PRESSURE EFFECTS IN REACTIONS OF C<sub>2</sub>H WITH CARBON MONOXIDE  
AND ETHANE; C<sub>2</sub>H RATE CONSTANTS

The time decay of an infrared transition originating from the ground state of C<sub>2</sub>H has been followed by diode laser kinetic spectroscopy using excimer laser flash photolysis of trifluoropropyne to produce C<sub>2</sub>H. Somewhat surprisingly, it was observed that C<sub>2</sub>H reacts with CO. As no potential decomposition products of the hypothetical adduct HC<sub>3</sub>O more stable than C<sub>2</sub>H and CO appear to exist, it seemed likely that the reaction produces HC<sub>3</sub>O stabilized by collision with a third body. Therefore, the dependence of the reaction rate upon buffer He gas pressure was studied. The pressure dependence, shown in Fig. 1, exhibits the expected proportionality of rate to He pressure. A third order rate constant of 2.4(6)×10<sup>-30</sup> cm<sup>6</sup> molec<sup>-2</sup> s<sup>-1</sup> was obtained for the reaction of C<sub>2</sub>H with CO.

The dependence upon buffer He gas pressure of the rate constants of several other C<sub>2</sub>H reactions was explored. As expected since the reaction almost certainly proceeds by H atom abstraction, no dependence of rate upon buffer gas pressure was observed in the reaction with CH<sub>4</sub>. However, very surprisingly as this reaction would be expected to proceed by H atom abstraction also, a mild dependence of the rate of reaction of C<sub>2</sub>H with C<sub>2</sub>H<sub>6</sub> upon He pressure was observed and is depicted in Fig. 2. At a total pressure of 24 Torr, the apparent second order rate constant is 3.6(2)×10<sup>-11</sup>

$\text{cm}^3 \text{ molec}^{-1} \text{ s}^{-1}$  for this reaction. It is difficult to visualize addition mechanisms for this reaction. Further studies aimed at determining the initial products of this reaction will be undertaken. Two other  $\text{C}_2\text{H}$  reactions with  $\text{O}_2$  and  $\text{CF}_3\text{CCH}$ , in which addition is probably the first step, exhibit no dependence of rate upon He pressure. For these reactions the adduct is probably stabilized by collision at even the lowest pressure studied ( $\approx 10$  Torr).

Second order rate constants of  $3.0(2)\times 10^{-12}$ ,  $1.3(3)\times 10^{-10}$ ,  $2.3(3)\times 10^{-13} \text{ cm}^3 \text{ molec}^{-1} \text{ s}^{-1}$  were obtained for the reactions of  $\text{C}_2\text{H}$  with  $\text{CH}_4$ ,  $\text{C}_2\text{H}_4$ , and  $\text{D}_2$  respectively. The  $\text{D}_2$  rate, when combined with our previous measurement of the rate of the  $\text{H}_2$  reaction, gives an isotope ration  $\text{H}/\text{D}$  of 1.9, which is not far from the value of  $\sqrt{2}$  expected for a loose transition state.

#### NO HNO PRODUCED IN THE THERMAL DeNOx PROCESS

In the accepted mechanism for the thermal deNOx process, the radical chain is maintained by branching into

The species,  $\text{HN}_2$ , has been the subject of several *ab initio* calculations all of which predicted that it decomposes spontaneously on a sub-nanosecond timescale.

Most observations on the reaction between  $\text{NH}_2$  and  $\text{NO}$  find a channel producing  $\text{OH}$ , but several investigations have specifically sought  $\text{H}$  atoms without success suggesting the *ab initio* calculations may have underestimated the stability of  $\text{HN}_2$  and that it may live long enough to react with  $\text{NO}$ , transferring its  $\text{H}$  atom and thereby avoiding the production of  $\text{H}$  atoms.

We have therefore searched for  $\text{HNO}$  in this system using diode laser kinetic spectroscopy producing  $\text{NH}_2$  by 193 nm flash photolysis of  $\text{NH}_3$  in the presence of  $\text{NO}$  and monitoring a known rotational component of the  $\text{NH}$  stretching vibration of  $\text{HNO}$ . No  $\text{HNO}$  signal is observed although we can easily observe  $\text{HNO}$  produced by reaction of  $\text{HCO}$  with  $\text{NO}$  in the same apparatus. We are currently quantifying

these observations to establish an upper limit for the branching of NH<sub>2</sub> to HNO in the reaction system (1b) + (3).

#### PRODUCT BRANCHING RATIOS FOR NH<sub>2</sub> + NO BETWEEN 300 K AND 1200 K

The reaction between NH<sub>2</sub> and NO lies at the heart of the "Thermal DeNOx" process. Unfortunately, four recent measurements showing that the room temperature reaction yields predominantly N<sub>2</sub> and H<sub>2</sub>O are inconsistent with the need of studies modelling the thermal deNOx process for a chain branching mechanism.

We reported last year that we had almost completed a study of the branching ratio between H<sub>2</sub>O and OH for this reaction at four temperatures: 25, 400, 700, and 925 °C. The branching ratio was determined by comparison of the observed intensities of the OH and H<sub>2</sub>O transient absorptions with the transient loss of absorption of NH<sub>3</sub> upon photolysis. This not only gives the fraction of NH<sub>2</sub> converted to OH or to water, but also shows how well these two product channels account for the reaction products. To do this, an infrared absorption cross-section for OH is required. We measured this relative to H<sub>2</sub>O by relating OH to H<sub>2</sub>O produced from the OH by two chemical kinetic schemes: the reaction at room temperature of OH produced by photolysis of HNO<sub>3</sub> with ethane and the reaction at 400 °C of OH (produced by reaction of O(<sup>1</sup>D) with H<sub>2</sub>) with H<sub>2</sub>. We submitted a paper on this OH cross-section to JQSRT which the editor indicated would be accepted, but shortly thereafter we learned of an OH cross-section measurement by Nesbitt that is about 40% higher than our value. After careful consideration, we concluded Nesbitt's results to be more reliable and withdrew our paper. The Nesbitt cross-section has the effect of making OH an even smaller channel. Thus our measurements on the deNOx reaction clearly make the accepted reaction scheme impossible because they indicate that the OH channel is far too small to support the process. Before publishing such a radical conclusion, we are rechecking our work.

### Figure Legends

Figure 1. The second order rate constant of  $C_2H + CO$  plotted as a function of buffer helium pressure. Trifluoropropyne pressure  $\approx 35-90$  mTorr,  $SF_6$  pressure  $\approx 90-240$  mTorr,  $CO$  pressure  $\approx 600-1200$  mTorr. The error bars are four estimated standard deviations of the second order rate constant in total length.

Figure 2. The second order rate constant of  $C_2H + C_2H_6$  versus helium pressure. Trifluoropropyne pressure  $\approx 35-90$  mTorr,  $SF_6$  pressure  $\approx 80-270$  mTorr,  $C_2H_6$  pressure  $\approx 35-60$  mTorr. The error bars are four estimated standard deviations of the second order rate constant in total length.
