison with 1980 BEA job counts. We could only use the place-of-residence shares for respondents to allocate the BEA data. Having done this allocation, it was found that the presumed jobholders by place of residence did not agree with the census count of employed persons. Multiple jobholding, which averages about 5 percent of the

labor force nationally, is one factor that can account for this difference. Another could be that the census is taken as of April 1, while BEA numbers are annual averages. Therefore, correction factors were calculated and held constant for the period 1981-2040. These are:

Benton	.925
Franklin	.958
Yakima	.840

The remainder of the linkage from jobs to labor force is the unemployment rate. April Employment Security data (except for 1989, revised numbers--but not seasonally adjusted--from the publication of Washington Labor Market) were used as the basis for 1981-1989 calibration. Benton County rates were unchanged, but Franklin and Yakima numbers were altered in a few cases so that resulting population estimates generally agreed with Office of Financial Management estimates. These unemployment rates are shown in Table 7. Jobs derived from the HED model were inflated using unemployment rates to produce the target labor force participation rates, as discussed below.

Table 7. Unemployment Rates by County and Year

Year	Benton	Franklin	Yakima
1980*	.056	.074	.092
1981	.067	.080	.118
1982	.111	.120	.150

1989	.071	.110	.120
1990	.060	.080	.095

*Census data

3.2 Labor Force Participation Rates

Labor force participation rates (Table 8) were based on five age group tabulations in the Washington State 1980 census report, with five-year age group detail filled in using Spokane MSA as a proxy. These were trended to year 1995 using post-1980 national Current Population Survey data; male rates tended to drop slightly, and female rates tended to increase. Following 1995, rates were held stationary.

Table 8. Model USA Labor Force Participation Rates

Ages	Males			Females		
	1980	1990	1995	1980	1990	1995
16-19	.524	.510	.500	.458	.465	.480
20-24	.827	.820	.815	.678	.728	.750
25-29	.918	.910	.905	.663	.730	.780
30-34	.940	.940	.940	.632	.750	.800
35-39	.945	.945	.945	.644	.750	.800
40-44	.937	.940	.940	.650	.750	.800
45-49	.920	.920	.920	.615	.750	.800

75+	.091	.085	.075	.032	.028	.026

3.3 Migration Rates

Because no single year data for migration into and out of counties are available that reflect actual, current migration behavior, a complex process was undertaken to approximate these actual migration patterns by age and sex for the three counties. The general process involved starting with high and low model migration rate patterns for single years of age that could reasonably be expected to bracket the actual patterns for in and out migration flows for males and for females. Sets of model patterns also were developed for the retirement age population. Migration rates for the population under age 18 were those used for females one generation older, where a generation equals 26 years. These model patterns were calibrated using 1970-1980 estimated net migration by five-year age group as target values. Net migration was calculated as a residual based on Census survival rates to give a "best estimate" of the pattern of net migration. The in and out migration flow patterns were adjusted based on an examination of historical State Economic Area data for 1950, 1960 and 1970 and on the 1975-1980 county migration data contained on special tape files. The Current Population Survey one year (1980-1981) and five year (1980-1985) rates were examined to establish reasonable scalar relationships. The scalars adjust the overall volume of in and out migration flows, and separate patterns for the directional flows were developed. A judgmental process was used to iterate toward an appropriate migration pattern that involved weighted average rates between the high and low model patterns and interpolation or smoothing across the full single year age distribution, given target rates at three

selected ages in the distribution. The model was run using trial parameter values and comparing net migration results to historical target patterns. Trial parameters were adjusted to achieve a reasonably close match. At this point, the shapes of the rate patterns remained fixed, but the scalars that control the overall levels of migration flows were allowed to vary until population numbers were attained that, when multiplied by labor force participation rates, yielded labor force numbers that closely agreed with target county total labor force values described above (within about one-half of one percent).

3.4 Fertility Rates

1980 age-specific fertility rates were calculated from vital statistics data and population size data by age and sex from the Census for counties, and these rates were used without change throughout the study period, with one exception. Comparison of model births and reported births (Health Department) from 1981 through 1987 indicated that the Yakima County Total Fertility Rate⁴ (used as a scalar in the model) be raised from 2.395 in 1980 to 2.5 in 1990.

3.5 Mortality Rates

The derivation of appropriate mortality rates presents a different problem. The counties in the study area are small enough that reliable life tables might be difficult to construct. Therefore 1979-1981 Washington State life tables were used as a proxy, using the "all races" tables. Life table death rates for selected ages were ratioed to the U.S. rates for the equivalent ages, by sex, and these relationships were held constant to future death rates based on the U.S. Census Bureau's most recent "middle series" national projections.⁵

3.6 Baseline Population Size and Composition Forecasts

Aside from the use of directional migration flows by age and sex (which, in theory, is more accurate where migration levels and directions change--as was the case for Benton-Franklin in the early 1980s), the demographic model is a fairly typical cohort-component model. Population is aged, mortality rates applied, iterative migration routines are used to converge the population to the labor force targets, and fertility rates are applied to yield births--with an adjustment for migration. The age-sex composition of the population is a by-product of the process discussed above and of the model applied to the data. Detailed data tables showing the age-sex composition of each county's population, under both the high and low scenarios, and covering each decade year are contained in the Appendix. Population pyramids also are included in

⁴The Total Fertility Rate (TFR) is the sum through all ages of the age-specific fertility rates, or the total number of children that would be born to a woman who experienced those age-specific rates throughout her reproductive life.

⁵Gregory Spencer, Projections of the Population of the United States, by Age, Sex, and Race: 1988 to 2080, Current Population Reports, Series P-25, No. 1018, January, 1989.

the Appendix to show graphically a comparison of age composition between the three counties and changes in age composition over time. These population pyramids display the proportion that each 5-year age group for males and females constitutes of each county's population in 1981 and in 2040. Briefly, in 1981 Benton County's pyramid reflects a "bulge" in the work force age groups and Yakima County reflects higher proportions of the population in the retirement ages. The 2040 forecasts for all three counties reflect the age effects of relatively constant, low fertility and increased longevity, as well as the cumulative effects of the migration assumptions in the model. In addition, by 2040 the baby boom population falls in the 75 years and older category, contributing to the higher proportions in that upper end age group. The low scenario age composition effects are similar. The population forecasts for the three counties, under the high and low employment scenarios, are shown in Table 9 and Figure 5.

TABLE 9. COUNTY POPULATION TOTALS
