Section 1

INTRODUCTION

This report on the use of siphon penstocks for hydroelectric installations has been prepared under DOE Contract DE-AC07-82ID12356 by Acres International Corporation and draws extensively on the information and data assembled by the following organizations:

- CHI Engineering Services;
- Clearwater Hydro;
- Gannett Fleming Water Resources Engineers, Inc.;
- Harza Engineering Company;
- J. Kenneth Fraser and Associates, P.C.;
- Mead and Hunt, Inc.;
- TKO Power - Ott Water Engineers, Inc; and
- Williams and Broome, Inc.

The purpose of the study was to review the design, construction, operation, and maintenance considerations for siphon penstocks. The discussions, data, and information presented are based on experiences with the following operational siphon penstock plants:

- Columbia Mills Hydroelectric Plant, Virginia;
- Jim Falls Minimum Flow Unit Hydro Development, Wisconsin;
- Lac Courte Oreilles Hydro Development, Wisconsin;
- Ontelaunee Hydroelectric Project, Pennsylvania;
- Pine Grove Dam Hydroelectric Station, Pennsylvania;
- Pocono Lake Hydroelectric Project, Pennsylvania;
- Schaads Reservoir Hydroelectric Project, California;
- Second Broad River Hydroelectric Project, North Carolina;
- Superior Dam Power Station, Michigan;
- Tierckenkill Falls Hydroelectric Project, New York; and
- Traicao Hydroelectric Project, Brazil.

The principal data for these projects are summarized on Table 1-1.

A general description of siphon penstocks is presented in Section 2. The benefits and drawbacks of siphon penstocks are summarized in Section 3. Sections 4, 5, 6, and 7 contain a review of the design, construction, operation, and maintenance considerations. The comparative costs of siphon penstocks versus conventional designs are discussed in Section 8. Recommendations for future design, based on the experiences with the above listed projects, are presented in Section 9. Section 10 contains the conclusions which have been made from the review of siphon penstock installations.

Descriptions, data, drawings, and photographs for the projects are included as appendices to this report.

** The Schaads Reservoir project has two generators and three turbines; one of the generators is driven by two turbines.

Section 2

DESCRIPTION OF SIPHON PENSTOCKS

At a "conventional" hydroelectric installation, the penstock conveys water from the forebay of the intake to the turbine, and passes through the water retaining structure (dam). The penstock has a downward gradient from the intake to the turbine. Therefore, when the penstock is filled with water, the internal pressure in the penstock is always positive. At a siphon penstock installation, the intake is below forebay (headwater) level as in a conventional installation, but the penstock rises to above the dam, or at least to above forebay level, before sloping down to the turbine. Water is conveyed through the penstock by siphon action; therefore, the pressure in the section of penstock above forebay level is negative. Figure 2-1 shows a general comparison between a conventional penstock installation and a siphon penstock installation.

Conveyance of water using a siphon is not new technology. Archaeological studies have indicated the use of siphons in Egypt around 1500 B.C. Lead pipe siphons were used by the Greeks and Romans to convey drinking water over heights. Siphons up to 20 ft in diameter are used on modern-day water supply and irrigation projects.

Siphon type installations were used on some of the early low-head hydroelectric stations. These plants had low specific speed Francis turbines with a relatively high runner setting; consequently, the wheel case was above headwater level. The siphon type intake was, therefore, necessary to convey water from the forebay to the turbine. An early siphon installation is illustrated in Figure 2-2. The trend toward physically large turbines with a low setting relative to tailwater level to prevent cavitation damage, and also the use of large horizontal units on low-head projects, has precluded the use of siphon type intakes. Over the past 10 years, however, with renewed activity in the development of small hydroelectric projects, there is increased interest in the use of siphon type penstocks, particularly at projects where a dam already exists.

There are two basic configurations of siphon penstocks:

- Siphon integral with the intake and powerhouse structure (Figure 2-3). The siphon is not a true "penstock", but rather an intake conduit.
- Siphon which is separate from the intake and powerhouse (Figure 2-4).

The latter configuration is most common for smaller, more recent siphon installations at hydroelectric projects.

The primary differences between a conventional hydro installation and a siphon penstock installation are:

Figure 2-1

Comparison of Conventional and
Siphon Penstock Installations

Figure 2-2

Early Siphon Installation

Figure 2-3

Siphon Integral with Intake and Powerhouse

Figure 2-4

Siphon Separate from Intake and Powerhouse

- At a conventional installation the pressure in the penstock is always positive; at a siphon installation the pressure is negative in the siphon area.
- A conventional installation requires an intake gate or valve to isolate the turbine waterpassages from the forebay; at a siphon installation the waterpassages can be isolated by admitting air into the crown of the siphon, thus "breaking" the siphon.
- At a conventional installation, the waterpassages may be filled by gravity to start the unit, either with the intake gate or valve, or with suitable piping. At a siphon penstock installation, a system such as a vacuum pump is required to fill the section of penstock above forebay level with water, thereby "priming" the siphon.

The principal limiting design factor for siphon penstocks is the siphon lift. The theoretical maximum height which a siphon can raise water is atmospheric pressure, which is about 33 ft of water (depending on the location relative to sea level). Various other factors (see Section 4.3) limit the practical siphon lift to approximately 25 ft. Therefore, the highest elevation of the siphon (i.e. the siphon crown as shown in Figure 2-4) must not be more than about 25 ft above minimum operating headwater level for the siphon to operate satisfactorily.

Section 3

BENEFITS AND DRAWBACKS OF SIPHON PENSTOCKS

There are several benefits to using siphon penstocks for hydroelectric projects. These include:

- Elimination of a Shutoff Device Upstream of the Turbines. Almost all hydroelectric installations have intake gates or valves upstream of a turbine to allow dewatering of the turbine for inspection and maintenance. The gate or valve is usually designed to be closed in an emergency, under flowing water conditions, to stop flow through the turbine in the event of loss of control of the turbine wicket gates. With a siphon installation, both the normal and emergency functions can be accomplished by simply admitting air into the crown of the siphon, thereby breaking the siphon and stopping the flow of water.
- Minimal Impact on Existing Dam. Installation of a conventional intake at an existing dam will usually require demolition of a segment of the dam. This requires extensive analysis and careful construction techniques to insure the structural integrity of the dam, particularly at older dams. The conduit passing through the dam will also have a negative influence on the stability of the dam. At earthen dams, a conventional intake with a penstock passing through the dam has the potential for a leak developing around the conduit, thereby resulting in dam failure due to piping. A pressure conduit through an earthfill dam is often prohibited by the dam owner.

In addition to the design problems associated with modification of an existing dam structure, there may also be questions of legal liability.

The use of a siphon penstock which conveys water over the top of a dam will usually have little or no impact on the dam. Problems and concerns with existing dams are therefore minimized.

- Elimination of Upstream Cofferdam. For most hydroelectric projects incorporating a conventional intake and pressure conduit, a cofferdam is required for construction of the plant. The cofferdam must be appropriately sized to prevent overtopping during construction.

For siphon installations at an existing dam, the power plant can be constructed behind the dam. In many installations, the siphon penstock and intake may be prefabricated and then lowered in place. The upstream cofferdam will then be unnecessary. This has a benefit from a capital cost point of view and may also allow a shorter construction period.

The above benefits enable construction costs to be minimized.

There are, however, a number of drawbacks of siphon penstocks, and these must be considered when evaluating the use of a siphon penstock for a particular project.

- Penstock Length and Configuration. A "straight-through" pressure conduit for a conventional intake-penstock arrangement is often shorter than a siphon penstock which must go up and over a dam. The increased length including additional bends will increase the capital cost of the penstock and may also increase head losses which will reduce generation.
- Limits with Regard to Siphon Lift. The maximum practical suction lift is approximately 25 ft. Where there is a large variation in headwater level, it may not be feasible to install a siphon penstock because of excessive suction lift requirements at low water level. If the top of the dam is significantly above headwater level (for example, at a flood control storage reservoir), a siphon penstock will not be feasible without making modifications to the dam. This will negate some of the advantages of the siphon penstock.
- Problems with Exposed Section of Penstocks. A siphon penstock which passes over a dam will usually have a larger length of exposed area when compared to a conventional pressurized penstock which passes through the dam. Consequently, there will be increased susceptibility to freezing. Exposed sections of penstock may also be subject to vandalism.
- Limits on Size. Siphon penstocks are not readily adaptable to large plant flows because the physically large penstock sections become more difficult to fabricate and unwieldy to install. With large diameters, penstock bend radii are increased, adding to the required length of the penstock. Furthermore, with the larger diameter, siphon lift may become a problem because the height to the top of the penstock must be considered when designing the siphon penstock. To reduce siphon lift, multiple penstocks may be installed and/or the cross section changed to rectangular. Usually these alternatives will be more costly than a single circular section pipe.

Section 4

DESIGN CONSIDERATIONS

4.1 - General

The layout for a hydroelectric installation is usually site specific, as no two sites have exactly the same features and characteristics. This is true whether the project includes a conventional or a siphon penstock arrangement. Therefore, neither the conventional nor the siphon penstock concepts lend themselves to standardized project "off-the-shelf" designs. Each of the principal design considerations for a siphon penstock project, i.e. siphon lift, siphon priming, removal of accumulated air, siphon break system, prevention of siphon overflow, intake, penstock design, penstock material, penstock support, and penstock freeze protection have to be studied for each project. None of the siphon penstocks described in this report are based on a standard design, although the siphon penstock for the Columbia Mills project was designed by the turbine manufacturer (ESAC) and was based on previous facilities which are operating in France. The arrangement for Columbia Mills is shown on Figure 4-1.

The standard electrical and mechanical components (e.g. vacuum pumps and valves, etc.) which are part of the siphon system, are "off-the-shelf" designs. In addition, standard pipe may be used for penstocks at very small installations.

The various design considerations for siphon penstock systems at hydroelectric projects are described in detail in the following subsections, after a discussion on the possible uses of model tests.

4.2 - Siphon Penstock Model Tests

A physical hydraulic model is often a valuable tool for the design of a hydroelectric project. Nevertheless, of all the siphon penstock designs described in this report, model tests were only performed on the Traicao project. At Traicao, model tests were conducted by the pump-turbine manufacturer (S. Morgan Smith) in 1938 on the complete waterpassages. Further tests were made in 1945 to improve turbine and pumping performance. Except for the Traicao and Lac Courte Oreilles projects, all of the plants are less than 600 kW capacity. Because of their small size, reasonably conservative design concepts were adopted rather than constructing and testing a hydraulic model.

For a siphon penstock plant, normally only the intake and penstock near the intake would be modeled. The purpose of the tests would typically be to ensure minimal head losses in the intake area, check there is satisfactory flow distribution at the intake, and ensure there are no adverse vortex formations at the intake. Siphon operations, such as priming and breaking the siphon and air accumulation at the siphon crown, is difficult to quantitatively model, as they represent two-phase flow phenomena which cannot be directly scaled to prototype size.

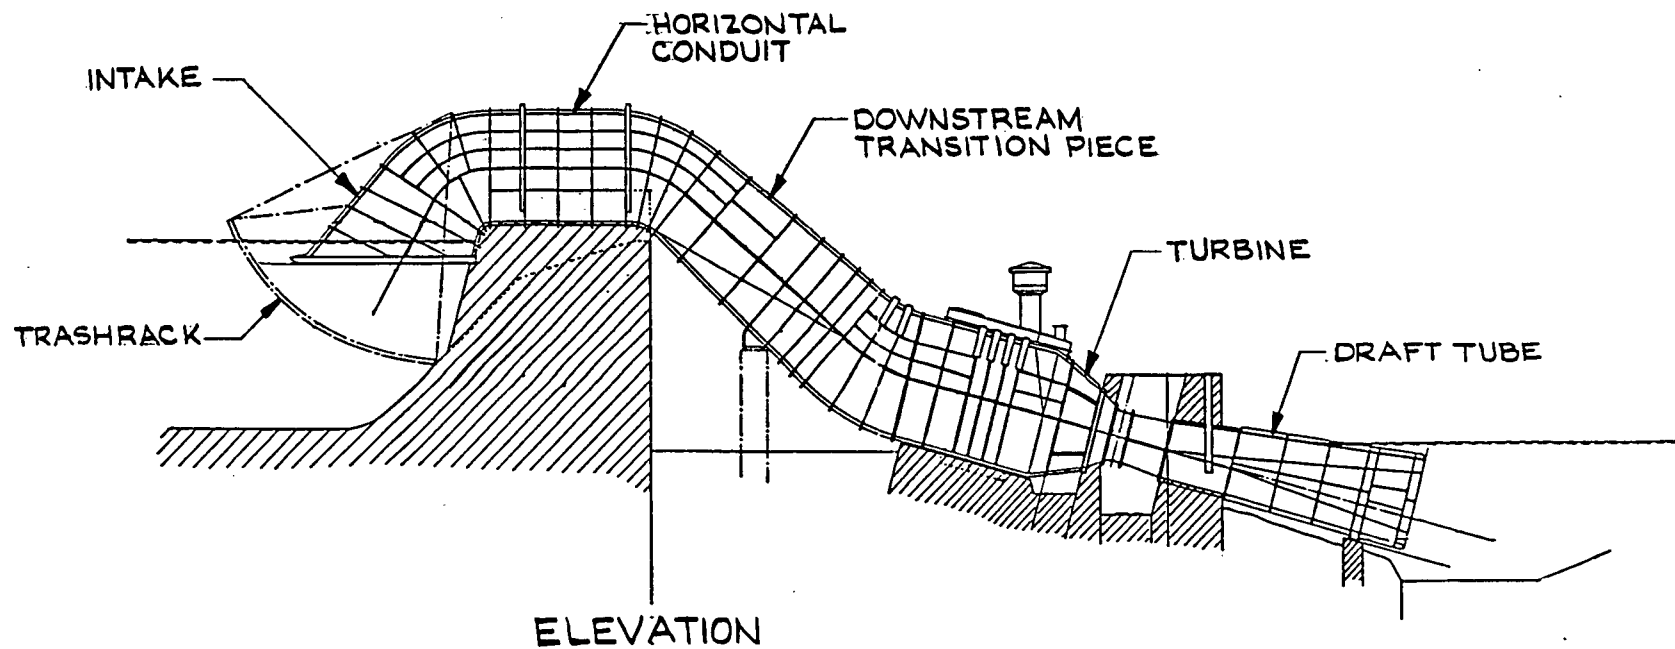

Figure 4-1

Columbia Mills Hydroelectric Plant

Two "generic" model studies which have been completed for siphon penstocks for hydroelectric projects are:

- "Cost and Design of Modular Small Hydroelectric Plants" EPRI EM 3334, June 1984; and
- "Evaluation of Siphon Performance", Phase II Draft Report, Energy Mines and Resources Canada, March 1987.

Topics addressed in these studies include:

- Intake submergence;
- Siphon priming;
- Siphon break;
- Air accumulation; and
- Effect of air on turbine performance.

It is recommended that model tests be considered for large siphon penstock installations, say greater than 1 MW, where there are concerns about head losses, flow distribution, and vortices.

4.3 - Siphon Lift

All siphons have a theoretical maximum lift between water level and the crown of the siphon, equivalent to one atmosphere of pressure (i.e., 33.9 ft of water at sea level). In practice this maximum lift must be reduced to allow for:

- The reduction in atmospheric pressure due to the elevation of the siphon;
- A reduction in local atmospheric pressure due to weather phenomena;
- The limits of the vacuum system which is used to prime the siphon and to remove accumulated air from the siphon crown; and
- The head losses from the intake to the crown of the siphon, plus the velocity head at the siphon crown.

The maximum recommended static lift for siphons is typically in the 20 to 25 ft range. The maximum static siphon lift for the various projects covered in this report is as follows:

<u>Project</u>	<u>Maximum Static Lift from Headwater to Crown of Siphon</u>
Columbia Mills	17.3 ft
Jim Falls	8.5 ft
Lac Courte Oreilles	25.5 ft
Ontelaunee	8.1 ft
Pine Grove Dam	22.0 ft
Pocono Lake	7.3 ft
Schaads Reservoir	10.0 ft
Second Broad River	9.4 ft
Superior Dam	13.0 ft
Tierckenkill Falls	3.8 ft
Traicao	19.9 ft

At Lac Courte Oreilles the maximum siphon lift exceeds the recommended lift when all of the influencing factors listed above are considered. However, this maximum lift only occurs with unusually low headwater levels (approximately once in 10 years). It was postulated by the designers that under these extreme conditions, the plant could operate with the penstock only half full at the apex, reducing the maximum siphon lift to 21 ft.

4.4 - Siphon Priming

General

When preparing a plant with siphon penstocks for operation, a method is required to fill the section of the penstock above headwater level with water (i.e., priming the siphon) prior to operation of the system. The plants covered by this report have a vacuum pumping system which evacuates air from the apex of the penstock, thereby priming the siphon. One or more electric motor-driven vacuum pumps are typically used.

At the Schaads Reservoir project, where normal headwater level is at or above the crown of the siphon, the penstock is first filled by gravity from the reservoir. (During operation, the hydraulic gradient drops below the siphon crown because of head losses and velocity head.) When headwater is below the siphon crown level, a portable, gasoline engine-driven vacuum pump is used to prime the siphon.

At some projects, a method is used to fill the section of penstock downstream of the siphon crown prior to operation of the vacuum system:

- A pump is provided at the Lac Courte Oreilles plant to pump water from tailwater to initially fill the section of the penstock between the siphon crown and the turbine. The vacuum system completes the priming operation. Special care was taken in machining the turbine wicket gates to ensure minimal leakage through the gates when filling the penstock.

- The Pine Grove Dam station has a long length of 6 ft diameter penstock (1230 ft) between the siphon crown and the turbine, and this is initially filled to headwater level through an 8 inch priming siphon, which is primed by the main vacuum system. Once the penstock downstream of the siphon is filled to headwater, the vacuum system completes the siphon priming.

Most installations have a method of positively stopping flow at the unit, either through turbine wicket gates or an intake valve. Starting of a unit is therefore done in two steps:

- With the shutoff device closed, the penstock is filled and the siphon primed; and
- The wicket gates or valve is opened to start the flow of water through the siphon and start the unit.

When the unit is shut down, only the wicket gates or the valve is closed, and the siphon is left primed. The siphon prime is broken only in an emergency or to dewater the penstock.

With more than one fixed discharge turbine on a common penstock, (e.g., Pocono Lake, Schaads Reservoir, Tierckenkill Falls) positive shutoff valves enable starting, stopping and isolating individual units. For this type of installation the priming is done under no-flow conditions with the valves closed.

Some turbines, however, have no shutoff device (Columbia Mills, Ontelaunee, and Traicao have semi-Kaplan turbines with no wicket gates; Second Broad River has fixed discharge units), and siphon priming and unit startup are one operation. Air is removed from the penstock with the vacuum system, and when water starts flowing over the invert of the siphon and through the turbine, the unit starts to rotate. The vacuum system continues to evacuate the air from the penstock to complete the priming, and this is assisted to some degree by air being drawn with the water through the turbine. With this type of installation, the siphon is broken each time the unit is shut down and must be primed for each startup.

Vacuum System

There are several designs of vacuum systems for siphon priming, ranging from rather simple systems with a single vacuum pump connected directly through piping to the crown of the siphon, to more complex systems incorporating multiple pumps and vacuum tanks. The arrangement depends on economic considerations, the size of the siphon penstock installation, and the preference of the owner/designer. Typical schematics for vacuum systems are shown on Figures 4-2 to 4-4, and various vacuum system components are shown in Figures 4-5 to 4-8. At plants with more than one siphon penstock, a common vacuum system may be provided.

Figure 4-7 Siphon Priming Column and Vacuum Breaker Valve - Jim Falls Minimum Flow Unit Hydro Development

Figure 4-8 Siphon Priming Valve and Vacuum Breaker Valve - Superior Dam Power Station

Except for the Schaads Reservoir project, which normally does not require a vacuum pump, all of the plants have ac electric motor-driven vacuum pumps. A summary of vacuum pump data for the various projects is given on Table 4-1.

Rotary liquid ring seal pumps are the most common. Pump power requirements range from 1.5 to 75 hp. The pump capacity depends on the volume of air to be removed and the desired priming time.

While a single vacuum pump is satisfactory for siphon priming, some plants have two pumps. The second pump provides backup in the event of failure of the first and also allows a more rapid initial priming of the penstock when the two pumps are operated together.

The Pine Grove Dam project, in addition to two vacuum pumps, has a 1-1/4 inch ejector which can be used to evacuate air in the event of loss of electrical power for the vacuum pumps. The ejector uses pressurized water from a nearby water main.

For vacuum systems with the vacuum pump(s) connected directly to the siphon crown, the pumps are controlled by water level switches or vacuum pressure switches in the siphon crown (pressure switches are unsatisfactory if there is significant variation in headwater level). At the Second Broad River plant, where there are no shutoff devices at the turbines and water flows through the unit as the siphon primes, it was found that the shutoff point for the vacuum pump could be determined by the rotational speed of the turbine/generator unit.

A vacuum tank is incorporated into some of the systems, and this serves to prevent frequent cycling of the vacuum pump(s), especially when the vacuum system is being used for removal of air accumulating at the siphon crown while the plant is operating. With a vacuum tank, the vacuum pump is controlled by vacuum pressure switches (similar to a compressor-receiver combination). A valve in the system allows air to be drawn from the penstock into the vacuum tank. The ratio of vacuum tank size (in cubic feet) to vacuum pump capacity (in cubic feet per minute) ranges from 0.04 to 1.6 for the different projects.

Where a single vacuum system is provided for more than one siphon penstock, suitable piping, valves, and controls are provided to allow priming of one siphon at a time.

The vacuum pumps and associated vacuum tanks may be located within the powerhouse with a vacuum line extending to the siphon crown. Alternatively, the complete system may be located near the siphon crown. A protective enclosure (building) is usually provided for the vacuum system when it is located near the siphon crown.

Siphon Priming Time

Siphon priming time is the time required to fill the penstock with water, including the apex of the penstock above headwater level, starting from the dewatered condition with atmospheric pressure in the siphon crown. The priming time is a function of the penstock volume and the capacity of the priming system.

*Each pump

The siphon priming time for the various projects is summarized on Table 4-2. Priming times vary from 2.5 minutes to 390 minutes per siphon. The selection of siphon priming time depends on:

- The volume of air to be removed; and
- The expected frequency of priming operation.

Because of the impracticality of providing a very large priming system, the priming time is typically longer for installations with a large penstock volume.

At plants which have a positive shutoff device at the turbine and do not require siphon priming each time a unit is started, a longer siphon priming time can be tolerated because priming is infrequent. Shorter times are usually selected where the siphon must be primed each time a unit is started.

4.5 - Removal of Accumulated Air

In a siphon system there is a tendency for air, which becomes entrained in the water, to separate out and accumulate at the crown of the siphon. If the air accumulation becomes very large, head loss will increase, and the siphon could eventually be broken. The amount of air which becomes entrained increases if there is turbulent water in the forebay or if there are vortices at the intake.

For most plants, provision is made for removal of accumulated air with the vacuum system used for penstock priming. The vacuum system is automatically operated by level or pressure controls. Experience at operating plants has shown that the flow of water through the penstock removes accumulated air quite well, and at the Columbia Mills, Ontelaunee, and Second Broad River plants, automatic air removal with the vacuum system was found to be unnecessary.

At Schaads Reservoir, where the siphon lift is very low, there is no provision for removal of accumulated air when the penstock is in operation.

4.6 - Siphon Break System

As mentioned in Section 3, one advantage of a siphon penstock is the ability to stop the flow of water through the unit by admitting air into the penstock to break the siphon. In effect, the device acts as an intake gate or valve.

The siphon break system consists simply of an air inlet (vacuum breaker) valve which, when opened, admits air into the penstock. At the Schaads Reservoir, Tierckenkill Falls, and Pine Grove Dam plants, the air inlet valve is manually operated. At all the other plants the valves are operated through automatic controls. Most of the automatically operated valves also have provisions for manual operation. The valve may be interconnected with the turbine control system, similar to an intake gate or valve, to break the siphon on turbine overspeed or unit creep.

Superior Dam	8,000	45	178	No
Tierckenkill Falls	750	45	17	No
Traicao	--	15-20	--	Yes

*per siphon

The air inlet (vacuum breaker) valve must be of substantial size, otherwise the air drawn through the valve will be swept through the turbine by the flowing water. The sizes of the valves used for the various plants are given in Table 4-3.

4.7 - Preventing Siphon Flow (During High Water Conditions)

A difficulty with siphon penstocks is the inability to stop flow during high water conditions if the headwater is above the high point of the siphon penstock. At plants where there is a positive shutoff device at the turbine, this is not a problem other than the loss of the emergency shutdown feature (i.e., the ability to break the siphon) and the inconvenience of not being able to dewater the penstock during high water. However, at plants with no shutoff device, a means must be provided to prevent rotation of the turbine when the unit is shut down.

At the Ontelaunee project, during high water conditions, the water level in the siphon can be depressed below the high point in the siphon by injecting low pressure compressed air into the siphon crown. The compressed air is provided by a vacuum system through valving which allows the liquid ring vacuum pump to act as an air compressor. The depression system is automatically activated by the station programmable controller which senses high water level and the unit off-line. The valving around the vacuum pump/compressor is solenoid operated.

At Columbia Mills, during flood conditions when the unit is shut down, the unit is manually secured with a chain wrapped around the torque tube between the generator and the speed increaser. This approach has proven to be unsatisfactory because the water level may rise rapidly, and the station operator may not always be available on short notice.

4.8 - Intakes

Intake Configuration

A horizontal intake (i.e., the flow direction is horizontal) with a vertical opening is usually most suitable for a conventional penstock design, except for a high head installation where the intake may be a vertical morning glory type. Many siphon penstock installations, where the penstock slopes up from the intake to the top of the dam, lend themselves to vertical (inverted morning glory) or inclined intakes with horizontal or nearly horizontal openings. Where the upstream face of the dam has a shallow slope, a horizontal intake is still suitable. Examples of intake configurations are shown on Figures 4-9 to 4-12.

The Tierckenkill Falls plant has a somewhat unique intake configuration (Figure 4-12). The plant flow is relatively small (12 cfs), and the intake consists of a horizontal extension of the penstock, with several intake openings cut in the side of the pipe.

Hydroelectric Project

Intake Submergence

Intakes for both conventional and siphon penstock designs must have suitable submergence to prevent air entraining vortices from forming in the water surface near the intake. The vortices may increase head loss, reduce unit power, and cause rough operation of the turbine equipment. In addition, for siphon penstock designs, the vortices could considerably increase the rate of air accumulation at the crown of the siphon. This will result in increased operation of the vacuum system.

To reduce civil costs, intake submergence is usually kept to a minimum, consistent with ensuring that the water surface is free from harmful vortices. There is no exact analytical approach for determining the minimum submergence requirement to prevent vortex formation. The problem is a complex one depending on intake configuration, size, flow rate, and inlet channel flow conditions. On large projects, model tests of the intake are common. Except for the Traicao project, there were no model tests for any of the projects on which this report is based.

An approximate approach to quantitatively analyzing intake submergence is to compare the relative submergence of the intake with the Froude number. A comparison of these parameters for both vertical and horizontal intake configurations is shown on Figures 4-13 and 4-14. Superimposed on the figures are suggested guidelines for intake submergence derived by Energy Mines and Resources Canada⁽¹⁾ for vertical intakes and by Gulliver et al⁽²⁾ for horizontal intakes.

At the Columbia Mills project, the intake has a semi-circular lip (Figure 4-15). The intake was designed by ESAC, the turbine manufacturer, and from their experience, the semi-circular lip assists in preventing vortex formation.

At the Lac Courte Oreilles project, an anti-vortex wall was constructed after the plant went into operation to eliminate vortices which were observed during initial operation (Figures 4-16 and 4-17). Anti-vortex baffles were also incorporated into the Pine Grove Dam intake (Figure 4-10).

To prevent vortices at the Pocono Lake intake, a timber grid was constructed to float immediately below the minimum water surface. The grid consists of 2 inch by 12 inch cypress timbers constructed horizontally on 12 inch centers and mounted under the platform on the top of the steel frame trashrack structure.

Plastic bottles floating behind the trashracks are used to prevent vortices at the penstock intakes for the Second Broad River plant.

Trashracks

Trashracks are provided at penstock intakes to prevent debris from entering the penstock and turbine waterpassages, and jamming in the wicket gates or damaging turbine components.

Anti-Vortex Backstop - Lac Courte Oreilles
Hydro Development

Trashracks are usually made of vertical steel bars with horizontal spacers and supports. Standard steel grating was used on the Second Broad River project; however, it was found that the racks were difficult to clean because of the interference of the horizontal bars. Wire mesh was installed on the Tierckenkill Falls intake; but the 12-gage mesh was judged to have insufficient rigidity to withstand blockage from debris even with the relatively small (12 inch by 35 inch) intake openings. Aluminum bars were used on the 4 ft by 3 ft by 3 ft rectangular box type intake for the Schaads Reservoir project.

Most horizontal intakes have the trashracks installed on the vertical or inclined face of the intake. Alternatively, a box type intake structure may be installed in front of the intake to reduce rack velocities. Vertical intakes usually incorporate a multi-sided rack structure with trashracks on three sides. A summary of trashrack data for the various projects is presented on Table 4-4.

Trashrack bar spacing depends on the size of the turbine and clearance in the runner waterpassages and wicket gates. The spacings vary from 0.5 inch at Tierckenkill Falls to 5.9 inches at Traicao. Considerations for fish entrainment may also govern the rack spacing in which case spacing may be limited to about 1 inch maximum (e.g., Second Broad River Plant).

Trashrack velocities vary from 0.14 to 2.9 ft/sec based on gross area at the racks. Where fish entrainment is a consideration, velocities have been limited to 0.3 to 1 ft/sec. The vertical intake with the rack structure on three sides lends itself quite well to low rack velocities.

The structural design considerations for trashracks are the same as for conventional installations and include:

- Differential head due to rack blockage; and
- Rack bar vibration due to vortex shedding with water flow past the rack bars.

For installations in northern climates (e.g. Jim Falls, Ontelaunee and Pocono Lake), the trashrack support structure which extends above water must be designed for horizontal ice load. A typical ice load would be 5,000 to 10,000 lbs per linear foot acting over a 2 ft depth at the water surface.

Trashrack Cleaning

Most of the plants with siphon penstocks are relatively small in both capacity and physical size, and the trashracks are manually cleaned. A deck is normally provided over the rack area which allows access for cleaning.

TABLE 4-4
SUMMARY OF TRASHRACK DATA

* V = Vertical
H = Horizontal
I = Inclined

** Smallest unit

At the Second Broad River project, a small custom made trash rake made from a "T" section and a chain hoist was installed. However, because of operating difficulties, its use was discontinued.

A manual hoist is installed at the Columbia Mills intake to assist in the removal of large trees which accumulate on the trashracks during flood periods.

Cleaning the trash screens at the Tierckenkill Falls plant is accomplished by drawing the water level down below the intake using a slide gate in the dam. A water hose is then used to clean the screens.

Siphon installations with penstocks on the upstream sloping face of an earthfill dam do not lend themselves to cleaning, either manual or mechanical, because of the horizontal distance from the waterline to the racks. In some cases there is no provision for cleaning. Some degree of rack cleaning can be achieved by breaking the siphon and allowing the reverse flow in the penstock between the siphon and the intake to dislodge debris from the racks. This method is employed at the Lac Courte Oreilles plant (in addition to manual cleaning); however, its effectiveness has not been determined. At Superior Dam, this approach is also used, but is not entirely satisfactory. There have been difficulties at Superior Dam with rack blockage resulting in increased velocities and causing vortex formation.

At Schaads Reservoir, the small intake was set 25 ft below headwater to minimize the possibility of blockage with debris.

4.9 - Penstock Design

The design approach for siphon penstocks is similar to that for conventional pressurized penstock design. Typical design codes and standards are:

- ASME Boiler and Pressure Vessel Code, Section VIII, Division 1 or 2;
- U.S. Bureau of Reclamation (USBR), "Welded Steel Penstocks," Engineering Monograph No. 3;
- Arthur, H.G. and Walker, J.W., "New Design Criteria for USBR Penstocks," Journal of the Power Division, ASCE. January 1970;
- Amstutz, E., "Buckling of Pressure-Shaft and Tunnel Linings," Water Power, November 1970;
- AISC "Manual of Steel Construction";
- U.S. Bureau of Reclamation (USBR), "Stress Analysis of Wye Branches," Engineering Monograph No. 32;

- Parmakian, J. "Minimum Thickness for Handling Steel Pipes", Water Power and Dam Construction, June 1982;
- AISI & SPFA "Steel Penstocks and Tunnel Liners," Steel Plate Engineering Data - Volume 4; and
- AWWA-MII - "Steel Pipe - A Guide for Design and Installation".

Load conditions which were considered on the various projects included as appropriate:

- Dead loads - pipe weight plus permanently connected appurtenances;
- Live loads - construction loads, wind loads, snow loads, and ice impact loads at the water line;
- Water pressure including waterhammer;
- Uplift due to air trapped at the crown of the siphon;
- Thrust loads;
- Earth pressure and weight of backfill;
- Temperature loads; and
- Earthquake.

For siphon penstocks the siphon crown plus adjacent piping above headwater must be designed for negative pressure. The negative pressure is the sum of:

- Maximum static suction lift;
- Head losses from the intake to the crown of the siphon; and
- Negative waterhammer due to flow acceleration (a consideration when the length of penstock upstream of the siphon crown is significant).

Commonly used formulae for circular steel penstock design for negative pressure are as follows:

$$P_{CRIT} = 73.4 \times 10^6 \frac{(t/D)^{5/2}}{(L/D)} \text{ (with stiffeners)}$$

$$P_{CRIT} = 50.2 \times 10^6 (t/D)^3 \text{ (without stiffeners)}$$

where

P_{CRIT} = critical buckling pressure (psi)
 t = penstock material thickness (in.)
 D = penstock inside diameter (in.)
 L = spacing of stiffener rings (in.)

The first formula (pipe with stiffeners) is attributed to Saunders and Windenburg and is otherwise known as "Roark's Short Tube Formula". It is valid if $D/t > 20$. The second formula (pipe without stiffeners) is known as the Stewart formula and automatically accounts for wall thickness variations, out-of-roundness, and other manufacturing tolerances. It is valid if $D/t > 43$, P_{CRIT} is 581 psi or less, and $L/D > 6$.

Several other formulae may be used and are listed in "ISO Views on Buckling" by V. Helden (Reference 3).

The rectangular penstock for the Columbia Mills project was designed using flat plate formulae. Stiffener spacing was selected to minimize vibration, based on the designer's experience with similar installations.

On some of the designs with steel penstocks, a corrosion allowance of 1/16 inch was applied when calculating the required thickness, but the majority did not consider such an allowance necessary.

Siphon penstocks were typically designed for the maximum possible negative pressure which could occur during operation. Some of the penstocks were designed for a full negative pressure of 1 atmosphere (14.7 psi). An exception is the Schaads Reservoir project, which has a relief valve in the penstock to prevent negative pressure from exceeding 10 ft of water (4.3 psi) in the event that the reservoir is drawn down too far. Safety factors for buckling varied considerably ranging from 1.5 to 5.7. A safety factor of 2 was generally adopted.

Penstock diameter is typically based on an economic evaluation of penstock cost and lost generation associated with head loss. Penstock velocities for projects covered by this report range from 2.5 ft/sec to 11.8 ft/sec, based on plant flow (Table 4-5), and are similar to velocities in conventional penstock designs.

4.10 - Penstock Material

Penstock materials for the projects covered in this report are summarized on Table 4-5. Structural grade steel is the most common material because of the relatively low design pressures.

While none of the projects has used glass fiber reinforced thermosetting resin pipe (RTR), it was evaluated for the Superior Dam project but rejected because of economic considerations and also concern for vandalism. However, RTR pipe has been used for numerous conventional penstocks and is suitable for siphon penstock designs.

**TABLE 4-5
PENSTOCK DATA**

<u>Project</u>	<u>Penstock Diameter (ft)</u>	<u>Velocity at Plant Flow (ft/sec)</u>	<u>Penstock Material</u>	<u>Type of Field Joint</u>

Tierckenkill Falls	1.4	8.21	High Density Polyethylene Pipe	Fusion Joints
Traicao	12.4x33.4*	5.03	Concrete	None

*Rectangular

At the Traicao project, the siphon is integral with the concrete powerhouse substructure.

Polyethylene pipe is commercially available in sizes up to 48 inches. At the Tierckenkill Falls project, the high density polyethylene pipe penstock has a nominal (outside) diameter of 18 inches.

A criterion used to select the pipe material at some of the projects was its resistance to vandalism. The advantage of reinforced concrete pipe is that it is less susceptible to this type of damage than other types of pipe. High density polyethylene pipe is the material most susceptible to vandalism, while RTR pipe may also present problems. Buried pipe is not considered susceptible to vandalism, and a shallow embankment was placed over sections of the Tierckenkill Falls penstock as a deterrent.

The protective coating systems for the steel penstocks are summarized on Table 4-6. Coal tar epoxy protective coating in accordance with AWWA C210 is most common. At Columbia Mills, it was decided not to paint the penstock because of delays in the project schedule. The interior of the penstocks at the Second Broad River plant were not painted because interior erosion did not appear to be a problem at other plants on the same river. However, shortly after the Second Broad River plant went into operation, rust build-up which increased friction losses was apparent, and it was concluded an interior coating would have been beneficial.

The exterior of the reinforced concrete penstock at Superior Dam was coated with white epoxy.

4.11 - Penstock Support

The method of penstock support is dependent on the arrangement and configuration of the penstock, the penstock material, the dam construction, and the surrounding site conditions. Considerations for design of various support systems included:

- Prevention of sliding;
- Penstock expansion;
- Resistance to uplift; and
- Containment of hydraulic forces.

The methods used on the various projects are as follows:

Columbia Mills (Figure 4-18). The short siphon penstock, which is rectangular in cross section, is installed over the crest of an existing dam. The dam was constructed of loose laid limestone with a concrete cap and an impervious upstream facing constructed of clay with a sand and gravel barrier. A new concrete support was poured for the penstock. This support incorporates dowels, which are drilled and grouted into the sloped surface of the existing concrete cap. The dowels serve as shear connectors to prevent sliding and tension connectors in the event the river is at flood stage (above the crown of the siphon), and there

Figure 4-18 Penstock Support - Columbia Mills Hydroelectric Plant

is a pocket of air in the siphon crown. The reinforcing steel for the new concrete support is interlocked with the stiffeners for the steel penstock.

- Jim Falls (Figure 4-19). The penstock is located over an existing concrete wall and earth dike. The penstock is supported at two points on the concrete wall and at the powerhouse. The supports incorporate teflon sliding surfaces to allow unrestrained movement. Thrust rings are provided at the powerhouse wall.
- Lac Courte Oreilles (Figure 4-20). The penstock is constructed on an earth dike and is continuously supported by a compacted, free-draining, gravel bedding over a 120 degree arc on the bottom side of the penstock. The upstream section of penstock has polystyrene insulation to retard frost penetration and heave under the penstock at the waterline. Concrete cradles are provided at the penstock intake, over the core wall at the apex of the siphon, and at the powerhouse.
- Ontelaunee (Figure 4-21). The penstock spans an existing concrete dam and is supported at the dam crest, upstream of the dam crest and at the intake. The supports are constructed of steel tubular columns which fit between circular stiffeners welded to the penstock. The base plates are held by anchor bolts, with elastomeric bearings provided for expansion. The penstock is also anchored at the turbine/generator foundation.
- Pine Grove Dam (Figure 4-22). The penstock is constructed on an existing earthfill dam and is supported on a continuous concrete saddle. The penstock is anchored at the siphon priming structure located at the top of the siphon.
- Pocono Lake (Figure 4-23). The siphon penstock is supported on an existing spillway crest. Concrete bedding was placed on the spillway crest, and the penstock is anchored by a new concrete abutment wall cast over the penstock. Structural steel supports are provided on the downstream side of the siphon crown.
- Schaads Reservoir (Figure 4-24). The majority of the penstock for the Schaads Reservoir project is buried in the earthfill dam. The area which passes through the core of the dam is concrete encased. The penstock is exposed upstream of the apex and has a floating concrete support.
- Second Broad River (Figure 4-25). The penstock is installed over an existing masonry dam and is supported on a concrete slab poured on top of the dam, as well as on a concrete pier on the downstream side of the dam. The slab on the top of the dam was poured around the penstock and is bolted to the existing dam.

Figure 4-24

Penstock - Schaads Reservoir Hydroelectric Project

Figure 4-25 Penstock Support - Second Broad River Hydroelectric Project

- Superior Dam (Figure 4-26). The portion of the penstock upstream of the siphon crown is continuously supported on a gravel bed. To prevent flotation under conditions of net uplift, the penstock is tied with steel straps to concrete blocks set into the gravel bed. The penstock is supported and anchored at the siphon crown by a cast-in-place concrete thrust block. On the downstream side of the siphon crown, the penstock is buried. A second downstream thrust block is located where the penstock bends to horizontal.
- Tierckenkill Falls (Figures 4-27 and 4-28). The penstock is made from high density polyethylene pipe with fusion joints. The intake, which consists of a horizontal pipe with screened openings, is clamped to the upstream face of the existing dam. The penstock is also clamped to the top of the dam at the siphon crown. The 500 ft of penstock between the siphon crown and the powerhouse follows a curved path and rests on the rock surface. Surface preparation or special support was not required. The penstock has two concrete anchor blocks, one located near the siphon crown and the other about 300 ft from the powerhouse. The penstock is also anchored at the powerhouse. The penstock has flanged joints cast into the concrete anchor blocks, which in turn are keyed and dowelled to the rock surface. The curved path of the penstock allows for thermal expansion. Loose chain anchors are also provided at intermediate points to restrain lateral movement.

4.12 - Protection From Freezing

At most of the siphon penstock installations, the piping at the crown of the siphon for the priming and vacuum break system is exposed to the environment. This presents potential problems with freezing during low temperature conditions.

Air bubblers are provided at some intakes to prevent ice formation in the trashrack and intake area (Figure 4-29).

At many plants, there is no special provision to prevent penstock freezing. While there is flow in the penstock, freezing is minimal. Methods used to prevent penstock freezing when the unit is shut down included:

- Breaking the siphon and allowing the penstock to drain;
- Providing a small bypass line near the generating unit to allow some flow in the penstock even when the units are shut down;
- Depressing the water level inside the penstock with compressed air; warm air is then forced into the penstock and bubbles out the intake; and

Figure 4-26

Figure 4-29 Bubbler System in Operation at Jim Falls Minimum Flow Unit Hydro Development Intake

Figure 4-30 Heat Traced Priming Line - Lac Courte Oreilles Hydro Development

- Inserting a bubbler probe in the penstock when the unit is shut down and the siphon is broken, to prevent ice formation at the water surface in the penstock.

Freeze protection of vacuum systems is provided by:

- Enclosing the vacuum pumps and tanks in a heated enclosure;
- Heat tracing exposed vacuum lines, priming valves, vacuum break valves and control valves (Figure 4-30); and
- Providing a heated enclosure around priming valves, vacuum break valves, and control valves (Figure 4-31).

The freeze protection provided at the various plants is summarized on Table 4-7.

Section 5 CONSTRUCTION

5.1 - Arrangement and Type of Contracts

The owner of a siphon penstock site has a wide range of options when establishing contracts for construction of the facility. The project may be constructed on a turnkey basis with one contractor responsible for the complete design, manufacture, and construction of the facility. The turnkey contractor will, however, typically employ several subcontractors who specialize in various aspects of the project work. At the opposite end of the spectrum, the owner may retain the services of one or more engineering organizations for the design and management of the project and may award multiple contracts for the various procurement and construction aspects of the work. These may include equipment supply, civil construction, and mechanical and electrical installation. Other possible contractual arrangements would fall between the two extremes mentioned above.

Contracts may be awarded on the following basis:

- Lump sum (fixed price);
- Cost plus (or time and materials); and
- Not-to-exceed price.

The same contractual options are applicable to the construction of a conventional facility.

The arrangement and type of contract may depend on the following:

- Owner's preference and experience;
- The extent to which owner wishes to become involved with project design and construction;
- Schedule; and
- Method of project financing.

The contractual arrangements for various projects in this report are summarized below. There is no apparent relationship between the number of contracts used and the cost or physical size of the project.

- Columbia Mills (Capital Cost \$630,000 (1984); Cost/kW \$1,510). The project was designed and constructed as a fixed-price turnkey project with the turnkey contractor employing one major subcontractor, the supplier of the turbine and generator equipment. The contract had a liquidated damages provision for late completion of construction.

- Jim Falls (Capital Cost \$2,477,000 (1985); Cost/kW \$4,950). There were three major contracts for the project. The first was an engineering contract to prepare specifications, design the facility, and evaluate bids for other contracts. The second contract was for supply of turbine/generator and controls. The third contract was for construction of the plant and installation of equipment.
- Lac Courte Oreilles (Capital Cost \$3,803,000 (1985); Cost/kW \$1,100). There were two major contracts on the project: an engineering contract for civil design; and a turnkey type contract for construction of the facility including supply and installation of equipment. The turnkey contract was for a fixed price and included the performance guarantees for the plant.
- Ontelaunee (Capital Cost \$960,000 (1987); Cost/kW \$1,810). An engineer was retained for design of the facility. There were four other major contractors:
 - General and mechanical contractor for construction and equipment installation;
 - Equipment contractor for supply of turbines, generators and controls, and low voltage switchgear;
 - Electrical contractor to supply remaining electrical equipment; and
 - Mechanical contractor to supply vacuum pumps and heating and ventilating equipment.
- Pine Grove Dam (Capital Cost \$2,632,000 (1984); Cost/kW \$5,510). The project had four main contracts. An engineer was retained for overall facility design. A general contract was awarded for construction of the facility including installation of piping and mechanical equipment except for the turbine and generator equipment. An electrical contractor supplied and installed miscellaneous electrical services. The turbine manufacturer supplied and installed the turbine, generator, and associated equipment and controls.
- Pocono Lake (Capital Cost \$560,000 (1985); Cost/kW \$1,960). There were four contracts for the project:
 - An engineering services contract with a not-to-exceed price;
 - A fixed price, general contract for civil construction and equipment installation;

- A fixed price turbine and generator contract for supply of turbine and generator equipment; and
- A fixed price contract for supply and installation of electrical controls.
- Schaads Reservoir (Capital Cost \$397,000 (1985); Cost/kW \$1,650). The project was constructed with three contractors: an engineer for facility design; a civil construction contractor; and an equipment contractor for supply and installation of mechanical and electrical equipment and controls.
- Second Broad River (Capital Cost \$272,000 (1985); Cost/kW \$940). The project owner designed the facility and did much of the construction. Major contracts were awarded for fabrication and supply of the penstocks, and for supply of the turbine and generator equipment. There were also several small "verbal" contracts which were on a time and materials basis. These included crane service, access road construction, switchgear building construction, installation of high voltage overhead cables, and excavation of the turbine bay.
- Superior Dam (Capital Cost \$1,866,000 (1985); Cost/kW \$3,270). There were three main contracts for the project:
 - An engineer for overall design;
 - An equipment contractor for supply and installation of turbine and generator equipment; and
 - A general contractor for facility construction.
- Tierckenkill Falls (Capital Cost \$285,000 (1986); Cost/kW \$4,070). The engineering for the project was performed by the owner. There were two contracts for equipment supply only; one for the turbine and generator equipment, and the other for the vacuum system. There were four construction contracts for the project:
 - A general contractor for civil construction and turbine and generator installation;
 - An electrical contractor to supply and install electrical systems;
 - A contractor to supply and install controls; and
 - A contractor to supply and install the control building.

5.2 - Construction Techniques

General

The construction methods for a siphon penstock installation are, in many ways, similar to those for a conventional plant. Major components are shop fabricated and shipped to the project site. The components are either installed directly or pre-assembled into a larger structure prior to installation. Blasting is typically used for rock excavation, and most of the concrete is cast-in-place, the same as for a conventional penstock arrangement. However, unlike a conventional design, the use of a siphon penstock will, in many cases, allow the upstream cofferdam to be eliminated since the dam, which is the principal water retaining structure, is left basically intact. Without the upstream cofferdam, construction of the intake foundations and supporting structures presents a challenge since the area will not be dewatered. Unconventional and innovative approaches to siphon penstock construction may be required.

Various aspects of siphon penstock construction are discussed in the subsections below.

Shop Fabrication

The extent of shop fabrication of siphon penstock components is typically the same as for conventional penstocks. To minimize the number of field joints, components are usually shop fabricated as large as practical, the limitations being the capabilities of the shop and/or shipping constraints. The largest shipping dimension will depend on the site location and type of access. Typical maximum cross-sectional dimensions are 8 ft wide by 10 ft high, although with special provisions, larger components can be transported. If barge access is available directly to the site, very large assemblies can be transported.

For the physically large installations (e.g., Lac Courte Oreilles), the intakes and penstocks were shop fabricated as separate components. Steel penstocks for the different projects were shop fabricated in lengths from less than 20 ft to 114 ft, the largest being for the Lac Courte Oreilles plant.

At some of the small sites (e.g., Pocono Lake), the intake and siphon crown were shop fabricated in one section. All of the penstock bifurcations were shop fabricated.

Unlike turbines, generators, gates and other mechanical/electrical components, the siphon penstocks are typically not shop assembled.

Individual trashrack panels were usually shop fabricated. The extent of shop fabrication of the structural steel trashrack support structures depended on the structure size.

Vacuum pumps are generally shop assembled and operationally tested in the manufacturer's facility.

Site Fabrication

For most projects, the shop prefabricated siphon penstock components were installed directly in position as part of the installation sequence. However, on some projects, the components were site fabricated into larger assemblies prior to installation.

- At the Second Broad River project, each siphon penstock and intake were fabricated in two sections. The two sections of steel construction were welded together prior to being lowered in place; and
- The intake and penstock for the Tierckenkill Falls plant were made entirely of polyethylene pipe with fusion joints made at the site. Standard pipe lengths and fittings were shipped to the site. The siphon structure was site fabricated prior to being lowered into place.

Installation of Penstock and Intake Sections Upstream of the Dam

- Columbia Mills. The siphon penstock is supported at the top of the dam, on a new concrete cap which was poured over the existing masonry construction. The concrete cap was poured behind a steel and plywood cofferdam/form erected in shallow water. The cofferdam/form was anchored to the dam with epoxy set anchor bolts drilled into the dam along the inside and outside perimeter of the formwork. The area was dewatered by pumping, with leakage controlled by cinders.

Prefabricated penstock components were assembled by bolting and field welding into two main penstock subassemblies; the upstream section consisted of the intake, transition, and siphon crown; and the downstream section which interconnects the siphon crown with the generating unit. The 15 ton intake and siphon crown section, which was about 30 ft long by 14 ft wide by 13 ft high, was lowered into place on the concrete cap on the dam with a 50 ton mobile crane.

The trashrack structure, which is located on three sides of the intake, is supported by vertical steel columns which were driven into the overburden upstream of the dam. The downstream portion of the rack structure is supported on the concrete cap on the dam.

- Jim Falls. The siphon intake is cantilevered from and supported on the existing concrete wall. The trashrack structure rests on a tremie concrete pad which was poured underwater without a cofferdam.

The siphon penstock was shipped to the site in three prefabricated sections. The sections were lowered into place on cradle

supports and field welded together. The trashrack structure was lowered into place fully assembled.

- Lac Courte Oreilles. The penstock is installed along the slope of an earth dam. The area of the penstock and intake was first dredged and then bedding material placed in the dredged area.

The crest of the dam was also excavated including minor demolition of the core. Steel piles were driven at each corner of the intake.

The intake transition was prefabricated and shipped to the site as a single piece. At the site, the trashrack support structure was assembled into the intake with the overall assembly being about 27 ft by 9 ft by 9 ft (Figure 5-1). The intake and trashrack support structure was then lowered into position and tremie concrete poured between the reservoir floor and the base of the intake. Penstock support cradles were installed, and the sections of penstock placed in position and welded. The entire upstream length of penstock (114 ft) was installed in a single section, which weighed 66,000 lbs and required two mobile cranes for handling.

- Ontelaunee. The siphon intake and trashrack structure is supported from an existing gate structure concrete wall. The supports are anchored to the wall both above and below water level using the Hilti HVA Adhesive Anchoring System. The support arrangement was designed to minimize the number of anchors which had to be installed underwater. The divers were trained for installation of the fasteners by Hilti.

The penstock was lowered into place in sections, using a mobile crane. The penstock had both field welded and field bolted joints.

- Pine Grove Dam. The siphon intake including concrete support structure was constructed in a conventional manner behind an earthfill cofferdam. The steel penstock was prefabricated in 40 ft lengths which were lowered into place using a mobile crane.
- Pocono Lake. The siphon penstock is cantilevered from an existing concrete dam crest. The trashrack structure is supported on the sloping upstream face of the dam.

The siphon penstock was prefabricated in the shop in sections and lowered into place at site with a mobile crane. Field joints were bolted. The trashrack structure was fabricated in the shop and shipped to the site in pieces. The trashrack structure was pre-assembled at the site with field welded joints and then lowered into place with a crane. The structure weighed about 22,000 lbs.

Figure 5-1 Preparing Intake Section for Installation at Lac Courte Oreilles

- Schaads Reservoir. The section of penstock upstream of the apex is about 60 ft long and is installed on the slope of the reservoir embankment. This section of penstock, which weighs about 3000 lbs, was floated at the intake end using a large inflated inner tube placed under the intake box. When the shore end of the penstock was properly located, the inner tube was punctured to allow the intake to sink into place.
- Second Broad River. The siphon penstock is supported by, and cantilevered from, a concrete cap poured over the existing dam. The penstocks were prefabricated in the shop and shipped to the site in two sections. The two sections were field welded together and the complete penstock lowered onto the dam with a 30 ton mobile crane (Figure 5-2). The concrete cap was poured after the three penstocks were in place (Figure 5-3).
- Superior Dam. The siphon penstock and intake structure is installed along the slope of an earthfill dam. A one-foot deep trench was dredged on the upstream slope of the dam for the penstock and intake. Prefabricated concrete anchor blocks, with embedded threaded rods for steel straps, were placed in a trench by a mobile crane. Bedding material was placed and compacted in the trench. The intake and adjacent penstock section were assembled on shore and lowered into the reservoir onto the anchor blocks and bedding. The total weight of this component was 130,000 lbs. Steel tie straps were installed and secured by a diver and bedding material poured around the base of the penstock. The brackets for the intake trashracks were also installed on shore prior to placing the assembly. The trashracks were lowered into place by crane and guided by a diver.
- Tierckenkill Falls. The 24-in diameter siphon intake is supported from the existing concrete dam. The upstream section, including the intake and siphon crown, was site fabricated in one section which weighed approximately 600 lbs, and placed in position by crane.
- Traicao. The siphon intake is integral with the powerhouse substructure and was constructed in the same manner as a conventional concrete powerhouse.

Installation of Penstock Downstream of Dam

The installation of penstock sections downstream of the dam is done generally in the same manner as for a conventional installation. The specific techniques depend on the penstock material and size, the penstock length, and the method of support. Methods of penstock support are discussed in Section 4.11.

Figure 5-2 Installation of Siphon Penstocks at Second Broad River Hydroelectric Project

Figure 5-3 Placing of Concrete Support for Penstocks at Second Broad River Hydroelectric Project

Construction Equipment

The type of construction equipment depends on the size and configuration of the project. "Conventional" construction equipment is used for land based activities. This will typically include:

- Drilling equipment;
- Earth moving equipment;
- Concrete handling and placing equipment;
- Mobile crane;
- Miscellaneous trucks;
- Compressed air and welding equipment; and
- Miscellaneous equipment, tools, and devices.

For siphon penstock installation, there is an increased use of barges for installation of intake and penstock sections upstream of the siphon crown. This is primarily because of the absence of an upstream cofferdam. Also, there may be added underwater construction requiring increased use of divers and diving equipment.

5.3 - Construction Schedule

The duration of construction for various projects is summarized on Table 5-1. Excluding the larger Traicao project, the duration of construction varied from seven to twenty-one months. In general, the larger projects required a longer construction schedule. Delivery and installation of the turbine and generator equipment was the critical item which governed many of the schedules.

Some projects had delays in the start date. Reasons included:

- Financing;
- Obtaining agency approval; and
- Obtaining a power purchase agreement.

Causes of delay in construction included:

- Generating unit control problems;
- High flows/water levels;
- Construction slow down due to cold weather;
- Difficulties with interfacing of existing structures because of unknown dimensions; and
- Penstock fabrication and erection errors.

On the average, the construction schedule took 2.75 months longer than initially scheduled.

5.4 - Construction Costs

A comparison of construction costs for the various projects is given in Table 5-2. On a cost/kW basis, the facility costs vary from about \$940 to \$5,510 per kW. Intake and siphon

Tierckenkill Falls	1986	70	12	79	85	260	285	4070

- Costs are at time of construction and have not been adjusted to a common year dollar.
- Information is not available where none is shown.

penstock costs typically represent 25 to 50 percent of the total project costs. Cost overruns associated with siphon penstocks have been related to:

- Underestimate of the amount of steel required for the siphon/intake structure (at Columbia Mills); and
- Difficulty interfacing new and existing structures because of inaccurate dimensions of the existing structures (at Ontelaunee).

On the average, the actual construction cost exceeded the estimated cost at the start of construction by 17 percent.

Section 6

OPERATION

6.1 - General

The siphon penstock installations may be divided into two categories:

- Those which have a method other than breaking the siphon, for positively stopping flow at the unit. This is done with an intake valve, turbine wicket gates, or both; and
- Those which have no shutoff device at the unit and flow may be stopped only by breaking the siphon.

For plants which fall under the first category (with a shutoff device), starting a unit is accomplished in two separate steps:

- With the shutoff device closed, the penstock is filled and the siphon is primed; and
- The intake valve or turbine wicket gates are opened to start flow of water through the siphon and to start the unit.

During a normal unit shutdown, only the turbine wicket gates or the valve is closed, and the siphon is left primed. The siphon is broken only in an emergency or to dewater the penstock.

For plants with no shutoff device, siphon priming is done as part of each startup operation, and the siphon is broken on each shutdown.

6.2 - Startup Procedures (at Plants with a Shutoff Device)

Siphon priming is normally initiated by an operator at the station. This may simply involve starting the priming operation through a pushbutton or require manually opening or closing specific valves. Manual valve operation is necessary when there is a common priming system for more than one penstock. Where the vacuum system incorporates two vacuum pumps (in lead-lag or main-standby modes), both pumps are used for siphon priming purposes.

The siphon priming operation is normally stopped automatically by pressure and/or level switches associated with vacuum system control.

Some plants have a means of filling the downstream leg of the penstock before starting the vacuum pumps (using pumps or a priming siphon). At these installations, there is manual interface between the initial filling operation and the start of the vacuum pumps.

Because the siphon is normally left primed, there is usually no significant benefit to having an automatic, unattended priming operation.

While the specific startup procedures vary from plant to plant, a typical start-up procedure is as follows:

- Check the following:
 - vacuum breaker valve is closed
 - turbine wicket gates/intake valve is closed
 - power is available to vacuum pumps
- Switch vacuum system to "run". Vacuum pumps start and air is evacuated from the penstock.
- When water level rises to the top of the siphon crown, the float operated valve in the air-vacuum line closes.
- The vacuum pumps continue to operate until shutoff by a pressure switch in the vacuum control tank.
- A signal is sent to the station programmable controller to start the unit.

Once the siphon priming is completed, the unit is started under remote automatic, local automatic, or local manual control.

6.3 - Shutdown Procedures (at Plants with a Shutoff Device)

As mentioned above, for normal shutdown the siphon remains primed. This facilitates unattended automatic restart of the unit. Unit shutdown consists of closing the turbine wicket gates or intake valve, and opening the generator breaker through an automatic or manual shutdown sequence in the same manner as for a conventional installation.

When it is necessary to dewater the penstock, the siphon is broken by manually initiating the opening of the vacuum breaker valve.

In an emergency or unusual situation, the siphon may be broken to stop flow of water through the turbine by protective devices associated with the generating unit. The protective devices will signal the vacuum breaker valve to open. The following conditions will typically initiate breaking the siphon:

- Unit overspeed;
- Loss of hydraulic pressure in the governor, gate positioner, or intake valve operator; and
- Unit creep.

6.4 - Startup Procedures (at Plants without a Shutoff Device)

The siphon priming operation is integral with unit startup and can be done through one or more of the following:

- Remote initiation and automatic sequencing;
- Local manual initiation and automatic sequencing; and
- Local manual sequencing.

A programmable controller is used for automatic startup at all plants except for Traicao. Relay type controls are used for the Traicao station which went into operation in 1944.

A typical start sequence is as follows:

- Unit start is initiated.
- Vacuum breaker valve closes.
- Vacuum pump(s) start.
- When water starts to flow over the apex of the penstock, the unit starts to rotate.
- When the unit reaches synchronous speed the generator breaker is closed.
- When the siphon is completely primed, the vacuum system is shutoff by pressure switches and/or level switches.

Except for the Traicao plant, all of the generating units at plants with no shutdown devices have induction generators. These machines are relatively easy to bring on-line since the breaker may be closed any time near synchronous speed (plus or minus about 2 percent).

At the Traicao station, the adjustable runner blades are positioned at a negative angle (-4 degrees) during priming, so that the unit will not rotate. When the air is almost completely evacuated from the siphon, the blades are opened to bring the unit to synchronous speed. When the unit is synchronized to the power system the generator breaker is closed.

6.5 - Shutdown Procedures (at Plants without a Shutoff Device)

Breaking the siphon prime is part of both normal and emergency shutdown of the unit. A normal shutdown typically involves the following sequence:

- If unit has adjustable blades, reduce load on unit by decreasing blade angle.
- Simultaneously trip generator breaker and open vacuum breaker valve. Alternatively, to minimize unit overspeed, the vacuum breaker valve may be set to open first, followed by tripping of the generator breaker a few seconds later.

Shutdown under emergency conditions is similar to that described in Section 6.3.

6.6 - Removal of Accumulated Air During Operation

Entrained air and air which comes out of solution will tend to accumulate at the crown of the siphon during plant operation. This is removed by automatic operation of the vacuum system through the pressure and/or level controls. It has been found that the flow of water through the penstock removes accumulated air quite well, and at the Columbia Mills and Second Broad River plants automatic air removal was found to be unnecessary.

6.7 - Operational Experience

Experience with operation of siphon penstocks has generally been very good. Most problems have been relatively minor in nature, and these are reviewed in Section 9.

Section 7 MAINTENANCE

7.1 - Maintenance Activities

Siphon penstock systems inherently have low maintenance costs. Inspection and cleaning of the trashracks may be the major maintenance activity, depending on the amount of debris in the river. Trashrack cleaning requirements are essentially the same as for a conventional penstock arrangement. Another activity is preventive maintenance for the siphon priming/vacuum system. The maintenance program for this system is usually based on equipment manufacturer's recommendations as well as operating experience with the facility.

A typical maintenance program for a siphon penstock facility has included:

<u>Item</u>	<u>Frequency</u>
– Inspect trashracks for debris	Site specific
– Clean trashracks	As required
– Inspect penstock interior (including sensors and control devices in penstock interior)	One to five years
– Recoat penstock	As required
– Clean motors, pumps, and miscellaneous equipment	Monthly to yearly
– Lubricate bearings	Monthly to yearly
– Vacuum pump maintenance	As recommended by manufacturer
– Check vacuum system valve operation	Monthly

Unplanned maintenance items at the various plants have included:

- Electrical sensor failure; and
- Expansion joint leakage.

7.2 - Spare Parts

The majority of spare parts at the various projects are for the turbines, generators, and associated equipment. At most plants, there are no spare parts for the siphon penstock

system. Where spare parts are provided, they are related to the vacuum system and typically include gaskets, vacuum pump shaft seals, valve components, and pipe fittings.

The most extensive inventory of spare parts for the siphon priming system is at the Pine Grove Dam project, and includes:

- Vacuum pumps
 - shaft seal assembly;
 - slinger;
 - lobe pins;
 - rotor nut, washer, key; and
 - gaskets.
- Ball valves
 - body seat;
 - stem seals; and
 - compression ring.
- Electrical
 - complete solenoid valve;
 - complete vacuum switch;
 - level probe relay package; and
 - one relay, switch and control of each type.

7.3 - Operating and Maintenance Costs

The approximate operating and maintenance costs for the siphon penstock plants presented in this report are summarized on Table 7-1. Present day costs, excluding rent, insurance and interconnection fee, range from \$20 per kW of installed capacity to \$77 per kW. The costs associated with operation and maintenance of the siphon penstock are relatively low, and would perhaps account for 5 to 10 percent of these total costs. This amounts to about \$5 per kW of installed capacity for siphon penstock operating and maintenance costs.

TABLE 7-1
OPERATION AND MAINTENANCE COSTS FOR SIPHON PENSTOCK PLANTS

FERC ACCOUNT NO.	DESCRIPTION	PRESENT DAY COST (\$1,000)

Section 8

COMPARATIVE COSTS - SIPHON VERSUS CONVENTIONAL DESIGN

8.1 - General

Like most other components of a hydroelectric project, the intake and penstock design is site-specific and must be evaluated for each individual project. When comparing the costs of a siphon penstock versus a conventional pressurized penstock design, the following should be evaluated:

- Capital costs;
- Schedule differences;
- Hydraulic costs (i.e., head losses); and
- Operation and maintenance costs.

8.2 - Capital Costs

The following are examples of capital cost comparisons between siphon penstock installations and projects with conventional penstock designs:

- At the Columbia Mills project, the overall project cost was estimated as 85 percent of that for a conventional design. In estimating the cost of a conventional design, specific consideration had to be given to the safety of the existing loose laid masonry dam. The total project cost (in 1984 \$) was \$630,000.
- The capital cost comparison for siphon and conventional penstock installations for the Jim Falls project is presented in Table 8-1. The siphon penstock had a capital cost savings of \$156,000 (in 1985 \$) over the cost of a conventional design.
- At the Lac Courte Oreilles project, it was estimated that a conventional intake and penstock would have additional costs associated with a cellular cofferdam and cutoff wall, increased excavation, and the need for intake control gates. The increase in costs was estimated to be as follows:

- Cofferdam and cutoff wall	\$465,000
- Increased excavation	18,900
- Intake gate equipment	<u>139,000</u>
TOTAL (1982 dollars)	\$622,900

This savings represents about 20 percent of the total project cost.

TABLE 8-1
JIM FALLS MINIMUM FLOW UNIT HYDRO DEVELOPMENT
COMPARATIVE COSTS FOR CONVENTIONAL AND SIPHON PENSTOCK INSTALLATION

<u>Items</u>	<u>Siphon</u>	<u>Conventional</u>
CAPITAL COSTS		
Powerhouse building	Same	Same
Turbine, generator, controls	Same	Same
Trashracks	Same	Same
Upstream cofferdam	--	\$132,000
Downstream cofferdam	Same	Same
Intake structure	--	\$ 27,600
Penstock	\$ 58,500	\$ 43,800
Vacuum system	\$ 14,400	--
Upstream stoplog gate	--	<u>\$ 12,000</u>
Subtotal (1984)	\$ 72,900	\$215,400
Escalation at 7.5%	5,500	16,200
AFDC	<u>1,300</u>	<u>3,700</u>
Comparative capital cost (1985)	<u>\$ 79,700</u>	<u>\$235,300</u>
Differential capital cost (1985)	(\$155,600)	Base

- On a capital cost per kWh generation basis, a siphon penstock system was estimated to be 12 percent less costly than a conventional intake penstock arrangement at the Ontelaunee project.
- The incremental cost of a conventional penstock over a siphon penstock for the Pocono Lake project was \$65,000 in 1984. This is about 12 percent of the total capital cost.
- The penstock options for the Schaads Reservoir project included:
 - Utilization of the existing 24-inch outlet works pipe; and
 - Construction of a new siphon penstock.

The cost of the siphon-type penstock was marginally higher than the repair costs associated with utilizing the existing outlet works pipe (\$77,500 versus \$75,000 in 1985). However, a siphon penstock system was selected because of a greater possibility of cost overruns due to the unknown conditions associated with repair of the existing pipe.

- A conventional penstock could not be installed at the Second Broad River plant because of concern for dam safety should penstock openings be cut in the dam. Nevertheless, the theoretical cost increment for a conventional design was estimated to be as follows:

– Excavation through dam	\$13,000
– Upstream cofferdam	8,600
– Butterfly valves at turbines including emergency power supply	18,000
– Wood stoplogs for penstock dewatering	7,000
– Additional concrete	12,500
– Deletion of vacuum system	<u>(5,700)</u>

TOTAL INCREMENTAL COSTS (1985 dollars)	\$53,400
---	----------

This savings is about 19 percent of the total project cost.

- In the feasibility studies for the Superior Dam project, three project configurations were considered:

Project Capital
Cost (1981)

- Three straight flow turbines with siphon penstocks placed over the dam \$1,087,000
- An integral intake and powerhouse with one Kaplan turbine 2,416,000
- An integral intake and powerhouse with two open flume turbines 2,727,000

The siphon penstock option was the most economic and was selected for further design. Eventually, the three-unit concept was replaced with a single-unit design utilizing a siphon penstock.

- At Tierckenkill Falls, a siphon penstock was installed for research/evaluation purposes, although a conventional intake/penstock arrangement was considered slightly more economic.

The foregoing comparisons should not be construed to indicate that siphon penstocks are usually the best choice for a small hydroelectric project. Since the comparisons are for projects where siphon penstocks were actually constructed, it is not surprising that the siphon penstock option was usually most economic. As mentioned previously, a site-specific evaluation of intake and penstock arrangements must be made at each project.

8.3 - Schedule Differences

The use of a siphon penstock rather than a conventional intake/penstock arrangement may offer some improvement in the overall project construction schedule, in that the upstream cofferdam may be eliminated. There may also be a benefit because there will be no required rework of an existing dam.

Of the eleven projects covered in this report, only three required an upstream cofferdam.

8.4 - Hydraulic Costs

A siphon penstock which must go "up and over" the dam will usually have increased head loss when compared to a conventional design primarily because of the increased number of bends in the conduit (at the Lac Courte Oreilles project, turning vanes were installed in the apex of the penstock to minimize bend losses). The added head loss will translate into reduced generation and therefore lost revenue. The difference in head losses is site-specific and must be evaluated on a plant-by-plant basis. As an example, the intake and penstock head losses for the two design options for the Jim Falls project (similar to Figure 2-1) are as follows:

<u>Type of Penstock</u>	<u>Head Loss at Full Flow (ft)</u>	<u>Head Loss/ Gross Head</u>
Conventional	0.95	0.031
Siphon	1.10	0.036

8.5 - Operation and Maintenance Costs

The vacuum system associated with a siphon penstock installation represents an additional operation and maintenance item for the facility. At the plants in this report, operation and maintenance costs associated with the vacuum system and other features of the siphon penstock have been relatively small; present day annual costs may be about \$5 per kW of installed capacity. A conventional penstock installation will have maintenance costs associated with the intake gate and hoist; however, these costs are expected to be almost negligible.

In evaluating the siphon penstock concept for the Jim Falls project, an annual levelized cost penalty of \$2600 (in 1985 dollars) was assessed to the siphon penstock scheme for operation and maintenance of the vacuum system.

Section 9

SIPHON PENSTOCK PROBLEMS AND SOLUTIONS

The siphon penstock installations on which this report has been based have operated quite satisfactorily. Nevertheless, like most projects, there have been some operating problems, most being relatively minor in nature.

Various problems associated with the design and operation of siphon penstocks, including recommendations for future design, are discussed below.

9.1 - Penstock Location

The intake and penstock section upstream of the dam are usually exposed and vulnerable to damage caused by debris and ice. At the Columbia Mills project, the trashrack structure was destroyed by debris during flood conditions. It is recommended that the location of the intake and siphon penstock be carefully reviewed relative to the possibility of flood and ice damage. An intake and penstock location remote from the center of the flood flow is preferable.

9.2 - Trashracks

At the Superior Dam project, there is no direct access to the trashracks for cleaning. The trash load in the river is higher than initially anticipated and the reverse flow associated with breaking of the siphon is not always satisfactory for rack cleaning. Extensive trash build-up has caused vortex formation.

For projects where trash is expected, a means of access for cleaning the racks should be provided. If it is anticipated that the unit may be required to operate for significant periods with considerable debris on the racks, a conservative submergence criteria should be used to minimize the effect of vortices.

Based on the experience at the Second Broad River project, it is recommended that trashracks be made of steel bar rather than steel grating (Figure 9-1). While the steel grating is less costly and easier to install, it is more difficult to clean.

For very small intakes, wire screening may be suitable; however, a very stiff screening material is recommended. At Tierckenkill Falls, 20 gauge, one-half inch galvanized wire mesh was used on the 12 inch by 35 inch openings (Figure 9-2). Operational experience indicated that this size screen had insufficient stiffness.

9.3 - Vacuum System Controls

A problem which has been common to many of the siphon penstock installations (Columbia Mills, Jim Falls, Lac Courte Oreilles, Pine Grove, Second Broad River) is the tendency of

Figure 9-1 Trashracks - Second Broad River Hydroelectric Project

Figure 9-2 Trashracks - Tierckenkill Falls Hydroelectric Project

the system to "overshoot" when the siphon becomes primed resulting in water being drawn into the vacuum system and vacuum pumps. Measures which have been proposed or adopted to prevent this problem include:

- Provision of a relatively high (about 4 ft) siphon control column at the crown of the siphon. The control column should be relatively large in diameter with an orifice at the bottom to prevent rapid water flow;
- Installation of duplicate level sensing devices;
- Setting the vacuum system shutoff level to well inside the penstock and allowing the flow of water through the penstock to remove the remaining air at the crown of the siphon;
- Designing the system to allow water to enter the vacuum tank and having provision to automatically drain the tank;
- Design the vacuum system with a water separator before the vacuum tank and have a second vacuum tank which can be filled with water and has provision for automatic draining when full; and
- Provision of a float operated air vacuum valve at the siphon crown. The rising water level raises the float to close off the vacuum line. Conversely air accumulation at the siphon crown will allow the float to drop and the air will be drawn into the vacuum tanks.

Where level switches are used to control the vacuum system, it is beneficial to have provision for field adjustment of the switch settings.

The pressure switches which control the vacuum pumps on the Superior Dam project are located with the vacuum tank in the powerhouse, about 100 ft from the crown of the siphon. Pressure switches located directly below and above the air vacuum valve at the siphon crown would give a better indication of the vacuum pressure at the siphon.

9.4 - Vacuum Breaker Line

If the vacuum breaker line is too small, the air flow will be insufficient to break the siphon, and the air will be drawn through the unit. This problem was noted at the Pocono Lake and Jim Falls plants which have 2-inch vacuum breaker valves (a 6-inch valve was subsequently installed at Jim Falls). A similar effect was observed with the 3/4 inch air inlet line at the Second Broad River plant. The required size of the air valve is a function of penstock size, water velocity and the magnitude of negative pressure at the siphon crown. From data on projects covered by this report, it appears that the diameter of the vacuum breaker should be at least 4.2 percent of the penstock diameter.

9.5 - Problems with Freezing

Freezing problems were reported at two projects. At Pine Grove Dam, freezing occurred in the 8 inch siphon priming line at the connection to the penstock. This problem was mitigated by applying heat tape and insulation to the line. Depending on the topography, burying of the priming line may also be a suitable method to prevent freezing.

At the Second Broad River plant, in spite of the normally temperate weather, one of the vacuum breaker valves froze on one occasion. The problem was solved by heat tracing the valves and associated piping.

9.6 - Vibration

The apex of each of the siphon penstocks on the Lac Courte Oreilles plant has turning vanes to minimize head losses at the siphon crown. Vortex formation at the intake caused air to be drawn into the penstock, and this resulted in vibration of the turning vanes. Installation of an anti-vortex backstop, as discussed in Section 4.8, eliminated both the vortex formation and the vibration.

Section 10

CONCLUSIONS

The review of design, construction, operation, and maintenance considerations for siphon penstocks, described in the previous sections of this report, has demonstrated that siphon penstocks are viable options for hydroelectric plants. Siphon penstocks are particularly attractive at installations with small units constructed at an existing dam. Cost savings may be significant; nevertheless, the actual economic and technical benefit of using a siphon penstock rather than a conventional design must be evaluated on a site-specific basis.

Present day siphon penstocks are generally custom designed to suit the physical constraints of the project site. The siphon penstocks may have either a horizontal or a vertical intake. Standard off-the-shelf components are used for items such as the vacuum system, and for very small installations standard pipe may be used for the penstock.

Priming of the siphon is usually accomplished with a vacuum system, although a supplementary system (such as pumps) may be used to fill the downstream leg of very long penstocks. The vacuum system consists of one or more vacuum pumps with the size dependent on the penstock volume. Priming systems may be either automatic or manually controlled. The vacuum system can be operated under static conditions when there is no flow through the turbine; and also can be used at installations with no shutoff devices, where turbine flow will start as soon as water flows over the siphon invert.

The design of a siphon penstock is similar to that for a conventional penstock arrangement although appropriate allowance must be made for negative pressure at the siphon crown. Penstock materials have included steel, concrete, and high density polyethylene. Aboveground and buried penstocks have been used and penstock support schemes are comparable to conventional installations.

Site construction may be somewhat different for a siphon penstock because the upstream cofferdam is usually eliminated. This generally results in some cost reduction; however, there may be an increase in underwater construction and a barge may be required for penstock installation. Divers may also be required.

Operation and maintenance costs associated with siphon penstocks are relatively low, and are in the order of \$5 per kW installed capacity per year.

Design and operating problems have been relatively minor and generally not unlike those for many conventional installations. The most common problem unique to siphon penstocks is in the controls which stop the vacuum system once siphon priming is complete.

In summary, the principal conclusions of the study are that small hydro plants with siphon penstocks:

- Are a proven technology;
- Operate effectively and efficiently with few operational problems;
- Are a viable economic alternative to a more conventional installation; and
- Are the preferred solution at sites with an existing dam where there is a need to minimize the interference with the existing structures.

APPENDIX A
COLUMBIA MILLS HYDROELECTRIC PLANT

COLUMBIA MILLS HYDROELECTRIC PLANT

The Columbia Mills Hydroelectric Plant is located on the left bank of the Maury River at an existing dam in Buena Vista, Virginia. The power plant, which has a single 417 kW, 17.2 ft head unit, was constructed in 1985.

The plant has an intake, short section of penstock and bulb type generating unit, all of which are exposed and of steel fabrication. Except for foundations for the intake, penstock and generating unit, the powerhouse has no concrete substructure.

The intake is rectangular in shape and has a horizontal opening. Sloped trashracks surround the intake on three sides. The trashracks are manually cleaned.

The rectangular penstock is of fabricated steel construction, 13.8 ft wide by 9.8 ft high. The intake and penstock are made from prefabricated sections with field welded and field bolted joints. The downstream portion of the penstock incorporates a transition to the turbine waterpassages. The penstock is supported at the dam and at turbine foundations. The overall length of the penstock is 83.1 ft, and the distance from the intake to the crown of the siphon is 23.8 ft.

The siphon priming system consists of a positive displacement vacuum pump and associated piping, valves, and controls. The vacuum pump and controls are housed in the control building located near the crown of the siphon. A vacuum breaker valve is also located at the crown of the siphon.

The generating unit has an inclined axis semi-Kaplan bulb turbine, and an induction generator driven through a parallel shaft speed increaser.

The turbine waterpassages are drained by opening the vacuum breaker valve located at the crown of the siphon. Stoplogs are installed downstream of the runner to permit dewatering the runner area.

The plant is operated on a run-of-river basis to maintain the headwater level at the top of the dam. Flows in excess of the turbine discharge pass over the dam. The unit is automatically controlled by a programmable controller.

APPENDIX B

JIM FALLS MINIMUM FLOW UNIT HYDRO DEVELOPMENT

JIM FALLS MINIMUM FLOW UNIT HYDRO DEVELOPMENT

The Jim Falls Minimum Flow Unit Hydro Development is located near Jim Falls, Wisconsin on the north bank of the Chippewa River. The power plant was constructed in 1986 and has a single 560 kW, 30.5 ft head unit.

The intake is an inverted morning glory type with a horizontal opening. The intake has vertical trashracks on all four sides. Access is provided for hand raking the trashracks.

The penstock is of steel construction with a nominal diameter of 6.5 ft. The penstock is made from prefabricated sections with field welded joints. The upstream portion of the penstock bends 90 degrees from the intake to cross the dam. On the downstream side of the dam the penstock bends downward and runs to the powerhouse. The penstock is supported by three cradle supports; two are located at the ends of the siphon crown and one is located at the upstream powerhouse wall. A bridge for the access road passes over the crown of the siphon.

The overall length of the penstock is 89 ft and the distance from the intake to the crown of the siphon is 27 ft.

The siphon priming system consists of two liquid ring seal vacuum pumps, a vacuum tank, an air/water separator with a water accumulator tank, and associated piping, valves, and controls. The vacuum pumps, tanks, separator, and controls are located within the powerhouse. The vacuum system is connected to the priming column at the crown of the siphon with a four inch line. A vacuum breaker valve is also located at the crown of the siphon.

The powerhouse has a reinforced concrete substructure with precast concrete slab walls. A composition roof on a metal deck with steel joist supports is provided. The generating unit has a vertical Francis turbine, with a vertical induction generator driven through a parallel shaft speed increaser. A butterfly type inlet valve is provided at the intake to the turbine.

The turbine is set above tailwater and is dewatered by closing the inlet valve. The penstock can be dewatered by opening the vacuum breaker valve and draining the water through the unit.

The majority of flow in the Chippewa River is directed through a power canal to the Jim Falls main powerhouse which operates as a run-of-river facility. The Jim Falls Minimum Flow Unit provides a continuous flow of 240 cfs in the Chippewa River in the area between the dam and the main powerhouse.

An operator is required to initiate the siphon priming operation and to start the generating unit. The plant has the capability for future remote startup of the unit.

LAC COURTE OREILLES HYDRO DEVELOPMENT

LAC COURTE OREILLES HYDRO DEVELOPMENT

The Lac Courte Oreilles Band of Lake Superior Chippewa Indians Hydro Development is located at a water storage dam in Sawyer County near Winter, Wisconsin, on the west bank of the Chippewa River. The 30 ft head power plant, which has two 1767 kW units and one 303 kW unit, was constructed below the existing dam, in 1986. The primary purpose of the dam is to store excess runoff, and then release water during low flow periods for use at downstream hydroelectric facilities.

The three unit project has two parallel 9 ft diameter penstocks. Each penstock supplies water to one of the larger units. One of the penstocks bifurcates at the powerhouse to supply the small unit. Each penstock has a horizontal rectangular intake with vertical trashracks along the two sides and the front. The intake incorporates a transition to the circular penstock. There are no trash handling facilities at the intake.

The penstocks are made from prefabricated steel sections with field welded joints. The upstream portion of the penstocks follows the upstream slope of the dam. An access road, supported by a bridge, passes over the downstream portion of the penstocks. The penstocks are continually supported by compacted, free draining bedding. Concrete cradle supports are provided immediately upstream of the powerhouse and at the crown of the siphon. The penstock diameter increases from 9 ft to 10 ft immediately upstream of the powerhouse.

The overall length of each penstock is 261 ft. The distance from the intake to the crown of the siphon is 121 ft.

The siphon priming system consists of two liquid ring seal vacuum pumps, and associated piping, valves, and controls. In addition, a pump is provided to fill the section of penstock downstream of the siphon crown with water prior to priming the siphon. The water pump, vacuum pumps, and controls are located within the powerhouse. The siphon break valve and vacuum header are located at the crown of the siphon inside a metal sided, woodframe structure.

The powerhouse is of reinforced concrete construction. The generating units have vertical Francis turbines with adjustable wicket gates. The generators are of the vertical induction type driven through parallel shaft speed increasers. The turbines are set above tailwater; therefore, the turbine waterpassages and penstock may be drained by breaking the vacuum in the penstock.

For most of the year, the plant is operated as a run-of-river facility to maintain relatively constant headwater level in Lake Chippewa. During the late winter, the level can be lowered about 15 ft so that the reservoir can store the spring runoff. Flood flows are handled through a spillway with three 20-ft wide tainter gates.

The generating units can be automatically or manually controlled. An operator is required to initiate the siphon priming operation.

APPENDIX D
ONTELAUNEE HYDROELECTRIC PROJECT

ONTELAUNEE HYDROELECTRIC PROJECT

The Ontelaunee Hydroelectric Project is located in Berks County, Pennsylvania on the west bank of Maiden Creek. The plant was constructed in 1987 at the existing Ontelaunee Dam. The 35 ft head plant has two generating units, a 530 kW unit which has a siphon penstock, and a smaller unit which is supplied from an existing 48 inch blowdown line.

The siphon penstock has a bellmouth intake with an opening inclined at 30 degrees to vertical. Sloping trashracks are installed at the front of the intake, and the trashracks are manually raked.

The penstock is of steel construction with a nominal diameter of 6 ft. The penstock is made from prefabricated sections with both field welded and bolted flanged joints. The upstream portion of the penstock rises vertically from the inclined intake and bends to pass horizontally over the dam. The downstream portion of the penstock slopes down from the dam toward the turbine where it bends to meet the vertical turbine casing.

The overall penstock length is approximately 130 ft, and the distance from the intake to the crown of the siphon is 45 ft. The penstock is supported by steel supports at the intake, 21 ft upstream of the dam crest, and at the dam crest. The penstock is also supported and anchored at the powerhouse. A bridged walkway passes over the penstock at the dam.

The siphon priming system consists of two liquid ring seal vacuum pumps, a receiver tank, a water level tank, and associated piping, valves, and controls. The vacuum pumps, tanks, and controls are located in an existing gate house. A vacuum breaker valve is located on the penstock at the upstream vertical-to-horizontal bend.

The powerhouse is of reinforced concrete construction founded on bedrock. The generating unit is a vertical, submersible type, with a semi-Kaplan turbine, a planetary-type speed increaser and a vertical induction generator. The generator is connected to the utility grid through the switchgear and transformer. The turbine and penstock system is dewatered by opening the vacuum breaker valve.

The plant is operated on a run-of-river basis to maintain a constant headwater level. Flows in excess of the combined capacity of both generating units and an adjacent water supply tunnel pass over the dam.

The unit is controlled by a programmable logic controller located in the gate house. The facility is fully automated and operates unattended.

APPENDIX E
PINE GROVE DAM HYDROELECTRIC STATION

PINE GROVE DAM HYDROELECTRIC STATION

The Pine Grove Dam Hydroelectric Station is located in Little Britain Township, Lancaster County, Pennsylvania, on the north bank of Octoraro Creek. The power plant was constructed at the existing Pine Grove Dam in 1985 and has a single 511 kW, 39 ft head generating unit.

The intake is an inverted morning glory type. Inclined trashracks are provided in the vertical wall of the intake structure on three sides of the intake. The trashracks are manually raked.

The penstock has a nominal diameter of 72 inches, and is of fabricated steel construction in the intake and siphon area. The 1,048 ft section of penstock between the siphon and the powerhouse is constructed of prestressed concrete cylinder pipe. The upstream portion of the penstock is horizontal from the intake structure to the dam embankment where it is buried and follows the upstream slope of the dam. The penstock bends to a horizontal position at the crown of the siphon then enters the siphon priming structure foundation, which is located near the right abutment of the dam. Downstream of the siphon priming structure, the penstock becomes exposed, bends downward, and follows the downstream slope of the embankment. The joint between steel and concrete penstocks, and the remaining downstream concrete penstock, are buried.

The siphon priming system consists of two rotary, liquid ring seal vacuum pumps, a vacuum tank, and associated piping, valves, and controls. An ejector, which operates with water from a nearby water main, provides siphon priming in the event of loss of power supply to the vacuum pumps. Prior to priming the siphon, the long section of penstock downstream of the siphon crown is filled from headwater using an eight-inch priming line, which itself is primed by the main vacuum system. The vacuum pumps, tank, and ejector are located in the siphon priming structure.

The generating unit has a semi-Kaplan tubular turbine with a butterfly valve at the turbine intake. The generator is a horizontal induction type driven through a parallel shaft speed increaser.

The turbine is dewatered by closing the inlet valve and installing stoplogs at the draft tube exit. The penstock system is drained by opening the six-inch vacuum breaker valve on the vent pipe in the siphon priming structure.

The plant is operated on a modified run-of-river basis to meet water supply requirements. Power generation is programmed to vary according to calendar months and reservoir level. The unit is automatically controlled by a programmable controller. An operator is required to initiate the siphon priming operation.

APPENDIX F

POCONO LAKE HYDROELECTRIC PROJECT

POCONO LAKE HYDROELECTRIC PROJECT

The Pocono Lake Hydroelectric Project is located in Pocono Lake Preserve, Monroe County, Pennsylvania at the north abutment of the existing dam and bridge on Tobyhanna Creek. The power plant, which has one 59 kW, 24.5 ft head unit and two 113 kW, 23.8 ft head units, went into operation in 1986.

The plant has a single penstock with an inclined bellmouth intake opening. The intake has a steel frame trashrack structure with bar panels on the top, bottom, and three sides. A 12-inch deep timber grid is mounted under the top of the trashrack frame to prevent vortex formation. The top and side panels of the trashrack are cleaned with a hand rake. There is no access for cleaning the bottom trashrack panel.

The penstock has a nominal diameter of 5 ft with a trifurcation to the generating units near the powerhouse. The penstock is made from prefabricated sections with flanged and bolted field joints. The upstream portion of the penstock is angled at approximately 45 degrees and is supported at the apex of the siphon on the existing spillway crest. The portion of the penstock between the spillway crest and the trifurcation is inclined at 20 degrees to horizontal, and has structural steel supports. The branches from the trifurcation also have structural steel supports.

The overall length of the penstock from the intake to the trifurcation is approximately 39 ft, and the distance from the intake to the crown of the siphon is 17 ft. The two 4 ft diameter branches of the trifurcation are approximately 38 ft long, and the 3 ft diameter branch is about 35 ft long.

The siphon priming system consists of a liquid ring seal vacuum pump and associated piping, valves, and controls. The controls are housed in the electrical control building, which is located adjacent to the existing spillway training wall. The vacuum pump is outdoors adjacent to the control building.

The generating units are vertical submersible type with fixed discharge propeller turbines and induction generators. The units are connected to the electrical grid through the switchgear and the transformer.

An inlet butterfly valve is provided upstream of each turbine and is the primary flow control for each unit. The turbines are dewatered and isolated from the penstock by closing the inlet valve. The penstock system is drained by stopping the siphon effect with the vacuum breaker valve.

The plant is operated on a run-of-river basis to maintain a constant headwater level. Flood flows in excess of the capacity of the units pass over the spillway. The units are automatically controlled by a programmable controller located in the control building. An operator is required to initiate the siphon priming operation and for dewatering the siphon penstock.

APPENDIX G

SCHAADS RESERVOIR HYDROELECTRIC PROJECT

SCHAADS RESERVOIR HYDROELECTRIC PROJECT

The Schaads Reservoir Hydroelectric Project is located in Calaveras County, California on the Middle Fork of the Mokelumne River. The power plant, which was constructed at the existing Middle Fork Dam, has a capacity of 240 kW and operates at a head of 90 ft. The project was operational in 1986.

The plant has a single penstock with a rectangular box-shaped intake screen. The intake screen is 3 ft wide by 4 ft high by 3 ft deep and is constructed of aluminum bars. The intake is submerged 25 ft below normal water level, and has no provision for cleaning.

The penstock is made from 30 inch steel pipe with butt welded joints. The portion of the penstock upstream of the crest, including the intake, follows the shape of the existing ground. A 152 ft section at the crest of the siphon, which passes through the core of the dam, has a 1 ft thick reinforced concrete encasement. Except for a short section near the powerhouse, the remainder of the penstock is buried.

The overall penstock length is 717 ft, and the distance from the intake to the crown of the siphon is approximately 71 ft. A 30 inch butterfly valve is installed in the penstock immediately upstream of the siphon crown.

Normal static water level is at the crown of the siphon; therefore, the siphon may be filled by gravity by opening the inlet valve upstream of the siphon crown. A portable, gasoline engine-driven vacuum pump is attached to the two-inch air valve at the crown of the siphon to prime the system when the reservoir level is below the invert of the siphon. A vacuum relief valve is provided immediately downstream of the siphon crown to prevent the negative pressure in the penstock from exceeding minus 10 ft of water.

The powerhouse has a concrete substructure, and a woodframe upper level with wood roof trusses and a metal roof. The generating units, controls, transformer, and battery charger are located within the powerhouse. The generating units have horizontal, fixed-discharge "reverse pump" type turbines each with a hydraulic-actuated inlet butterfly valve. One turbine drives a 20 kW induction generator. Two other turbines are connected by a belt-drive system to a common 220 kW induction generator.

The turbines can be dewatered by closing the inlet valves. The penstock system is drained by closing the valve upstream of the siphon crown and opening the air vent at the crown of the siphon.

The plant is operated in a peaking mode. A pressure-operated bypass valve maintains the required minimum releases when all the units are off. The existing outlet works are used to provide the required minimum releases when the siphon is not primed. Flood flows in excess of the capacity of the units pass over the spillway.

The units are automatically controlled by water level sensors, a programmable timer, and relays. The siphon priming operation is initiated by an operator.

SECOND BROAD RIVER HYDROELECTRIC PROJECT

SECOND BROAD RIVER HYDROELECTRIC PROJECT

The Second Broad River Hydroelectric Project is located near Forest City, North Carolina at an existing dam on the Second Broad River. The facility went into operation in 1986 and has three 112 kW, 20 ft head units.

Each of the three units has a siphon penstock with a conical intake which extends down into the water at a 55-degree angle. The trashrack structure, which surrounds the three penstocks, is constructed of floor grating with steel supports. The plant has an automatic trash rake; however, an operator is required for trash removal. The penstocks are welded steel construction each with a nominal diameter of 4.33 ft. Each penstock is constructed from two prefabricated sections with a site welded joint. The penstock section downstream of the siphon crown drops vertically to a submersible generating unit which is bolted to the end of the penstock. A concrete slab at the top of the dam supports the penstocks and acts as a thrust block. A concrete support is also provided on the downstream side of the dam at the bottom of the penstocks.

The overall length of each penstock is 44.5 ft, and the distance from the intake to the crown of the siphon is 14.5 ft.

The three penstocks have a common siphon priming system consisting of a positive displacement lobe type vacuum pump and associated piping, valves, and controls. Vacuum breaker valves are located at the crown of the siphon on each penstock.

Each generating unit is integral with and supported by the siphon penstock. A cross beam supported by two concrete piers provides additional support for the generating units. Two of the units have semi-Kaplan turbines, and one has a fixed discharged propeller turbine. The generators are induction type driven through planetary speed increasers. Five-foot long draft tubes, bolted to the end of the turbines, direct discharge back into the river.

Each siphon penstock is dewatered by opening the vacuum breaker valve at the crown of the siphon.

The plant is operated on a run-of-river basis to maintain a constant headwater. Flood flows in excess of the combined capacity of the units pass over the dam.

The units are automatically controlled by a programmable controller located in the switchgear house. The vacuum pump automatically initiates the siphon priming operation during startup.

Because of mechanical difficulties with the three submersible generating units, the three units were subsequently replaced with a single propeller-type hydraulic turbine. However, the three siphon penstocks were retained.

APPENDIX I
SUPERIOR DAM POWER STATION

SUPERIOR DAM POWER STATION

The Superior Dam Power Station is located in Ann Arbor, Michigan on the left bank of the Huron River. The power plant, which has a single 570 kW, 14 ft head unit, was constructed at the existing Superior Dam adjacent to the spillway radial gate chute and went into operation in 1986.

The intake consists of a horizontal Y-shaped transition to the single penstock. The intake has a vertical opening with vertical rack bars. There is no direct access for rack cleaning.

The penstock is of steel-lined reinforced concrete construction with a nominal inside diameter of 8 ft. The penstock is made from prefabricated sections with rubber gasketed bell and spigot-type joints. The upstream portion of the penstock is angled at about 20 degrees and follows the contour of the dam. This section of penstock is continually supported on a sand and gravel bed and is secured in place with concrete blocks and metal tie straps. At the crown of the siphon, the penstock has a 45-degree bend, which is encased in a reinforced concrete thrust block. The penstock is buried between the thrust block and the powerhouse. An access road for the dam passes over the penstock on the downstream side of the thrust block.

The overall penstock length is 150 ft, and the distance from the intake to the crown of the siphon is 56 ft.

The siphon priming system consists of two liquid ring seal vacuum pumps, a vacuum tank, and associated piping, valves, and controls. The vacuum pumps, tank and controls are located within the powerhouse, with a four-inch line connecting the vacuum system with the priming valve at the crown of the siphon. A vacuum breaker valve is also located at the crown of the siphon.

The powerhouse is founded on soil and has a reinforced concrete substructure and superstructure, and a metal roof. The generating unit is an inclined axis tubular unit with an adjustable blade propeller turbine with adjustable wicket gates. The generator is an induction type driven through a parallel shaft speed increaser. The turbine is controlled by an electronic positioner. The generator is connected through switchgear and a step-up transformer to the electrical grid.

Draft tube stoplogs are provided for dewatering the turbine waterpassages. The waterpassages are isolated from the headwater level by breaking the siphon in the penstock.

The excavated tailrace channel directs water flow back into the river.

The plant is operated on a run-of-river basis to maintain constant headwater level. Flows in excess of the turbine discharge are handled by the radial spillway gate. Flood flows in excess of the combined capacity of the unit and the gate pass over the ungated barrel arch spillway.

The unit is automatically controlled by a programmable controller in the powerhouse. An operator is required to initiate the siphon priming operation.

TIERCKENKILL FALLS HYDROELECTRIC PROJECT

TIERCKENKILL FALLS HYDROELECTRIC PROJECT

The Tierckenkil Falls Hydroelectric Project is located in Rensselaer, New York on the south bank of Mill Creek approximately 500 ft downstream from an existing dam. The subsurface powerhouse contains one 23 kW unit and one 55 kW unit, each rated at 105 ft head. The plant went into operation in 1986.

The intake, which is a horizontal extension of the penstock, consists of nine 12-inch wide vertical openings cut half way around the intake pipe. The intake openings are covered with 20 gauge, 1/2-inch galvanized wire screen which is fastened to the pipe with stainless-steel bands. There are no trash handling facilities at the intake.

The penstock is high density polyethylene pipe with a nominal inside diameter of 1.36 ft. The penstock sections have butt-fusion joints, and flanged joints at the anchor blocks. The vertical upstream portion of the penstock, which is connected by a 90-degree bend to the horizontal intake pipe, conforms to the shape of the dam. Heavy steel, horseshoe-shaped collars secure the intake and upstream penstock to the dam. The downstream portion of the penstock follows the contour of the streambed for approximately 200 ft and then bends 45 degrees to head overland toward the powerhouse. A portion of the overland penstock is covered by a shallow embankment. Concrete anchor blocks are provided immediately downstream of the dam, about 200 ft downstream of the dam, and at the powerhouse. Chain type restraints are also provided at strategic locations.

The overall penstock length is 532 ft, with a distance of 12 ft from the intake to the crown of the siphon.

The siphon priming system consists of a rotary vane vacuum pump, a vacuum tank, and associated piping, valves, and controls. The aboveground control building adjacent to the powerhouse contains the vacuum pump, tank, and controls. The priming valve, located at the dam, is connected to the crown of the siphon by three-inch piping. The vacuum system is connected to the priming valve by a nominal two-inch polyethylene pipe.

The subsurface powerhouse is a prefabricated concrete modular structure which extends from the ground surface to below the streambed. The generating units have vertical "reverse pump" turbines each with a pneumatically operated inlet butterfly valve and direct-connected vertical induction generator. The generators are connected to the utility grid through the switchgear and the station transformer.

The penstock system is drained by opening the vacuum breaker valve in the priming valve enclosure at the dam.

Discharge from the turbines is directed back into the creek through the two outfall pipes.

The plant is operated on a run-of-river basis and maintains constant headwater level allowing a flow of at least one cfs over the weir at the crest of the dam for aesthetic purposes. Flood flows in excess of the combined capacity of the units and the weir pass over the dam.

The units are automatically controlled by a programmable logic controller located in the control building. An operator is required to initiate the siphon priming operation. The vacuum priming system thereafter functions automatically to maintain operational readiness even during extended periods of inoperation.

APPENDIX K

TRAICAO HYDROELECTRIC PROJECT

TRAICAO HYDROELECTRIC PROJECT

The Traicao Hydroelectric Project is a pumping/generating plant located near Sao Paulo, Brazil, on the Pinheiros Canal between the Tiete River and the Rio Grande Reservoir. The power plant has four 2000 kW, 21 ft head units which were installed in 1944, 1946, 1957, and 1977.

Each of the four units have siphon intakes (in the turbine direction) which are integral with the concrete powerhouse substructure. The intakes are similar in configuration to an inverted elbow draft tube. Each intake has a rectangular cross section with the intake opening inclined at an angle 15 degrees from vertical. Trashracks are provided at each intake opening.

The overall length of each penstock is 107.5 ft, and the distance from each intake to the crown of the siphon is 63.5 ft.

The powerhouse has a reinforced concrete substructure with a steel superstructure. Each pump/generating unit has a vertical, axial flow, adjustable-blade propeller type pump-turbine. The pump-turbines have no wicket gates, and flow is stopped by breaking the siphon. The motor-generators are a direct connected, vertical synchronous type. The turbines are controlled by a hydraulic governor. The motor-generators are connected to the utility grid through the switchgear and the station transformers. The siphon is primed using vacuum pumps, and two vacuum breaker valves are provided at each unit for breaking the siphon.

The turbine waterpassages are dewatered by installing stoplogs in the intake and draft tube waterpassages.

The plant is mainly operated as a pumping station and operates as a generating facility when the Rio Grande Reservoir has excess water.
