Appendix A Nominal ILAW Inventory

TWRS O&UP Case 3 by LAW feed batch with offgas losses

(Components are decayed to starting date.

units are Ci for radionuclides and kg-mol for chemicals)

Appendix A Nominal tLAW Inventory
TWRS&UP Case 3 by LAW feed batch with offgas losses
(Components are decayed to starting date,
units are Ci for radionuclides and kg-mol for chemicals)

Batch	Starting Date	Total m3 glass	Processing Days	Days to fill cask	Al(OH)4- kg-mol	Al+3 kg-mol	As+5 kg-mol	B+3 kg-mol	Ba+2 kg-mol	Be+2 kg-mol	Bi+3 kg-mol	Ca+2 kg-mol	Cd+2 kg-mol	Ce+3 kg-mol	Cl- kg-mol	CO3-2 kg-mol	Cr(OH)4- kg-mol	Cr(TOTAL) kg-mol	Cs+ kg-mol

Appendix A Nominal ILAW Inventory

TWRS O&UP Case 3 by LAW feed batch with offgas losses

(Components are decayed to starting date,
units are Ci for radionuclides and kg-mol for chemicals)

Appendix A Nominal ILAW Inventory

TWRSO&UP Case 3 by LAW feed batch with offgas losses

(Components are decayed to starting date.

units are Ci for radionuclides and kg-mol for chemicals)

Appendix A Nominal ILAW Inventory

TWRS0&UP Case 3 by LAW feed batch with offgas losses

(Components are decayed to starting date,

units are Ci for radionuclides and kg-mol for chemicals)

Appendix A Nominal ILAW Inventory

TWRS0&UP Case 3 by LAW feed batch with offgas losses

(Components are decayed to starting date,

units are Ci for radionuclides and kg-mol for chemicals)

Batch	Starting Date	Total m3 glass	Processing Days to fill cask	Days	235-U	236-U	237-Np	238-Pu	238-U	239-Pu	240-Pu	241-Am	241-Pu	242-Cm	242-Pu	243-Am	243-Cm	244-Cm	Ag+

Appendix A Nominal ILAW Inventory
TWRS&UP Case 3 by LAW feed batch with offgas losses
(Components are decayed to starting date,
units are Ci for radionuclides and kg-mol for chemicals)

Appendix A Nominal ILAW Inventory

TWRS O&UP Case 3 by LAW feed batch with offgas losses

(Components are decayed to starting date,
units are Ci for radionuclides and kg-mol for chemicals)

Appendix A Nominal ILAW Inventory

TWRS O&UP Case 3 by LAW feed batch with offgas losses

(Components are decayed to starting date,

units are Ci for radionuclides and kg-mol for chemicals)

Appendix A Nominal ILAW Inventory

TWRS&UP Case 3 by LAW feed batch with offgas losses

(Components are decayed to starting date,

units are Ci for radionuclides and kg-mol for chemicals)

Appendix A Nominal /LAW Inventory

TWRS&UP Case 3 by LAW feed batch with offgas losses

(Components are decayed to starting date.

units are Ci for radionuclides and kg-mol for chemicals)

Appendix A Nominal ILAW Inventory

TWRS O&UP Case 3 by LAW feed batch with offgas losses

(Components are decayed to starting date,

units are Ci for radionuclides and kg-mol for chemicals)

Appendix A Nominal ILAW Inventory
TWRS O&UP Case 3 by LAW feed batch with offgas losses
(Components are decayed to starting date,
units are Ci for radionuclides and kg-mol for chemicals)

Appendix A Nominal ILAW Inventory

TWRS&UP Case 3 by LAW feed batch with offgas losses

(Components are decayed to starting date,

units are Ci for radionuclides and kg-mol for chemicals)

Appendix A Nominal ILAW Inventory
TWRS&UP Case 3 by LAW feed batch with offgas losses
(Components are decayed to starting date,
units are Ci for radionuclides and kg-mol for chemicals)

Batch	Starting Date	Total m3 glass	Processing Days	Days to fill cask	Al(OH)4- kg-mol	Al+3 kg-mol	As+5 kg-mol	B+3 kg-mol	Ba+2 kg-mol	Be+2 kg-mol	Bi+3 kg-mol	Ca+2 kg-mol	Cd+2 kg-mol	Ce+3 kg-mol	Cl- kg-mol	CO3-2 kg-mol	Cr(OH)4- kg-mol	Cr(TOTAL) kg-mol	Cs+ kg-mol

Appendix A Nominal ILAW Inventory
TWRS O&UP Case 3 by LAW feed batch with offgas losses
(Components are decayed to starting date,
units are Ci for radionuclides and kg-mol for chemicals)

Appendix B

Additional Information on Biases and Uncertainties for Selected Radionuclides

Discussion on Selected ILAW Inventory Components

Tritium. The global and model estimates for tritium are highly dependant on vapor/liquid partitioning assumptions that distribute tritium between airborne releases, process condensate releases to cribs and evaporator bottoms sent to the tanks. The HDW model assumes that 100 percent of tritium in fuel is routed to tank wastes. Due to losses to atmosphere and condensate, actual tank inventories are significantly less.

The best basis inventory (tank by tank summation) includes some tritium sample-based estimates for individual tanks, but nearly all values are estimated by the HDW model. Since most of the best-basis values are from the HDW model the best basis inventory is expected to be conservative relative to the actual inventory.

No tritium is expected to survive the vitrification process to end up in the ILAW packages (Kirkbride 1999). Tritium is expected to be discharged from the pretreatment and waste vitrification facilities in the process condensates as tritiated water. The excess process condensates that are not recycled are routed to Effluent Treatment Facility.

Carbon-14. The activation product ^{14}C is produced primarily from neutron activation of nitrogen impurities in the fuel and cladding. Most of the individual tank best-basis estimates and all of the global inventory are derived from HDW model results (Kupfer 1999). HDW predictions of ^{14}C production have a likely bias of 0.80. Additional uncertainty may exist, associated with losses of ^{14}C to atmospheric emissions (Harmsen 1998).

Nickel-59 and Nickel-63. These radionuclides are generated by neutron activation of nickel impurities in the fuel cladding. Nearly all the best basis inventory values are derived from the HDW model results. Beginning in 1959 the aluminum alloy fuel cladding contained 9,000 to 13000 ppm nickel. Prior to1959 the fuel cladding alloy contained no more than 100 ppm nickel. The HDW model assumes a constant 800 ppm, thus ^{59}Ni and ^{63}Ni activation products are biased high for pre-1959 wastes and biased low for post 1959 wastes. Modeling of the effect of this variation in nickel impurity in the fuel cladding resulted in higher total inventory values by a factor of 1.18 for ^{59}Ni and a factor of 1.35 for ^{63}Ni (Harmsen 1998). The best basis inventory is considered accurate although few sample results are available.

Co-60. The ORIGEN2 estimates for activation product, ^{60}Co, assume a cobalt impurity level of 10 ppm in cladding and 0 ppm in core uranium. Since the actual levels of cobalt in uranium are unknown but probably not zero, it is predictable that the HDW model results are low. Improved modeling of the cobalt impurity increased the HDW tank inventory by a factor of 2.75. The best-basis tank sum is considered to be the more accurate estimate, since almost half of the tank sum is based on sample data.

Selenium-79. Most of the best-basis (tank-by-tank summation) and all of the global inventory estimate for ^{79}Se are based on the HDW model. Recent Chinese measurements indicate the half life of ^{79}Se should be increased from 0.65×10^5 years to 8.05×10^5 years (Harmsen 1998). Curie values for ^{79}Se based on the HDW model can be reduced by about a factor of twelve by using the updated half life value. ORIGEN2 based calculations of ^{79}Se production should be reduced by a

factor of 0.85 to account for a lower fission yield. The total tank inventory is considered to be conservative, since it neglects previous removals such as cribbing.

Strontium-90 and Yttrium-90. The tank summation and global inventories for ^{90}Sr agree within 20%. These inventories account for the quantity of ^{90}Sr separated in B-Plant and routed to capsules, offsite, plant residuals, and solid waste. The majority of the tank summation inventory is based on samples.

Zirconium-93, Niobium-93m, Cadmium-113m, Tin-126, and Samarium-151. The ^{93}Sr, ^{93m}Nb, ^{113m}Cd, ^{126}Sn, and ^{151}Sm values in the best basis inventory are almost entirely derived from the HDW Rev 4 model and are subject to the model limitations. The HDW model over-estimates the distribution of these isotopes to tanks 241-AZ-101 and 241-AZ-102 based on the special ORIGEN2 run for these tanks and under-estimates the inventory of these isotopes in the rest of the tanks. The tank-by-tank summation corrects the inventory of 241-AZ-101 and 241-AZ-102 but does not adjust the inventory of the rest of the tanks (i.e., HDW values are used). The result is that the best-basis inventory slightly under-estimates the ^{93}Zr, ^{93m}Nb, ^{113m}Cd, ^{126}Sn, and ^{151}Sm inventories (Kupfer 1999).

The HDW curie value of ^{126}Sn should be reduced by a factor of 0.4 to account for a recently updated half life value, and by a factor of 0.78 to account for better fission yield value (Harmsen 1998). The HDW calculated values for ^{113m}Cd should be reduced by a factor of 0.66 to account for better fission yield and cross section values (Harmsen 1998).

Technetium-99. The best basis value for ^{99}Tc agrees reasonably well with the process knowledge based (global) estimate. The best basis value is likely the more valid since the global estimate does not account for known losses of ^{99}Tc that occurred during fuel separation operations (Kupfer 1999).

There is good evidence that 20% or more of the technetium produced was lost to the waste stream during initial fuel reprocessing, mainly co-processed with the UO_3 and sent offsite, but with minor losses to the environment as well (Schmittroth 1995).

The HDW global inventory for ^{99}Tc may be biased high by about 32% due to it's not accounting for the fractional separation of Tc to the uranium product stream in the uranium recovery, PUREX and REDOX processes (cribbing, offsite shipment, U contaminant). Approximately 60% of the tank summation inventory is based on the HDW model (Kupfer 1999).

The batchwise ILAW inventory for Case 3 from the TWRSO&UP meets the Phase 1 contract specifications for average activity, but not the 80% removal requirement.

Ruthenium-106. Ninety-nine percent of the ^{106}Ru inventory is found in tanks 241-AZ-101 and 241-AZ-102 (Kupfer 1999).

Antimony-125. Eighty-nine percent of the ^{125}Sb inventory is found in tanks 241-AZ-101 and 241-AZ-102. The best basis inventory estimates from the special ORIGEN2 run for these tanks shows about 25 percent more ^{125}Sb than does the global (HDW model) for these tanks. The

^{125}Sb best-basis inventory of the rest of the tanks is nearly all from the HDW model values (Kupfer 1999).

Iodine-129. The best-basis of ^{129}I is somewhat larger than the global estimate. The global (HDW model) estimate conservatively assumes that all of the ^{129}I in the fuel was routed to the waste tanks. Thus the reason for the higher tank sum is not inherently obvious. The difference could be due to sample error, but is likely not due to underestimated model values. Both best basis and global inventory values are likely to be significantly higher than actual values (Kupfer 1999).

The calculated ^{129}I production in the fuel could be reduced by a factor of 0.76 to account for a better fission yield value (Harmsen 1998).

Cesium-134. Then ^{134}Cs values in the best-basis inventory are primarily derived from the HDW Rev 4 model and are subject to the model limitations. The HDW model slightly under-estimates the distribution of ^{134}Cs to tanks 241-AZ-101 and 241-AZ-102. The tank-by-tank summation corrects the inventory of 241-AZ-101 and 241-AZ-102 but does not adjust the inventory of the rest of the tanks. The result is that the best-basis inventory slightly under-estimates the ^{134}Cs inventory (Kupfer 1999).

The TWRSO&UP inventory as currently configured does not remove ^{134}Cs or Cs+ from the LAW feed along with ^{137}Cs removals. Therefore the ^{134}Cs and Cs+ values were adjusted so that the ILAW to BBI ratios were the same as for ^{137}Cs. This adjustment was applied to the Appendix HA values.

Cesium-137 and Barium-137m. The ^{137}Cs inventory in the ILAW is constrained by the BNFL Inc. Phase 1 contract specifications.

The best-basis values for ^{137}Cs and ^{137m}Ba agree with the global values.

Europium-152. The ^{152}Eu values in the best-basis inventory are primarily derived from the HDW Rev 4 model and are subject to the model limitations. The HDW model overestimates the inventory of ^{152}Eu to tanks 241-AZ-101 and 241-AZ-102 based on the special ORIGEN2 run for these tanks and underestimates the ^{152}Eu inventory in the rest of the tanks. The tank-by-tank summation corrects the inventory of 241-AZ-101 and 241-AZ-102 but does not adjust the inventory of the rest of the tanks, i.e., HDW values are used. Tanks 241-AZ-101 and 241-AZ-102 contain 28 percent of the ^{152}Eu inventory. The result is that the best-basis inventory slightly underestimates the ^{152}Eu inventory (Kupfer 1999).

Europium-154. The best basis of ^{154}Eu is significantly larger than the global estimate. The global ^{154}Eu estimates for 241-AZ-101 and 241-AZ-102 from the HDW model are 30 percent lower than the best-basis ORIGEN2 estimates. Tanks 241-AZ-101 and 241-AZ-102 account for 40 percent of the best-basis inventory. The balance of the best basis inventory, which includes sample values and engineering estimates is about 25 percent higher than the balance of the global HDW model estimate (Kupfer 1999).

Europium-155. The best basis of ^{155}Eu is significantly larger than the global estimate. The ORIGEN2 estimates of ^{155}Eu in tanks 241-AZ-101 and 241-AZ-102 are about 90 percent higher than the respective global (HDW model) estimates. The best basis inventory uses an ORIGEN2 ^{155}Eu value for 241-AZ-101 and a HDW model value for 241-AZ-102. The engineering estimate for 241-AZ-102 included a sample-based heel inventory of ^{155}Eu that was determined to be ludicrous. Most of the best-basis estimates for the remaining tanks (152) are from the HDW model with only 23 tanks based on sample data or engineering estimates. The best basis inventory of the remaining tanks is about 23 percent higher than the balance of the global HDW model estimate (Kupfer 1999).

Neptunium-237. The best-basis value for ^{237}Np is about 30 percent higher than the global ^{237}Np estimate. This difference appears to be due to the ^{237}Np inventories in 241-AN-103 and 241-AN-105 which account for 30 percent of the best-basis total tank inventory. The best-basis values for these two tanks are the largest contributors to the tank-summation value and are several times larger than the values estimated by the HDW model. The best-basis values for 241-AN-103 and 241-AN-105 are based on "bounding value estimates" that are derived from analytical detection limit data (Kupfer 1999).

For most of the Hanford processing history, more than 70% of the neptunium was recovered (Schmittroth 1995).

The HDW global inventory for Np may be significantly uncertain due to the use of approximate factors, which account for extraction losses (Harmsen 1998).

Plutonium-238, -239, -240, -241, -242. Plutonium inventories in the BBI are primarily based on accountability records and samples. The tank sum ^{239}Pu and ^{240}Pu inventories are significantly higher than those estimated by the global inventories.

Americium-241 and –243, and Curium-242, -243, and –244. The tank summation inventories for this group of radionuclides are significantly higher (50 percent to 3-fold) than those estimated by the global model (HDW). Comparisons of sample based and model predicted ^{241}Am inventories for selected tanks suggests that sample results are biased high. This could be the reason for the tank summation inventory of ^{241}Am being 1.5 times greater than the global model prediction. A major reason for the discrepancy in sample versus model based inventory values for ^{243}Cm and ^{244}Cm is traced to sample results for tank 241-AW-105. Here the sample based inventory is essentially equivalent to the model based inventory for all 177 tanks. The large sample based inventory value for tank 241-AW-105 appears to be an anomaly since the other zircaloy cladding waste receiver tank (241-AW-103) contains 4000 fold less by sample determination. There is possibility of analytical errors for both Am and Cm isotopes (Kupfer 1999).

Uranium-233, -234, -235, -236, and –238. Many of the uranium isotopic inventory estimates are based on the total uranium analysis of samples. The global basis uses accountability and sample data, with the result that global inventory values closely match tank summation values. These inventories are significantly lower than those estimated from total uranium by the HDW Rev. 4 model. The HDW model assumes that significant amounts of TBP (uranium recovery

process) waste remain in the tanks while sample results and observations from Rodenhizer (1987) and MacCready (1957) confirm that recovery of uranium was more efficient (Kupfer 1999).

Thorium-232. There are no analytical data for ^{232}Th. The best-basis tank summation thus reflects HDW inventory values which are about two-fold higher than estimates based on accountability measurements made during the thorium fuel processing campaigns in 1966 and 1970 (Kupfer 1999).

Radon-226, Actinium-227, Radon-228, Thorium-229, and Protactinium-231. The tank summation inventories for these isotopes (alpha decay chain daughters of ^{232}Th, ^{233}U, ^{234}U, and ^{235}U) are based essentially on the HDW model estimates, due to lack of any direct analytical data from samples. The estimate for these daughter radionuclides is in error due to the lack of proper second-order decay functions in the HDW model. With the exception of ^{228}Ra, these daughter nuclides are expected to slowly buildup in Hanford tank wastes, not reaching peak activity levels until thousands of years in the future (Kupfer 1999).
The HDW model performs separations of uranium, plutonium, and neptunium after decaying the reactor production values to 1/1/1994, rather than at the time of fuel separation. Thus, the uranium, plutonium, and neptunium decay daughters ^{226}Ra, ^{227}Ac, ^{228}Ra, ^{229}Th, ^{231}Pa, and ^{232}Th, are overpredicted by as much as a factor of 50. Conversely, the ^{233}U that builds in from the decay of ^{237}Np is removed along with the rest of the uranium in the HDW model, resulting in a ^{233}U prediction that is low by as much as a factor of 84 for some tanks (Harmsen 1998).

Tungsten and Thorium. For the tungsten and thorium components, there were no batch inventories or Best Basis tank inventories. For these cases, the global estimate (Kupfer 1999) was the only inventory.

Appendix C

Radioisotope Half Lives

Radioisotope Half Lives

Table C-1 lists the half life values from the ORIGEN2 library. These are the half lives used in generating the input to the HDW model from the reactor production. Slightly different half lives may have been used for other steps in arriving at the ILAW inventories.

Table C-1. Half Lives from ORIGEN2 Library for Selected Radionuclides

Isotope	Half-life, years
3-H	1.23E+01
14-C	5.73E+03

Appendix D

Comparison with Interim PA ILAW Inventory

Comparison with Interim PA ILAW Inventory

Table D-1 compares the nominal ILAW inventory values from Table 4.2 and the bounding ILAW values from Table 4.3 with the ILAW inventories developed for the Interim PA (Schmittroth 1995). Some of the differences can be attributed to the contract controls on components such as ^{137}Cs, ^{90}Sr, ^{99}Tc, and TRU. Other differences can be attributed to different assumptions on the losses to product and removals during the fuel processing and on the fraction of the tank waste components that are incorporated into the ILAW product.

Table D-1. Comparison of Nominal and Bounding ILAW Radionuclide Inventory with Interim PA Inventory.

Component	Nominal Total Ci	Upper Bound Total Ci	Interim PA ILAW Inventory Ci
3-H	0.00E+00	2.46E+04	8.94E+04
14-C	0.00E+00	4.38E+03	7.73E+00

Appendix E

Quality Assurance

Quality Assurance

Quality assurance for this report is provided through the following peer review process. A peer review plan was established that identified three technical reviews to be performed on the Inventory Data Package for the Immobilized Low-Activity Tank Waste Performance Assessment. Fluor Daniel Northwest, Inc. (FDNW) was responsible for an internal review of the document. The Pacific Northwest National Laboratory (PNNL), Numatec Hanford Company (NHC), and Lockheed Martin Hanford Company (LMHC) were responsible for the Hanford technical reviews of this document. NHC is responsible for the TWRSO&UP inventory studies. LMHC is responsible for developing the BBI inventories. PNNL is responsible for the privatization regulatory DQO.

The Hanford reviewers, upon completion of their reviews, provided the author (D. Wootan) with written documentation of their comments. Acceptance of the comment resolutions was indicated by reviewer's signature on the Engineering Data Transmittal (EDT).

The peer review members were selected based on their experience and knowledge of specific subject areas. The internal peer review was provided by Donald Hammervold and R. Puigh. Bruce Higley was chosen from NHC to provide the technical review based on his knowledge of the TWRSO&UP inventory studies. Robert Watrous was chosen from LMHC for his knowledge of BBI inventory studies. Karyn Wiemers was chosen from PNNL for her knowledge of the characterization requirements for the LAW feed.

EXECUTIVE SUMMARY

The current Immobilized Low-Activity Waste (ILAW) disposal planning utilizes the existing disposal vaults from the grout program suitably modified to receive ILAW packages and new disposal facilities currently in their early design phase. The existing disposal vaults were originally constructed by the former grout program in the late 1980's and early 1990's. These vaults were designed to contain a liquid low-level waste (LLW) grout mixture during the curing and solidification period, and to serve as a disposal structure for the resulting grouted waste monolith. Five vaults were constructed. One vault was filled before termination of the program leaving four empty vaults available for use.

Each vault is 37.6 m (123.5 ft) long and 15.4 m (50.5 ft) wide, with a roof clearance of 10.4 m (34.0 ft), providing 579 m^2 (6,236 ft^2) of floor space. The vaults are constructed of reinforced concrete, and were designed and constructed in compliance with RCRA requirements for both hazardous waste surface impoundments and land disposal units. Each vault is built above a RCRA-compliant leak detection and collection system. The leak detection system consists of a sealed concrete slab sloped to a collection sump fitted with a riser pipe to the surface. The system is capable of collecting, detecting, sampling, and removing any leachate that might escape from the primary vault structure.

A conceptual design activity has been performed to modify the existing disposal vaults to accept and ultimately serve as a disposal facility for the ILAW from the Hanford waste tanks (Pickett 1998a). The existing asphalt layer and concrete "topping" layer above the precast concrete roof slabs will be removed from the four available vaults. For each vault, side wall and end wall extensions 1.8 m (6.0 ft) high will be added to the original top of the side and end walls, respectively. To support the unloading of ILAW packages from the transportation vehicles, rails for a gantry crane are to be placed on top of the side wall extensions and will run the full length of the vaults.

A conceptual design for the new ILAW disposal facilities (Pickett 1998b) utilizes a long concrete vault concept divided into cells. Each vault will be an underground, open-topped, concrete vault approximately 23 m (76 ft) wide and 207.8 m (686 ft) long. The total vault height was increased to 11.0 m to accommodate the new waste package dimensions. The top of the vault walls will extend 1 m (3.3 ft) above grade. Each vault will be divided into 11 cells, separated by concrete partition walls

Each vault is built above a RCRA-compliant leak detection and collection system. It consists of a cast-in-place reinforced concrete basin approximately 209.5 m (687.3 ft) long, 24.7 m (81 ft) wide with walls 1.07 m (3.5 ft) high. The basin floor is 0.6 m (2 ft) thick and contains steel reinforcing bars within. The catch basin is lined with two flexible membrane liners, and on top of these lie a layer of gravel with perforated collection pipe routed to sumps, one at each end of a vault. Liquids entering the sump can be removed by use of a portable pump lowered down a riser pipe.

Interim closure for each filled cell in the new disposal facility will consist of using inert backfill material followed by a "controlled density fill," unreinforced concrete. A waterproof membrane will be placed above the "controlled density fill." After all cells in the vault have been filled and interim closed, a closure cap consisting of a capillary break followed by a modified RCRA C cap will be placed over the entire vault. A similar closure is assumed for the existing disposal vaults. Each vault will be interim closed using the process used for the cell closure for the new disposal facility. After all vaults have been filled and interim closed, a similar closure cap will be placed over all four vaults.

The design for the ILAW disposal facilities has not yet been finalized. Facility uncertainty cases have been identified that may impact disposal performance. Alternate concepts for disposal of the ILAW waste are still being considered. Alternate trench concepts are provided to explore the sensitivity of the proposed ILAW disposal performance to different disposal concepts. In December, 1999 the Department of Energy has identified the remote handled trench as the baseline concept for ILAW disposal at Hanford.

1.0 INTRODUCTION

Based on the Hanford Federal Facility Agreement and Consent Order (Tri-Party Agreement) (Ecology 1996) the U.S. Department of Energy (DOE) and River Protection Project (RPP) team are proceeding with engineering activities to support the eventual disposal of low-activity waste from the Hanford underground storage tanks. The Tank Waste Remediation System (TWRS) Environmental Impact Statement (EIS) (DOE 1996) and the subsequent Record of Decision (ROD) (DOE 1997) stipulate that the low-activity portion of the tank waste shall be vitrified.

The DOE Order 5820.2A (DOE 1988) provided early guidance and requirements for the disposal of radioactive waste on a DOE site. This Order has been superceded by DOE Order 435.1 (DOE 1998a). One requirement in both Orders is the need to develop and maintain a site-specific performance assessment for the proposed disposal facility. This performance assessment must provide reasonable assurance that public health and environmental resources will be protected consistent with local, state, and federal regulations.

The Hanford Immobilized Low-Activity Tank Waste Performance Assessment (DOE 1998b) was issued in 1998 to provide the first formal performance assessment in support of the eventual disposal of low-activity tank waste at Hanford. The analyses within this report used two conceptual facility models (Eiholzer 1995) based on early project planning. Since that time there has been an evolution in the planning for this proposed disposal action. Specifically, the DOE has entered into a contract with BNFL, Inc. that will ultimately lead to the vitrification of approximately 8.6% (6000 packages of 70,000 [Kirkbride 1999]) of the current low-activity waste from the underground tanks. The DOE has proposed that four existing grout vaults be modified and ultimately used for the disposal of the low-activity tank waste (Burbank 1999). Finally, a conceptual design has been developed for new disposal facilities for the low-activity tank waste [Pickett 1998b].

The purpose of this report is to provide a description of the waste package and disposal facilities based on the latest information. This information will be used in the next performance assessment to support the development of models used to assess the overall system performance in meeting established performance objectives (DOE 1998b). This performance assessment is currently scheduled to be issued in 2001. Data on the waste form will be taken from the current BNFL, Inc. planning and contract requirements (BNFL 1998, Taylor 1999). Data on the facility design will be taken from the planned modification to the existing grout vaults (Pickett 1998a) and the conceptual design developed for the new disposal facility (Pickett 1998b). Data on the engineered barriers will be taken from the current draft version of the disposal facility closure plan (Hohl 1998).

2.0 LOW-LEVEL WASTE PACKAGE

The DOE has entered into a contract with BNFL, Inc. to design and ultimately process approximately 9% of the ILAW from the Hanford tanks. (The contract identifies a minimum of 6,000 packages and Kirkbride (1999) estimates approximately 70,000 ILAW packages are

needed for all the ILAW). The product description and specifications defined in this section are based on the current DOE contract (DOE 1998b) and the BNFL, Inc. reports submitted to the DOE as part of the contract negotiations. The definition of the product form and specification for the remaining 91% of the Hanford tank waste is not defined at this time. For the purposes of the ILAW Performance Assessment activities, all the ILAW waste products are assumed equivalent to the BNFL, Inc. descriptions and DOE specifications identified in this first contract.

The ILAW product for the first phase to be provided by BNFL, Inc. consists of a silicate glass monolith sealed in a stainless-steel package. The headspace above the silicate glass in the package is filled with silicate sand (BNFL 1998). The stainless steel package has external dimensions of 1.4 m x 1.4 m x 1.4 m, -0 m/+0.05 m (tolerances). The stainless steel wall thickness of the package is 6 mm. The package top is 12 mm plate and the bottom is 8 mm plate. BNFL, Inc. plans to load each ILAW package to within 85% capacity (by volume) and fill the void space with silicate sand such that the remaining free fill space is less than 5% (by volume). (BNFL , Inc. is also considering an alternative inert filling material that may be introduced in liquid form, such as grout.) The top lid will be welded using the tungsten-inert gas (TIG) process. The waste package data are summarized in Table 1. Other canister geometries for the waste package are currently being considered (see section 6.1).

The current contract with BNFL, Inc. (DOE 1998b) also places the following restrictions on the waste packages. The accessible external surface temperatures of the waste package shall not exceed 50° C. The packages shall contain no detectable free liquid. The compressive strength of representative samples shall be equal to or greater than 3.45E6 Pa. At least 75% of the initial compressive strength shall be retained after samples are subjected to thermal degradation, radiation degradation, biodegradation, and immersion degradation. Each fully loaded package shall be able to withstand a compression load of 100,000 kg force.

3.0 DISPOSAL FACILITY DESIGNS

Two disposal facility designs have been developed for the disposal of ILAW product. The first ILAW disposal facilities are currently planned to be the four existing Grout Vaults that will be modified to accept the ILAW waste packages (Pickett 1998a). The Grout Vaults will hereafter be referred to as the existing disposal vaults. The new ILAW disposal facilities are currently designed to consist of rows of concrete cells located below grade. These two facility designs will be used to hold ILAW waste packages generated under the current contract between DOE and BNFL, Inc. (DOE 1998b). Future disposal facility designs may include trench disposal, the reuse of processing canyon facilities, and the reuse of the storage tanks. The analyses of any of these options will be performed in future performance assessments, once plans are developed. A limited examination of trench disposal will be considered as part of the uncertainty cases for the next ILAW Performance Assessment.

In this section, a description of the current facility design concepts for the disposal of ILAW waste packages is provided. For the purposes of the 2001 PA there are the only two design concepts. Therefore, sufficient new disposal facility trenches having the current design

(Pickett 1998b) are assumed to be available for the disposal of ILAW from the Hanford waste tanks.

Table 1: Waste Form and Canister Data for the 2001 PA

Silicate Glass Monolith Dimensions: 1.4 m x 1.4 m x 1.2 m (85% waste fill fraction) Minimum Surface Area: 10.6 m^2 (degree of cracking an uncertainty parameter) Glass composition : to be determined Glass corrosion rate: to be determined
Canister Data Material: stainless steel Shape: rectangular prism (1.4 m x 1.4 m x 1.4 m) Wall Thickness: side walls 6mm bottom 8mm top 12mm Number of canisters: 68741*
Canister Fill Data (by free volume) Void space: <5% Glass Monolith: 85% Silicate Sand: 10 - 15% (depends on void space)

*Reference (Kirkbride 1999)

3.1 Existing Disposal Facility

The major components of the existing disposal facility design are the below-grade disposal vaults, the under-vault catch basin, the asphalt diffusion barrier, and the leachate detection, collection, and removal system. The vault and catch basin structures constitute a double-liner composite system. An elastomeric asphalt urethane coating on the vault interior and the concrete vault structure were initially installed to provide the primary composite liner. The secondary composite liner, located below the vault, is the concrete catch basin covered with a high-density polyethylene (HDPE) flexible membrane liner. An asphalt diffusion barrier surrounds each vault. The leachate detection, collection, and removal system allow monitoring of the system's performance during operations prior to closure.

Construction of the original Grout Vaults was completed in 1995. Specifications for these vaults and their construction are documented in (Koci 1994). A conceptual design study was completed in 1998 that described how the vaults could be modified to accommodate currently planned ILAW waste packages (Pickett 1998a). Materials used in the original construction are specified in Koci 1994.

3.1.1 Location

The existing disposal facility lies east of AP tank farm and Canton Avenue, north of Hanford grid coordinate N40000, west of W45000, and south of N41500 (see Figures 1 and 2). The existing disposal facility is at the western edge of the Tank Waste Vitrification Area.

3.1.2 Design

The dimensional data for the existing disposal facility are summarized in Table 2.

Table 2: Dimension Data Summary for Existing Disposal Facility

Concrete Structures			
Basin:			
	Bottom footprint (edge):		20.3 m x 41.3 m
	Bottom edge elevation:		185.6 m (609 ft) [maximum]
	Bottom thickness:		0.6 m (minimum)
	Height:		1.7 m (bottom edge to top of basin side wall)
Vault:			
	Bottom:	outside	39.6 m x 18.6 m
		Inside	15.4 m x 37.7 m
	Bottom edge elevation:		186.5 m (612 ft)
	Thickness:		1.4 m
	Sidewalls:		11.7 m high (measured from bottom of vault)
	Thickness:	N/S walls	0.8 m
		E/W walls	1.4 m bottom
			0.5 m top
Diffusion Barrier			
	Bottom thickness:		0.9 m
	Sidewall:		
		Height:3-sides	11.1 m (measured from bottom of vault)
		East side	10.3 m
		Thickness:	1.0 m

3.1.2.1 Concrete Catch Basin

The foundation for the four concrete catch basins consists of an 46 cm (18-in.) asphalt pavement laid on top of an 46 cm (18-in.) base of asphalt-coated gravel. The diffusion barrier material is placed in 15 cm (6-in.) layers over the subgrade. See Koci 1994 for specifications of the lower diffusion barrier materials.

The concrete catch basin is constructed of reinforced concrete. Its major components are concrete, having a compressive strength of 316 kg/ cm^2 (4,500 lb/in^2), Grade 60 reinforcing steel, having an ultimate tensile strength of 4218 kg/ cm^2 (60,000 lb/in^2), and ASTM A36 steel-plate water stops. See Figure 3 for the detailed design of the concrete catch basin.

The concrete catch basin is the foundation for the lower flexible membrane liner (FML). This liner is a 0.15 cm (60-mil) thick HDPE sheet placed directly on the concrete surface of the catch basin. The catch basin is cleaned of dirt and debris prior to liner placement. The basin is formed to provide a 20 cm (8-in.) radius on inside corners and a 5 cm (2-in.) radius on outside corners. The radiused corners keep the basin stress concentrations to a minimum. The basin surface in contact with the flexible membrane liner is given a steel trowel finish. The HDPE liner was fabricated from large pieces of sheeting to proper size and shape, keeping field joints to minimum. Corner pieces were preformed to proper size and shape at the factory. The seam welding technique was qualified for both shop and field work.

The HDPE liner is compatible with the radiation field intensity at the catch basin (DOE-RL 1988). It was installed by qualified personnel experienced in liner installation. Particular care was taken to ensure that liner sections were correctly seamed.

3.1.2.2 Leachate Detection, Collection, and Removal System (LDCRS)

A 10 cm (4-in.) perforated steel leachate collection pipe is laid in the catch basin trough, on top of the HDPE liner. The pipe is covered with a geotextile fabric that will prevent gravel infiltration, but allow liquids to drain from the liner into the perforated pipe and leachate collection system. A layer of small gravel then is placed in the catch basin to a thickness of 0.3 m (1 ft) near the edges of the basin and 1.2 m (4 ft) at the low point of the trough. The gravel is washed and sieved before placement to remove fines and large rocks. Care is taken in handling and placing drainage gravel to prevent contamination that could be caused by blowing sand and debris. Contamination by fine material could cause a reduction in permeability that would slow the leachate movement and lengthen detection time. A geotextile is laid over the gravel to prevent seepage of concrete into the drainage gravel during the vault floor construction. A temporary plastic sheet was placed over each catch basin to protect the catch basin geotextile and gravel prior to vault construction. The perforated collection pipe leads to an embedded pipe and sump. The pipe and sump liner are carbon steel. Sump access is through a 66 cm (26-in.) access riser. See Figures 3 for details.

3.1.2.3 Concrete Vault

The below-grade concrete disposal vaults are of rectangular design and are constructed to the American Concrete Institute (ACI), *Concrete Sanitary Engineering Structures*, ACI 350R-83 (ACI 1983c) requirements.

The vault is built on top of the gravel layer of the LDCRS. The vault is constructed of reinforced concrete having a compressive strength of 316 kg/ cm^2 (4,500 lb/in^2) Grade 60 reinforcing steel, having an ultimate tensile strength of 4218 kg/ cm^2 (60,000 lb/in^2), and ASTM A36 steel plate water stops. The original vault roof was constructed of concrete plates laid on top of the vault. See Figure 4 for details.

The following construction techniques were used to ensure that the vault concrete cracks are minimized:

- Replacing 15% of the cement with pozzolan (fly ash). The reduced cement helps reduce the heat of hydration and the pozzolan densifies the concrete.

- Using ice when necessary to ensure that the plastic concrete has a maximum temperature of 70° F at time of placement .

Using insulated forms or curing blankets to minimize thermal gradients during the curing period.

- Using a low water to cement ratio.

The exterior sides of the vault are covered by the exterior drainage system. This system is formed by a drainage net (HDPE geogrid) and a nominal 0.15 cm (60-mil) HDPE flexible membrane liner. A 5 cm (2-in.) thickness of insulation and geotextile were placed against the exterior drainage system of the catch basin before placing the asphalt paving diffusion barrier. Liquids entering this system from the vault are drained to the LDCRS.

3.1.2.4 Diffusion Barrier

The diffusion barrier was placed under each catch basin and vault as part of the foundation, and around the sides and top of each vault with a minimum thickness of 1 m (40-in.). The diffusion barrier controls the diffusion of moisture into the vault, and the diffusion of radio-active and hazardous contaminants from the vault.

The bottom portion of the diffusion barrier under the first four vaults is made of a 46 cm (18-in.) thick layer of asphalt-coated gravel placed on compacted soil, then an 46 cm (18-in.) thick layer of asphalt pavement.

3.1.2.5 Soil Backfill

Backfill material around the vaults is withdrawn from stockpiled excavated soils and will be compacted to 90% maximum dry density in accordance with ASTM D1557.

3.1.2.6 Modifications to the Exiting Disposal Vaults

The modifications to the existing disposal vaults to support waste package emplacement will include demolition of the roof portions of each original grout vault and modifications to the vault side walls and LDCRS.

To uncover the four existing grout vaults (218-E-16-102 through 218-E-16-105), an approximate area of 107 by 137 m (350 by 450 ft) from the existing grade elevation of 200 m

(656 ft) to a 198 m (649.5 ft) elevation will be excavated. A slope of 1-½:1 from the 200 m (656 ft) elevation to new grade will be maintained around this area. In addition to removing compacted backfill around the vaults, the excavation consists of removing and hauling the following materials to the Richland Landfill:

1. The 1.0 m (3-ft 4-in.) deep asphalt and concrete topping (diffusion break) above the vaults, 0.6 m (2-ft) deep by 1.0 m (3-ft 4-in.) wide asphalt covering around three sides of the vaults, and 1.4 m (4-ft 6-in.) deep by 1.0 m (3-ft 4-in.) wide asphalt covering on the east side of each vault will be excavated. The existing concrete vault pits and pump pits located on the top of each vault will be removed. Existing piping and conduits embedded within the asphalt topping and HVAC inlet on each vault will be removed before hauling the asphalt. The HVAC exhauster and ductwork located between Vaults 102 and 103 and above their roofs will also be removed.

2. The precast concrete cover blocks (1.2 m (4-ft) wide by 16.6 m (54-ft 6-in) long by 0.7 m (2-ft 2-in) thick) that make up each vault roof will be removed.

3. Leachate concrete pump pit, located on the east side of each vault, will be removed. Existing 66 cm (26 in.) pipe to leachate collection sump and 21 cm (8 in.) pipe for leak detection will be cut to the new grade level to maintain the functionality of the leak detection system. Both of these pipes will be provided with new blind flanges.

4. Existing electrical concrete duct banks and manholes with existing cables will be removed.

5. The interior floor and wall surfaces of vaults are coated with an asphaltic coating. Because the coating contributes to the fire loading in the vaults, it must be removed. Removal of the coating will be done by mechanically scraping it from the concrete surfaces or by sandblasting.

The existing walls of each vault will be extended 1.8 m (6 ft) high to provide shielding. Extended concrete walls will taper in thickness from 0.6 m (2 ft) at the base of the existing wall to 0.5 m (1-ft 6-in.) at the top for north and south sides of vaults (Figure 5). The extended concrete walls will remain 0.8 m (2.5 ft) thick for east and west sides of vaults. The vertical rebar of the existing concrete walls will be exposed to splice them mechanically with the new rebar of the wall extension.

Figure 5 shows the waste package loading for package dimensions of 1.2 m x 1.2 m x 1.8 m.

Given the current ILAW waste package dimensions (1.4 m x 1.4 m x 1.4 m), each existing vault will be capable of holding 25 x 10 packages in a given layer and a total of 7 layers in a given vault. Therefore, each existing disposal vault will hold 1750 packages.

Eighty pound (80-lb) American Society of Civil Engineers (ASCE) rated rails will be provided on top of the north and south walls for each vault for a 15-ton gantry crane. These rails will be extended for approximately 14.6 m (48 ft) into the waste package delivery/crane maintenance area. The rails in this area will be supported by W14 steel beams and 46 cm (18-in.) square, concrete columns.

3.2 New ILAW Disposal Facility

The current design for the new ILAW disposal facility consists of a set of disposal vaults located in the south-central part of the 200 East Area (see Figure 1). Each waste disposal vault will be an underground, open-topped, concrete vault approximately 23 m (76 ft) wide, and 207.8 m (686 ft) long. The total vault height was increased to 11.0 m to accommodate the new waste package dimensions. The top of the vault walls will extend 1 m (3.3 ft) above grade. A removable shield wall will extend an additional 1 m (3.3 ft) above the top of the vault walls to support vault loading. Each vault will be divided into 11 cells, separated by concrete partition walls. Underneath the vault will be a concrete catch basin with a leachate detection and collection system.

Each cell being filled will have a moveable, bridge-crane equipped, Gantry Building over it. Two Gantry Buildings are planned for the facility. The Gantry Building will remain in place over a cell after it is filled with ILAW packages to aid in performing partial closure of the cell.

Each vault is built above a RCRA-compliant leak detection and collection system. It consists of a cast-in-place reinforced concrete basin approximately 209.5 m (687.3 ft) long, 24.7 m (81 ft) wide with walls 1.07 m (3.5 ft) high. The basin floor is 0.6 m (2 ft) thick and contains steel reinforcing bars within. The catch basin is lined with two flexible membrane liners, and between these liners lie a layer of gravel with perforated collection pipe routed to sumps, one at each end of a vault.

3.2.1 Location

Approximately 36 hectares (90 acres) of land is allocated for the ILAW Disposal Facility in 200-East Area southwest of PUREX (202-A Building) between 1st and 4th Streets and west of Canton Avenue bounded on the east at coordinate E574653 and on the west at coordinate E574170 (Figures 1 and 6). The land is considered uncontaminated and vacant (Burbank 1997).

The preferred alternative has the storage vaults/trenches oriented with their length in a north–south direction and the Control/Administration Building located at the northwest corner along 4th Street (see Figure 7). In this alternative, the site is divided along its length into three segments. The north segment will be set aside for waste disposal vaults and will include one vault for Phase 1 and the Control/Administration Building. The middle segment will be set aside for a combination of disposal vaults and/or trenches. The south segment will be set aside for waste disposal trenches, although vaults could be constructed. Each segment will be enclosed by

chain link security fencing with 3-strand barbed wire. For the 2001 PA base analyses, all vaults are assumed to be concrete vaults as described below.

3.2.2 Design

The dimensional data for the new ILAW disposal facility vaults are summarized in Table 3.

3.2.2.1 Site Work

For Phase 1 construction and operation, portions of the site (approximately 15 hectares [37.5 acres]) will be cleared, grubbed, and leveled to facilitate the construction of one disposal vault, the Control/Administration Building and parking area, perimeter and service roads, and perimeter fence and lighting (Figure 6). Clearing and grubbing will involve complete removal and disposal of all brush, roots, and other deleterious materials. Several hectares of mature sagebrush will be affected by this construction activity.

Table 3: Dimensional Data Summary for the New ILAW Disposal Facility

Concrete Structures		
Basin		
	bottom footprint (edge):	24.7 m x 209.5 m
	bottom edge elevation* :	187.1 m (613.8 ft)
	bottom thickness:	0.6 m (minimum)
	height:	1.7 m (5.5 ft)(bottom edge to top of basin side wall)
Vault		
	Bottom : outside	207.8 m x 23.0 m
	inside cell	18.3 m x 21.0 m
	Bottom edge elevation*:	188.0 m (616.8 ft)
	Thickness:	1.0 m
	Side walls	11.0 m (high** measured from bottom of vault)
	Outer wall thickness:	1.0 m
	Cell wall thickness:	0.45 m

* Grade elevation assumed to be 198 m
**See Section 5.2 for discussion

3.2.2.2 Concrete Catch Basin

The concrete catch basin is part of the secondary containment for the leachate collection system (Figure 8). The catch basin is cast-in-place reinforced concrete, approximately 209.5 m

(687.0 ft) long, 24.7 m (81 ft) wide with walls 1.07 m (3.5 ft) high. The basin floor is 61 cm (24 in.) thick and reinforced with 2.2 cm (.88-in.) steel reinforcing bars at 20 cm (8 in.) on center, top, and bottom both ways. The catch basin floor slopes at 2% towards a trench in the center. The trench slopes toward each end of the basin from the center. The interior dimensions of the concrete catch basin extend a minimum of 25 cm (10 in.) beyond the vault walls. This allows the basin to catch any leachate that may leak through either the vault floor or the walls.

The catch basin is lined with two flexible membrane liners (FML). The upper FML serves as the primary liner; the lower FML, along with the concrete catch basin, serves as the secondary composite liner. The liner material for the FML will be high-density polyethylene (HDPE).

The concrete catch basin serves as the foundation for the FML. The interior concrete surfaces will be formed to provide a 20 cm (8-in.) radius on inside corners and a 5 cm (2-in.) radius on outside corners. Concrete surfaces in contact with the FML will have troweled finishes.

A layer of gravel that serves as a portion of the leachate collection system is placed over the primary liner. The vault is then built on top of these components.

3.2.2.3 Leachate Detection Collection and Removal System (LDCRS)

The leachate collection pit leak detection system can detect liquids that leak into the leachate collection system. The leachate system will be monitored in the control room.

A perforated collection pipe and a layer of gravel placed over the primary liner allows collected liquids to drain to a sump at either end of the vault for sampling and removal. Liquids entering the sump will be detected by instrumentation during the facility operation phase. Samples can be removed by lowering a sample collection device down the leachate riser. Leachate could be removed by use of a portable pump lowered down the riser pipe. Collected liquids will be pumped to a portable tank for disposal. The leachate collection system is shown in Figure 8.

Between the two FML layers is a drainage net that allows any liquid trapped between the liners to drain freely to a sump at either end. This sump is separate from the leachate collection sump, and liquids in the two sumps cannot mix. Liquids entering the sump will be detected by instrumentation and removed by a portable pump lowered down a riser pipe. Collected liquids will be pumped to a portable collection tank for testing and disposal.

3.2.2.4 Concrete Vault

The current underground, reinforced concrete vault design is approximately, 23 m (76 ft) wide, 207.8 m (686 ft) long, and 9.1 m (29.8 ft) deep (outer dimensions, see Figure 9). The elevation of the vault bottom is 186.5 m (612 ft) with respect to sea level. The vault wall will

extend 1 m (3.3 ft) above grade to act as a barrier against the tractor/trailer transport vehicle and to keep away any water run-off. The top of the vault extension walls will have slots (320 mm [12.8 in.] wide by 320 mm [12.8 in.] high) in the center. Removable shielding walls will be inserted in these slots before placement of waste packages into the cell. The north–south tractor/trailer drive-through on each side of the vault will be paved with asphalt. Gravel aprons will be provided on the east and west sides of the Gantry Buildings to allow for vehicle traffic past the outside of the building. The exterior walls and the concrete base will be 1 m (3.3 ft) thick. The vault will be divided into 11 cells, separated by 0.45 m (1.5 ft) thick concrete partition walls.

Figure 9 shows that waste package loading assuming the waste package dimensions are 1.2 m x 1.2 m x 1.8 m. Given the currently planned waste package dimensions, each cell will be capable of holding 12 x 14 packages in a given layer. A total of 6 layers are planned for a given cell. This will require extending the total height of the vault by 1.9 m for the ILAW performance assessment calculations. For the ILAW analysis the vault is assumed to extend only 1.0 m above the grade. Therefore, the elevation of the vault bottom is 188.0 m (see Table 4). The grade elevation at the new facility site is assumed to be 198.0 m (649.5 ft). The vault is sized to contain 1008 ILAW packages (1.4 m x 1.4 m x 1.4 m) per cell. The total vault capacity is 11,088 packages.

4.0 ENGINEERED BARRIERS AND SOIL

The closure cap system is an essential part of the overall disposal system. As such, the closure cap system design must be addressed as an integral part of the design for the overall disposal facility system and developed in parallel with the other major parts of the system. The functional objectives, design requirements, and associated performance goals for the closure cap system must be defined accordingly.

The following subsections provide a more detailed description of the regulatory guidance and requirements guiding the closure cap system design.

Current conceptual design work for both the existing and new ILAW disposal facilities indicates the closure cap barrier system will be composed of a layered assemblage of different barriers. Refer back to Figure 10 for a cross-sectional illustration of the concept used for the current conceptual design. The general configurations for both the existing and new disposal facilities are shallow-land burial systems using a vault enclosure for the emplaced waste products. The vault enclosure would be surrounded by a layered system of engineered barriers.

The closure cap will sit on top of the temporary closure cover of the vault. Each layer within the closure cap will be sloped with a two percent grade to allow runoff and minimize erosion. A barrier overhang will be used to control potential water infiltration problems at the edges of the barrier. "Barrier overhang" is the terminology used to describe the projection of the functional barrier surface beyond the perimeter of the waste zone. The barrier overhang will extend 6 m (9.7 ft) beyond the edge of the disposal vault. Beyond the barrier overhang, the barrier layers above the low-permeability layer(s) will extend further but at a steeper slope of 3:1

(horizontal:vertical) until they reach the existing ground elevation. The grading fill layer of the barrier located underneath the low-permeability layer(s) will extend beyond the barrier overhang as well. This layer will support the other 3:1 sloped layers extending beyond the barrier overhang.

The specific choice of barrier materials, barrier thickness, and degree of capping barrier slope are all still subject to change. They will be tailored to the function and performance requirements for these uppermost layers as the design and performance assessment work progresses. Figure 11 provides a cross-sectional elevation view of the closure cap barrier system concept. This or a similar barrier layer system will be built over the vaults following completion of waste emplacement, backfilling, and then temporary and final roofing of the vault. The approximate height of this assemblage of barriers would be at least 1.7 m (5.6 ft) (BHI 1996). Table 4 provides a comprehensive summary of the key functions and characteristics of each of the proposed barrier layers for this particular concept.

Detailed assessments of four surface barrier designs that constitute potential generic remedial alternatives for 200 Area waste sites were assessed in a recent focused feasibility study (BHI 1996). The designs presented in this study were as follows:

Hanford Barrier. Designed to provide 1,000-year isolation of waste sites containing Greater than Class C Low Level Waste (LLW), Greater than Class C mixed waste, and significant inventories of transuranic (TRU) constituents.

Modified RCRA Subtitle C Barrier. Designed to provide 500-year isolation of waste sites with dangerous waste, Category 3 LLW, Category 3 Low Level (LL) mixed waste, and Category 1 LL mixed waste (see Table 5).

Standard RCRA Subtitle C Barrier. Designed to provide 30-year isolation of dangerous waste sites.

Modified RCRA Subtitle D Barrier. Designed to provide 100-year isolation of waste sites with Category 1 LLW and nonhazardous/nonradioactive solid waste.

The Modified RCRA Subtitle C Barrier is assumed to be the appropriate surface barrier design for the ILAW disposal facilities. This assumption is based on the following information:

The ILAW disposal facilities will not contain significant quantities of TRU constituents nor LLW with greater-than-Class C activity.

The proposed disposal facilities may contain waste regulated as dangerous waste, but this may not apply if the waste is delisted. However, the ILAW disposal facilities will contain LLW with Category 3 activity.

4.1 Partial Closure Activities

Partial closure activities for the new ILAW disposal vaults will consist of constructing a temporary closure cover over an individual disposal cell within a vault after the cell is filled with ILAW packages. This will be done for each disposal cell within a vault. The Gantry Building will remain over the cell until the temporary closure cover is installed. The purpose of this temporary barrier will be to prevent infiltration of water from the time that the cell is filled to when the final closure cap is added. A final closure cap will be constructed once all of the cells within a vault are filled and the Gantry Buildings are moved from the vault.

The following activities will occur for each cell once it is filled with ILAW packages:

Concrete shield covers (1.4 m x 1.4 m x 0.3 m) are placed above waste packages

Empty spaces between the rows of waste packages will be filled with a filler material (assumed to be sand).

The top surface of the concrete shield covers will be covered with 0.1 m (4 in) (minimum) of a filler material (assumed to be sand).

The filler material layer will be covered by 0.5 m (1.6 ft) of controlled density fill.

The temporary shielding walls above the extension walls of the cell will be relocated to the next cell. The slots of the cell wall where the temporary shielding walls were located will be filled with controlled density fill.

A temporary geomembrane liner will be laid over the cell after controlled density fill has been placed to prevent rain water intrusion. Once the liner is placed, the Gantry Building can be moved from the cell.

This partial closure activity is assumed to also apply to the existing disposal vaults.

Table 4: Summary of Modified RCRA Subtitle C Barrier Layers

Layer No.[1]	Thickness cm (in.)	Layer Description	Specifications	Function
1	50 (20)	Silt loam topsoil with pea gravel admix	McGee Ranch silt loam containing 15 wt. % pea gravel, 2.36 to 9.5 mm in diameter, conforming to ASTM D448 No. 8 aggregate; to be placed at a bulk density of approximately 1.46 g/cc.	The topsoil material was identified for optimal water retention properties and should provide a good rooting medium for cover vegetation. The pea gravel is designed to minimize wind erosion of the silt loam without significantly affecting its moisture retention capabilities.
2	50 (20)	Compacted topsoil	McGee Ranch silt loam without pea gravel, compacted to 90% of optimum dry density as determined by standard Proctor test; in-place bulk density will be approximately 1.76 g/cc.	Same as Layer 1. Layer 2 provides a supplemental soil moisture storage capacity. Compaction of this layer is intended to retard the rate of infiltration of soil moisture. The extended residence time of moisture in Layer 2 will increase the amount of moisture removed by evapotranspiration.
3	15 (6)	Sand filter	Clean, screened sand meeting the following particle sizes: D_{15} = 0.15 to 0.50 mm, D_{50} = 0.375 to 1.2 mm, and D_{85} = 0.70 to 2.5 mm.	This layer is part of a two-layer graded filter designed to prevent the migration of topsoil particles into Layer 5.
4	15 (6)	Gravel filter	Clean, screened aggregate meeting the following particle sizes: D_{15} = 1.5 to 2.0 mm, D_{50} =15 to 20 mm, and D_{85} <37.5 mm.	Same as Layer 3.
5	15 (6)	Lateral drainage aggregate	Naturally occurring aggregate, minus 32-mm (1 1/4-in.) material, conforming to the grading identified in WDOT M41-10,	The lateral drainage layer will intercept and divert moisture along a 2% slope to the margin of the cover for collection

Layer No.[1]	Thickness cm (in.)	Layer Description	Specifications	Function
			9-03.9(3) for base course, with D_{10} >1 mm and k >1 cm/s.	and/or discharge.
6	15 (6)	Asphaltic concrete with spray-applied asphalt coating	Asphaltic concrete, consisting of asphalt conforming to WDOT M41-10, 9-02.1(4) - Grade AR-4000W, and aggregate with particle size gradation conforming to ASTM C 136. Asphalt will make up 7.5 wt. % of total mixture. A spray-applied, styrene-butadiene asphalt material will be sprayed onto the asphaltic concrete surface in two layers, each 100 mils thick minimum.	This layer will function as a hydrologic barrier and as a biointrusion barrier.
7	10 (4)	Asphalt base course	Crushed aggregate, minus 16-mm (5/8-in.) diameter material, conforming to WDOT M41-10, 9-03.9(3) for top course surfacing material.	The function of the material in this layer is to provide a stable base for placing and supporting the asphalt layer.
8	Variable	Grading fill	Clean, bank run sand and gravel conforming to WDOT M41-10, 9-03.18.	This layer will provide a smooth, level subgrade for construction of the overlying layers.

[1] Barrier layers are listed in sequence from top to bottom (BHI 1996)

4.2 Closure Cover Installation

This section provides a general description of the techniques used for the installation of the closure cap. The closure cover for the existing vaults will be continuous over all four units while individual covers will be used for the new ILAW vaults. The closure cover for the existing vaults will use the shielding berm for the high point of the cover and one direction over all four vaults. Individual covers over each new disposal vault are planned because separate excavations are planned for construction of each vault, which requires that they be separated a greater distance to allow for clearance of the 1-1/2 to 1 excavation slopes. A continuous cover over these vaults would result in consumption of excessive quantities of material. The closure cover installation process will consist of the following tasks.

Gravel will be added to obtain a two percent slope. The height of this gravel layer will be such that the total cap thickness at the edge of the vault is 5 m (as per NRC requirements [10CFR61]).This layer will be smoothed to establish a smooth, planar-base surface for accurate and controlled placement of the overlying layers. A 10 cm (4 in.) thick asphalt base course will be placed over the gravel. This base course layer will provide a stable base for placement of the overlying low-permeability asphalt layer. Grade stakes are used to ensure that thicknesses and overall slopes are maintained.

The next task will be the installation of a water infiltration barrier. The asphaltic concrete mixture will be specially formulated to produce a minimum hydraulic conductivity and will be applied 15 cm (6 in.) thick. A spray-applied asphalt will then be applied over the layer to seal any voids or defects in the surface. This layer will function as a low-permeability barrier as well as an intrusion barrier. A slope of two percent will carry infiltration to the layer edges where it will enter the surrounding soil. The asphalt will prevent burrowing animals from reaching the waste and will act as a barrier against inadvertent intrusion by man.

Next, a 15 cm (6 in.) thick layer of drainage gravel will be laid down. The function of this layer will be to allow moisture that reaches this layer to laterally migrate to the barrier edge.

The next task will be the installation of a two-layer graded filter layer. The first of these two layers installed will be a 15 cm (6 in.) thick gravel filter layer. The gravel in this layer will be sized to be compatible with the lateral drainage gravel layer below and the forthcoming sand filter layer above. Once the gravel filter layer is installed, a 15 cm (6 in.) thick sand filter layer will be installed. The purpose of these two layers is to prevent topsoil particles from moving downward and clogging the lateral drainage layer.

After the filter layers are installed, a 50 cm (20 in.) thick layer of compacted topsoil will be installed. This layer will supplement the moisture storage capacity of the layer to be installed above it. The material used for the topsoil will be McGee Ranch silt loam without pea gravel. The topsoil will be compacted to 90 percent of optimum dry density as determined by standard Proctor test. The in-place bulk density of the topsoil will be approximately 1.76 g/cm^3.

Another 50 cm (20 in.) thick layer of topsoil will be installed next. This layer also contains McGee Ranch silt loam in it, but it will also contain 15 wt.% pea gravel, 2.36 to 9.5 mm in

diameter, mixed uniformly. The topsoil mixture will be placed at a bulk density of approximately 1.46 g/cm^3. The pea gravel is designed to minimize wind erosion of the silt loam without significantly affecting its moisture retention capabilities. Construction quality assurance will be conducted throughout installation of each layer to ensure that the appropriate slopes are maintained and that the desired compaction is attained.

Next, the ground will be prepared for planting and fertilized. Once this is complete, the ground will be seeded with mixed perennial grasses and planted with shrubs.

5.0 ILAW DISPOSAL FACILITY CONCEPTUAL MODELS

The existing and new ILAW disposal facility designs will form the basis for the performance assessment calculations scheduled for the 2001 PA. To facilitate these calculations, conceptual models have been developed for the base analysis case. These conceptual models incorporate the important design features impacting contaminant transport from the waste product to the far field vadose zone. From these conceptual models, numerical models will be developed to conduct the transport calculations for important waste products from the waste form to the far field vadose zone. Other numerical models will be used to calculate the transport of these released waste products through the vadose zone and the groundwater to potential receptors identified in the scenarios for the ILAW PA (Mann 1999).

The disposal facility conceptual models identify the vault geometry and layout, the planned materials of construction, and selected information on the waste packages. Additional information on the materials of construction and the near field material properties pertinent to waste product transport are provided in the near-field data packages (Meyer 1999 and Kaplan 1999). Additional information on the waste form can be found in the waste form data package (McGrail et al.1999).

For the 2001 ILAW PA, all waste packages are assumed to have the design given in Table 1 of this report. The minimum surface area for the glass monolith within each package is assumed to be 10.6 m^2 (geometric surface area of the rectangular prism 1.4 m x 1.4 m x 1.2m). Cracking that occurs within the monolith during cooling is assumed to increase the surface area available for dissolution. The initial surface area estimate is provided by McGrail 1999. The nominal void space is assumed to be 1% (by free volume). The filler material is assumed to be 14% silicate sand (by free volume).

5.1 Existing Disposal Facility Conceptual Model

Section 3.1 of this report describes the current status of the existing disposal facility design. To facilitate the numerical calculations, the vault layout and geometrical dimensions have been simplified. The layout of the existing disposal vaults is shown in Figure 12. The figure provides a top view of the vault layout and the distance between the vaults. In the conceptual model, the ancillary modifications made to the site to support the loading of the disposal vaults have been removed. Specifically, the support structure for the Gantry Building,

the rail extensions and their supporting structures for the bridge crane, and the paved and graveled areas supporting the loading of the vaults have been removed so that only backfill soil is in the immediate vicinity of the existing disposal vaults.

Figure 13 provides a simplified geometry for the existing disposal vaults. In this simplified conceptual model, the leachate tank and sampling port are assumed to be effectively closed so that they do not provide any preferential path for moisture influx or contaminant transport. The catch basin is simplified to be a rectangular pad, that is 0.6 m (2 ft) thick everywhere. The HDPE layer is ignored in the model since its function as a moisture barrier is assumed to degrade in less than 100 years. The drainage pipe to the leachate tank is also not included in the model. The vault is assumed to sit on a gravel layer that is uniformly 0.3 m (1 ft) thick. The dimensions of the conceptual model vault are the same as given in Figures 4 and 5 and as provided in Table 2.

Also shown in Figure 13 is the diffusion barrier that surrounds most of each vault. This diffusion barrier is 1 m (3.3 ft) thick on the vault side walls and 0.9 m (3.0 ft) on the bottom of the disposal vault. Between the diffusion barrier and the concrete vault a layer, composed of 5.0 cm (2 in) thermal board, geotextile and HDPE mesh, has been applied to provide a path to the LDCRS for any moisture leaving the concrete vault. This layer will be exposed during the modifications planned for these vaults. This layer is assumed to be sealed during the closure process.

The inside dimensions for each vault are 15.4 m (50.5 ft) wide by 37.6 m (123.5 ft) long by 12.2 m (40 ft) in height. One layer of waste packages corresponds to 10 x 25 = 250 waste packages. Each vault will hold 7 waste package layers. Assuming the waste package geometry is a 1.4 m cube, the spacing between each waste package (including the walls) is 9.3 cm (3.7 in) along the width dimension and 10.2 cm (4.0 in) along the length dimension. This volume is assumed to be filled with silicate sand.

The interim closure for the existing disposal vaults is assumed to be as described in Section 4 of this report (see Figure 9 for general layer description). The waste packages will be stacked 7 layers high to a height of 9.8 m (32 ft). A 10 cm (4 in) filler material layer (assumed to silicate sand) is also placed between each layer of waste packages. The concrete shield covers are assumed to be 1.4 m x 1.4 m x 0.3 m and are placed just above the top layer of waste packages. The filler material is assumed to have a depth of 1.0 m (3.3 ft) above the concrete shield covers. A "controlled density fill" consisting of a mixture of portland cement, fly ash, aggregate, water, and admixtures is then placed on top of the inert filler material layer. The depth of the "controlled density fill" is 0.45 m (1.5 ft). A waterproof membrane layer (assumed to be 60 mil HPDE is placed over the interim closed vault.

The orientation and design for the final closure cap for the existing disposal vaults is described in Section 4. The cap orientation is shown in Figure 10 and extends 6 m beyond the layout of all four existing vaults. Note that the cap is placed with its western edge on an existing shield berm and slopes downward from west to east over all four vaults. The slope of the closure mound outside the area of the cap is in a 3:1 slope to the existing ground elevation.

5.2 New ILAW Disposal Facility Conceptual Model

Section 3.2 of this report describes the current status of the new ILAW disposal facility design. To facilitate numerical calculations the vault layout and geometrical dimensions have been simplified. The layout of the new disposal vaults is shown in Figure 14. The figure provides a top view of the vault layout and the distance between the vaults. In the conceptual model, the ancillary modifications made to the site to support the loading of the disposal vaults have been removed. Specifically, the support structure for the Gantry Building, the rail extension and their supporting structure for the bridge crane, and the paved and gravel areas supporting the loading of the vaults have been removed so that only backfill soil is in the immediate vicinity of the disposal vaults. Based on the Kirkbride (1999) estimate of approximately 70,000 packages needed for disposal of all planned ILAW waste, only 6 new disposal vaults would be required to complete the disposal of all ILAW (assuming the existing disposal vaults are fully utilized).

Figure 15 provides a simplified geometry for the new disposal vaults. In this simplified conceptual model, the leachate tanks and sampling ports are assumed to be effectively sealed during closure so that they do not provide any preferential path for moisture influx or contaminant transport. The catch basin is simplified to be a rectangular pad, that is 0.6 m (2 ft) thick everywhere. The HDPE layers are ignored in the model since their function as a moisture barrier is assumed to degrade in less than 100 years. The drainage pipes to the leachate tanks are also not included in the model. The vault is assumed to sit on a gravel layer that is uniformly 0.3 m (1 ft) thick. The dimensions of the conceptual model vault are the same as given in Figures 8 and 9 and as provided in Table 3.

Each new vault is divided into 11 equivalent cells (see Figure 9). The inside dimensions for each cell are 18.3 m (60 ft) long by 21 m (68.9 ft) wide by 8.1 m (26.6 ft) in height. The vault height was assumed to be increased to 10.0 m so that the vault could accommodate 6 layers of waste packages. One layer of waste packages corresponds to 12 x 14 = 168 waste packages. Each vault will hold 6 waste package layers. Assuming the waste package geometry is a 1.4 m cube, the spacing between each waste package (including the walls) is 9.3 cm (3.7 in) along the width dimension and 11.5 cm (4.5 in) along the length dimension. This free space is assumed to be filled with silicate sand.

The interim closure for the new disposal vaults is assumed to be as described in Section 4 of this report (see Figure 9 for general layer description). The waste packages will be stacked 6 layers high. A 10 cm (4 in) filler material layer (assumed to silicate sand) is also placed between each layer of waste packages. The concrete shield covers are assumed to be 1.4 m x 1.4 m x 0.3 m and are placed on the top layer of waste packages. The filler material layer is assumed to have a depth of 0.3 m (1.0 ft) above the concrete shield covers. A "controlled density fill" consisting of a mixture of portland cement, fly ash, aggregate, water, and admixtures is then placed on top of the filler material layer. The depth of the "controlled density fill" is 0.45 m (1.5 ft). A waterproof membrane layer (assumed to be 60 mil HPDE is placed over the interim closed vault.

The orientation and design for the final closure cap for the new disposal vaults is described in Section 4. The cap orientation is shown in Figure 10 and extends 6 m beyond the layout of

each new vault. Note that the cap is shaped like an inverted "v" and placed with its apex along the length dimension (north-south) and centered over each vault. The slope of the closure mound outside the area of the cap is in a 3:1 slope to the existing ground elevation.

6.0 FACILITY UNCERTAINTY CASES

A number of assumptions are currently associated with our understanding of the disposal facilities to be used in the disposal of ILAW waste. Planning has identified concepts to be used and locations for the disposal of initial waste to be provided by BNFL, Inc. under contract to the DOE. These designs are not finalized. Also, the closure system to be used for the disposal facilities has not been finalized. Sections 3 and 4 of this report provide the facility parameters to be used in the best estimate calculations for the performance assessment. Section 5 contains the disposal facility conceptual models for the ILAW base analysis case. In this section of the report we define sensitivity cases that may be used to assess the sensitivity of the performance assessment to uncertainties in the facility design.

6.1 Waste Form Geometry

The facility conceptual design has been based on a waste package geometry of 1.2 x 1.2 m x 1.8 m. Recent BNFL, Inc. planning has been considering different dimensions and geometries for the waste package. For example Kirkbride (1999) analysis of Phase I processing has used a waste package having dimensions of 1.4 m x 1.4 m x 1.4 m. Kirkbride (1999) also refers to a cylindrical geometry having a similar volume (Taylor 1999); however the dimensions for this cylindrical form have not been finalized.

Also, the projected waste loading into the 1.4 m x 1.4 m x 1.4 m was assumed to be 2.3 m^3 of waste product. The remaining volume was assumed to be filled with a filler material. The final free volume void space in the waste package was assumed to be 1%.

The uncertainty in the waste form geometry and waste loading into the packages impacts the total inventory in a given vault. A reasonable upper bound for waste loading in the disposal vaults assumes the package geometry is 1.2 m x 1.2 m x 1.8 m and each package has 95% of the available volume filled with waste glass (BNFL 1998). This optimizes the number of packages in the disposal vaults and maximizes the waste loading in each package.

6.2 Vault Layout

The layout for the existing facilities has been established; however, the new ILAW facilities are currently in the design phase. The current design layout was based upon the results from the ILAW PA analyses (Mann 1998). However, the design layout may change. The current layout for the new ILAW facility has each trench with its longest length perpendicular to the projected groundwater flow path. An alternate orientation could have each trench with its longest length parallel to the projected groundwater flow path.

6.3 Facility Closure

The current design for the closure cap for both the existing and the new ILAW disposal facilities is described in Section 4. Alternate closure cap designs exist. For example the Hanford barrier (Myers 1994) was assumed for the last performance assessment. Another case that could be considered is when there is no closure cap installed on the disposal facility. Another closure cap case (modified RCRA C with capillary break) that should be considered is the inclusion of a capillary break beneath the asphalt layer in the modified RCRA C base design. Although such a capillary break has not been designed, the dimensions for the capillary break above the asphalt barrier are assumed. Specifically, a sand layer, 1 m (3.3 ft) thick would be immediately below the asphalt layer and the gravel layer below this sand layer would be at least 0.3 m (1 ft) thick.

Failure of the closure cap before its design life also needs to be considered. For example seismic activity or subsidence of the disposal facility could lead to a break in the closure cap.

6.4 Side Hydraulic Diverter

The earlier disposal facility conceptual design (Eiholzer 1995) included a side hydraulic diverter to channel moisture away from the facility. While the current design does not contain such a diverter, its potential incorporation into future designs cannot be dismissed. An earlier study (Mann 1995) showed the impact of such a diverter on the earlier ILAW disposal facility concepts. The side wall diverter is assumed to be a 1 m (3.3 ft) thick layer next to the concrete vault walls that extends to the bottom of the vault.

6.5 Alternate Concepts

Several alternate concepts for disposal of the ILAW have been considered by the River Protection Project. These disposal options include: reuse of the process canyon facilities, reuse of the storage tanks, and other trench disposal concepts.

Several trench concepts may be envisioned to reflect the uncertainty in the new disposal facility design. For example the current, new disposal vault geometry and vault layout could be assumed with either a concrete bottom pad or backfill soil and the side walls made of backfill soil. This vault would be installed above a leachate collection system similar to the one described later in this section. The closure cover is assumed to be equivalent to the closure cap described in Section 4.

One trench concept that is receiving additional consideration is the Remote Handled (RH) trench concept. Under the ILAW disposal alternative described below the disposal facility is a Resource Conservation and Recovery Act (RCRA) compliant landfill (i.e., double lined trench with leachate collection system). Many operational aspects and ancillary activities of the landfill (e.g., leachate collection and disposition, storm water control, installation of surface barrier at

closure, etc.) would be similar to that incorporated into the Radioactive Mixed Waste Burial Trench, which was designed and constructed under the Solid Waste Program. However, operational activities related to ILAW package receipt and emplacement in the trench would be modified to accommodate the potentially higher radiation dose rate from remote-handled ILAW.

In December, 1999 the Department of Energy identified the Remote Handled trench as the baseline concept for ILAW disposal at Hanford. The RH trench complex would be constructed in the same location as the new ILAW disposal facility. The RH trench concepdtual model is depicted in Figure 16. The RH trench internal dimensions 260 m long by 80 m wide by 10 m deep. The trench sides have a 3:1 slope. Trench construction requires excavation of 1.9×10^5 m^3. The trench liner surface area is about 2.9×10^4 m^2.

The trench is provided with a primary and secondary liner as depicted in Figure 17. Beneath both the primary and secondary liner is an admix layer (bentonite clay/soil mixture) 0.5 m and 1 m thick, respectively. The operations layer is comprised of crushed concrete and soil. The thickness of this layer is assumed to be 0.9 m (3.0ft).

The specific design shown in Figure 17 was taken from the remote maintained Radioactive Mixed Waste (RMW) Land Disposal Facility (drawing H-2-131579 Rev. 3). The primary and secondary drainage gravel are for the two drainage collection systems associated with RCRA compliant disposal facilities. Both the primary and secondary drainage layers are comprised of a geocomposite drainage layer on top of HDPE. The geocomposite cage consists of geonet bonded to geotextile. Geotextile is placed above each gravel layer. The specifications for these materials as used in the RMW Land Disposal Facility Trenches are given in WHC Project W-025 specifications (WHC1994).

Because the trench walls have a fairly shallow slope (3 m run for every 1 m rise) each successive layer can be increased in both length and width. Whereas the first layer could be 14 packages wide by 132 packages long (14 by 132 matrix), the second layer could be a 22 by 140 matrix (assuming 1.5 m center to center packing of the ILAW packages). The upper-most (4^{th}) layer could be a 42 by 160 matrix. The net result is that while a baseline new ILAW disposal facility trench capacity is 11,088 ILAW packages, the RH trench capacity could theoretically be 16,448.

Packing the ILAW packages in such large, contiguous matrix (42 by 160 packages for the 4^{th} lift [a single layer of ILAW packages and cover soil]) would, however, create operational impediments. About 100 ecology blocks would be required to create a shielding array between the leading face and operations area of the 4^{th} lift. When it became necessary to advance the ecology blocks, movement of such a large number would be a significant undertaking, potentially requiring several shifts to complete. During this period the trench would be unavailable for ILAW package receipt.

To facilitate continuous receipt operations the matrix size is limited to a smaller size than that which would contiguously cover the entire layer. These smaller sized matrices, termed burial cells, provide the following benefits.

- Corridors are created within the disposal matrix to facilitate access for operational activities such as the emplacement of cover soil
- The size of the exposed leading face is minimized
- The number of ecology blocks required to establish an effective radiation shield is reduced to a number that can easily be moved in a single shift
- A larger portion of the trench can be covered with a rain curtain, thereby reducing the quantity of collected leachate that must be dispositioned.

A conceptual layout of a trench with these burial cells is depicted in Figure 16. Specific details of the trench packing is presented in Table 5. Given this packing density, approximately 6 trenches are needed to accommodate the entire Phase 1 and Phase 2 ILAW production.

Table 5. Trench Packing Characteristics.

Layer	Cells per layer	Matrix size per cell	Packages per layer
1	2	6 x 132	1,584
2	3	6 x 140	2,520
3	4	7 x 150	4,200
4	6	6 x 160	5,760
		Total packages per trench	14,064

The details for the closure cover shown in Figure 16 have not been designed. For this report the closure cap is assumed to have the same relative thickness, materials and slope as the modified RCRA subtitle C closure cap defined in Section 4.

Figure 18 depicts the conceptual model layout dimensions. The layout assumes a 5 m spacing between caps for each vault. Each vault layout is depicted with the inner rectangle representing the bottom of the vault (200 m x 20 m), the middle rectangle representing the top of the vault (260 m x 80 m), and the outer rectangle includes the trench wall dimensions (272 m x 92 m).

QUALITY ASSURANCE

Quality assurance for this report is provided through the following peer review process. A peer review plan was established that identified two technical reviews to be performed on the Facility Data Package for the Immobilized Low-Activity Tank Waste Performance Assessment. Fluor Federal Services (FFS) was responsible for an internal review of the document. The Numatec Hanford Company (NHC), Pacific Northwest National Laboratory (PNNL), and Bechtel Hanford Company (BHI) were responsible for the Hanford technical review of this document. NHC has subject mater experts on the facility design and the engineering studies that have been performed for the disposal facilities. PNNL has responsibility for the incorporation of the facility design into the modeling calculations for contaminant transport. BHI manages the Vadose Zone/Groundwater Integration Project and is responsible for assuring that appropriate data and models are used for Hanford risk assessments.

The Hanford reviewers, upon completion of their reviews, provided the author (R. Puigh) with written documentation of their comments. Acceptance of the comment resolutions was indicated by reviewers' signature on the Engineering Data Transmittal (EDT).

The peer review members were selected based on their experience and knowledge of specific subject areas. The internal peer review was provided by Raziuddin Khaleel. Dewey Burbank was chosen from NHC to provide the technical review. He was chosen based on his knowledge of the disposal facility design activities. Dr. B. McGrail and Philip Meyer from PNNL were chosen to appoint technical reviewers for the facility data report to assure the report contains all relevant information needed for the contaminant transport model calculations. Dr. Graham represents the point of contact for the review of the data package by the Hanford Site Vadose Zone/Groundwater Integration Project. Dr. Graham is responsible for appointing other Hanford technical experts as deemed necessary to review this data package.

Design data for the existing disposal vaults were developed under Westinghouse Hanford Company QA/QC procedures associated with design. The conceptual design data for the existing facility modifications and the new disposal facilities were developed under QA/QC practices for FDNW, Inc.

Summary

Lockheed Martin Hanford Company (LMHC) is designing and assessing the performance of disposal facilities to receive radioactive wastes that are currently stored in single- and double-shell tanks at the Hanford Site. The preferred method of disposing of the portion that is classified as immobilized low-activity waste (ILAW) is to vitrify the waste and place the product in near-surface, shallow-land burial facilities. The LMHC project to assess the performance of these disposal facilities is known as the Hanford ILAW Performance Assessment (PA) Activity, hereafter called the ILAW PA project. The goal of this project is to provide a reasonable expectation that the disposal of the waste is protective of the general public, groundwater resources, air resources, surface-water resources, and inadvertent intruders. Achieving this goal will require predictions of contaminant migration from the facility. To make such predictions will require estimates of the fluxes of water moving through the sediments within the vadose zone around and beneath the disposal facility. These fluxes, loosely called recharge rates, are the primary mechanism for transporting contaminants to the groundwater.

Pacific Northwest National Laboratory (PNNL) assists LMHC in their performance assessment activities. One of the PNNL tasks is to provide estimates of recharge rates for current conditions and long-term scenarios involving the shallow-land disposal of ILAW. Specifically, recharge estimates are needed for a fully functional surface cover, the cover sideslope, and the immediately surrounding terrain. In addition, recharge estimates are needed for degraded cover conditions. The temporal scope of the analysis is 10,000 years, but could be longer if some contaminant peaks occur after 10,000 years.

The elements of this report compose the Recharge Data Package, which provides estimates of recharge rates for the scenarios being considered in the 2001 PA. Table S.1 identifies the surface features and time periods evaluated. The most important feature, the surface cover, is expected to be the modified RCRA Subtitle C design. This design uses a 1-m-thick silt loam layer above sand and gravel filter layers to create a capillary break. A 0.15-m-thick asphalt layer underlies the filter layers to function as a backup barrier and to promote lateral drainage. Cover sideslopes are expected to be constructed with 1V:10H slopes using sandy gravel. The recharge estimates for each scenario were derived from lysimeter and tracer data collected by the ILAW PA and other projects and from modeling analyses.

For the best estimate case, we proposed using a recharge rate of 0.1 mm/yr for the surface cover with a shrub-steppe plant community. This rate is lower than the cover design goal of 0.5 mm/yr because it is closer to the actual drainage rate measured with lysimeters and inferred with modeling. The simulation results showed that erosion of 20% of the silt loam layer did not impair this performance nor did the deposition of 20 cm of dune sand. For the sandy gravel sideslope, we proposed using a recharge rate of 50 mm/yr. This rate is lower than the 75 mm/yr used in the ILAW 1998 PA. For the soil type known as Rupert sand with a shrub-steppe plant community, we proposed using a recharge rate of 0.9 mm/yr. This rate is lower than the 3 mm/yr used in the ILAW 1998 PA. For the soil type known as Burbank loamy sand with a shrub-steppe plant community, we proposed using a recharge rate of 4.2 mm/yr. This soil type was not considered in the ILAW 1998 PA. For the Hanford formation sediments during construction, we proposed using a recharge rate of 55.4 mm/yr. Recharge in Hanford formation sediments during construction was not considered in the ILAW 1998 PA.

Table S.1. Recharge Estimates for the Best Estimate Case (and Reasonable Bounding Cases) During Each Period of Interest to the ILAW 2001 PA.

Surface Feature	Estimated Recharge Rates for the Best Estimate Case (and Reasonable Bounding Cases) (mm/yr)			
	Time Period of Recharge Evaluation			
	Pre-Hanford	During Disposal Operations	During Surface Cover Design Life	After Surface Cover Design Life
Modified RCRA Subtitle C Cover	NA	NA	0.1 (0.01, 4.0)	0.1 (0.01, 4.0)
Cover Sideslope	NA	NA	50 (4.2, 86.4)	50 (4.2, 86.4)
Rupert Sand	0.9 (0.16, 4.0)	0.9 (0.16, 4.0)	0.9 (0.16, 4.0)	0.9 (0.16, 4.0)
Burbank Loamy Sand	4.2 (2.8, 5.5)	4.2 (2.8, 5.5)	4.2 (2.8, 5.5)	4.2 (2.8, 5.5)
Hanford Formation Sediments	NA	55.4 (50, 86.4)	NA	NA
NA = Not applicable.				

A limited number of sensitivity tests were conducted using numerical simulation. The results showed that the surface cover limited recharge to less than 0.1 mm/yr regardless of the plant type, the presence of plants, or any of the climate change conditions. In contrast, recharge in the Rupert sand showed a significant sensitivity to vegetation type and climate change conditions, but less sensitivity to small variations in hydraulic properties.

Several alternative conceptual models were considered to indicate the effects of conceptual model uncertainty. Under the climate change condition most likely to promote recharge (i.e., increased precipitation and decreased temperature), recharge through the cover remained <0.1 mm/yr in contrast to recharge in Rupert sand, which increased from 2.2 to 27 mm/yr. Replacement of the shrub cover with cheatgrass had no impact on recharge through the surface cover but it increased recharge in Rupert sand from 2.2 to 33.2 mm/yr. Irrigation on the surface cover caused recharge to increase from 0.1 to 26.4 mm/yr as the irrigation efficiency was reduced from 100% to 75%.

Using the available recharge estimates, we identified a set of reasonable bounding rates. The design feature with the largest projected range in performance was the sideslope (4.2 to 87.5 mm/yr). Given that sideslopes could represent a significant fraction of the surface cover footprint, we believe that efforts to improve sideslope performance are warranted.

Planning for FY 2000 includes activities to

- extend the length of record from the lysimeter facility
- estimate recharge rates using tracer data from the borehole samples to be collected in the year 2000

- add needed capability to the simulation model to address multiple plant species, seasonal effects, and snowmelt

- collect vegetation data to fill existing data gaps, including plant water status during the late fall to early spring period, differences in rooting patterns beneath shrubs and in the inter-shrub spaces, and maximum depth of rooting

- initiate a field measurement activity to get site-specific estimates of water status and fluxes within and well below the plant root zone.

Issues remaining to be addressed include the precision of lysimeter leak tests to support the use of lower recharge estimates, possible facility deposition of chloride that could impact tracer analyses, and the importance of temperature and water vapor flow when recharge rate estimates are lower than 1 mm/yr. In addition, the impacts of unstable and preferential flow and flaws in the cover need to be evaluated.

1.0 Introduction

Lockheed Martin Hanford Company (LMHC) is designing and assessing the performance of disposal facilities to receive radioactive wastes that are currently stored in single- and double-shell tanks at the Hanford Site. The preferred method of disposing of the portion that is classified as immobilized low-activity waste (ILAW) is to vitrify the waste and place the product in near-surface, shallow-land burial facilities.

The LMHC project to assess the performance of these disposal facilities is known as the Hanford ILAW Performance Assessment (PA) Activity, hereafter called the ILAW PA project. The goal of this project is to provide a reasonable expectation that the disposal of the waste was protective of the general public, groundwater resources, air resources, surface-water resources, and inadvertent intruders. Achieving this goal will require predictions of contaminant migration from the facility. To make such predictions will require estimates of the fluxes of water moving through the sediments within the vadose zone around and beneath the disposal facility. These fluxes, loosely called recharge rates, are the primary mechanism for transporting contaminants to the groundwater.

Pacific Northwest National Laboratory (PNNL) assists LMHC in their performance assessment activities. One of the PNNL tasks is to provide estimates of recharge rates for current conditions and long-term scenarios involving the shallow-land disposal of ILAW (LMHC 1999).

The ILAW 1998 PA examined the long-term environmental and human health effects associated with the planned disposal of the vitrified low-level fraction of the waste presently contained in the Hanford high-level waste tanks (Mann et al. 1998). In support of that PA, Rockhold et al. (1995) provided estimates of recharge rates using historical data. Since then, the ILAW project has made significant investments in site-specific data collection. In addition to the ILAW activities, other projects have collected data that are relevant to the ILAW disposal. In preparation for a revision of the ILAW PA, called the 2001 PA, a number of data packages are being prepared (LMHC 1999). These packages will bring together recently collected site-specific ILAW data as well as relevant data collected by other projects.

Figure 1.1 shows the boundaries and major facilities of the Hanford Site (PNNL 1999). Figure 1.2 shows the locations of the two disposal sites that are being considered (Mann 1999): the ILAW Disposal Site (located southwest of the PUREX Plant) and the Existing Disposal Site (located east of the PUREX plant and formerly known as the Grout Vaults). For each disposal site, recharge rate estimates are needed for a fully functional surface cover, the cover sideslope, and the immediately surrounding terrain. In addition, recharge estimates are needed for degraded cover conditions. Mann (1999) indicated that the temporal scope of the ILAW 2001 PA is 10,000 years, but could be longer if some contaminant peaks occur after 10,000 years.

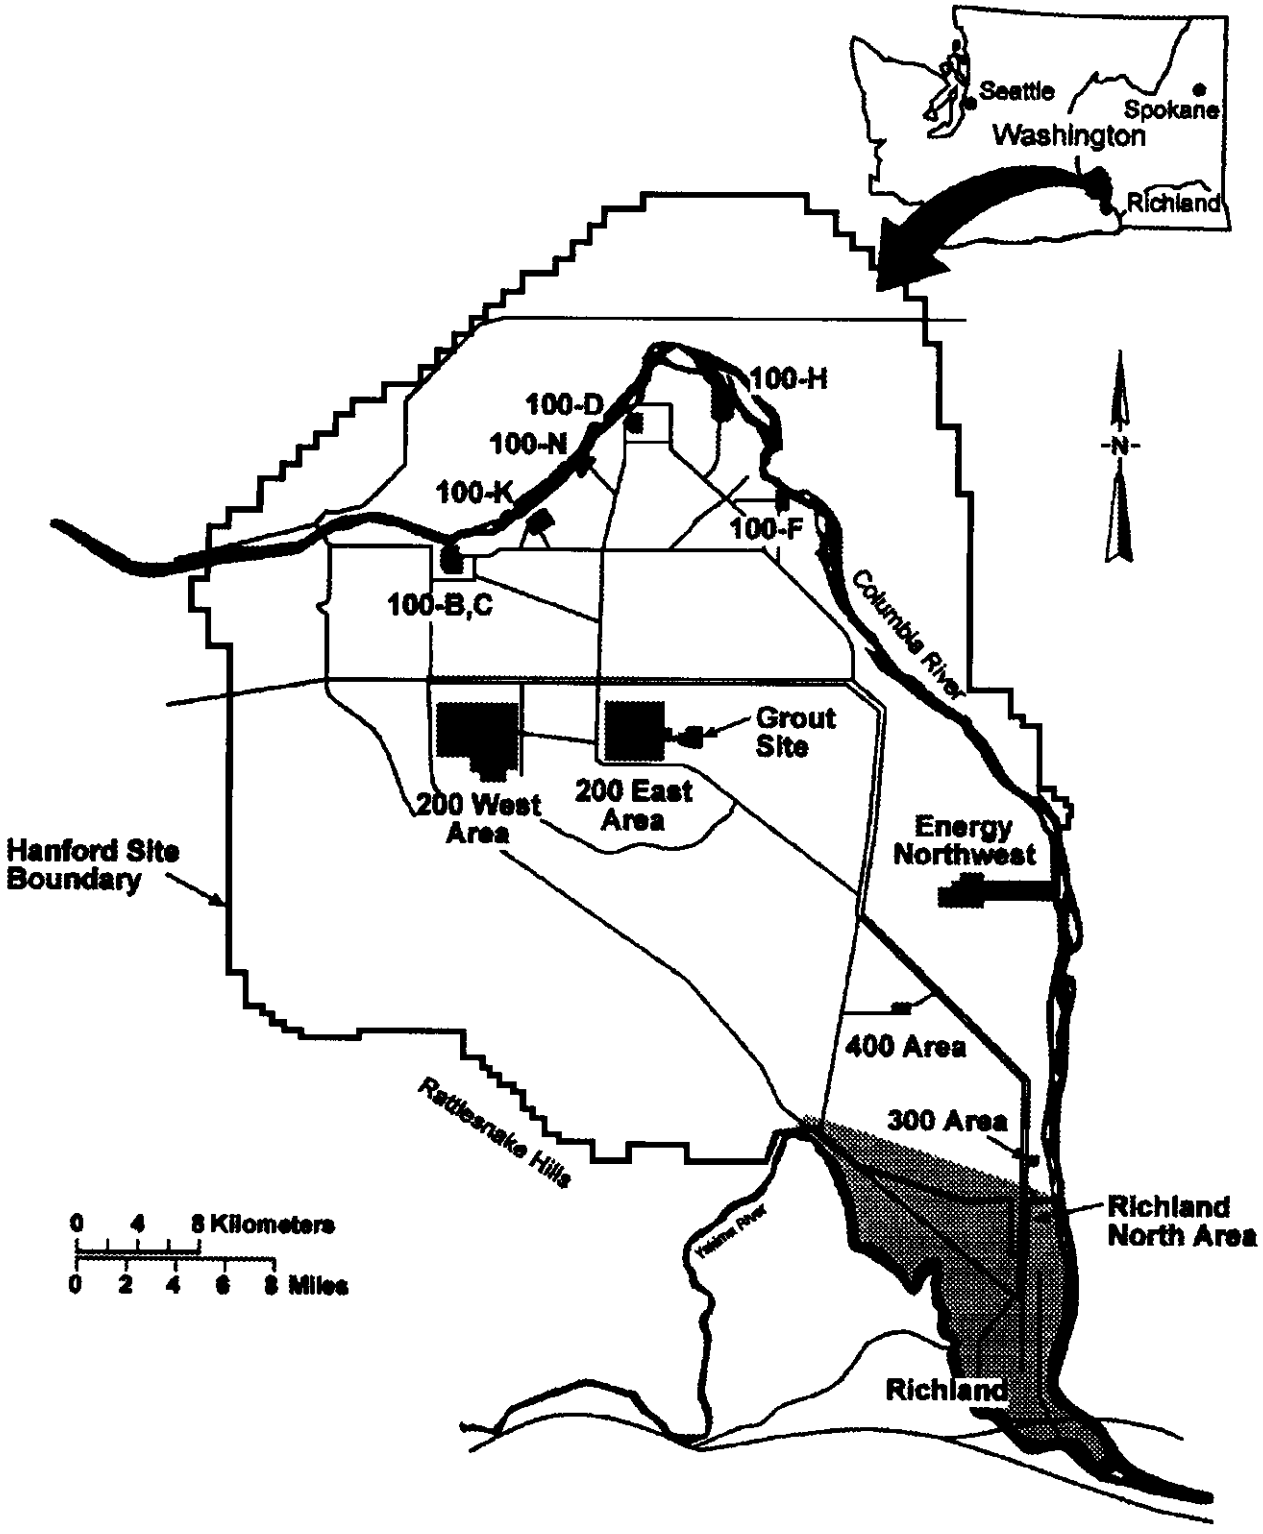

Figure 1.1. Map of the Hanford Site and Its Location Within Washington

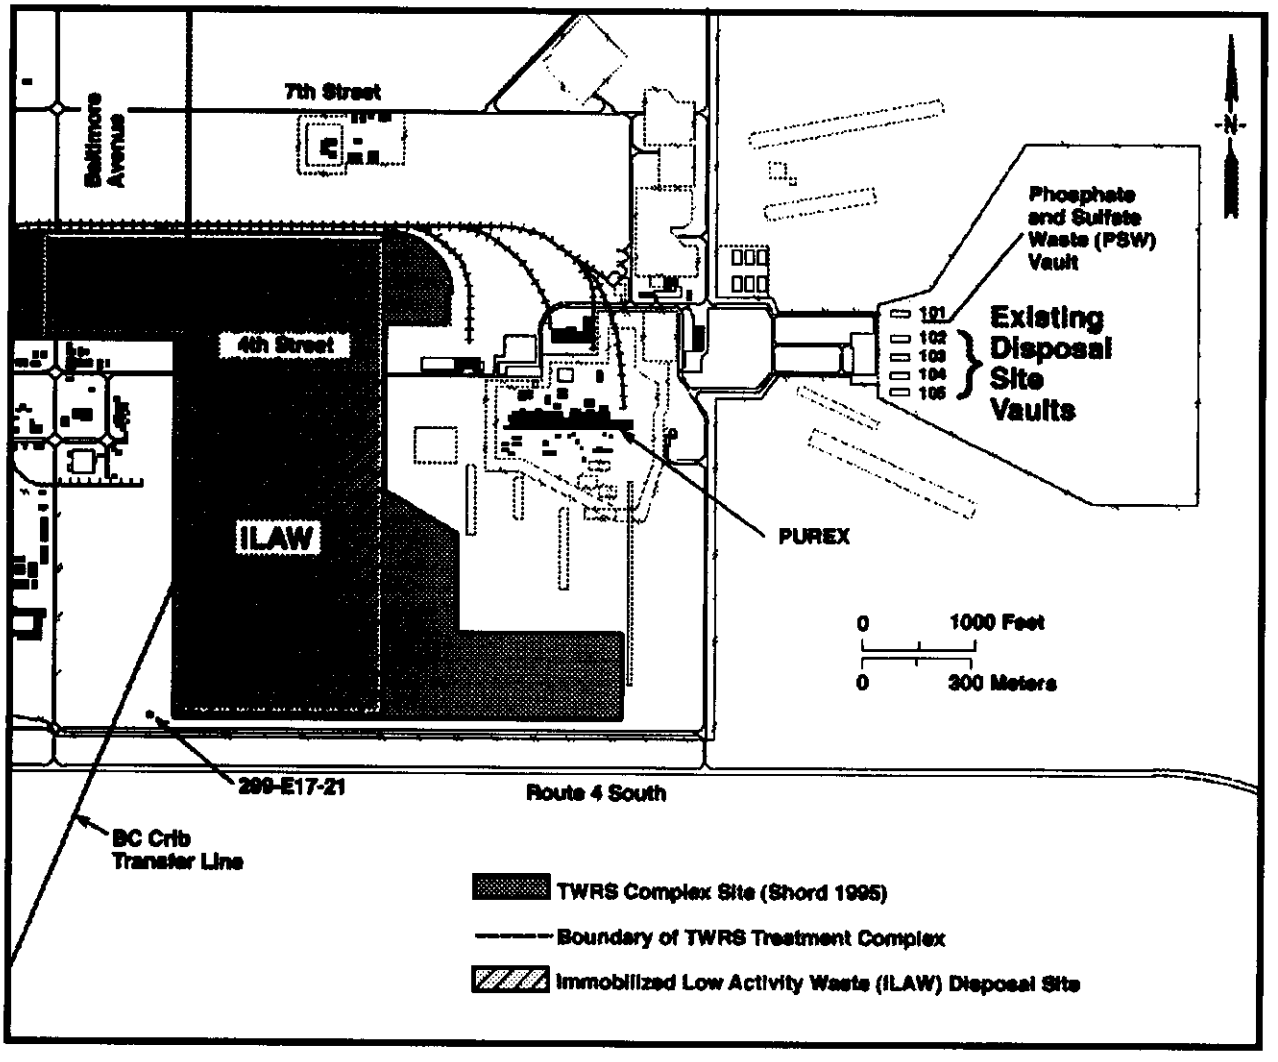

Figure 1.2. Locations of the ILAW Disposal Site and the Existing Disposal Site Vaults Within the Southeast Corner of the 200 East Area at Hanford. The ILAW Disposal Site is part of the Tank Waste Remediation Systems (TWRS) Treatment Complex, which lies within the larger TWRS Complex Site.

The elements of this report make up the Recharge Data Package. The objective of this data package is to provide recharge estimates for the scenarios being considered in the 2001 PA. Multiple estimation techniques were used to satisfy the objective, including lysimetry, tracer studies, and modeling studies. The report identifies how the data were used to generate recharge rate estimates for the best estimate case and reasonable bounding cases, as well as indicate the uncertainties in these estimates.

2.0 Background

The Hanford Site was established in 1944 as a U.S. Government nuclear materials production facility. During its history, Site missions included nuclear reactor operation, storage and reprocessing of spent nuclear fuel, and management of radioactive and hazardous wastes. Today, activities on the Site involve environmental restoration, energy-related research, and technology development. Fifty-five years of operations have resulted in the accumulation of significant quantities of radioactive and hazardous wastes as well as their intentional and unintentional release to the environment.

2.1 Source and Destination of ILAW

The legacy of the earlier Hanford missions consists of more than 209,000 m^3 of radioactive and mixed waste stored in 177 buried single- and double-shell tanks in the Hanford Site 200 Areas (Mann et al. 1998). This waste will be retrieved and separated into two fractions: high-level waste to be sent to a federal geologic repository and low-activity waste to be immobilized (i.e., ILAW) and placed in a near-surface disposal system on site. Immobilization will be accomplished through the vitrification process, which will turn the waste slurry into a glass product. Some of the more important radionuclides include ^{79}Se, ^{90}Sr, ^{99}Tc, ^{129}I, ^{126}Sn, and ^{137}Cs, as well as isotopes and progeny of uranium, plutonium, neptunium, and americium (Mann et al. 1998).

Although plans are not final, some form of glass product will be produced and placed in metal containers. These containers will be stacked within belowground disposal vaults. The spaces between containers will be filled with something like sand and the top of the vault sealed with a controlled density fill. A protective surface cover will be constructed over the vaults prior to closure.

2.2 Definition of Recharge

The precise definition of recharge is that flux of water reaching ("recharging") the water table. We have no effective way of measuring recharge at the water table, so we resort to shallow unsaturated measurements and analyses. With these, we estimate the deep drainage flux, i.e., that flux leaving the evapotranspiration zone and ostensibly traveling to the water table. Given sufficient time, the deep drainage flux will eventually manifest itself as the recharge flux. However, when deep drainage fluxes change, the change may not be manifested at the water table for hundreds to thousands of years. The length of time will depend on the vadose zone thickness and hydraulic properties and the initial and final deep drainage rates. Sediment stratification can lengthen that time further.

For the 2001 PA, scenarios involving changes in recharge rates should address the time delay between deep drainage rate changes and changes in the flux reaching the water table.

2.3 Prior Estimates of Recharge at Hanford

In the early years of the Hanford Site, the perception was that recharge occurred only along the upper elevations of Rattlesnake Mountain and the valleys to the north, and it did not occur across the remainder of the Site. The Hanford Defense Waste Environmental Impact Statement assumed that natural recharge was essentially zero in and around the storage and disposal areas (DOE 1987). A panel of nationally recognized scientists was convened in 1985 to discuss the recharge issue. The reviewers disputed the notion of zero recharge. Data collected before and after the 1985 review showed clearly that recharge can and does occur under favorable conditions. Gee et al. (1992) presented evidence that recharge rates can vary from nearly zero in silt loam soils covered by sagebrush to more than 100 mm/yr in gravel-covered soils without vegetation.

Rockhold et al. (1995) presented a review of past work related to recharge. Appendix B of their report describes the numerous studies conducted since 1969 using field measurements of soil water, matric potential, and temperature; tracer measurements; lysimeter measurements; and numerical modeling. All of these studies showed the potential for recharge to occur if conditions are right (i.e., coarse-textured rather than fine-textured soil, sparse plant community, and shallow-rooted rather than deep-rooted plants).

2.4 1998 PA

Mann et al. (1998) is commonly referred to as the 1998 PA. It was the initial effort to demonstrate the feasibility of safely disposing of ILAW at the Hanford Site. Because the ILAW PA project was only just beginning, the analyses were conducted using reasonable estimates of the parameters without having site-specific information. The intention was to initiate a program to collect data relevant to the actual disposal sites and glass product (see next section).

In lieu of site-specific data, Rockhold et al. (1995) assembled their best estimate of recharge rates to use in the 1998 PA (called the preliminary PA in 1995). Their recommendations were

> "The existing recharge data were used to provide recharge estimates that can be used in preliminary performance assessment calculations. Estimates are provided for the barrier, the barrier edge, the surrounding natural ecosystem, and the entire Hanford Site. We recommend assuming a recharge rate of 0.5 mm/yr through the Hanford protective barrier. This assumption is supported by an 8-year record of lysimeter data (Table 3.1) and is consistent with engineering design specifications over the 1000-year design life of the barrier (Wing 1994). At the barrier edge, a higher recharge rate of 75 mm/yr should be assumed. This assumption is based on four years of data for a lysimeter with a graveled surface (Table 3.1) that is similar to the riprap sideslope of the protective barrier. This estimate does not include possible overland flow or lateral drainage from the barrier. Beyond the barrier, the recharge rate of the natural ecosystem can be represented with one of two rates. If the plant community is assumed to be sagebrush, an estimate of 5.0 mm/yr should be used. This is a conservative value chosen to be slightly greater than all the rates reported by Prych (1995) using tracer measurements. If the plant community is assumed to be cheatgrass, an estimate of 25.4 mm/yr should be used. This value is based on an 8-year record of water content observations at the Grass

Site in the 300 Area (Fayer and Walters 1995). For the entire Hanford Site, we recommend using the recharge distribution map reported by Fayer and Walters (1995)."

2.5 ILAW PA Project Activities

Shortly after publication of Rockhold et al. (1995), a panel of nationally recognized scientists was convened to review the ILAW project needs for recharge information. The panel concluded that enough information existed to proceed with the 1998 PA, but that site-specific data would be needed to provide technically defensible estimates.[1] They supported efforts to use lysimetry, tracers, and modeling. The panel noted that the results might not change the recharge estimates significantly but would strengthen the technical credibility of the final recharge estimates used in the performance assessment. The panel also cautioned that uncertainty in conceptual models and supporting data should not be ignored.

Since 1995, the ILAW PA project has conducted several studies to improve the estimates of natural recharge. These studies included direct measurements of recharge using lysimetry (Appendix A), tracer evaluations of recharge (Appendix B), and numerical simulations of recharge (Appendix C). In addition to these basic studies, the ILAW PA project also supported auxiliary studies. Appendix D analyzes the origin of sand dunes at Hanford and summarizes the results of trenching a dune along the southern edge of the new ILAW Disposal Site. Appendix E describes the results of surface sediment sampling to determine the possibility of deposition of facility emissions (and their possible impact on tracer analyses). Appendix F summarizes the results of vegetation studies designed to characterize the current plant community at the disposal sites and provide better parameters for numerical simulations of recharge. Appendix G briefly summarizes the Quality Assurance Plan.

3.0 Affected Environment

An adequate evaluation of the impacts of ILAW disposal requires an understanding of the environment within which the ILAW will be disposed. In this section, we have summarized information on the climate and meteorology, geology and soils, hydrology, and ecology. Portions of this summary were extracted from existing reports, including Neitzel et al. (1998), Hoitink et al. (1999), and Reidel and Horton and Horton and Reynolds (1998). For brevity, references in the original text were not included here.

The Hanford Site lies within the semiarid Pasco Basin of the Columbia Plateau in southeastern Washington State (Figure 1.1). The Hanford Site occupies an area of about 1450 km^2 (~560 mi^2); only about 6% of the land area has been disturbed and is actively used for the storage of nuclear materials, waste storage, and waste disposal. The Columbia River flows through the northern part of the Hanford Site and forms part of the Site's eastern boundary. The Yakima River runs near the southern boundary of the Hanford Site and joins the Columbia River at the city of Richland, which bounds the Hanford Site on the southeast. Rattlesnake Mountain, Yakima Ridge, and Umtanum Ridge form the southwestern and western boundaries. The Saddle Mountains form the northern boundary of the Hanford Site. Two small east-west ridges, Gable Butte and Gable Mountain, rise above the plateau of the central part of the Hanford Site. Adjoining lands to the west, north, and east are principally range and agricultural land. The cities of Kennewick, Pasco, and Richland (Tri-Cities) constitute the nearest population centers and are located southeast of the Hanford Site.

3.1 Climate and Meteorology

The Cascade Mountains, 100 km to the west, greatly influence the climate of the Hanford area by means of their "rain shadow" effect. This mountain range also serves as a source of cold air drainage, which has a considerable effect on the wind regime on the Hanford Site. Climatological data have been collected at the Hanford Meteorological Station (HMS) since 1945 (Hoitink et al. 1999). The HMS is located between the 200 East and 200 West Areas at an elevation of 223 m. The data are representative of the general climatic conditions for the region and describe the specific climate of the 200 Area Plateau. The two ILAW disposal sites are close to the HMS and at nearly the same elevation.

Precipitation. Between 1946 and 1998, annual precipitation at the HMS averaged 174 mm (6.89 in.) and varied between 76 and 313 mm. Table 3.1 shows how monthly averages have varied in that time. The wettest season on record was the winter of 1996-1997 with 141 mm (5.4 in.) of precipitation; the driest season was the summer of 1973 when only 1 mm (0.03 in.) of precipitation was measured. Most precipitation occurs during the winter, with more than half of the annual amount occurring from November through February. Days with more than 13 mm (0.5 in.) precipitation occur on average less than one time each year. Rainfall intensities of 13 mm/h (0.5 in./h) persisting for 1 hour are expected once every 10 years. Rainfall intensities of 25 mm/h (1 in./h) for 1 hour are expected only once every 500 years.

Table 3.1. Monthly Precipitation Variations Between 1946 and 1998 at the HMS

Month	Monthly Precipitation (mm)		
	Maximum	Mean	Minimum
January	62.7	23.6	2.0
February	53.3	16.0	0.0
March	47.2	13.0	0.5
April	39.1	11.4	0.0
May	51.6	13.5	0.0
June	74.2	13.5	0.0
July	44.7	5.6	0.0
August	34.5	6.1	0.0
September	34.0	8.1	0.0
October	69.1	14.0	0.0
November	67.8	23.1	0.0
December	93.7	25.7	2.8
Annual		173.5	

Monthly average snowfall ranges from 8 mm (0.32 in.) in March to 137 mm (5 in.) in December. The record monthly snowfall of 600 mm (23.4 in.) occurred in January 1950. The seasonal record snowfall of 1420 mm (56 in.) occurred during the winter of 1992–1993. Snowfall accounts for about 38% of all precipitation from December through February.

Air Temperature. Daily maximum temperatures vary from normal maxima of 2°C (35°F) in late December and early January to 35°C (95°F) in late July. There are, on the average, 52 days during the summer months with maximum temperatures ≥32°C (90°F) and 12 days with maxima ≥38°C (100°F). From mid-November through early March, minimum temperatures average ≤0°C (32°F), with the minima in late December and early January averaging -6°C (21°F). During the winter, there are, on average, 3 days with minimum temperatures ≤-18°C (~0°F); however, only about one winter in two experiences such temperatures. The record maximum temperature is 45°C (113°F), and the record minimum temperature is -31°C (-23°F). Table 3.2 shows the range of monthly temperatures since 1946. The highest winter monthly average temperature at the HMS was 6.9°C (44°F) in February 1958, while the record lowest average temperature was -11.1°C (12°F) during January 1950. The record maximum summer monthly average temperature was 27.9°C (82°F) in July 1985, while the record lowest average temperature was 17.2°C (63°F) in June 1953.

Humidity. Since 1950, the average annual relative humidity at the HMS has been 54%; annual values ranged from 49 to 59%. December had the highest monthly average humidity (80%), with values that ranged from 69 to 91%. July had the lowest monthly average humidity (33%), with values that ranged from 22 to 46%.

Table 3.2. Monthly Air Temperature Variations Between 1946 and 1998 at the HMS

Month	Monthly Air Temperature (°C)		
	Maximum	Mean	Minimum
January	5.8	-0.8	-11.1
February	6.9	3.1	-3.6
March	10.8	7.3	4.1
April	14.6	11.6	8.6
May	13.3	16.6	13.3
June	24.9	20.7	17.2
July	27.9	24.7	21.4
August	27.5	23.9	21.0
September	22.4	19.0	14.9
October	15.3	11.7	8.8
November	8.1	4.5	-4.0
December	3.6	0.2	-6.1
Annual		11.9	

Solar Radiation. Since 1953, the average annual daily solar radiation at the HMS has been 172 W/m^2 (355 ly). Daily values were lowest in December, ranging from 4.4 to 95 W/m^2 and having an average value of 85 W/m^2. Average daily values were highest in July (305 W/m^2), but the highest daily value occurred in May (406 W/m^2).

Wind. Prevailing wind directions on the 200 Area Plateau are from the northwest in all months of the year. Secondary maxima occur for southwesterly winds. Summaries of wind direction indicate that winds from the northwest quadrant occur most often during the winter and summer. During the spring and fall, the frequency of southwesterly winds increases with a corresponding decrease in northwest flow. Winds blowing from other directions (e.g., northeast) display minimal variation from month to month. Monthly average wind speeds are lowest during the winter months, averaging 10 to 11 km/h (6 to 7 mi/h), and highest during the summer, averaging 13 to 15 km/h (8 to 9 mi/h). Wind speeds that are well above average are usually associated with southwesterly winds. However, the summertime drainage winds are generally northwesterly and frequently reach 50 km/h (30 mi/h). These winds are most prevalent over the northern portion of the Hanford Site.

3.2 Geology and Soils

Reidel and Horton and Horton (1999) provides a detailed description of the geology of the Hanford Site and the two ILAW disposal sites. A brief geology description is presented here to assist those readers who may not have access to Reidel and Horton and Horton (1999).

The Hanford Site lies within the Columbia Plateau, which is formed from a thick sequence of basalt flows. These flows have been folded and faulted over the past 17 million years, creating broad structural and topographic basins separated by asymmetric anticlinal ridges. Sediments up to 518 m (1700 ft) thick

have accumulated in some of these basins. The basalt flows are exposed along the anticlinal ridges, where they have been uplifted as much as 1097 m (3600 ft) above the surrounding area. Filling the synclinal basins in the basalt flows are sediments of the late Miocene, Pliocene, and Pleistocene age. The Hanford Site lies within one of the larger basins, the Pasco Basin. The Pasco Basin is bounded on the north by the Saddle Mountains and on the south by Rattlesnake Mountain and the Rattlesnake Hills. Yakima Ridge and Umtanum Ridge trend into the basin and subdivide it into a series of smaller anticlinal ridges and synclinal basins. The largest syncline, the Cold Creek syncline, lies between Umtanum Ridge and Yakima Ridge and is the principal structure containing the DOE waste management areas.

3.2.1 Geology

The two ILAW disposal sites are situated on the Cold Creek bar, a geomorphic remnant of the cataclysmic floods of the Pleistocene epoch. As the floods raced across the lowlands of the Pasco Basin and Hanford Site, the flood waters lost energy and began leaving behind deposits of gravels. The disposal sites are about 3 km (2 mi) north of the axis of the Cold Creek syncline, which controls the structural grain of the basalt bedrock and Ringold Formation. The basalt surface and Ringold Formation trend roughly southeast-northwest parallel to the major geologic structures of the site. As a result, the Ringold Formation and the underlying basalt dip gently to the south off the Umtanum Ridge anticline into the Cold Creek syncline. Geologic mapping at the Hanford Site has not identified any faults in the vicinity of the ILAW disposal sites. The closest faults are along the Umtanum Ridge-Gable Mountain structure north of the site and the May Junction fault east of the site.

The stratigraphy of the ILAW disposal sites consists of the basalt flows overlain by the Ringold Formation, the Hanford formation, and Holocene eolian deposits. All recharge-related measurements and estimates occur within the Hanford formation and eolian deposits; they are described below.

Hanford Formation. The Hanford formation is an informal name that represents all the deposits of the cataclysmic floods of the Pleistocene (1.6 million to 13,000 years ago). Glacial Lake Missoula formed in the Clark Fork River valley in Montana behind continental glaciers that spread south as far as the present Columbia Plateau. The lake may have given way as many as 40 times in the late Pleistocene, allowing the impounded water to spread across eastern Washington and form the Channeled Scablands. These flood waters collected in the Pasco Basin and formed Lake Lewis, which slowly drained through the small water gap in the Horse Heaven Hills called Wallula Gap.

Three principal types of deposits were left behind by the Missoula Floods: 1) high-energy deposits consisting of gravel; 2) coarse to fine sand deposits representing an energy transition environment; and 3) low-energy, slackwater deposits consisting of rhythmically bedded silt and sand of the Touchet Beds. Gravel-dominated strata consist of coarse-grained sand and granule-to-boulder gravels that display massive bedding, plane to low-angle bedding, and large-scale cross-bedding in outcrop. Sometimes the gravel strata lack a matrix material; such gravel strata have an open-framework appearance. The sand-dominated facies consists of fine- to coarse-grained sand and granules that display plane lamination and bedding and, less commonly, plane and trough cross-bedding in outcrop. Small pebbles and pebbly interbeds (<20 cm [8 in.] thick) may be encountered. The silt content of these sands varies, although

where its content is low, an open-framework texture may occur. The silt-dominated facies consists of fine- to coarse-grained sand grading up to silt to form normally graded rhythmites 0.07 to 1.0 m thick. Plane lamination and ripple cross-lamination is common in outcrop.

The Hanford formation is about 90 m (300 ft) thick at the ILAW disposal sites and consists predominantly of sands and gravelly sands. The sandy sequence is interpreted to lie between a slightly gravelly sand and a lower sandy gravel to gravelly sand. The Hanford formation thickens both to the north and south of the site. The lower gravel to gravelly sand is about 35 m (115 ft) thick and probably thins to the east on an irregular Ringold surface. The water table is in this lower gravel sequence. The Hanford formation sandy sequence is about 60 m (200 ft) thick and is the dominant facies in the ILAW disposal areas. The upper 6 m (20 ft) is composed of an irregularly distributed gravelly sand sequence. At other locations at Hanford, vertically oriented sediment features known as clastic dikes cut across the typically horizontal sediment layers (Fecht et al. 1999). These dikes could act as preferential pathways for water and contaminant transport. Clastic dikes have not yet been observed at the ILAW, probably because most of the area remains untouched by construction activities.

Holocene Deposits. Holocene deposits consisting of silt, sand, and gravel form a thin (<5 m [16 ft]) veneer across much of the Hanford Site as well as the ILAW disposal sites. The southern 200 m (656 ft) of the new ILAW Disposal Site is covered with a stabilized sand dune that is as much as 8 m (26 ft) high. Appendix D describes the nature of the dune and its relationship to the active dune field that lies to the south and southeast. Mature sagebrush is present on the ILAW sand dune, indicating that the dune has been stable since the 1940s at least. Clastic dike features are not visible on the soil surface.

3.2.2 Soils

The Holocene deposits and exposed Hanford formation sediments have experienced soil development and evolved into identifiable soil types. Hajek (1966) produced a soil map of the Hanford Site. Figure 3.1 shows that only two soil types cover the ILAW disposal sites: Rupert sand and Burbank loamy sand. These soils were described by Hajek (1966) as follows:

Rupert Sand. "This mapping unit represents one of the most extensive soils on the Hanford Project. The surface is a brown to grayish brown (10YR5/2) coarse sand, which grades to a dark grayish brown (10YR4/2) sand at about 36 in. Rupert soils developed under grass, sagebrush, and hopsage in coarse sandy alluvial deposits, which were mantled by wind-blown sand. Relief characteristically consists of hummocky terraces and dune-like ridges. This soil may be correlated as Quincy sand, which was not separated here. Active sand dunes are present. Some dune areas are separated; however, many small dunes, blow-outs, and associated small areas of Ephrata and Burbank soils are included."

Burbank Loamy Sand. "This is a dark-colored [surface is very dark grayish brown (10YR3/2); subsoil is dark grayish brown (10YR4/2)], coarse-textured soil which is underlain by gravel. The surface soil is usually about 16 in. thick but can be 30 in. thick. The gravel content of the subsoil may range from 20 to 80 volume percent. Areas of Ephrata and Rupert are included."

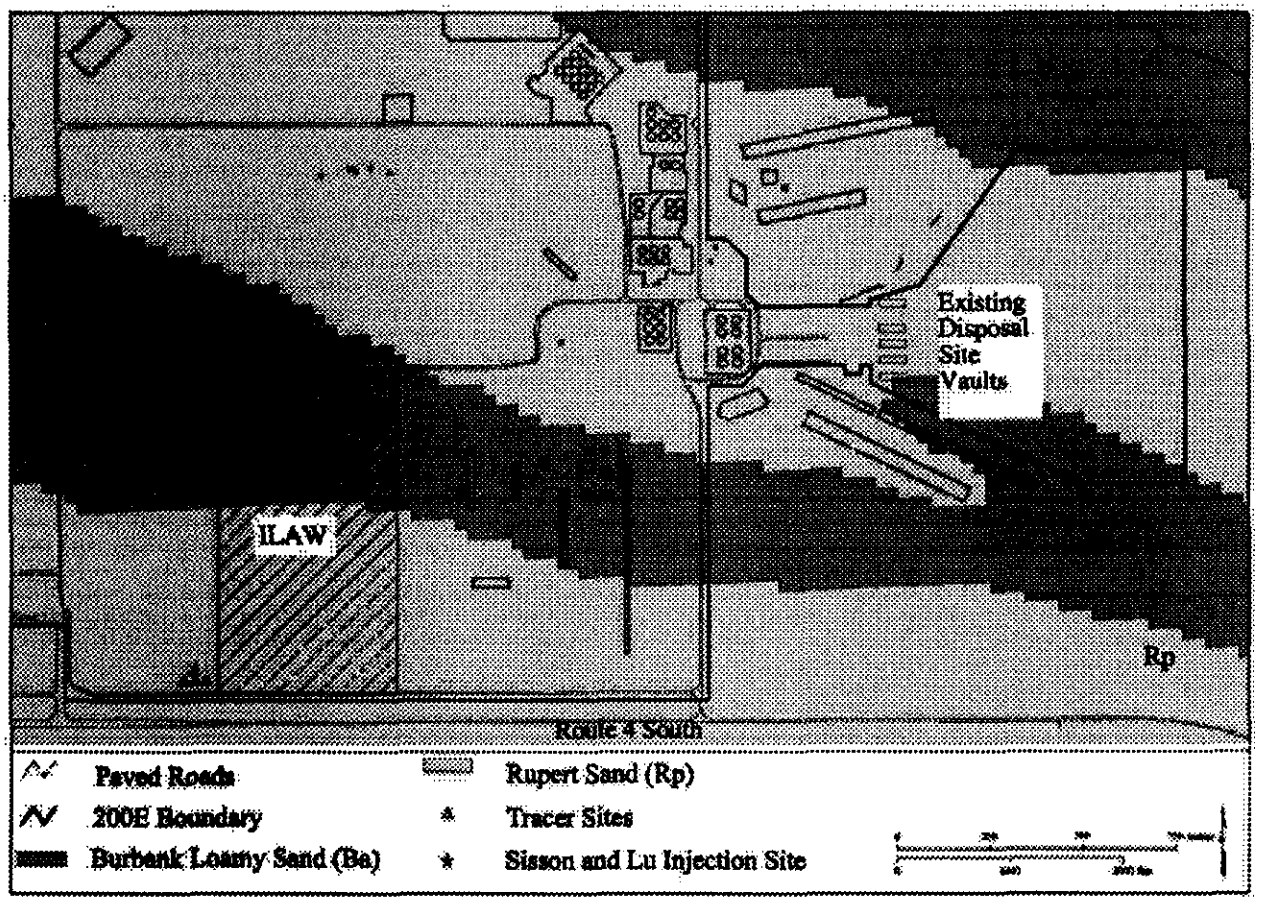

Figure 3.1. Soil Types at the Disposal Sites

Figure 3.2 shows that the topography of the two sites is similar. At the new ILAW Disposal Site, the topography is relatively flat with elevations that range between 219 and 222 m. The dune along the southern edge rises above the surrounding terrain by as much as 9 m, with a peak elevation of about 229 m. The eastern most portion of the dune has been excavated for other construction purposes. The remaining portion of the dune is not expected to exist once construction is completed.

Elevations at the Existing Disposal Site range between 204 to 206 m, about 15 m below the ILAW Disposal Site. Figure 3.2 shows the excavation for the existing disposal facility and the spoils pile directly to the east. About 300 m to the north, the topography drops off to the northeast with a slope reaching as high as 7%. The relative flatness of both disposal locations means that the final topography will be determined by the surface cover and grading of the surrounding soils.

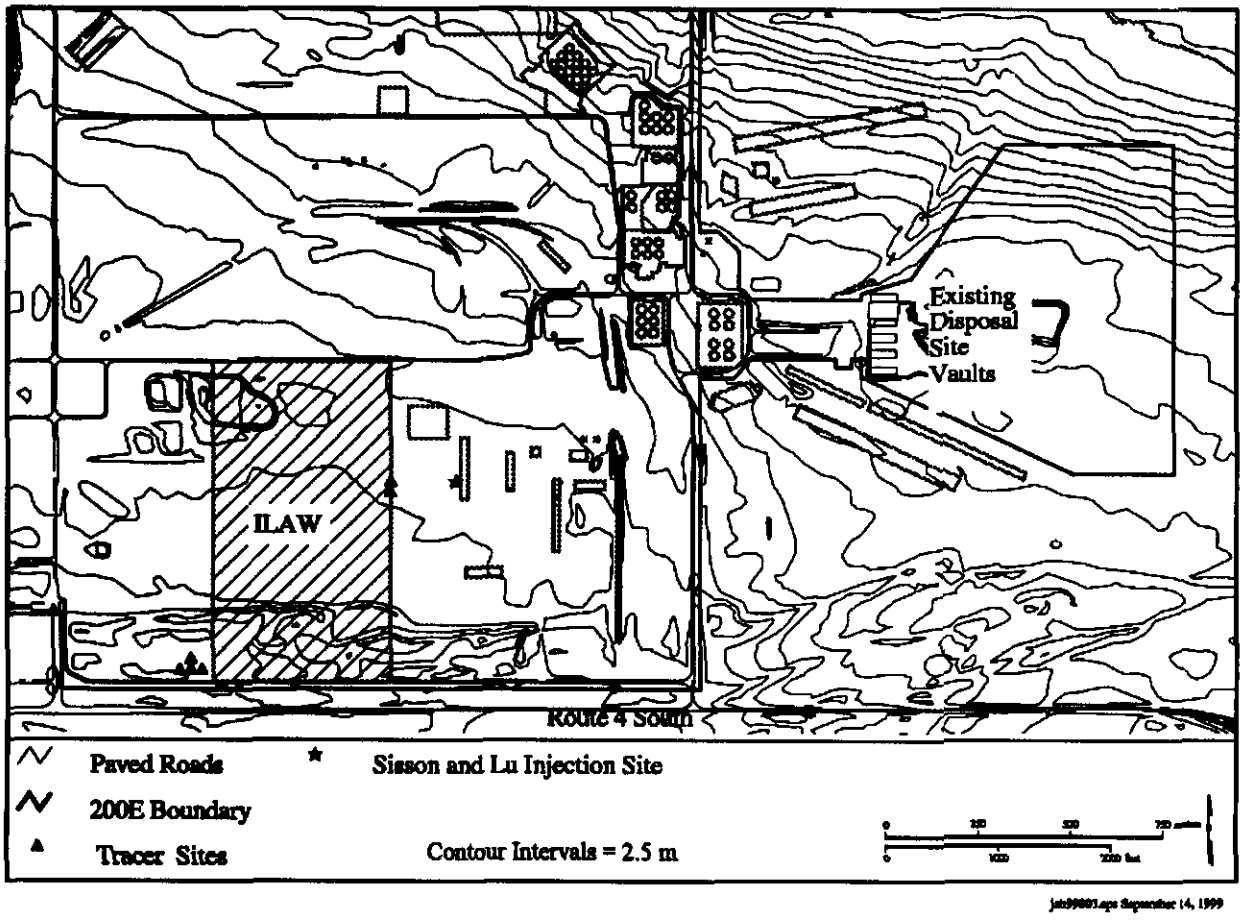

Figure 3.2. Topography at the Disposal Sites

3.3 Hydrology

The primary surface-water features associated with the Hanford Site are the Columbia and Yakima rivers. The Columbia River is the second largest river in the contiguous United States in terms of total flow and is the dominant surface-water body on the Hanford Site. Annual flows near Priest Rapids Dam just upstream of Hanford averaged nearly 3360 m^3/s (120,000 ft^3/s) during the 68 years prior to 1985. The Yakima River, which follows a small length of the southern boundary of the Hanford Site, has an average annual flow of only about 104 m^3/s (3712 ft^3/s) based on nearly 60 years of records. Cold Creek and its tributary, Dry Creek, are ephemeral streams within the Yakima River drainage system. Both streams drain areas along the western part of the Hanford Site. Surface flow, which may occur during spring runoff or after heavier-than-normal precipitation, infiltrates and disappears into the surface sediments. The ILAW disposal sites are located well above and away from these surface-water features and are unaffected by them in any direct manner.

Natural recharge rates across the Hanford Site range from near 0 to more than 100 mm/yr (4 in./yr), depending on surface conditions (Gee et al. 1992). Low recharge rates occur in fine-textured sediments

where deep-rooted plants occur. The larger values are interpreted to occur in areas having a coarse gravelly surface and no vegetative cover (e.g., disturbed areas such as around the tank farms).

The hydrogeology of the Pasco Basin is characterized by several confined aquifers within the basalt flows and one unconfined aquifer above the basalt flows. The aquifer above the basalt is a regionally unconfined and locally semi-confined aquifer and is contained largely within the sediments of the Ringold Formation and Hanford formation.

The water table beneath the ILAW disposal sites is within the Hanford formation. Normally, groundwater flows from west to east. However, artificial recharge from wastewater disposal activities has perturbed the flow directions. Currently, the water table is flat beneath the ILAW disposal sites, so a groundwater flow direction cannot be deduced. As wastewater discharges decrease and eventually cease, we expect the general west-to-east flow to resume.

The unsaturated zone beneath the land surface at the two ILAW disposal sites is approximately 96 m (315 ft) thick. This vadose zone lies entirely within the Hanford formation and eolian sediments. The water table in the northeast corner of the new ILAW Disposal Site was at an elevation of approximately 120 m (400 ft) in 1998. The water table surface was within the lower gravel sequence of the Hanford formation; the contact between the Hanford and Ringold formations is 6 m (20 ft) below the water table.

3.4 Ecology

The Hanford Site is characterized as a shrub-steppe ecosystem that is adapted to the region's mid-latitude semiarid climate. Such ecosystems are typically dominated by a shrub overstory with a grass understory. In the early 1800s, dominant plants in the area were big sagebrush (*Artemisia tridentata*) and an understory consisting of perennial Sandberg's bluegrass (*Poa sandbergii*) and bluebunch wheatgrass (*Pseudoregneria spicata*). Other species included threetip sagebrush, bitterbrush, gray rabbitbrush, spiny hopsage, bluebunch wheatgrass, needle-and-thread grass, Indian ricegrass, and prairie Junegrass.

With the advent of settlement, livestock grazing and agricultural production contributed to colonization by non-native vegetation species that currently dominate portions of the landscape. Although agriculture and livestock production were the primary subsistence activities at the turn of the century, these activities ceased when the Site was designated in 1943. Range fires that historically burned through the area during the dry summers eliminate fire-intolerant species (e.g., big sagebrush) and allow more opportunistic and fire resistant species to establish. Of the 590 species of vascular plants recorded for the Hanford Site, approximately 20% are non-native. The dominant non-native species, cheatgrass, is an aggressive colonizer and has become well established across the site. Over the past decade, several knapweed species have also become persistent invasive species in areas not dominated by shrubs.

The plant community at the two ILAW disposal sites is shrub-steppe dominated by big sagebrush, Sandberg's bluegrass, and cheatgrass. Figure 3.3 shows that most of the new ILAW Disposal Site has this cover but that the Existing Disposal Site has a significant fraction of area where disturbance occurred

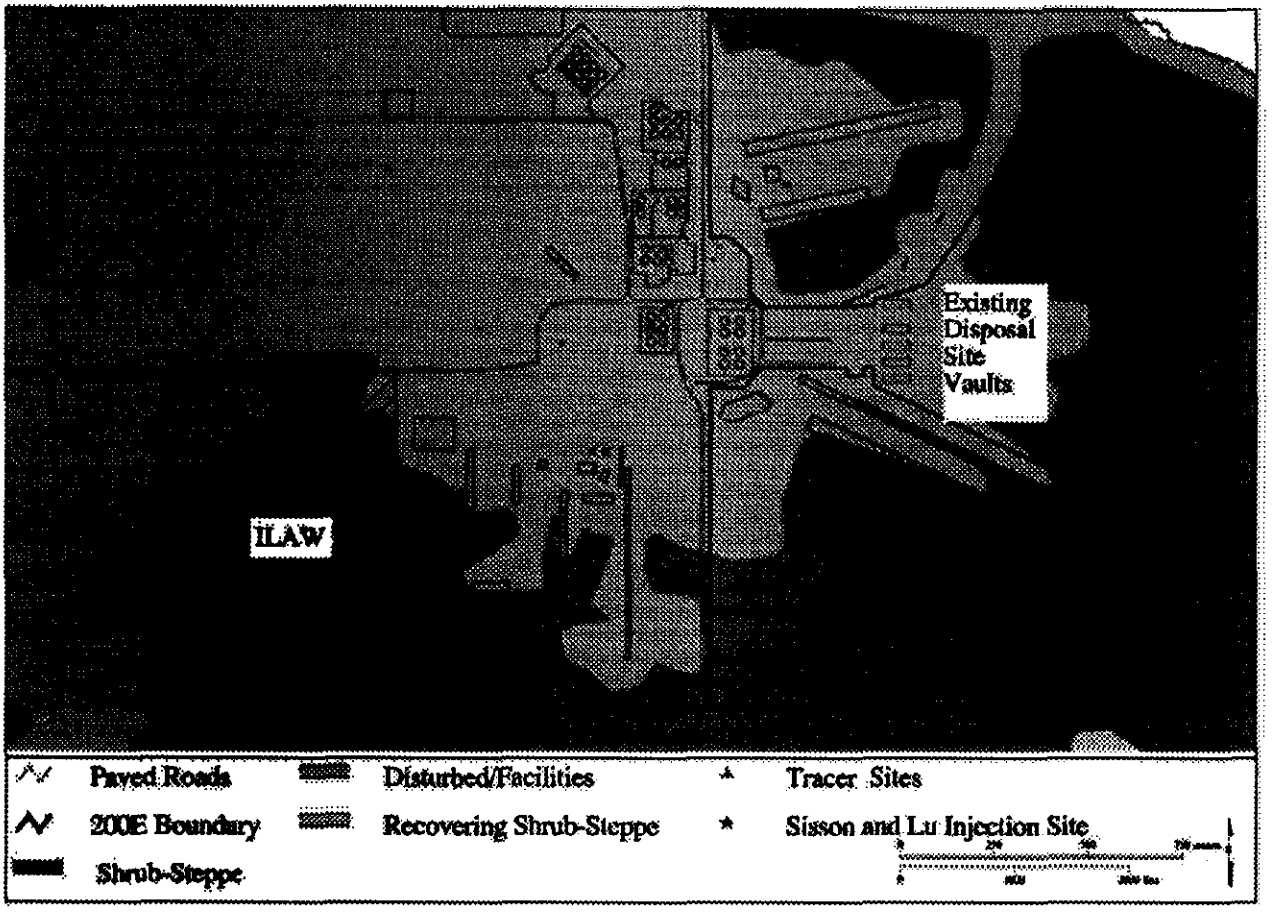

Figure 3.3. Vegetation Types at the Disposal Sites

during construction of the vaults. Appendix F describes some of the data collected recently to characterize the plant community at these two sites.

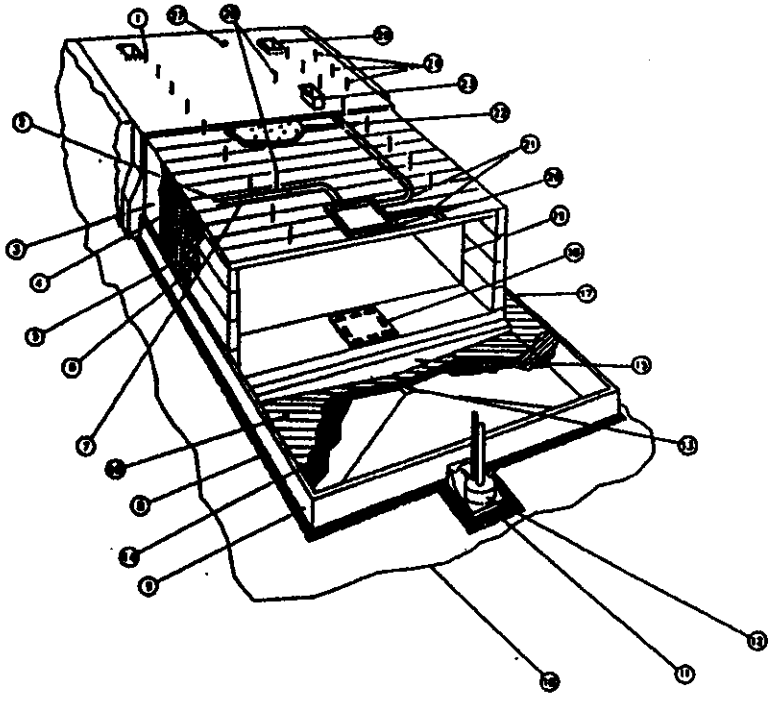
Approximately 300 species of terrestrial vertebrates have been observed on the Hanford Site, including approximately 40 species of mammals, 246 species of birds, 4 species of amphibians, and 9 species of reptiles. Terrestrial wildlife include Rocky Mountain elk, mule deer, coyote, bobcat, badger, deer mice, harvest mice, grasshopper mice, ground squirrels, voles, and black-tailed jackrabbits. The most abundant mammal on the Site is the Great Basin pocket mouse. Bird species commonly found in the shrub-steppe habitats at Hanford include the western meadowlark, horned lark, long-billed curlew, vesper sparrow, sage sparrow, sage thrasher, loggerhead shrike, and burrowing owls.

Butterflies, grasshoppers, and darkling beetles are among the more conspicuous of the approximately 1500 species of insects that have been identified from specimens collected on the

Hanford Site. The actual number of insect species occurring on the Hanford Site may reach as high as 15,000. Insects are more readily observed during the warmer months of the year.

The side-blotched lizard is the most abundant reptile species that occurs on the Hanford Site. Short-horned and sagebrush lizards are reported, but occur infrequently. The most common snake species includes gopher snake, yellow-bellied racer, and Pacific rattlesnake. The Great Basin Spadefoot Toad, Woodhouse's Toad, Pacific tree frog, and bullfrogs are the only amphibians found on the Site.

Wildlife species observed at the two ILAW disposal sites include mule deer, black-tailed jackrabbits, cottontail rabbits, coyotes, side-blotched lizards, gopher snakes, sage sparrows, shrikes, meadowlarks, and horned larks.



4.0 Disposal Facility Designs

The ILAW will be disposed in vaults and trenches at two locations within the 200 East Area at Hanford. Once completed, both burial facilities will receive a final surface cover and the surrounding land will be re-vegetated.

4.1 Subsurface Disposal Facilities

The two disposal facilities for ILAW are the Existing Disposal Site (formerly the Grout Site) and the proposed new ILAW Disposal Site (Figure 1.2).

Existing Disposal Facility. The existing disposal facility consists of five subsurface concrete vaults that were built and completed by 1995. Kincaid et al. (1995) described the site and facility extensively. One of the vaults was completed prior to the others and received a grouted waste called phosphate-sulfate waste. The remaining four vaults were built in pairs but never used. Figure 4.1 shows the engineered nature of these vaults. Figure 4.2 shows how the vaults were arranged in pairs. Spacing between each vault is roughly 10 m. The total areal extent of the four empty vaults is about 40 by 90 m. The vaults are currently covered with gravel as indicated just below the RCRA cover in Figure 4.2, but the protective barrier and RCRA cover shown in Figure 4.2 were never placed.

ITEM	DESCRIPTION
1	GROUT CAP INJECTION PORTS
2	GROUT FEED LINE
3	1/2" THERMAL BOARD (2 LAYERS)
4	GEOTEXTILE
5	(HDPE) PLASTIC CURTAIN
6	DRAINAGE NET (2 LAYERS) IS
7	EXCESS LIQUID TRANSPORT LINE
8	DIFFUSION BREAK
9	CONCRETE BASIN
10	STRUCTURAL BACKFILL OR NATIVE SOIL
11	CONCRETE SUMP ENCASEMENT
12	LEACHATE COLLECTION SUMP & RISERS
13	LEACHATE REMOVAL PIPE
14	HDPE LINER
15	DRAINAGE GRAVEL
16	GEOTEXTILE
17	GEOTEXTILE OVER GRAVEL & UNDER VAULT
18	60 mil HDPE PLASTIC SPLASH PAD SECURED WITH EIGHT 70 lb SANDBAGS
19	ASPHALT COATING
20	VAULT PIT
21	EXCESS LIQUID TRANSFER LINES FROM PUMP PITS
22	CONCRETE CAP
23	CCTV CAMERA ASSEMBLY
24	GROUT CORE SAMPLE ACCESS
25	EXCESS LIQUID PUMP PITS
26	LEVEL ELEMENTS
27	VENTILATION INLET

NOTES:
1. HDPE-HIGH DENSITY POLYETHYLENE
2. CCTV-CLOSED CIRCUIT T.V.

Figure 4.1. Grout Disposal Facility - Grout Disposal Vault, Cutaway View (after Mann et al. 1998)

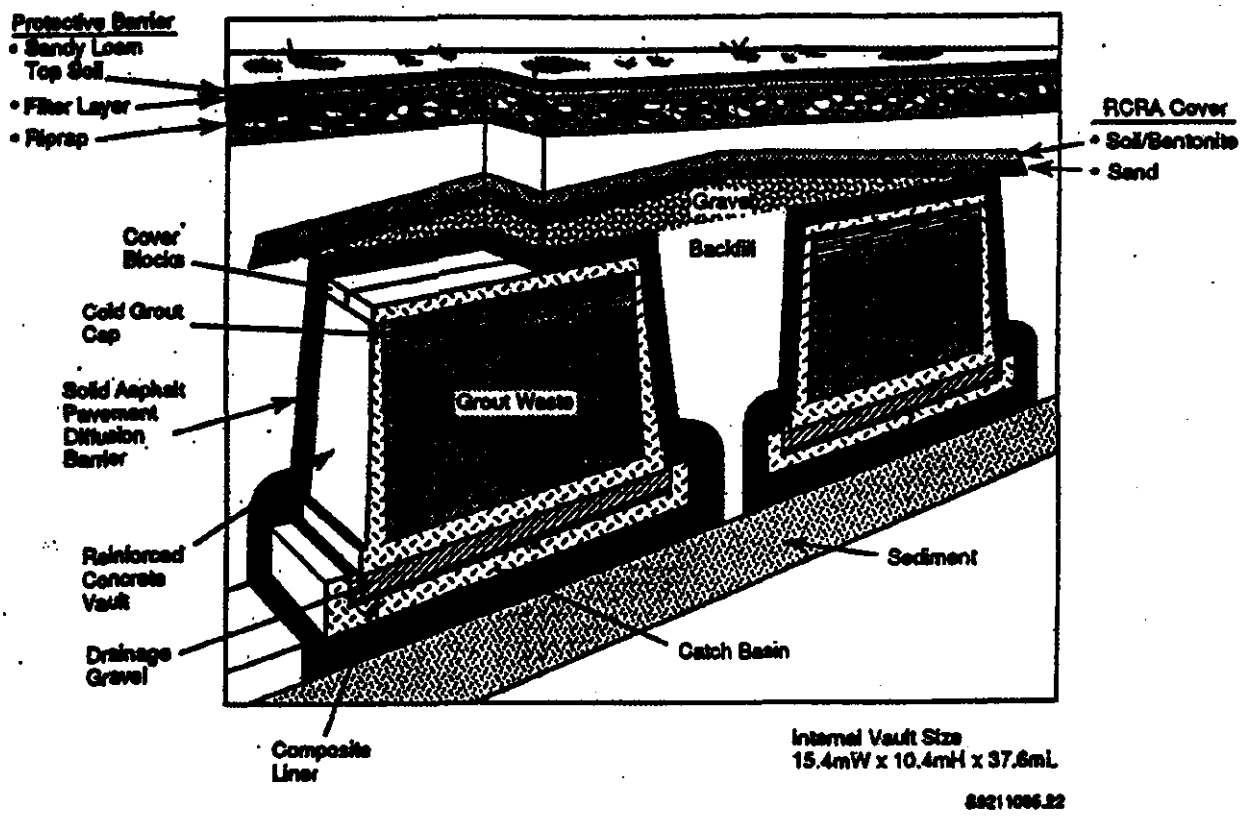


Figure 4.2. Grout Disposal Facility - Closed Vault Pair (after Mann et al. 1998). The RCRA cover and protective barrier were never constructed.

Placement of the ILAW in the existing disposal facility will involve excavation and modifications to the vaults. We expect that the vaults will be returned to their original condition after being filled. A final surface cover (Section 4.2) will then be emplaced. After the final cover is placed, we expect the vertical distance from the soil surface to the top of the ILAW to be no less than 5 m.

New ILAW Disposal Facility. Several designs have been proposed for the new ILAW disposal facility (Burbank and Klem 1997; Mann et al. 1998; PHMC 1998; Burbank and Hohl 1999; Puigh 1999) but a final decision has not yet been made. Fortunately, all of the designs have enough similar details to proceed with the analyses. The current plan is to build concrete vaults below grade. Nominal dimensions of the vaults will be 23 m wide, 208 m long (oriented north-south), and 9.1 m high. The long dimension of the vaults will be segmented to allow incremental filling followed by sealing with a controlled density fill. Each vault will have a leachate detection and collection system. Once all segments of a vault are completely filled, a surface cover (Section 4.2) will be placed within 180 days. Vault spacing is expected to be 50 m. After the final cover is placed, we expect the vertical distance from the soil surface to the top of the ILAW to be no less than 5 m.

4.2 Surface Cover

Burbank and Klem (1997) considered three cover designs in their cost calculations, but recent project discussions indicated the current preferred design is the modified RCRA subtitle C design proposed by DOE/RL (1996). The following description is taken loosely from that report (entitled "Focused Feasibility Study of Engineered Barriers for Waste Management Units in the 200 Areas").

The modified RCRA subtitle C cover is the baseline cover design for sites containing dangerous waste and several categories of low-level and mixed waste. This cover was designed to provide long-term containment and hydrologic protection for a performance period of 500 years. The performance period was based on radionuclide concentration and activity limits for Category 3 low-level waste. Table 4.1 lists the design criteria. The Modified RCRA Subtitle C Barrier is composed of eight layers of durable material with a combined minimum thickness of 1.7 m (5.5 ft). Table 4.2 provides the layer thicknesses and descriptions. This design incorporates *Resource Conservation and Recovery Act of 1976* "minimum technology guidance," with modifications for extended performance. One major change is the elimination of the clay layer, which may desiccate and crack over time in an arid environment. The geomembrane component also has been eliminated because of its uncertain long-term durability. The design incorporates provisions for biointrusion and human intrusion control. However, the provisions are modest relative to the corresponding features in the Hanford Barrier design, reflecting the reduced toxicity of the subject waste and the reduced design-life criterion.

Table 4.1. Summary of Design Criteria for the Modified RCRA Subtitle C Barrier

1.	Minimize moisture infiltration through the cover.
2.	Design a multilayer cover of materials that are resistant to natural degradation processes.
3.	Design a durable cover that needs minimal maintenance during its design life.
4.	Design a cover with a functional life of 500 years.
5.	Prevent plants from accessing and mobilizing contamination (i.e., prevent root penetration into the waste zone).
6.	Prevent burrowing animals from accessing and mobilizing contamination.
7.	Ensure that the top of the waste is at least 5 m (16.4 ft) below final grade or include appropriate design provisions to limit inadvertent human intrusion.
8.	Facilitate drainage and minimize surface erosion by wind and water.
9.	Design the low-permeability layer of the cover to have a permeability less than or equal to any natural subsoils present.
10.	Design the cover to prevent the migration and accumulation of topsoil material within the lateral drainage layer (i.e., clogging of the lateral drainage layer).
11.	For frost protection, the lateral drainage layer and the low-permeability asphalt layer must be located at least 0.75 m (30 in.) below final grade.

Table 4.2. Summary of Modified RCRA Subtitle C Barrier Layers

Layer No.	Thickness cm (in.)	Layer Description	Specifications	Function
1	50 (20)	Silt loam topsoil with pea gravel admix	McGee Ranch silt loam containing 15 wt% pea gravel, 2.36 to 9.5 mm in diameter, conforming to ASTM D448 No. 8 aggregate; to be placed at a bulk density of approximately 1.46 g/cc.	The topsoil material was identified for optimal water retention properties and should provide a good rooting medium for cover vegetation. The pea gravel is designed to minimize wind erosion of the silt loam without significantly affecting its moisture retention capabilities.
2	50 (20)	Compacted topsoil	McGee Ranch silt loam without pea gravel, compacted to 90% of optimum dry density as determined by standard Proctor test; in-place bulk density will be approximately 1.76 g/cc.	Same as Layer 1. Layer 2 provides a supplemental soil moisture storage capacity. Compaction of this layer is intended to retard the rate of infiltration of soil moisture. The extended residence time of moisture in Layer 2 will increase the amount of moisture removed by evapotranspiration.
3	15 (6)	Sand filter	Clean, screened sand meeting the following particle sizes: D_{15} = 0.15 to 0.50 mm, D_{50} = 0.375 to 1.2 mm, and D_{85} = 0.70 to 2.5 mm.	This layer is part of a two-layer graded filter designed to prevent the migration of topsoil particles into Layer 5.
4	15 (6)	Gravel filter	Clean, screened aggregate meeting the following particle sizes: D_{15} = 1.5 to 2.0 mm, D_{50} =15 to 20 mm, and D_{85} <37.5 mm.	Same as Layer 3.
5	15 (6)	Lateral drainage aggregate	Naturally occurring aggregate, minus 32-mm (1 1/4-in.) material, conforming to the grading identified in WDOT M41-10, 9-03.9(3) for base course, with D_{10} >1 mm and k >1 cm/s.	The lateral drainage layer will intercept and divert moisture along a 2% slope to the margin of the cover for collection and/or discharge.
6	15 (6)	Asphaltic concrete with spray-applied asphalt coating	Asphaltic concrete, consisting of asphalt conforming to WDOT M41-10, 9-02.1(4) - Grade AR-4000W, and aggregate with particle size gradation conforming to ASTM C 136. Asphalt will make up 7.5 wt% of total mixture. A spray-applied, styrene-butadiene asphalt material will be sprayed onto the asphaltic concrete surface in two layers, each 100 mils thick minimum.	This layer will function as a hydrologic barrier and as a biointrusion barrier.
7	10 (4)	Asphalt base course	Crushed aggregate, minus 16-mm (5/8-in.) diameter material, conforming to WDOT M41-10, 9-03.9(3) for top course surfacing material.	The function of the material in this layer is to provide a stable base for placing and supporting the asphalt layer.
8	Variable	Grading fill	Clean, bank run sand and gravel conforming to WDOT M41-10, 9-03.18.	This layer will provide a smooth, level subgrade for construction of the overlying layers.

The designs proposed by DOE/RL (1996) do not provide guidance for sideslopes. We expect that the final cover will be elevated relative to its surroundings, thus requiring sideslopes. Although the ILAW project has not yet chosen a sideslope design, the result of sideslope testing at Hanford can be used to indicate possible sideslope performance.

4.3 Closure Conditions Around the Surface Cover

Burbank and Klem (1997) indicated that the disturbed lands around the cover would be re-contoured and re-vegetated with native plant species. We expect that typical Hanford procedures for surface grading and re-vegetation will be pursued. We assume that some effort will be made to promote any surface water drainage away from the cover. We also assume that the topsoil used will be similar to the existing topsoil to promote re-vegetation. An alternative conceptual model is that the Hanford formation sands from the excavation will be used for the topsoil.

5.0 Analysis Cases and Tests

The mandate for the recharge task was to identify the scenarios that must be evaluated for the 2001 PA and provide estimates of appropriate recharge rates. These scenarios must be framed within the categories of the best estimate case and reasonable bounding cases. In addition, sensitivity tests must be conducted and alternative conceptual models evaluated to demonstrate our understanding of the system. Section 6.0 describes the methods used to estimate recharge. Section 7.0 describes the estimates and their assignment to the best estimate case and the bounding cases.

5.1 Best Estimate Case

The best estimate case represents the situation where all disposal facility features function as expected assuming a shrub-steppe plant community, current climate, no irrigated farming, and no significant subsidence impacts on the cover. Based on the facility design, there are five surface features that need separate evaluations:

- Modified RCRA Subtitle C Cover
- Cover sideslope
- Rupert sand
- Burbank loamy sand
- Hanford formation sediments.

These features will be evaluated for conditions that existed prior to Hanford, during disposal facility operations, during the design life of the surface cover, and following the design life of the surface cover. Table 5.1 shows which features are evaluated for each time period of interest to the 2001 PA. After the cover design life of 500 years, the performance of a possibly degraded surface cover will be evaluated (see the upper bounding cases in next section).

Table 5.1. Surface Features To Be Evaluated During Each Period of Interest to the 2001 PA

Surface Feature	Time Period of Recharge Evaluation			
	Pre-Hanford	During Disposal Operations	During Surface Cover Design Life	After Surface Cover Design Life
Modified RCRA Subtitle C Cover			√	√
Cover Sideslope			√	√
Rupert Sand	√	√	√	√
Burbank Loamy Sand	√	√	√	√
Hanford Formation Sediments		√		

5.2 Reasonable Bounding Cases

To specify that a bounding case is "reasonable" presumes some knowledge of its probability of occurrence. Some cases, such as complete replacement of shrub-steppe by cheatgrass, are theoretically possible but not probable (or reasonable). We consider these cases as alternative conceptual models and discuss them in Section 5.4. Some cases, such as renewed glacial activity, were considered too speculative for consideration.

For the reasonable bounding cases, we assumed a shrub-steppe plant community, current climate, and no irrigated farming. We identified a single lower reasonable bounding case that represents the situation in which recharge rates are at their lowest possible values. We identified two upper reasonable bounding cases in which recharge rates are at their highest possible values. These bounding cases represent possible variations in how the system might work and give an indication of the level of uncertainty in the recharge estimates.

5.2.1 Lower Bounding Case

We interpret this case to be a fully functional surface cover and a dense shrub-steppe community on the cover and the surrounding soils.

5.2.2 Upper Bounding Cases

We interpret these cases to be situations in which recharge is potentially higher than the best estimate case because of degradation of the cover or variations in soil and plant effects.

Erosion of the Surface Cover. Wind and water erode 0.2 m of silt loam from the surface of the cover.

Dune Sand Deposition on the Surface Cover. Wind deposits a 0.2-m layer of dune sand.

5.3 Sensitivity Tests

Recharge sensitivities can be determined through the controlled manipulation of selected parameters and processes. For this report, we elected to vary vegetation (type, presence, and density), soil hydraulic properties, and climate.

5.4 Uncertainty Tests

In our conceptual model of recharge, we assumed a shrub-steppe plant community, current climate conditions, and no irrigated farming. Three alternative conceptual models were prepared and tested to demonstrate the impact of these assumptions on recharge estimates.

Vegetation Change. Through fire, disturbance, disease, or successful competition with the native species, the shallow-rooted alien species cheatgrass becomes the dominant plant. Cheatgrass is so successful that it precludes the deeper-rooted plants from re-establishing.

Climate Change. Precipitation rates increase and temperatures decrease to the maximum levels inferred from a pollen record that covers the last 100,000 years.

Irrigation. If, for whatever reason, farming is allowed on or near the disposal sites, irrigation will be a necessity.

A fourth assumption that we made, no significant subsidence, is currently being evaluated (LMHC 1999). Once the likelihood and degree of subsidence is established, we will evaluate the impacts on our recharge estimates.

6.0 Recharge Estimation Methods

Recharge rates at the Hanford Site can range from near zero to more than 100 mm/yr (Gee et al. 1992). To effectively cover this range, three complementary methods are used to estimate recharge rates: lysimetry, the tracer technique, and computer simulations. For a discussion of these and other methods, see the January-February 1994 issue of the *Soil Science Society of American Journal*. This issue contains a series of papers that were presented at a symposium titled "Recharge in Arid and Semiarid Regions." Rockhold et al. (1995) described how these methods were used at Hanford. Some of that description is included here along with additional considerations relevant to the presence of the subsurface ILAW disposal facility.

6.1 Lysimetry

The goal of lysimetry is to provide both performance data and model testing data for specific combinations of soil, vegetation, and precipitation. A lysimeter is a system that can be used to collect water that has flowed through and below the reach of the evaporation process and plant roots to become deep drainage and eventually recharge. The only method available for directly measuring recharge is lysimetry. One of the strengths of lysimetry is that it can provide a control volume in which a number of water balance components can be measured directly. This control volume provides the data needed to calibrate numerical models that can then be used to forecast recharge.

The Hanford Site has used lysimeters for multiple purposes (Gee and Jones 1985; Freeman and Gee 1989; Wittreich and Wilson 1991; Gee et al. 1993; Ward et al. 1997). The lysimeters used to provide data for this report include containers that isolate the soil from its surroundings and field-scale pads that collect drainage but do not isolate the soil.

The primary source of lysimeter data is the Field Lysimeter Test Facility (FLTF). Appendix A describes this facility and provides an overview of the data available. The facility was constructed in FY 1987 to test the performance of capillary barrier cover designs (Gee et al. 1989). The FLTF contains 18 large lysimeters (surface area > 2 m^2; depth from 1.5 to 3.0 m) and six smaller lysimeters (surface area is 0.07 m^2; depth 3.0 m). Treatments include variations of material types and thicknesses, the presence of vegetation, and the use of irrigation to mimic the increased precipitation of a possible future climate. Data from this facility include drainage, water content, matric potential, temperature, and vegetation observations.

Another source of lysimeter data for this report is the Hanford Prototype Barrier, a full-scale barrier constructed above an actual waste site (Ward et al. 1997). The Prototype Barrier design differs slightly from most of the tests in the FLTF in that the surface silt loam layer is 2 m thick (rather than 1.5 m) and the upper meter contains gravel for erosion control (only two FLTF lysimeters contain gravel in the silt loam layer, and only in the upper 0.3 m). More importantly, the Prototype Barrier differs from the FLTF tests in that it is a full-scale test that includes sideslope effects.

The Prototype Barrier is instrumented to measure variables such as water content, matric potential, temperature, and drainage. One of the unique and valuable features of the Prototype Barrier is the presence of asphalt collection pads for drainage collection. These pads are part of the asphalt layer that underlies the entire Prototype Barrier. Individual collection pads were constructed using asphalt curbing to separate the different collection zones. Four 322-m^2 collection zones underlie the main portion of the Barrier. Two similar zones lie beneath each of the two different sideslope designs (one is sandy gravel, the other is basalt riprap). In addition, a collection lysimeter was constructed beneath the northeast portion of the barrier, under the asphalt layer that lies beneath the basalt sideslope treatment. This lysimeter provides a measure of the effectiveness of the asphalt layer in preventing drainage.

Although they provide the only direct measure of recharge, lysimeters have disadvantages. Lysimeters are usually fixed in space, which limits their ability to quantify the effects of spatial variability. The soils filling the lysimeter may not represent the natural stratification or layering that may be present. The length of record is much shorter than time periods of interest. The lysimeter walls and base alter the natural gradients of temperature, air flow, and vapor flow that could be of importance when trying to measure recharge rates less than 1 mm/yr. Lysimeter walls restrict lateral root growth and promote downward growth. When they involve irrigation, the lysimeter tests are subject to the "oasis effect," in which heat from the un-irrigated surroundings increases the evapotranspiration rate above what it would have been if the entire area had been irrigated. Finally, one of the issues with using lysimeters is verifying that no leaks of drainage water have occurred.

6.2 Tracers

The goal of the tracer method is to estimate historical recharge using measurements of tracer distributions in the soil and sediments of the vadose zone. The advantage of this method is that multiple tracers are available that enable estimates of recharge rates for durations of tens to thousands of years. The vertical distribution of tracers represents the integration of many recharge events and can be used to estimate the mean recharge rate for the time scale of interest for a performance assessment.

The two tracers used for this report are chloride (Cl) and chlorine-36 (^{36}Cl). Chloride originates from sea water, is deposited naturally, and can provide recharge estimates spanning hundreds to thousands of years. Chlorine-36 originates from two sources: cosmic irradiation of atmospheric chloride and nuclear weapons testing. The natural process of cosmic irradiation produces very minute quantities of ^{36}Cl. In contrast, nuclear weapons testing in the 1950s and early 1960s injected considerable quantities of ^{36}Cl into the atmosphere. The ^{36}Cl originated from sea level testing, which caused the thermal neutron irradiation of chloride in sea water (Phillips 1994). The quantities of ^{36}Cl created by the testing were far higher than natural production rates and thus became a marker in the environment. The ^{36}Cl data can be used to estimate the average recharge rate over the last 40 years. Appendix B describes the tracer data collected for the ILAW PA project.

Both chloride and ^{36}Cl are conservative, nonvolatile, and almost completely retained in the soil when water evaporates or is transpired by plants (Phillips 1994). Some chloride is taken up by plants (e.g., Rickard and Vaughan 1988; Sheppard et al. 1998). Over hundreds to thousands of years, we expect plant cycling has a minimal impact on the evolution of the chloride distribution in the profile beneath plant

nets. In contrast, bomb-pulse ^{36}Cl has been around only ~40 years, so caution must be exercised when interpreting such data. In soils with high pH and high adsorption of other anions, anion exclusion can result in faster movement of chloride. Previous studies have shown a direct correlation between clay content and anion exclusion (Warrick et al. 1971). Most of the sandy soils on the Hanford Site have relatively low percentages of clay, so the effects of anion exclusion in these soils should be relatively minor.

Appendix B describes the calculation of chloride deposition at the ILAW Disposal Site. The value, 38.4 mg/m^2/yr, is consistent with earlier estimates that ranged from 32.7 to 49.4 mg/m^2/yr (Murphy et al. 1996; Prych 1998). At a site to the west of the 200 West Area, Murphy et al. (1996) estimated the deposition rate to be 40.0 ± 7.3 mg/m^2/yr. Although year-to-year variability in chloride deposition rates likely exists, we expect the long-term average is adequately represented.

Phillips (1994) suggested that systematic uncertainties in estimated chloride deposition rates can be as great as 20% if the chloride mass balance technique is extended to estimate recharge rates prior to the Holocene epoch (approximately 10,000 years ago). Because the Hanford Site was flooded by glacial melt water about 13,000 years ago, we are not extending our interpretation beyond that time. Therefore, we expect that the uncertainty in chloride deposition rates at the Hanford Site is less than 20%.

There is some uncertainty about the local influence that Hanford Site operations may have had on the time-dependent concentrations of both chloride and ^{36}Cl deposited at Hanford. The issue of locally generated chloride is under review (see Appendix E). Murphy et al. (1991) examined the issue relative to ^{36}Cl and concluded there was no nearby source that would confuse the ^{36}Cl signal in the sediment.

The primary source of tracer data for this report is the analyses of samples collected from boreholes that were drilled by the ILAW PA project in 1995 and 1998. The analyses are described in Appendix B. In addition, a few measurements of tracer profiles have been performed by other projects at the Hanford Site (Murphy et al. 1996; Prych 1998). These data were also used for this report. Descriptions of the measurement procedures can be found in Appendix B, Murphy et al. (1991), Murphy et al. (1996), and Prych (1998). The analysis methods are briefly described below.

Chloride. Recharge is estimated from the chloride concentration within a soil profile as follows:

$$J_R = \left(\frac{Cl_o}{Cl_{sw}} \right) P \qquad (6.1)$$

where J_R is the liquid water flux at the depth of measurement, Cl_o is the chloride concentration of the precipitation, Cl_{sw} is the chloride concentration in the soil water, and P is the annual precipitation rate. Because chloride can be deposited by dry fallout, the value of Cl_o is adjusted to represent the total annual wet and dry chloride deposition rate divided by the annual precipitation rate. The value of Cl_{sw} can be determined by plotting cumulative chloride content with depth against cumulative water content at the same depths. The slopes of straight-line segments correspond to Cl_{sw} for the depth interval (Phillips

1994). Changes in the slopes of different line segments, corresponding to the different depth intervals, can represent the temporal variability of recharge rates and/or deposition rates.

Chlorine-36. An upper limit of the average recharge can be estimated from $^{36}Cl/Cl$ ratios by integrating the water content profile above the depth of the peak ratio or the centroid of the $^{36}Cl/Cl$ profile. A rough estimate can also be obtained by dividing the depth of the peak or centroid by the time since the bomb tests. A disadvantage of this method is that ^{36}Cl could still be within the root zone and thus yield too high an estimate of recharge (Tyler and Walker 1994). The likelihood of this problem happening increases for those sites at Hanford where recharge rates are lower than 10 mm/yr. Plant uptake and release can complicate the interpretation of the ^{36}Cl signal.

6.3 Modeling

The goals of modeling are to provide short-term estimates of recharge rates when there are little to no data and to leverage the existing short-term data into estimates of long-term recharge rates. Simulations of recharge at Hanford have been successful at highlighting the important factors that affect recharge and predicting recharge rates for specific cases. Modeling is the primary tool for forecasting recharge rates for future climate and land use scenarios. The simulations also allow the results of the lysimetry and tracer methods to be merged on a consistent basis.

The UNSAT-H computer code was used to estimate recharge rates for this report (Fayer and Jones 1990). UNSAT-H can simulate nonisothermal water flow processes in both liquid and vapor phases and hysteresis in the soil hydraulic properties. This model has been tested using data from several of the lysimeter experiments at Hanford and elsewhere (Fayer et al. 1992; Fayer and Gee 1992; Khire et al. 1997). Fayer and Gee (1997) tested UNSAT-H and a simpler model and concluded that UNSAT-H provided far better estimates of drainage through a surface cover. Scanlon (1992) used a similar unsaturated flow model to estimate recharge rates in the Chihuahuan Desert of Texas. Appendix C describes the modeling activity undertaken to estimate recharge rates for this report.

One of the disadvantages of numerical modeling is that it requires numerous parameters to represent climate, soils, and vegetation characteristics. In many instances, these parameters are unknown or only marginally known. Another disadvantage is the use of conceptual simplifications to make the modeling tractable. For example, Appendix F suggests that the current plant model may need to be revised. Numerical modeling with a code such as UNSAT-H is the most flexible method for estimating recharge rates, but its data-intensive needs and conceptual simplification could lead to recharge estimates that have the most uncertainty.

6.4 Additional Considerations

Several features of the ILAW disposal could affect the analysis of recharge rates, including physical effects, water consumption, temperature, and preferential flow. Physically, the vaults/disposal volume will be located 3 m below the base of the surface cover. At this depth, we do not anticipate any direct physical effect on recharge rates. The very low permeability of the vaults could affect the flow of air through the vadose zone, but we assume that any air exchange with the deep vadose zone is too small to

affect recharge rates significantly. The vaults could also affect the overall temperature gradient within the vadose zone, but we assume the effect to be too small to affect recharge rates significantly.

Silicate glasses such as the ILAW undergo corrosion when in water. The rate of corrosion depends on factors such as glass composition and the availability of water, which is consumed in the corrosion process. The maximum consumption rate was calculated to be 0.34 g of water per gram of glass (BP McGrail, personal communication). This level of water consumption will set up a matric potential gradient that causes water to move toward the ILAW. We recognized that this consumption might increase water flow through the cover. However, we assumed that, because the water was consumed in the corrosion process, the overall effect of this increased downward water movement was not significant to the analysis of recharge.

Radionuclides within the ILAW will undergo radioactive decay and thus generate heat. McGrail and Bacon (1998) reasoned that the long half-life and small concentration of radionuclides in ILAW would minimize any temperature increase over ambient conditions. Using the latest inventory of ^{90}Sr and ^{137}Cs in the ILAW, McGrail and Bacon (1998) estimated the maximum temperature increase would be 0.25°C between the vault center and the immediately surrounding soil. They concluded that this small temperature rise was within the expected seasonal temperature fluctuations at the site (about 2°C) and therefore not a significant factor affecting the performance of the disposal facility. We assumed that this small temperature perturbation would not affect recharge rates significantly.

Preferential flow paths such as clastic dikes could affect recharge under the right conditions. However, the vadose zone in and around the disposal facility will be excavated, thus eliminating any dikes that may be present near the soil surface. Therefore, we assumed that dikes would not be a factor in recharge. Preferential flow could also occur as a result of focused overland flow, such as at the toe of the cover sideslope. We intend to address this recharge mechanism in the next revision of the data package, once the surface cover and facility designs are more definite. Finally, preferential flow can occur at a very local scale as a result of flow instabilities that lead to "fingering." Hendricks and Yao (1996) found that, for a sand dune in New Mexico, instabilities occurred during a precipitation event only when the total precipitation exceeded 4 cm. At Hanford, total precipitation in a 24-h period has exceeded 4 cm only twice between 1947 and 1997 (by less than 1 cm in both cases). Therefore, we assumed that flow instabilities would not be a dominant phenomenon affecting recharge at Hanford.

7.0 Results

The recharge estimation process uses data from multiple and sometimes conflicting sources. The estimation process was an effort to maximize the value of the information in hand without forgetting the limitations of that information. In this section, we analyze the data and recharge estimates for the best estimate and bounding cases, demonstrate some recharge sensitivities, estimate recharge for three alternative conceptual models, and assign recharge rates to the best estimate and bounding cases. Following that, we outline the activities planned for FY 2000 and end with a summation of the known remaining issues.

7.1 Analyses for the Best Estimate and Reasonable Bounding Cases

For each of the surface features identified in Section 5.0, we have assessed the data available for estimating recharge rates. Where data are conflicting, we present alternate recharge estimates.

7.1.1 Modified RCRA Subtitle C Cover

The surface cover over the ILAW vaults will determine the flux of water directly down to and around the vaults. The FLTF data collected under ambient precipitation conditions showed that drainage rates through the cover were less than 0.001 mm/yr (Appendix A). For the drainage caissons, this rate represents about 3 mL/yr. When rates are seemingly this low, we should exercise caution because other factors could be affecting the results and ought to be considered (e.g., temperature gradients, leaks, and water storage within the basalt). Simulations of the cover indicated rates would be less than 0.1 mm/yr, but no attempt was made to see if the rate might be lower. In the previous PA (Mann et al. 1998), a recharge rate of 0.5 mm/yr was assigned to the cover. This value represented the design objective of the Hanford Prototype Barrier (Wing 1994). The data and simulations reported here support the use of a lower recharge estimate for the cover. Although there are indications of lower rates, we propose using a rate of 0.1 mm/yr for an intact surface cover with or without vegetation.

7.1.2 Sideslope

The surface cover may be elevated above the surrounding terrain. If so, the cover will need sideslopes to maintain its stability as well as to blend into the terrain. No specific sideslope designs have yet been chosen. However, the ongoing testing of sideslopes at the Hanford Prototype Barrier provided some useful performance data. Two sideslopes are being tested: basalt riprap and sandy gravel. The high cost of basalt riprap makes the use of sandy gravel attractive. Ward et al. (1997) reported that drainage though the sandy gravel sideslope was 31.4% of the precipitation in a 3-year period. Assuming that fraction remained constant for the long-term average precipitation rate of 160 mm/yr, the long-term drainage rate would be 50 mm/yr. Assuming a 1:10 (V:H) sandy gravel sideslope with vegetation (the same as the Prototype), we estimate a recharge rate of 50 mm/yr under ambient precipitation.

The asphalt layer terminates under the sideslope. The water draining through the sideslope will be collected and routed laterally and infiltrate just beyond the edge of the asphalt. Ward et al. (1997)

detected this infiltration zone at the Hanford Prototype Barrier. In addition to the sideslope drainage water, the asphalt layer will also convey any water that drains through the cover's surface layer. This additional water should be inconsequential relative to the quantity of sideslope drainage water.

7.1.3 Rupert Sand

Rupert sand covers most of the two disposal sites. We assume that, following closure, the disturbed area surrounding the covers will be reconstituted to mimic Rupert sand. The chloride tracer data in Appendix B suggest a range of recharge rates depending on location and depth. The chloride data above the 5- to 10-m depth represent more recent recharge rates. The analysis of these data shows a recharge rate ranging from 0.013 to 0.065 mm/yr, with an overall average of 0.03 mm/yr. In contrast, the chloride data below 10 m represent recharge rates thousands of years ago (based on the accumulated chloride above 10 m). These data indicate a recharge rate range from 0.16 to 1.8 mm/yr, with an average rate of 0.9 mm/yr. If we ignore the time difference and simply average the multiple estimates, we get an average recharge rate of 0.4 mm/yr.

We have some concern about chloride contamination from nearby facilities. The presence of facility-generated chloride within the soil profile would cause, if unrecognized, an underestimate of the recharge rate using the traditional chloride method. Figure 7.1 shows a photograph looking southeast over the new ILAW Disposal Site. In the foreground are the 200 East Area coal-fired power plant and the water purification plant. Both facilities are suspected to be emitters of chloride. The coal plant, in particular, is a likely source because it began operations in late 1944 and did not use emission controls until 1980, when a baghouse (to filter out particulates) was installed. The new ILAW Disposal Site is directly downwind given that the prevailing wind direction is from the northwest. To determine whether coal plant emissions had deposited chloride at the tracer sampling sites, we collected soil samples from ten locations and analyzed them for multiple constituents, including known constituents of coal. Appendix E describes the testing and results, which were inconclusive but suggestive of deposition. Additional testing is being performed to clear up the uncertainty. If chloride from local facilities was deposited at the ILAW sites, we should still be able to use the deeper chloride data that reflect pre-Hanford conditions.

Appendix B shows that bomb-pulse ^{36}Cl still resides entirely within the root zone (the upper 2 m of soil). While still in the root zone, ^{36}Cl cannot be used to estimate recharge. However, we can establish a rough upper limit. Assuming an average root zone water content of 0.1 cm^3/cm^3, the recharge rate would have to be much less than 5 mm/yr to explain the absence of ^{36}Cl below 2 m.

We have two other estimates of recharge in Rupert sand. One of those estimates was derived from the simulations in Appendix C that suggested a recharge rate of 2.2 mm/yr. The other estimate came from Murphy et al. (1996), who measured chloride concentrations in Rupert sand located near the Wye barricade. This site is about 13 km to the southeast of the ILAW disposal sites. At that distance, the site should be unaffected by any emissions from the coal plant or other facilities. The shrub density in that general area is far less than at the ILAW Disposal Site. Using the chloride tracer method, Murphy et al. (1996) estimated a recharge rate of 4 mm/yr. This value is much higher than the estimates for the ILAW

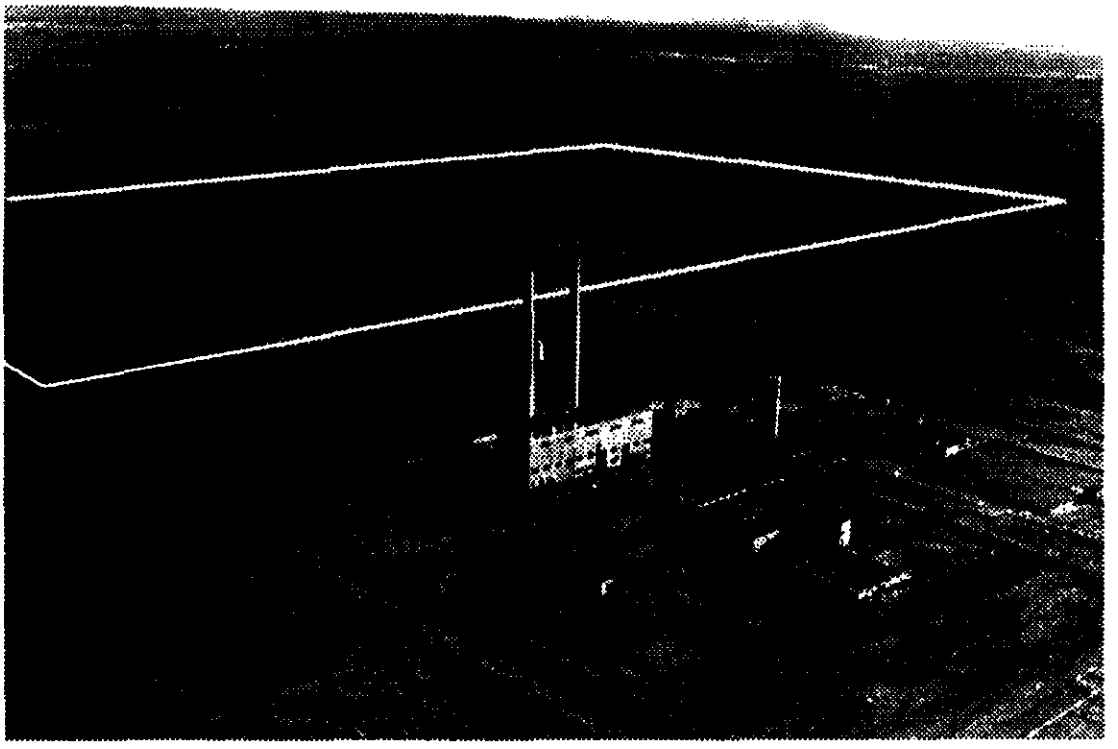

Figure 7.1. Aerial View of the New ILAW Disposal Site. The viewing direction is southeast. The 200 East Coal Power Plant and Water Purification Plant are in the foreground. The Existing Disposal Site, which is not shown, is 1.4 km directly east of the coal plant.

Disposal Site despite both sites being classified as shrub-steppe on Rupert sand. The distinctly different recharge estimates likely reflect differences in soil hydraulic properties and vegetation between the two sites.

There is enough variability in the data to exercise caution with this estimate. We propose using the average ILAW-specific estimate of 0.9 mm/yr for Rupert sand based on the deeper chloride data until the concern about facility emissions is resolved.

7.1.4 Burbank Loamy Sand

Prych (1998) estimated recharge for Burbank loamy sand using samples from two boreholes drilled less than 1 km north of the ILAW disposal sites. Using the chloride data above the 10-m depth, Prych estimated rates of 0.02 and 0.04 mm/yr. Using the chloride data below the 10-m depth, Prych estimated the recharge rates to be 2.8 and 5.5 mm/yr, which yields an average rate of 4.2 mm/yr. The borehole site is further from the coal plant than the ILAW sites, but it is directly downwind of the peak wind direction (from the southwest). The simulation results in Appendix C showed a recharge rate of 5.5 mm/yr in this soil.

Because of our concern about the shallower chloride data, we would rather use the mean of the deeper chloride estimates reported by Prych (1998). Therefore, we propose using a recharge rate of 4.2 mm/yr for Burbank loamy sand.

7.1.5 Hanford Formation Sand

During vault construction and filling, Hanford formation sand will be exposed and vegetation will likely not exist. Fayer and Walters (1995) reported that an unvegetated 7.6-m deep lysimeter containing Hanford sand drained 443 mm from July 1985 to June 1993 for an average rate of 55.4 mm/yr. For the conditions envisioned during facility construction, we propose using a recharge rate of 55.4 mm/yr.

During construction, we expect water will be used for dust control and compaction. The most likely period for water application will be late spring to early fall when the soil is typically driest. Under these conditions, we expect that the added water will not drain deep enough to impact recharge rates.

7.2 Sensitivity Tests

Some of the modeling results in Appendix C indicate the sensitivity of certain parameters and processes. These include vegetation presence, type, and abundance; soil properties; and climate.

7.2.1 Vegetation

The simulation results showed that the recharge rate through the surface cover was not sensitive to the type of plant or even to the presence of plants, at least to the model precision level of 0.1 mm/yr that was achieved. In contrast, recharge under the Rupert sand increased from 2.2 mm/yr under shrub-steppe to 33.2 mm/yr under cheatgrass to 44.3 mm/yr when plants were absent. Without plants, recharge under the Burbank loamy sand increased by a factor of 10 (from 5.2 to 52.5 mm/yr).

The robustness of the vegetation on Rupert sand was also tested by varying the leaf area index to encompass the range of values measured at the ILAW Disposal Site in 1998 (Appendix F). Increasing the shrub leaf area index by 60% reduced the predicted recharge from 2.2 to 1.6 mm/yr. Decreasing the shrub leaf area index by 60% increased the predicted recharge from 2.2 to 5.6 mm/yr. In both cases, the variation in recharge was within a factor of 2 to 3 of the base estimate of 2.2 mm/yr.

7.2.2 Soil Properties

The simulation results showed a minor sensitivity to soil properties. Two alternate hydraulic property descriptions for Rupert sand were used in separate simulations. These properties were obtained from a field infiltration test conducted at the new ILAW Disposal Site. The resulting predicted recharge rates were 2.7 and 3.3 mm/yr, compared to the base case estimate of 2.2 mm/yr.

7.2.3 Climate

The simulation results showed that the surface cover would be unaffected by any envisioned change in climate. In contrast, the simulation results showed that recharge in the soils would be significantly affected. Using Rupert sand, the nine combinations of three temperature regimes and three precipitation regimes yielded estimated recharge rates that ranged from less than 0.1 to 27 mm/yr. When precipitation was 50% of modern levels, recharge was less than 0.1 mm/yr regardless of the temperature scenario. For modern precipitation levels, estimated recharge ranged from 0.6 to 7.5 mm/yr for the high to low temperature regimes, respectively. For the high precipitation regime (128% of modern levels), the recharge rates increased, ranging from 5.2 to 27 mm/yr.

7.3 Uncertainty Tests

One method to gauge the uncertainty in recharge estimates is to analyze alternative conceptual models. The model results in Appendix C were used to address a change in the vegetation, a change in the climate, and irrigation.

One of the two cover degradation scenarios was that 20% of the silt loam layer was eroded. The simulation results in Appendix C showed that the eroded cover with shrub-steppe vegetation performed as well as the intact cover, i.e., it limited drainage to less than 0.1 mm/yr. The second degradation scenario involved the deposition of 20 cm of dune sand on the cover. The simulation results showed that the cover with dune sand and shrub-steppe vegetation also performed as well the intact cover. The simulation results also showed that the replacement of shrubs with cheatgrass for this particular situation resulted in drainage of 18.4 mm/yr, and the removal of all plants caused drainage to increase to 32.7 mm/yr. We expect that deep-rooted plants like sagebrush will always be present, therefore we propose using a rate of 0.1 mm/yr for the degraded cover scenario.

7.3.1 Vegetation Change

The simulation results in Appendix C showed that a surface cover without vegetation limited recharge to less than 0.1 mm/yr. This level of performance is as good as a cover with shrub-steppe vegetation. Without conducting a simulation with cheatgrass, we assumed that a cover with cheatgrass would limit recharge to less than 0.1 mm/yr. The same simulation results were obtained for an eroded cover without plants, showing how robust the silt loam cover is at reducing recharge, even in the absence of plants.

The results in Appendix C indicate that a shift from shrub-steppe to cheatgrass on the Rupert sand will raise the recharge rate from 2.2 to 33.2 mm/yr. This higher estimate of recharge is not unreasonable. Fayer and Walters (1995) used water content measurements to estimate recharge rates for a cheatgrass community growing on Rupert sand in the 300 Area. For an 8-year period, they estimated the average recharge rate was 25.4 mm/yr.

7.3.2 Climate Change

The prediction of climate change is a current research topic. Because we cannot foresee the future, we have used the past to see what has happened and possibly could happen again. Appendix C describes the analysis. Under climate change conditions most likely to promote recharge (i.e., higher precipitation and lower temperature), the surface cover continued to limit drainage to less than 0.1 mm/yr as did the eroded surface cover. With 20 cm of dune sand on the cover, this climate scenario resulted in a recharge rate of 16.9 mm/yr. Recharge in the Rupert sand jumped from 2.2 to 27 mm/yr and in the Burbank loamy sand from 5.2 to 36.8 mm/yr. In all cases, a shrub-steppe community was present.

7.3.3 Irrigation

All of the land use options currently being considered for Hanford exclude farming on and near the waste disposal sites. Because such institutional controls cannot be guaranteed to survive forever, we evaluated the impacts of irrigated agriculture on recharge. Appendix C describes the numerical simulations that were conducted. For a potato crop grown on the surface cover, recharge was 26.4 and <0.1 mm/yr for irrigation efficiencies of 75 and 100%, respectively. For Rupert sand, the rates were 57 and 30 mm/yr for the same efficiencies. We assumed there would be no farming on Burbank loamy sand because of the high gravel content. An effort was started in FY 1999 to evaluate current and projected irrigation practices around Hanford (LMHC 1999). The results of that effort will be used to improve and refine our recharge estimates for irrigated farming.

7.4 Assignment of Recharge Rates to Scenarios

The data and analyses just discussed were used to assign recharge rates to each of the scenarios identified in Section 5.0. The estimated rates were assigned to the best estimate and to the lower and upper bounding cases.

7.4.1 Best Estimate Case

Table 7.1 shows the estimated recharge rates for each surface feature during each phase of the disposal evaluation. As discussed in Section 7.1, the cover, cover sideslope, and Hanford formation estimates are based on lysimeter data. The Rupert sand and Burbank loamy sand estimates are based on chloride data.

7.4.2 Reasonable Bounding Cases

The lower bounding case represents the situation in which recharge rates are at their lowest possible values. The upper bounding cases represent situations in which recharge rates are at their highest possible values. Table 7.2 summarizes the rate assignments for both cases. We did not include climate change, sand dune migration, or irrigation effects in setting the bounding estimates.

Table 7.1 Recharge Estimates for the Best Estimate Case for Disposal Facility Features During Each Period of Interest to the ILAW 2001 PA. These estimates reflect current climate conditions. The surface cover, Rupert sand, and Burbank loamy sand have shrub-steppe vegetation.

Surface Feature	Estimated Recharge Rate (mm/yr)			
	Time Period of Recharge Evaluation			
	Pre-Hanford	During Disposal Operations	During Surface Cover Design Life	After Surface Cover Design Life
Modified RCRA Subtitle C Cover	NA	NA	0.1	0.1
Cover Sideslope	NA	NA	50	50
Rupert Sand	0.9	0.9	0.9	0.9
Burbank Loamy Sand	4.2	4.2	4.2	4.2
Hanford Formation Sediments	NA	55.4	NA	NA
NA = Not applicable.				

Table 7.2. Recharge Estimates for the Reasonable Bounding Cases During Each Period of Interest to the ILAW 2001 PA

Surface Feature	Estimated Upper and Lower Reasonable Bounding Recharge Rates (mm/yr)			
	Time Period of Recharge Evaluation			
	Pre-Hanford	During Disposal Operations	During Surface Cover Design Life	After Surface Cover Design Life
Modified RCRA Subtitle C Cover	NA	NA	0.01, 4.0	0.1, 4.0
Cover Sideslope	NA	NA	4.2, 86.4	4.2, 86.4
Rupert Sand	0.16, 4.0	0.16, 4.0	0.16, 4.0	0.16, 4.0
Burbank Loamy Sand	2.8, 5.5	2.8, 5.5	2.8, 5.5	2.8, 5.5
Hanford Formation Sediments	NA	50, 86.4	NA	NA
NA = Not applicable.				

The lower bounding case was a fully functional surface cover and a dense shrub-steppe community on the cover and the surrounding soils. We proposed using a recharge rate of 0.01 mm/yr for the cover. Lysimeter evidence suggests the rate is lower, but we are not yet ready to claim credit for that lower rate. We proposed using a rate of 4.2 mm/yr for the cover sideslope. This rate actually comes from our best estimate for Burbank loamy sand. This soil type has a large fraction of gravel (similar to a sandy gravel sideslope) and a shrub-steppe plant community (which sideslope tests to date have not included). We proposed using a recharge rate of 0.16 mm/yr for Rupert sand. This rate is the lowest of the four rates

estimated from site-specific chloride data. We proposed using a recharge rate of 2.8 mm/yr for the Burbank loamy sand. This rate is the lower of two rates estimated from chloride data. We proposed using a recharge rate of 50 mm/yr for the Hanford formation sediments during construction. This rate actually comes from drainage data collected from the sandy gravel sideslope test at the Prototype Barrier. The sideslope test has no shrubs and an extremely sparse cover of annuals.

The upper bounding case was a degraded surface cover and a sparse shrub-steppe community on the cover and the surrounding soils. We proposed using a recharge rate of 4.0 mm/yr for the cover. This rate was the estimate derived from Rupert sand with a sparse shrub cover. Simulation results suggest the rate is lower, but we are not yet ready to claim credit for that lower rate. We proposed using a rate of 86.4 mm/yr for the cover sideslope. This rate actually comes from lysimeter drainage data collected from an unvegetated sandy gravel test in the FLTF. We proposed using a recharge rate of 4.0 mm/yr for Rupert sand. This rate was the estimate derived from chloride data in Rupert sand with a sparse shrub cover. We proposed using a recharge rate of 5.5 mm/yr for the Burbank loamy sand. This rate is the higher of two rates estimated from chloride data. We proposed using a recharge rate of 86.4 mm/yr for the Hanford formation sediments during construction. This rate actually comes from lysimeter drainage data collected from an unvegetated sandy gravel test in the FLTF.

7.5 Plans for FY 2000

The ILAW PA project continues to support data collection and analysis activities to improve the estimates of recharge for its scenarios of interest. Current plans call for FY 2000 activities in lysimetry, tracers, modeling, vegetation studies, the initiation of field tests, and continuation of updates to the Recharge Data Package. These plans are described briefly below; details can be found in LMHC (1999).

We will continue to monitor the lysimeters at the FLTF. For some lysimeters, the performance data will eventually span 14 years (by the year 2001), providing a valuable data set for verifying barrier performance and testing model predictions. A subset of the lysimeters is being used to collect performance data for degraded and modified barriers and for recharge in the adjacent land following a change in vegetation, all under both ambient and enhanced precipitation. These tests were initiated in FY 1998 and FY 1999 and will provide performance data through the year 2001.

The chloride and ^{36}Cl tracer methods will again be employed to estimate recharge rates. Additional ILAW boreholes will be drilled in a manner similar to the borehole drilled in FY 1998 (see Appendix B). Additional shallow boreholes (~15 m) may be drilled near the new boreholes to provide additional sediment material. The sediments will be analyzed using procedures similar to those used previously and recharge rates will be estimated for each borehole.

The capabilities of the UNSAT-H computer code will be increased to address multiple plant species, plant response to seasonality effects, and snow/snowmelt effects. These additional capabilities will

address comments received during an earlier peer review workshop (Honeyman 1995).[1] The modified version of the code will be formally documented and the theory and user manual will be published. The modified code will be tested using data from the lysimeters and the vegetation subtask. An uncertainty analysis will be conducted using UNSAT-H within an existing uncertainty analysis framework.

Based on previous work, additional transects will be sampled for roots in the ILAW Disposal Site. The data will be collected to depths deeper than sampled earlier (i.e., at least 2 m) to confirm the observation of shrub/inter-shrub differences and to provide data to describe the spatial variability of rooting patterns. Based on these and earlier data, a hypothesis will be proposed for describing such rooting behavior. The results will be used to support recharge simulations. We will continue to sample plant water status throughout the year so that the relationship of plant behavior to weather will be clearer and more quantifiable. These measurements will be coordinated with the Field Recharge Study (see below) so that correlations can be made between soil water status and plant water status. Based on these and earlier data, a hypotheses will be proposed for describing transpiration during these times. The results will be used to support recharge simulations.

Acceptance of the ILAW PA will depend, in part, on demonstrating a good understanding of the processes that affect natural recharge rates at the two disposal sites. Although lysimeter, modeling, and tracer studies are being conducted and will be useful, some direct field testing at the sites is necessary. The objectives of the field recharge study are to observe field water behavior during several winters, document the variability of such behavior, provide soil water status information for the vegetation task (i.e., the study of plant water status), and provide a set of field data for model testing. Two locations will be identified at the disposal sites and instrumented to measure water content and matric potential at multiple depths within and below the root zone. The layout will be designed to differentiate between water movement beneath shrubs and water movement in the inter-shrub spaces. These measurements will be coordinated with the Vegetation Task so that correlations can be made between soil water status and plant water status. The data will also be used to support the design of a waste form release field test (LMHC 1999).

Beyond FY 2000, several issues need to be more fully evaluated. These issues include unstable and preferential flow, uniformity and longevity of the cover, and flaws in the cover. These flaws include differential settling and cracking, discontinuities, and points of flow convergence.

7.6 Remaining Issues

As with any estimation activity involving multiple data sources, spatial variability, and time frames of thousands of years, there are many issues and concerns that need and deserve attention. Three of the more important issues are lysimeter drainage resolution, possible facility deposition of chloride, and the importance of temperature and water vapor flow when recharge rates are low.

(a) Honeyman JO. 1995. Letter to L Erickson transmitting the results of the 1995 workshop entitled "Summary of peer review comments resulting from the second Hanford groundwater recharge workshop." May 22-23, 1995, Richland, Washington.

Lysimeters that have materials in them do not lend themselves well to testing for leaks because the presence of the material can affect the leak test, which is the case for most of the leak tests conducted to date. Recently, some lysimeters were emptied for new tests. The interiors of the lysimeters were in good shape and showed no obvious sign of corrosion near the base where a sealant had been applied. These lysimeters were leak tested, but the tests were short in duration. While we can say the leak rate was less than 0.5 mm/yr, we cannot say with certainty that there was no leakage. Overall, the leak tests show that there were no major leaks, but they have not been precise enough to state unequivocally that the leak rate is zero. The next time a lysimeter is to be emptied for a new test, it should be leak tested much more extensively to verify that leakage is less than 0.01 mm/yr.

The appropriate use of the chloride method to estimate recharge rates in the 200 Areas depends on resolving the issue of possible facility emissions of chloride. Appendix E suggested that sulfate may be a marker of coal plant emissions, although sulfate is somewhat less mobile than chloride (Bohn et al. 1979). Several soil profiles will be analyzed for sulfate in the summer of 1999. If high sulfate and chloride concentrations are not depth-correlated, then we can use the entire chloride profile to estimate deep drainage fluxes along with their dates (see Appendix B). If they are depth-correlated, indicating deposition of coal plant emissions, we will continue to use the deeper chloride data that are located below the sulfate pulse (and presumably pre-Hanford). However, we will not be able to age-date the fluxes using the chloride accumulation technique.

Some of the recharge estimates are in the range of 1 mm/yr and less. At these rates, temperature and vapor flow are more important to accurate estimates of recharge than they are when rates are greater than 10 mm/yr. Past studies have considered these processes using field measurements of temperature and matric potential (e.g., Enfield et al. 1973). However, the methods used to estimate recharge for the ILAW disposal sites did not fully address these processes. Lysimeters, by their nature, de-couple the interior soil from the surrounding soil, thus preventing vapor flow and altering temperature gradients. Because it moves only in liquid water, the chloride tracer cannot indicate the magnitude of the vapor flow contribution to recharge (positive or negative). One way to gather data relevant to low recharge rates is to install instrumentation at the ILAW Disposal Site. In situ measurements of temperature and matric potential gradients at multiple depths would help resolve the magnitude of the low recharge fluxes.

8.0 Conclusions

LMHC is conducting a performance assessment for the proposed disposal of ILAW in the 200 East Area of the Hanford Site. The goal of the PA is to provide a reasonable expectation that the disposal is protective of the general public, groundwater resources, air resources, surface water resources, and inadvertent intruders. PNNL assists LMHC in their performance assessment activities. One of the PNNL tasks is to provide estimates of recharge rates for current conditions and long-term scenarios involving the shallow-land disposal of ILAW. Specifically, recharge estimates are needed for a fully functional surface cover, the cover sideslope, and the immediately surrounding terrain. In addition, recharge estimates are needed for degraded cover conditions. The temporal scope of the analysis is 10,000 years, but could be longer if some contaminant peaks occur after 10,000 years.

The elements of this report compose the Recharge Data Package, which provides estimates of recharge rates for the scenarios being considered in the 2001 PA. The estimates were derived from lysimeter and tracer data collected by the ILAW PA and other projects and from modeling analyses.

For the best estimate case, we proposed using a recharge rate of 0.1 mm/yr for the surface cover with a shrub-steppe plant community. This rate is lower than the cover design goal of 0.5 mm/yr because it reflects the actual performance measured with lysimeters and inferred with modeling. The simulation results showed that erosion of 20% of the silt loam layer did not impair this performance nor did the deposition of 20 cm of dune sand. For the sandy gravel sideslope, we proposed using a recharge rate of 50 mm/yr. This rate is lower than the 75 mm/yr used in the 1998 ILAW PA. For the soil type known as Rupert sand and a shrub-steppe plant community, we proposed using a recharge rate of 0.9 mm/yr. This rate is lower than the 3 mm/yr used in the 1998 ILAW PA. For the soil type known as Burbank loamy sand and a shrub steppe-plant community, we proposed using a recharge rate of 4.2 mm/yr. This soil type was not considered in the 1998 ILAW PA. For the Hanford formation sediments during construction, we proposed using a recharge rate of 55.4 mm/yr. Recharge in Hanford formation sediments during construction was not considered in the 1998 ILAW PA.

A limited number of sensitivity tests were conducted. The results showed that the surface cover limited recharge to less than 0.1 mm/yr regardless of the plant type, the presence of plants, or any of the climate change conditions. In contrast, recharge in the Rupert sand showed a significant sensitivity to vegetation type and climate change conditions, but less sensitivity to small variations in hydraulic properties.

Several alternative conceptual models were considered to indicate the effects of conceptual model uncertainty. Replacement of the shrub cover with cheatgrass had no impact on recharge through the surface cover, but it increased recharge in Rupert sand from 2.2 to 33.2 mm/yr. Under the climate change condition most likely to promote recharge (i.e., increased precipitation and decreased temperature), recharge through the cover remained <0.1 mm/yr in contrast to this recharge in Rupert sand, which increased from 2.2 to 27 mm/yr.

Irrigation on the surface cover caused recharge to increase from 0.1 to 26.4 mm/yr as the irrigation efficiency was reduced from 100 to 75%.

Using the available recharge estimates, we identified a set of reasonable bounding rates. The design feature with the largest projected range in performance was the sideslope (4.2 to 87.5 mm/yr). Given that sideslopes could represent a significant fraction of the surface cover footprint, we believe that efforts to improve sideslope performance are warranted.

Issues remaining to be addressed include the precision of lysimeter leak tests to support the use of lower recharge estimates, possible facility deposition of chloride that could impact tracer analyses, and the importance of temperature and water vapor flow when recharge rate estimates are lower than 1 mm/yr. In addition, the impacts of unstable and preferential flow and flaws in the cover need to be evaluated.

Appendix A

Field Lysimeter Test Facility Data to Support the ILAW 2001 PA

A.1 Introduction

Lockheed Martin Hanford Company (LMHC) is designing and assessing the performance of disposal facilities to receive radioactive wastes that are currently stored in single- and double-shell tanks at the Hanford Site. The preferred method of disposing of the portion that is classified as immobilized low-activity waste (ILAW) is to vitrify the waste and place the product in near-surface, shallow-land burial facilities. The LMHC project to assess the performance of these disposal facilities is known as the Hanford ILAW Performance Assessment (PA) Activity, hereafter called the ILAW PA. Acceptance of ILAW disposal at Hanford depends on demonstrating that public health and the environment are adequately protected. Achieving this goal will require predictions of contaminant migration from the facility. To make such predictions will require estimates of the fluxes of water moving through the sediments within the vadose zone beneath and around the disposal facility. These fluxes, loosely called recharge rates, are the primary mechanism for transporting contaminants to the groundwater.

Mann (1999) indicates that two disposal sites will be considered: the ILAW Disposal Site (located southwest of the PUREX Plant) and the site of the former Grout Vaults. For each, recharge rate estimates are needed for a fully functional surface cover, its sideslope, and the immediately surrounding terrain. In addition, recharge estimates are needed for degraded conditions and for the case of irrigated farming directly on the cover. Mann (1999) indicates that the temporal scope of the 2001 ILAW PA is 10,000 years, but could be longer as some contaminant peaks occur after 10,000 years.

Pacific Northwest National Laboratory (PNNL) assists LMHC in their performance assessment activities. One of the PNNL tasks is to provide defensible estimates of recharge rates for current conditions and long-term scenarios involving the shallow-land disposal of ILAW (LMHC 1999). A major goal of the recharge task is to collect sufficient data for the conditions and scenarios deemed to be important for evaluating the performance of the disposal facilities. These rate estimates will be provided using lysimetry, tracer studies, and modeling studies.

The recharge task uses the lysimeters at the Field Lysimeter Test Facility (FLTF) in the 200 West Area to collect recharge-related data. The two goals of the lysimeter work are to accurately quantify the recharge flux for scenarios pertinent to the ILAW project and provide a set of long-term monitoring data with which to test the recharge model (e.g., Fayer et al. 1992). This model will be used to extend the observations and estimate recharge rates for potential future scenarios. This appendix summarizes the lysimeter data that have been collected from the FLTF through March 31, 1999.

A.2 Background

The Protective Barrier Program constructed the FLTF in FY 1987 to test the performance of capillary barrier cover designs (Gee et al. 1989; Wing 1994). Figure A.1 shows the location of the FLTF within the 200 Areas. Figure A.2 shows the layout of the FLTF.

The facility contains a total of 24 lysimeters of three types: 14 drainage, 4 weighing, and 6 small-tube lysimeters. The drainage lysimeters are vertical cylinders that are 3 m deep and 2 m in diameter (surface area of 3.08 m^2). The drainage lysimeters compose the walls of the FLTF.

The weighing lysimeters are boxes with length and width dimensions of 1.5 m and a depth of 1.7 m. The boxes rest on platform scales to enable hourly weight measurements of water gain and loss. The weighing lysimeters are at the south end of the FLTF (Figure A.2).

The small-tube lysimeters are vertical cylinders that are 3 m deep and 0.3 m in diameter (surface area of 0.07 m^2). Unlike the others, the small-tube lysimeters are clear Plexiglas to facilitate root and soil observations. These lysimeters are arrayed along the inner walls of the FLTF but are not shown in Figure A.2.

Treatments involve variations of material types and thickness, presence of vegetation, and the use of irrigation to mimic the possible increased precipitation of future climate. Data from this facility include drainage, water content, matric potential, temperature, and vegetation observations. Discussions of the early data from this facility can be found in Gee et al. (1989), Campbell et al. (1990), Campbell and Gee (1990), and Gee et al. (1993a).

Because a surface barrier is part of the current conceptual model of the ILAW Disposal Site, the data collected at the FLTF are being used to support recharge estimation for the performance assessment. In 1994, the emphasis of the Protective Barrier Program switched from monitoring the FLTF to constructing and monitoring a prototype barrier in the 200 East Area (Gee et al. 1993b). The change in program emphasis created an opportunity for the ILAW PA disposal project to conduct testing in the facility for soil-vegetation-climate treatments of importance to the ILAW PA project.

Fayer and Felmy (1996)[1] described the testing and measurement techniques supported by the ILAW PA project from June 1995 to September 1996. The ILAW-supported activities were at a reduced level relative to the measurement activity conducted under the Protective Barrier Program. Since 1996, the irrigation and monitoring activities have continued on the same limited basis and results have been described briefly in monthly reports. In FY 1998, seven lysimeters were modified to address three important PA scenarios: sand deposition on the barrier, erosion of barrier material, and complete coverage of the barrier by a sand dune. In FY 1999, two additional lysimeters were modified to collect performance data on the modified Resource Conservation and Recovery Act (RCRA) Subtitle C surface

cover design (DOE/RL 1996). The ILAW project is considering this design as a cost-effective substitute to the Hanford Protective Barrier (Myers and Duranceau 1994).

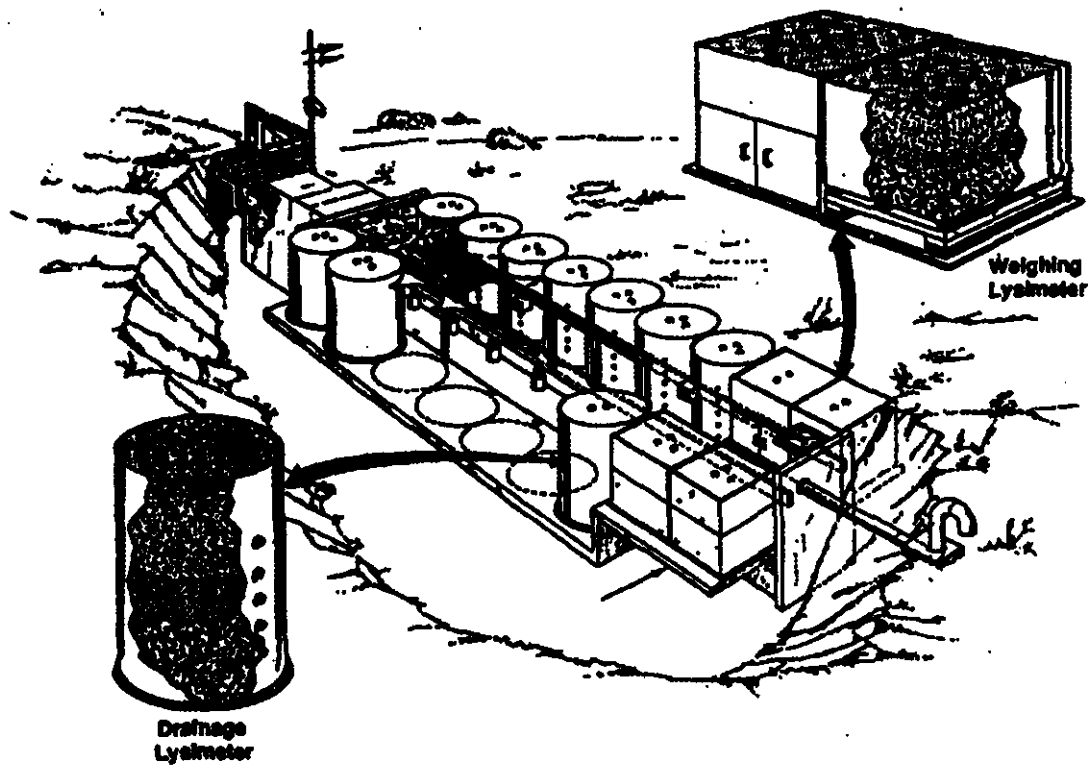

Figure A.2. Artist's Rendering of the FLTF

A.3 Methods

When the FLTF was constructed in 1987, three tests (and seven treatments) were being conducted. When testing was completed for some of the lysimeters, those lysimeters were converted to new tests and treatments. As of March 31, 1999, the number of tests had expanded to 11 and the number of treatments had expanded to 24, reflecting various combinations of soil type and layering, vegetation, and precipitation. The 11 tests and associated data collection activities and frequencies are described below.

A.3.1 Test Descriptions

Gee et al. (1989), Campbell et al. (1990), Campbell and Gee (1990), and Gee et al. (1993a) provided descriptions of the first five tests. More detail is provided below for the tests initiated in FY 1998 and 1999. Table A.1 summarizes all of the tests and treatments.

Hanford Barrier. The objective of this test was to collect data on the performance of a Hanford Barrier. The general configuration consisted of 1.5 m of silt loam that rested on a sequence of materials grading

Table A.1. Summary of Treatments and Applicable Dates at the FLTF as of March 31, 1999 ("a" indicates irrigation was accelerated till drainage commenced; "g" indicates sagebrush planted but died, leaving only grasses; treatment 7 lysimeters received special precipitation and evaporation conditions after March 14, 1988; dates in bold italics indicate current configurations).

Vegetation Symbols are: NV = no vegetation, SRV = shallow rooted vegetation, and DRV = deep rooted vegetation										

from sand to gravel filter layers and finally resting on basalt riprap. This test included shrub-steppe vegetation and no vegetation comparisons (treatment numbers 1 through 4, and 7 in Gee et al. 1993a).

Hanford Barrier with Gravel Admix. The objective of this test was to collect data on the impact of a gravel admix on the performance of a Hanford Barrier. The basic configuration was a Hanford Barrier, with the exception that the top 0.2 m of silt loam was amended with pea gravel. The gravel content was 15% by weight. This test included shrub-steppe vegetation but addressed only ambient precipitation (treatment number 5 in Gee et al. 1993a).

Eroded Hanford Barrier. The objective of this test was to collect data on the performance of an eroded Hanford Barrier. The basic configuration was a Hanford Barrier, with the exception that the silt loam layer thickness was reduced from 1.5 to 1.0 m. This test included shrub-steppe vegetation (treatment number 6 in Gee et al. 1993a and 18 in this appendix).

Gravel Mulch. The objective of this test was to collect drainage data on the performance of a gravel mulch layer above Hanford formation sand. The basic configuration was 0.15 m of coarse gravel above 1.35 m of screened pitrun sand (to remove the gravel), on top of unscreened pitrun sand (described below). This test did not include vegetation (treatment numbers 8 and 10 in Gee et al. 1993a). Although not its primary purpose, this test may be useful for characterizing deep drainage rates at the high-level waste tank farms at Hanford.

Pitrun Sand. The objective of this test was to collect drainage data on the performance of a coarse gravelly sand taken from a nearby borrow pit (hence "pitrun" sand). The basic configuration was 1.5 m of screened pitrun sand (to remove the gravel), on top of unscreened pitrun sand. This test included shrub-steppe vegetation (treatment numbers 9 and 11 in Gee et al. 1993a).

Basalt Sideslope. The objective of this test was to collect drainage data on the performance of basalt riprap that could be used to construct sideslopes for surface covers. The basic configuration was 1.5 m of unscreened basalt riprap. This material is being tested for sideslope use on a larger scale at the Hanford Prototype Barrier in the 200-BP-1 Operable Unit (Ward et al. 1997). Beneath the basalt layer was a 0.15-m thick asphaltic concrete layer that was underlain by gravel and more basalt riprap. Resting on top of the asphaltic concrete was about 2 to 3 cm of silt loam, within which was embedded a 2.54-cm outside diameter fiberglass wick. The wick was splayed out within the silt loam to maximize contact, but exited through the drain outlet as one piece. This test did not include vegetation (treatment numbers 12 and 13 in Gee et al. 1993a).

Sandy Gravel Sideslope. The objective of this test was to collect drainage data on the performance of unprocessed local sandy gravel that could be used to construct sideslopes for surface covers. The basic configuration was 1.5 m of sandy gravel resting on an asphaltic concrete layer in a manner similar to the basalt sideslope test. The sandy gravel material was tested for sideslope use on a larger scale at the Hanford Prototype Barrier in the 200-BP-1 Operable Unit (Ward et al. 1997). This test did not include vegetation (treatment numbers 14 and 15 in Gee et al. 1993a). Although not its primary purpose, this test may be useful for characterizing deep drainage rates at the high-level waste tank farms at Hanford.

Hanford Prototype Barrier. The objective of this test was to collect data on the performance of the Hanford Prototype Barrier design. The basic configuration was 1.0 m of silt loam amended with pea gravel (15% by weight) above 1.0 m of silt loam, which gave a combined thickness of 2.0 m. Beneath the silt layer were sand and gravel filter layers, then the asphaltic concrete layer described in the basalt sideslope test description. A full-scale cover of the same design was built in the 200-BP-1 Operable Unit (Ward et al. 1997). The test at the FLTF included shrub-steppe vegetation (treatment numbers 16 and 17 in Gee et al. 1993a).

Hanford Barrier Erosion/Dune Sand Deposition. The objective of this test was to collect data on the performance of the Hanford Barrier after experiencing some erosion of the silt loam layer and subsequent deposition of dune sand. The top 20-cm of silt loam was removed from four lysimeters containing a Hanford Barrier. The excavated silt loam was replaced with dune sand to study the effect of sand deposition. The dune sand was obtained from the dune that is aligned along the southern edge of the ILAW Disposal Site (Reidel et al. 1998). All instruments remained as before. This test included shallow-rooted vegetation, primarily cheatgrass (treatment numbers were 19 and 20).

Sand Dune Migration. The objective of this test was to collect data on the performance of a sand dune that might migrate onto the surface cover. Two lysimeters were completely filled with dune sand. These lysimeters will provide data on the impact of a dune forming on a barrier, as well as provide data on the behavior of dunes that might form around a barrier and elsewhere at the Hanford Site. The dune sand was obtained from the dune that is aligned along the southern edge of the ILAW Disposal Site (Reidel et al. 1998). Tensiometers were installed to measure matric potential at three depths: 100, 150, and 210 cm. An aluminum access tube was inserted vertically for neutron probe measurements of water content. Time-domain-reflectometry probes were installed horizontally to measure water content at nine depths (5, 30, 60, 90, 120, 150, 180, 210, and 240 cm). A tenth time-domain-reflectometry probe was installed vertically from 5 to 35 cm. An array of thermocouples was installed to measure temperature variations. This test included shallow-rooted vegetation, primarily cheatgrass (treatment numbers were 21 and 22).

Modified RCRA Subtitle C Cover. The objective of this test was to collect data on the performance of a modified RCRA Subtitle C barrier that was proposed by DOE/RL (1996). This barrier design meets the requirements for a RCRA Subtitle C barrier but uses a thinner silt loam soil than the Hanford Prototype Barrier (1.0 rather than 2.0 m). In addition, the silt layer has two modifications. The first is that the upper 0.5 m of silt loam is amended with pea gravel at the rate of 15% by weight. The second feature is that the lower 0.5 m of silt is compacted. The rationale for the compacted layer was to create a low-conductivity layer to impede downward drainage (DOE/RL 1996). We expect the compacted layer will initially hinder root growth and make it difficult to establish and maintain shrubs. However, we expect roots will eventually penetrate the compacted layer, reduce its density, and thus no other treatment in the FLTF has a layer that has been compacted. Table A.2 describes the materials and the depth intervals within the lysimeters.

The configuration in the lysimeters differs from the modified RCRA Subtitle C design in three ways. First, we discovered that one sand filter layer was not enough to prevent sand movement into the gravel filter. We added a coarser sand layer (No. 8 sand) between the 20/30 sand and the gravel filter. This

Table A.2. Material Configuration for the Test of the Modified RCRA Subtitle C Cover

Material	Depth Intervals (m)	
	D7	D9
Warden Silt Loam with 15% gravel	0-0.5	0-0.5
Warden Silt Loam (compacted to 1.6 g/cm^3)	0.5-1.0	0.5-1.0
#2030 Granusil #4075 Silica	1.0-1.10	1.0-1.10
#8 Mesh Granusil #2095 Silica	1.10-1.15	1.10-1.15
1.9 cm (0.75 in.) Chips (gravel filter)	1.15-1.3	1.15-1.3
3.18 cm (1.25 in.) Chips (lateral drainage)	1.3.-1.7	1.3.-1.5

arrangement is the same filter sequence used in the other lysimeters. The overall sand layer thickness remained unchanged at 0.15 m.

The second change involved the lateral drainage layer. The specified material (3.18 cm minus) met the particle size requirements, but the conductivity was much less than 1 cm/s. We replaced this material with 3.18-cm chips, which had conductivity in excess of 1 cm/s.

The final change involved the density of the lower silt loam layer. We had an extremely difficult time trying to compact it to the specified density of 1.76 g/cm^3. We tried a tamping bar, a gas-powered plate compactor, a gas-powered upright compactor, and a hydraulic hole compactor. The tamping bar and plate compactor were unable to give us densities above 1.5 g/cm^3. The upright compactor was better (about 1.6 g/cm^3), but was still not near the target of 1.76 g/cm^3. We expected the hydraulic compactor to be the most compactive of all. However, Northwest Testing, using a commercial density meter, determined that the effort of the hydraulic system was not exceeding the densities achieved with the upright compactor.

The square design of the hydraulic compactor made it difficult to be effective in a round lysimeter with a neutron probe access tube in the center. Also, its end plate was large (roughly 28 cm^2); a smaller end plate may have enabled the hydraulic compactor to be more successful. After trying several methods, we completed compacting the silt loam layer with the gas-powered upright compactor. A single soil core from D9 (43.18-cm long, 2.54-cm diameter) yielded a density of 1.6 g/cm^3.

Both lysimeters contain a tensiometer to measure matric potential at the 100-cm depth, a neutron probe access tube to measure water content, and a series of thermocouples to measure soil temperature distributions. This test included shrub-steppe vegetation (treatment numbers were 23 and 24).

A.3.2 Data Collection Methods and Frequency

The types of data needed to estimate recharge and test models include water contents and storage, matric suction, temperature, drainage, and vegetation characteristics. Some measurements were conducted manually, while others are made automatically using the facility data logger system. Each lysimeter has a unique combination of sensors, sensor placement, and measurement frequency. Most details are provided by Gee et al. (1989); any variations are explained below.

Weather. Weather data were collected at the Hanford Meteorological Station (HMS), which is located at the same elevation about 0.5 km west of the FLTF (Hoitink et al. 1999). The HMS is a complete weather station, providing hourly measurements of all variables, including air temperature, dewpoint temperature, solar radiation, wind speed, cloud cover, and precipitation. The station is operated by another project.

Irrigation. A subset of lysimeters received irrigation to mimic an increased precipitation regime. Untreated water from the Columbia River was applied in increments ranging from 3 to 35 mm per application. The rate was typically 4 mm/h. During several years, up to 73 mm of water were applied in a single irrigation event to simulate a 1,000-year storm. The total quantity and frequency of application were determined by the target amount, which was either two or three times the monthly average. The water was delivered through six nozzles spaced 0.41 m apart along a 2.4-m boom that was connected to the water source. The boom was 0.5 m above the ground surface and was moved automatically down the length of the facility at the rate of about 0.7 m/min. Four rain gauges were positioned within the irrigation path and monitored during each application. The weight resolution of the weighing lysimeters was better than the rain gauges, so lysimeter W4 was used to check the application rate.

Water Content. Water content was measured primarily with a neutron probe. The measurement frequency was bi-weekly in the first 6 years and sporadic thereafter. The measurement depths were every 15 cm, starting at the 15-cm depth. In lysimeters containing silt loam layers, measurements were not made below the silt loam-sand interface. In FY 1999, the two lysimeters containing dune sand were instrumented with time-domain-reflectometry probes that coincided with neutron probe measurement depths. Water contents were not measured in the sideslope treatments or in the clear tube lysimeters.

Water Storage. Water storage was measured directly in the weighing lysimeters. In the other lysimeters, water storage was calculated by integrating the water content measurements for the entire profile. Water storage was not measured in the sideslope treatments or the clear tube lysimeters.

Matric Potential. Matric potential was measured intermittently with tensiometers and a pressure transducer. In most lysimeters, two depths were monitored: 100 and 150 cm. In the dune sand treatment, an additional tensiometer was placed at the 210-cm depth. Thermocouple psychrometers were placed in several lysimeters and read independently of the regular data logger program. Matric potential was not measured in the sideslope treatments or the clear tube lysimeters.

Soil Temperature. Soil temperature was measured with copper-constantan thermocouples placed at various depths and lateral positions within the lysimeters. The temperatures were measured hourly in some cases, but mostly daily, all by the data logger system. Soil temperature was not measured in the sideslope treatments or the clear tube lysimeters.

Drainage. Drainage was measured by collecting free water from the outlet located at the base of each lysimeter. The collected water was weighed immediately at the facility. The nominal collection frequency was bi-weekly. Drainage was measured in all lysimeters.

Vegetation. Field observations were used to characterize the phenology of species during the spring of 1988, which was the first growing season. In 1989 and 1992, the height, width, and areal coverage of plants were measured. Minirhizotrons were installed in several lysimeters to monitor root growth. The minirhizotrons, which were 5-cm inside diameter glass cylinders, permitted video camera observations of root activity and location. Monthly observations of plant activity were initiated in November 1998. Each lysimeter is surveyed to identify the species present and their areal coverage, and the height of shrubs.

A.4 Results

The FLTF has been operated for more than 11 years and, in that time, yielded significant quantities of data. Examples are presented below that illustrate the type of data collected since it was constructed in 1987. Following the data examples is a synthesis of observations relative to the potential for drainage in each of the eleven tests described in Section 2. Finally, the results are discussed relative to unresolved issues and future activities.

A.4.1 Data Examples

A.4.1.1 Weather

Figure A.3 shows that monthly average air temperatures for the period of FLTF operation (defined as November 1987 to March 1999) have been consistently higher than the temperatures for the period from 1961 to 1990. The averages for the period of FLTF operation were warmer by amounts ranging from

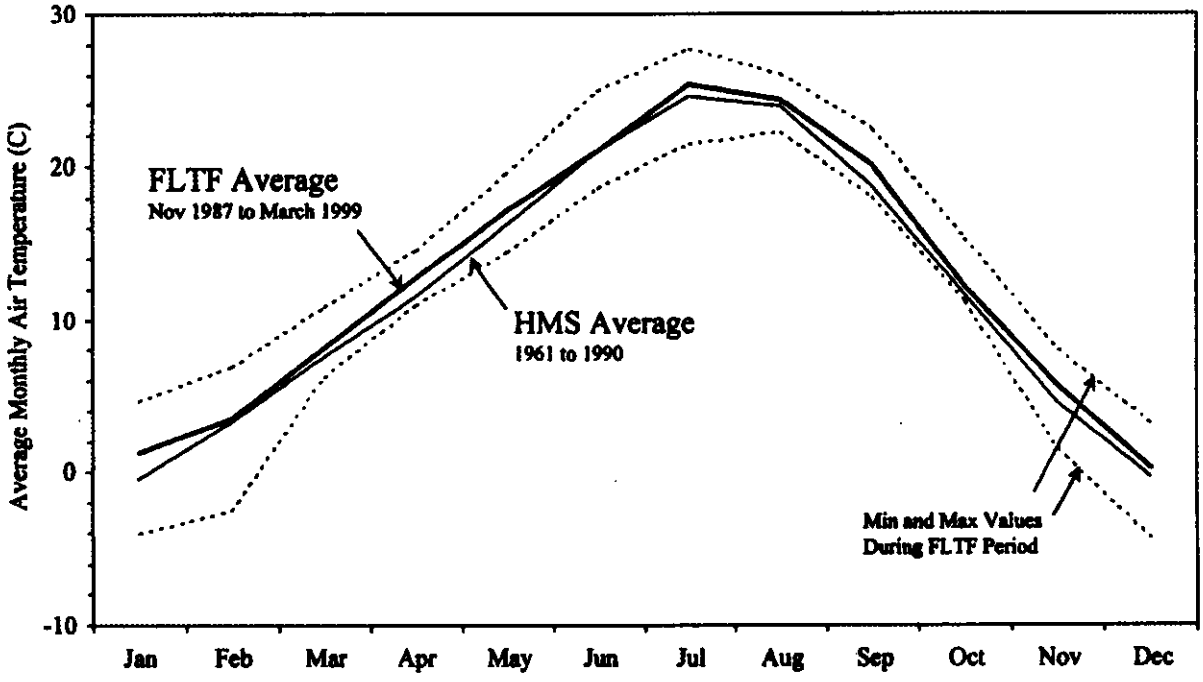

Figure A.3. Monthly Air Temperatures Measured at the HMS

0.1 to 1.7°C. Six monthly records for maximum temperature were either set or tied (one monthly minimum record was also set). Overall, average annual air temperature was 0.8°C warmer than the average temperature from 1961 to 1990.

Figure A.4 shows that monthly precipitation amounts were mostly higher than normal amounts. During the FLTF period of operation, monthly amounts ranged from 2.7 mm less than normal to 6.8 mm greater. Four maximum monthly precipitation records were set. The maximum annual precipitation record of 313 mm was set in 1995. This record was nearly broken in the following year when annual precipitation totaled 310 mm. During the FLTF period, two records for maximum monthly snowfall were set: 57.4 cm in December 1996 and 43.2 cm in February 1989. The annual snowfall record of 142.5 cm was set during the winter of 1992-1993. During the FLTF period, the annual average precipitation was 191 mm, which was 30 mm greater than the 1961 through 1990 average of 161 mm.

A.4.1.2 Irrigation

Figure A.5 shows that the irrigation applications were sufficient to maintain the target rate in most years. Deviations occurred during lysimeter modifications, when it was not possible to run the system because of open lysimeters and construction material.

A.4.1.3 Water Content

Figure A.6 shows how water content varied annually in the Hanford Barrier for the driest condition (lysimeter D4, with ambient precipitation and vegetation) and the wettest condition (lysimeter D10, with irrigation but without vegetation). Water content in D4 was initially high (between 0.15 and 0.2 cm^3/cm^3)

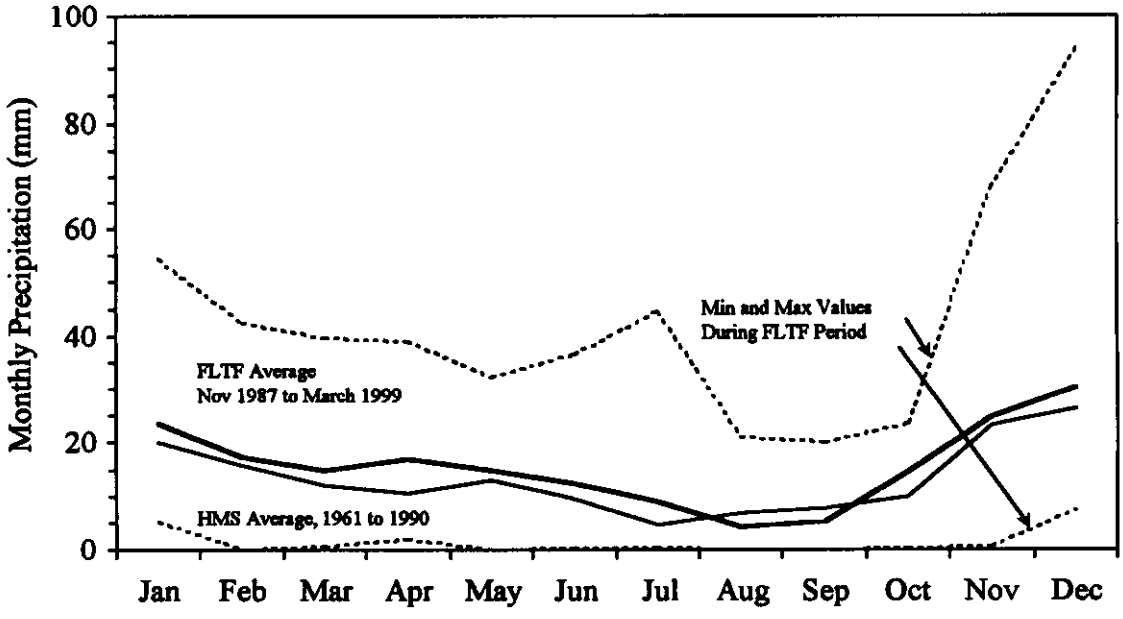

Figure A.4. Monthly Precipitation Measured at the HMS

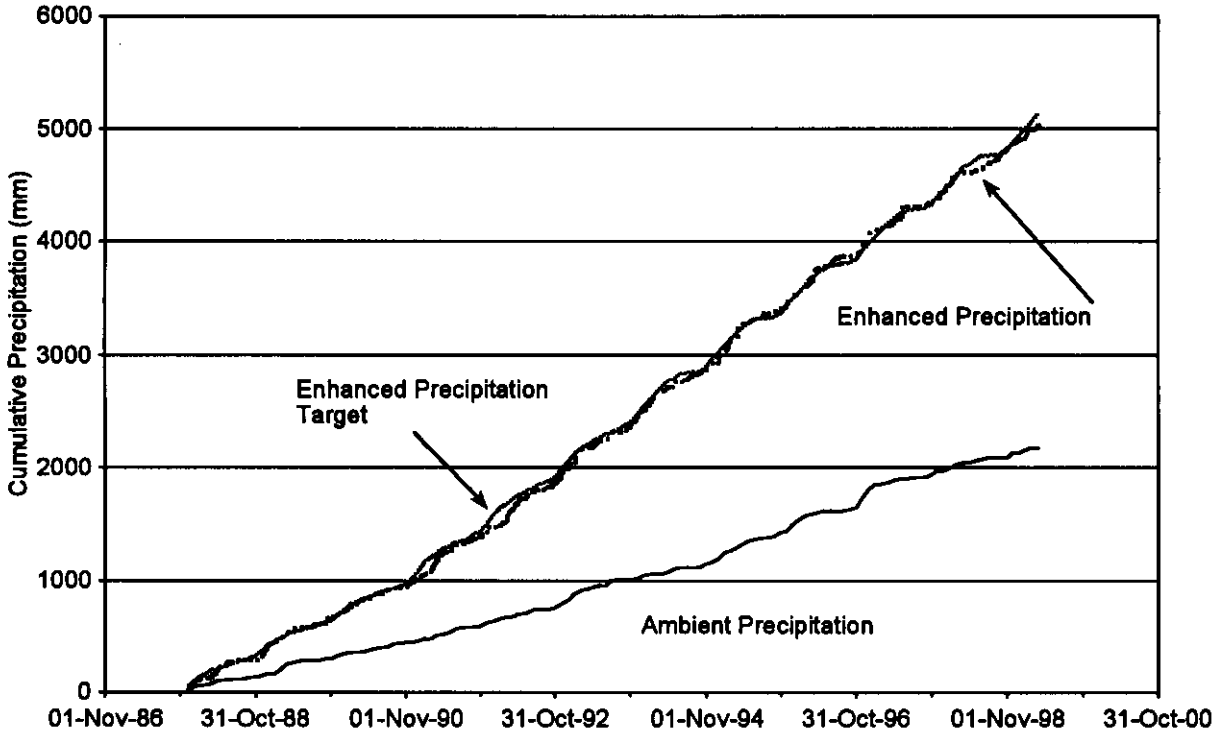

Figure A.5. Precipitation Treatments and the Enhanced Precipitation Target

but quickly dropped to 0.05 to 0.07 cm^3/cm^3 at all depths in the first summer. This rapid drop in water content at all depths demonstrates the ability of plants to extend roots deep into the profile quickly and extract existing water. In subsequent winters, water content increased in the 30- to 60-cm depth range, but hardly changed at all at deeper depths. The winter increases at 30 cm varied year-to-year, giving some indication of the impact of weather variations. In summers, water content always dropped to the same range, about 0.05 to 0.07 cm^3/cm^3 at all depths. This minimum range appears to be the limit to which plants can extract water.

Water content in D10 was much higher than in D4. During the first 3 years, when irrigation raised the water application to 2x normal precipitation, the high water content in winter ranged from 0.22 to 0.33 cm^3/cm^3. When irrigation was increased to achieve 3x normal precipitation, the high water content in winter ranged from 0.25 to 0.42 cm^3/cm^3. Theoretically, the distribution of water received in each year was the same. However, water content in D10 shows distinct differences from year to year. These differences may be related to several factors, including variations in weather (e.g., warm versus cool spring) changes in vegetation, and responses to irrigation (for some months, ambient precipitation was high and obviated the need for irrigation). Another factor could be the irrigation schedule. Our goal was to apply water each month so that the total amount of water received was consistent with the target (either 2 or 3x the normal monthly precipitation). As mentioned earlier, we were not able to do so consistently.

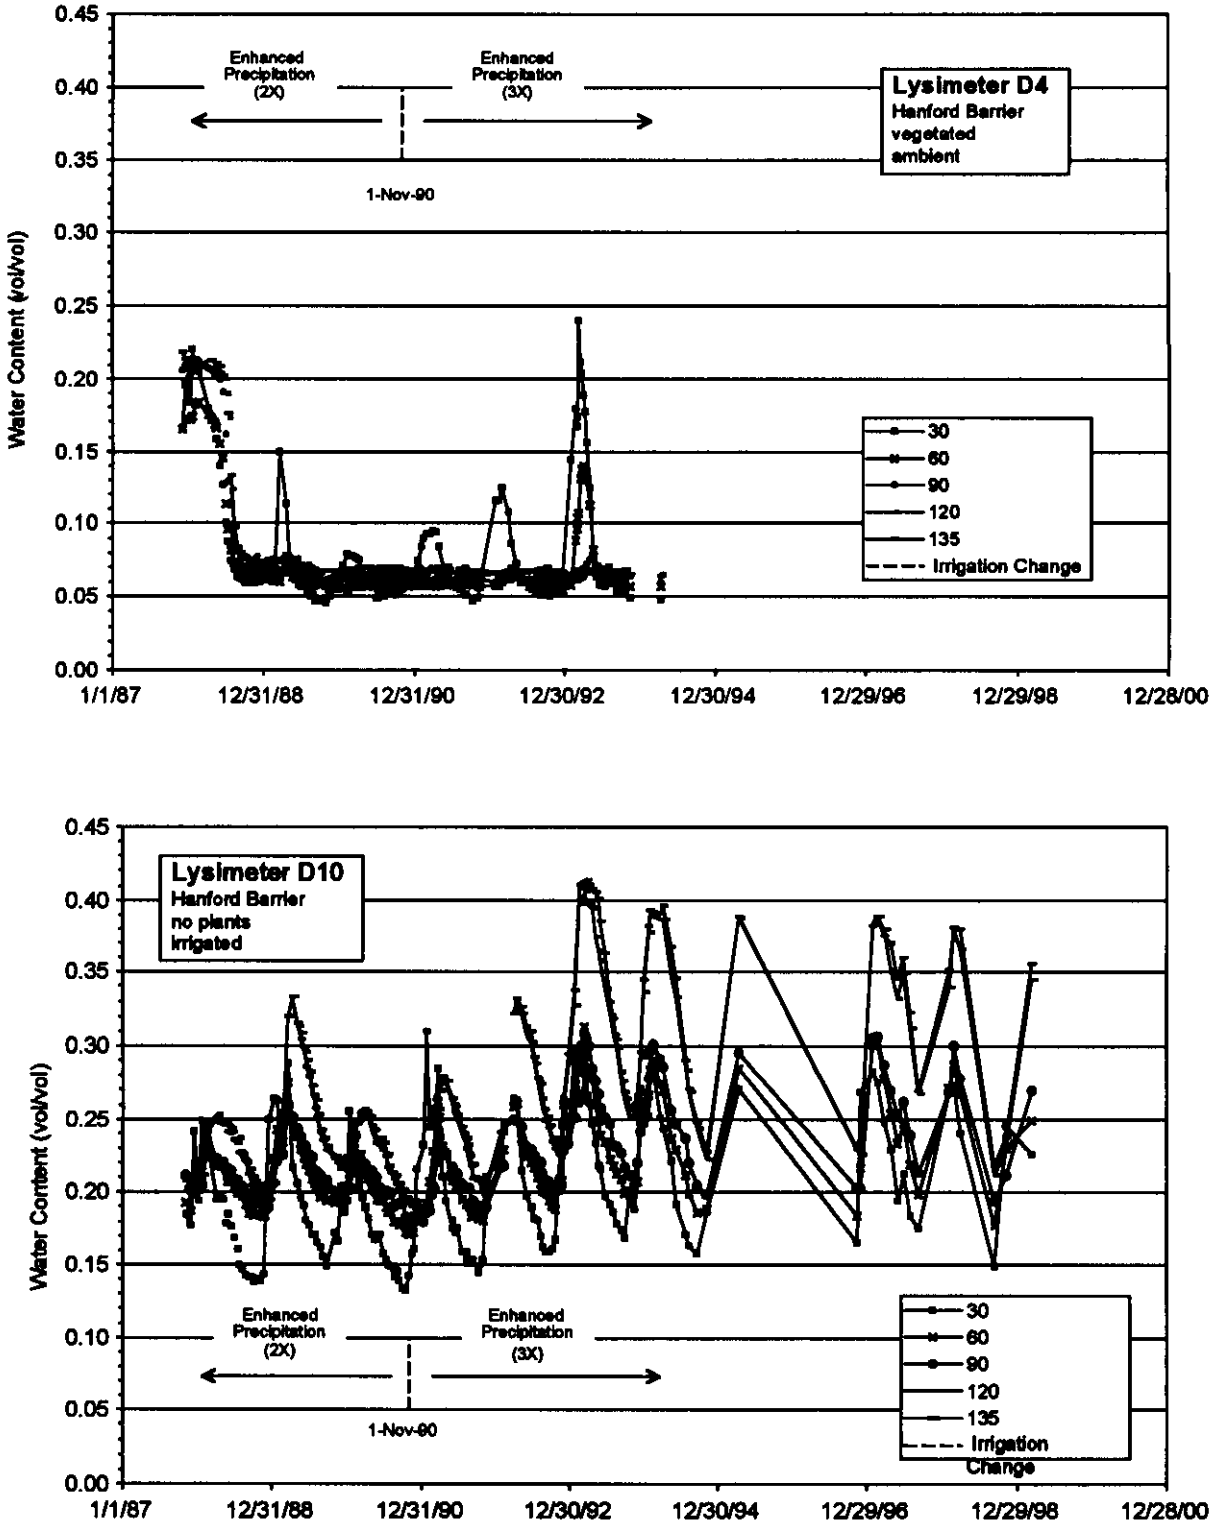

Figure A.6. Annual Water Content Variations for Several Depths Within the Hanford Barrier

Water content in D10 during the summer months was as low as 0.14 cm^3/cm^3 at the shallower depths. In the first three summers, the water content appeared to persist for a month or two before rising in the fall. This low water content may represent a minimum value that the evaporation process can accomplish under the enhanced precipitation regime. At the deeper depths, water content rarely dropped below 0.2 cm^3/cm^3 in the summer.

A.4.1.4 Water Storage

Figure A.7 shows how water storage varied annually in the Hanford Barrier for the driest condition (lysimeter W1, with ambient precipitation and vegetation) and the wettest condition (lysimeter W4, with irrigation but without vegetation). More than 200 mm of water was removed in the first year, which reduced storage to a minimum of about 100 mm. After the first year, winter water storage was never as high as the initial storage, indicating that W1 started much wetter than could be sustained by ambient conditions. In the summers, storage always returned to a consistent minimum of about 80 mm.

In contrast to W1, much more water was stored in W4. Under 2x precipitation, the peak water storage was 450 mm, and under 3x precipitation, the peak was 590 mm. Despite attempts to replicate the same precipitation regime each year, water storage in W4 showed distinct year-to-year differences, probably for the same reasons outlined above for water content. In summers, water storage never reached a recognizable minimum value, indicating that the lysimeter continued to lose water all summer.

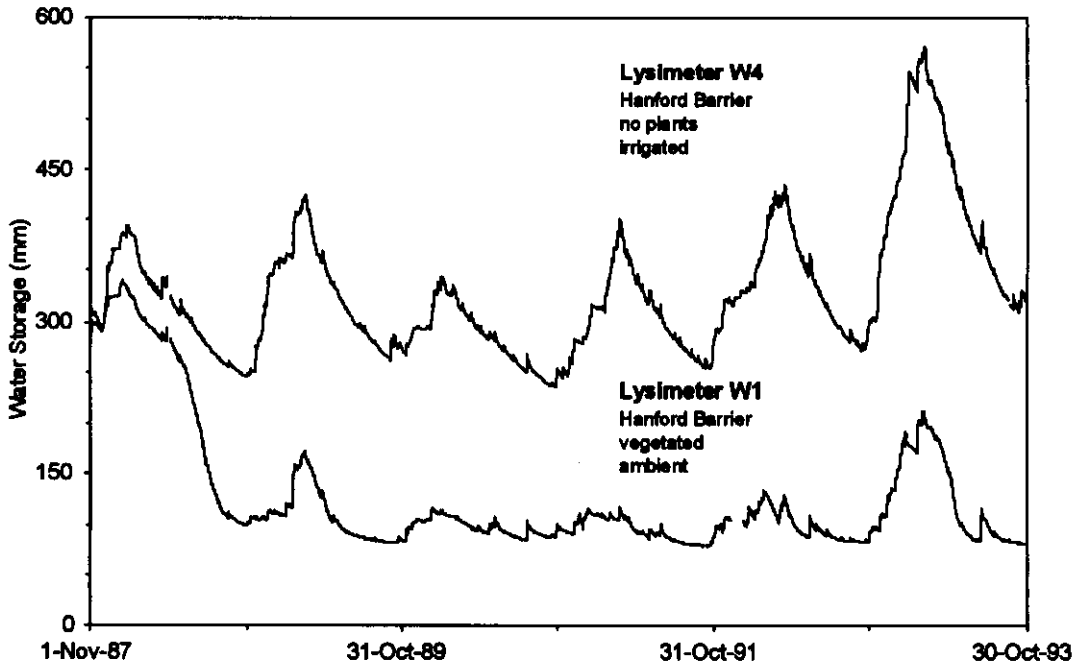

Figure A.7. Daily Water Storage for the Hanford Barrier

A.4.1.5 Matric Potential

Only a few lysimeters had matric potentials high enough to measure with a tensiometer. For these, Figure A.8 shows that potentials at the 150-cm depth were quite consistent from 1995 through 1997. In November 1997, D12 and W4 were modified: 20 cm of silt loam was removed and replaced with 20 cm of dune sand (treatment No. 20). In the following summer, potentials in D10 dropped as in previous years, but potentials in D12 and W4 remained above -100 cm. All three lysimeters were mostly unvegetated, so the contrast in potentials is due primarily to the impact of the surface soil. The dune sand is much less able than the silt loam to store water near, and/or transmit water to, the evaporation surface. These lysimeters were intended to be unvegetated in 1998, but tumbleweeds invaded all three lysimeters and grew to a height of 30 cm in a 1-month period before being removed in May. The results can be seen in Figure A.8 as the rapid drop in matric potentials in the spring of 1998.

Thermocouple psychrometers were placed in several lysimeters, but data from only five of these sensors were reported for a single date, October 22, 1989 (Campbell and Gee 1990). For one of the three psychrometers at the 150-cm depth in W2 and W4, the matric potentials were -0.6 and -0.9 MPa, respectively. For the three psychrometers at the 150-cm depth in W3, the matric potentials were -2.1, -2.5, and -3.1 MPa. These data clearly show the ability of plants in W3 to extract water and reduce the soil water matric potential. Differences among the three potentials in W3 also give an indication of the variability that is possible over a very short distance (< 1.2 m).

In addition to tensiometers and psychrometers, some soil samples were collected and analyzed for matric potential using the filter paper method (Gee et al. 1993a). Samples were collected from six depths

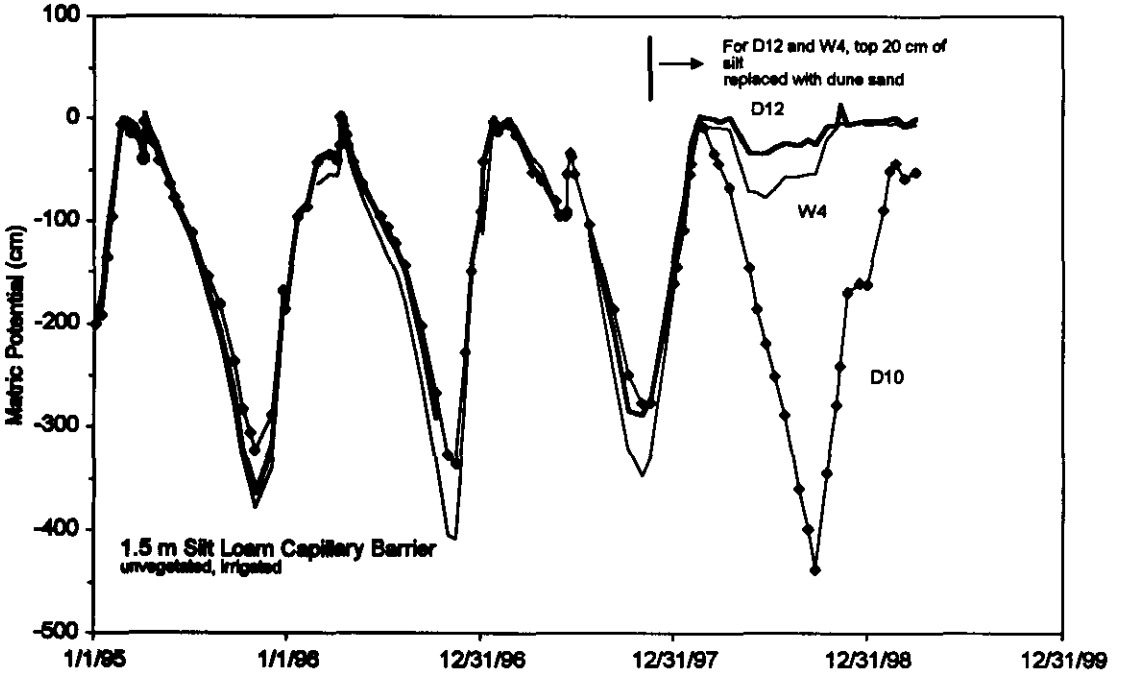

Figure A.8. Matric Potentials at the 150-cm Depth in the Irrigated Hanford Barrier with No Plants

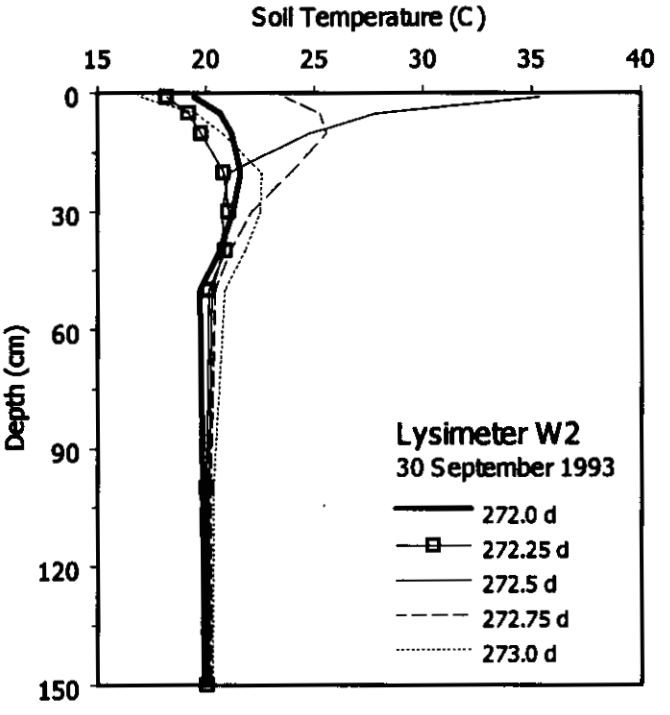
(0.5, 1, 5, 10, 15, and 20 cm) in six lysimeters on three dates in October 1991 and two dates in July 1992. The results showed that matric potentials at the soil surface were lower than -100 MPa in all treatments examined; the absolute minimum potential observed was -210 MPa. At the 20-cm depth, the matric potentials in the unvegetated lysimeters were nearly all less than -1.4 MPa, regardless of precipitation treatment. Potentials in the vegetated lysimeters ranged from -1.8 to -48.8 MPa under ambient precipitation and -5.7 to -14.7 MPa under enhanced precipitation.



A.4.1.6 Temperature

Hourly soil temperatures were recorded for the thermocouples in the weighing lysimeters and in some of the drainage lysimeters. Figure A.9 shows how temperature varied with depth and time in W2 on September 30, 1993. The response in Figure A.9 is typical of soil temperatures. Near-surface temperatures exhibit the largest temperature range whereas deep temperatures barely change in a day. The progression of the temperature pulse through the soil is delayed and the peak is damped relative to the pulse at the soil surface. The result of the delay and damping is that temperature at the 150-cm depth has a seasonal rather than daily cycle.

A.4.1.7 Drainage

Since the fall of 1989, all of the lysimeters containing vegetated Hanford Barrier treatments had no drainage, even under the 3x precipitation treatment. We did not include 1987 and 1988 because of the leak tests (Campbell and Gee 1990), which we could not separate from actual drainage. Through September 1989, two of the vegetated lysimeters drained less than 0.1 kg in 1989, but we suspect this was residual water from leak testing conducted in 1988. In the 10 years since then, no water has drained from vegetated Hanford Barrier lysimeters. The drainage design specification for the Hanford Barrier was to limit drainage to less than 0.5 mm/yr. The FLTF observations are strong evidence that the Hanford Barrier design functions much better than designed.

Between 1989 and 1999, the two drainage caissons (D1 and D8) containing the unvegetated Hanford Barrier test that received ambient precipitation drained an average of 0.05 and 0.2 mm/yr. The drainage always occurred in mid to late summer and was attributed to vapor flow (Campbell and Gee 1990). Figure A.10 shows how the annual drainage amounts for lysimeters D1 and D8 varied. A similar seasonal drainage pattern was observed prior to 1993 in the two drainage caissons containing the unvegetated Hanford Barrier that received enhanced precipitation. Results from these lysimeters are also included in Figure A.10. Two questions arise from these results. First, does the drainage water originate from the basalt riprap and gravel (i.e., residual water from construction and leak testing) or from the silt loam layer above? Second, if seasonal temperature changes are affecting drainage, is the design of the lysimeter facility in any way responsible? Ward et al. (1997) reported "small seasonal discharges" from the Hanford Prototype Barrier test plots. These vegetated test plots were in a full-scale surface cover; thus avoiding any complications such as might be possible in the FLTF. Their data set covered 3 years of monitoring following construction. If they continue to occur during the next several years, the seasonal discharges will provide strong evidence that temperature cycles in the silt loam layer induce water movement into the underlying gravel.

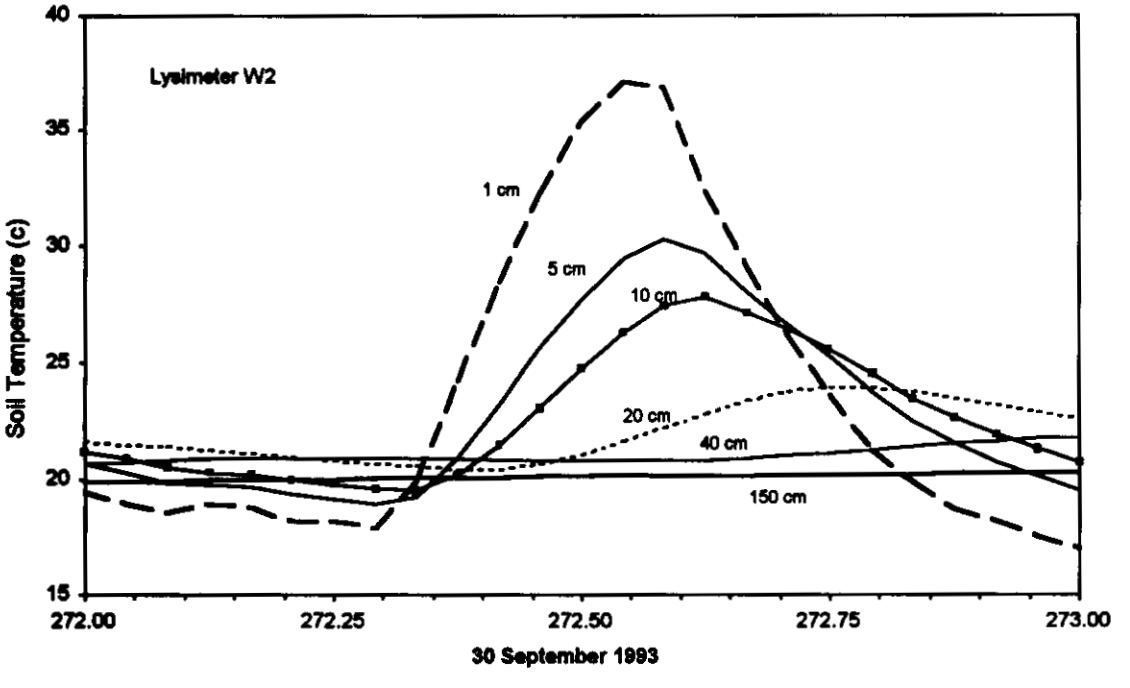


Figure A.9. Soil Temperatures

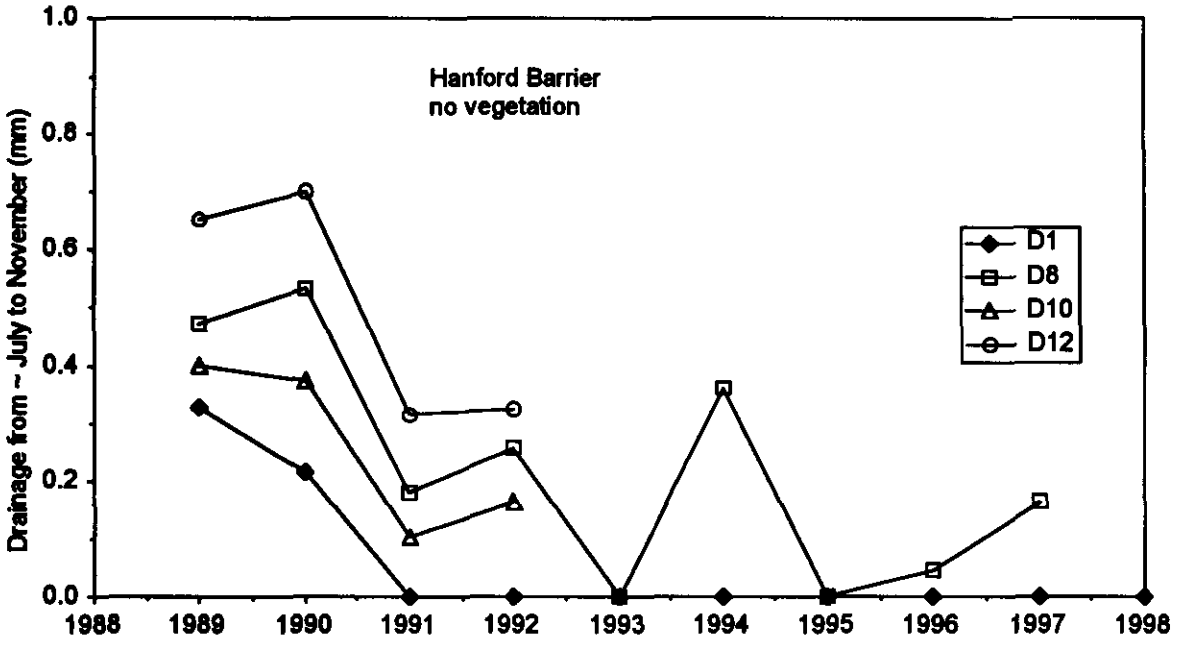

Figure A.10. Annual Drainage from the Lysimeters Containing the Unvegetated Hanford Barrier

The four weighing lysimeters, containing the Hanford Barrier test, had zero drainage. In these lysimeters, there is no coarse gravel or basalt layer within which vapor could move downward and condense at greater depths. A complicating factor is that these lysimeters are susceptible to unusual temperature changes. They have an air gap along the sides (to allow free movement up and down on the scale) and their bottoms are somewhat "de-coupled" from the ground temperature because of the scale.

The only condition that led to significant drainage from a Hanford Barrier treatment was 3x precipitation and no vegetation. Figure A.11 shows that, for the first 3 years (under 2x precipitation), the three lysimeters containing an unvegetated Hanford Barrier had no significant drainage. Three years after increasing to 3x precipitation, these lysimeters had significant drainage. The onset of drainage coincided with the melting of a large snowpack in February 1993. In early 1997, a similar event occurred that also resulted in significant drainage from these lysimeters. In the intervening years, and in 1998, individual lysimeters had small amounts of drainage, but there was no consistency in amount. Such differences indicate the drainage variability that could be expected in a real cover.

After D12 and W4 were modified in November 1998, the drainage pattern of the three lysimeters diverged. D10 continued to have very little drainage, while D12 and W4 began to have more drainage than was collected in all of the previous years combined. The increase in drainage resulted from the replacement of 20 cm of silt loam with dune sand on the surface. This result is consistent with the observed increase in matric potential in D12 and W4.

Figure A.12 shows that drainage from the sideslope treatments was consistently significant in every year. The sandy gravel lysimeters drained 536 mm under ambient precipitation (992 mm) and 1424 mm

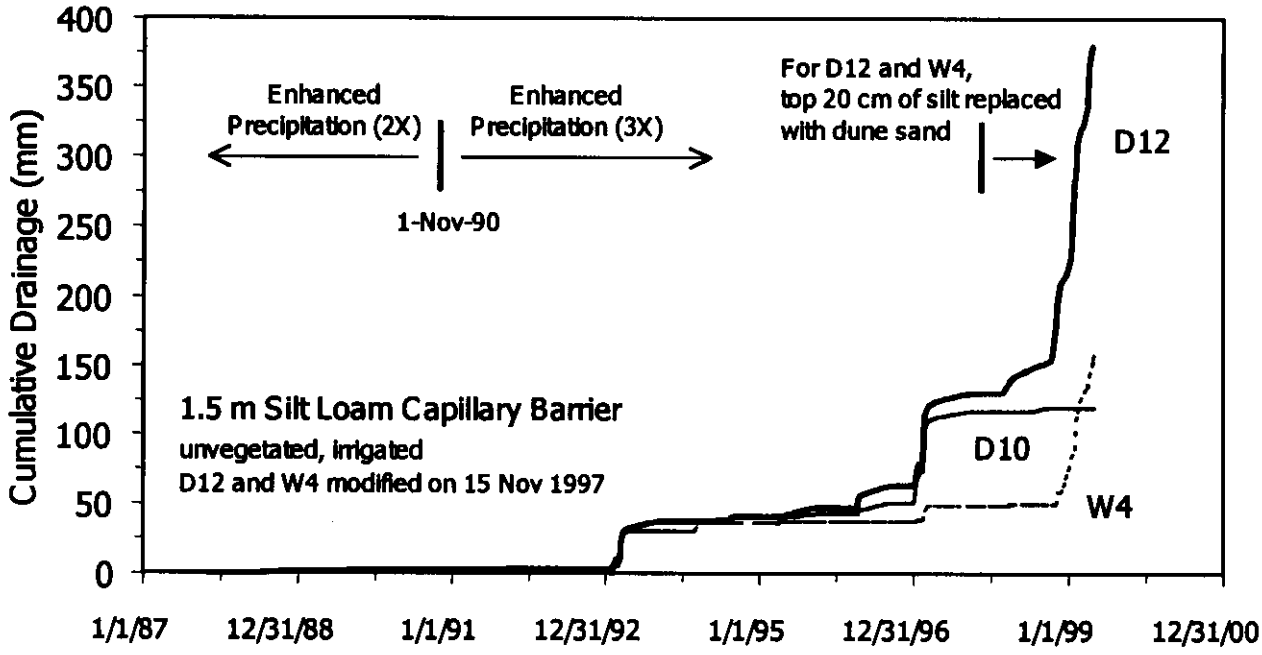

Figure A.11. Cumulative Drainage from Irrigated Lysimeters Containing the Unvegetated Hanford Barrier

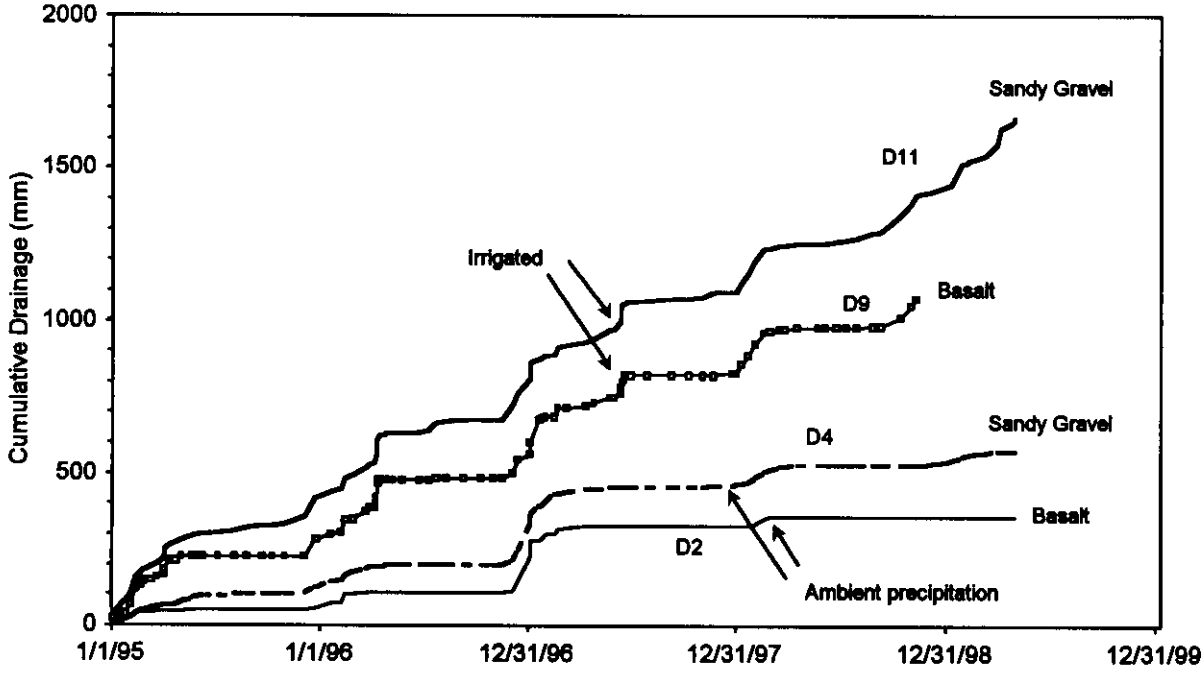

Figure A.12. Cumulative Drainage from the Lysimeters Containing Sideslope Tests

under enhanced precipitation (1978 mm) from mid-November 1994 through 1998. For the 4.1-year period, the average drainage rates were 130 and 345 mm/yr, respectively. These rates represent 54% of the amount of water received under ambient conditions and 72% under enhanced precipitation. The level of ambient precipitation received during this time was 48% higher than normal. It may be that, if precipitation rates subside to more-normal levels, the percentage that becomes drainage may fall to something less than 54%. If the percentage remained the same, then the drainage rate associated with the normal precipitation (160 mm/yr) would be 86.4 mm/yr. This rate could also be applied to conditions at the tank farms in the 200 Areas. The precise value for each tank farm would depend on the distribution of sand and gravel on the surface. In addition, this rate does not account for any effects caused by the increased temperature around the tanks.

The higher percentage (of precipitation becoming drainage) for the enhanced precipitation treatment may truly reflect what could happen under wetter regimes. It may also be related to the method of applying irrigation water. With this method, 10 to 20 mm of irrigation water were applied in a single event rather than as more numerous smaller events. Large events may penetrate the profile more deeply, where the water would be less susceptible to evaporation.

Under both precipitation regimes, the basalt sideslope had less drainage and, in some years, had no drainage. These lysimeters drained 357 mm under ambient precipitation and 1051 mm under enhanced precipitation from mid-November 1994 through 1998. For the 4.1-year period, the average drainage rates were 87.1 and 256 mm/yr, respectively. These rates represent 36% of the amount of water received under ambient conditions and 53% under enhanced precipitation. For the long-term average precipitation rate of 160 mm/yr, the basalt drainage data translate to a long-term drainage rate of 57.6 mm/yr.

One theory why drainage rates through basalt riprap are lower than those through sandy gravel is that the voids between the basalt fragments are so large. Significant amounts of air can move in and out of these large voids and thus effectively extend the drying region deeper into the profile than is normal for soil (Ward et al. 1997). Another factor at the FLTF is the design of the test. The lysimeters containing the sideslope treatments have an asphaltic concrete layer at 1.5 m. On top of this layer is about 2 to 3 cm of silt loam within which was embedded a 2.54-cm outside diameter fiberglass wick. The wick was splayed out within the silt loam to maximize contact, but exited through the drain outlet as one piece. We had some difficulty with this arrangement. First, the wick was jammed as it passed through the outlet and we believe this restricted drainage from the lysimeter. By delaying drainage, water was left standing in the caisson and susceptible to evaporation. Second, the silt loam has a fair amount of storage capacity. Water stored in this layer would not have drained through the wick when potentials dropped below -20 cm. This stored water would also be susceptible to evaporation.

Figure A.13 shows that there was significant drainage from four of the clear tube lysimeters, the two with pitrun sand and the two with gravel mulch. The clear tube lysimeters containing the Hanford Barrier configuration (C3 and C6) never had drainage. The pitrun sand lysimeters had drainage in some but not all years. Although the lysimeters are vegetated, the plants were unable to prevent drainage. From February 8, 1990, through February 11, 1998, drainage rates averaged 23.6 and 52.4 mm/yr for the ambient (C2) and enhanced precipitation (C5) treatments, respectively. These drainage rates represented 12 and 11%, respectively, of the total amount of precipitation and irrigation received from 1990 to 1998.

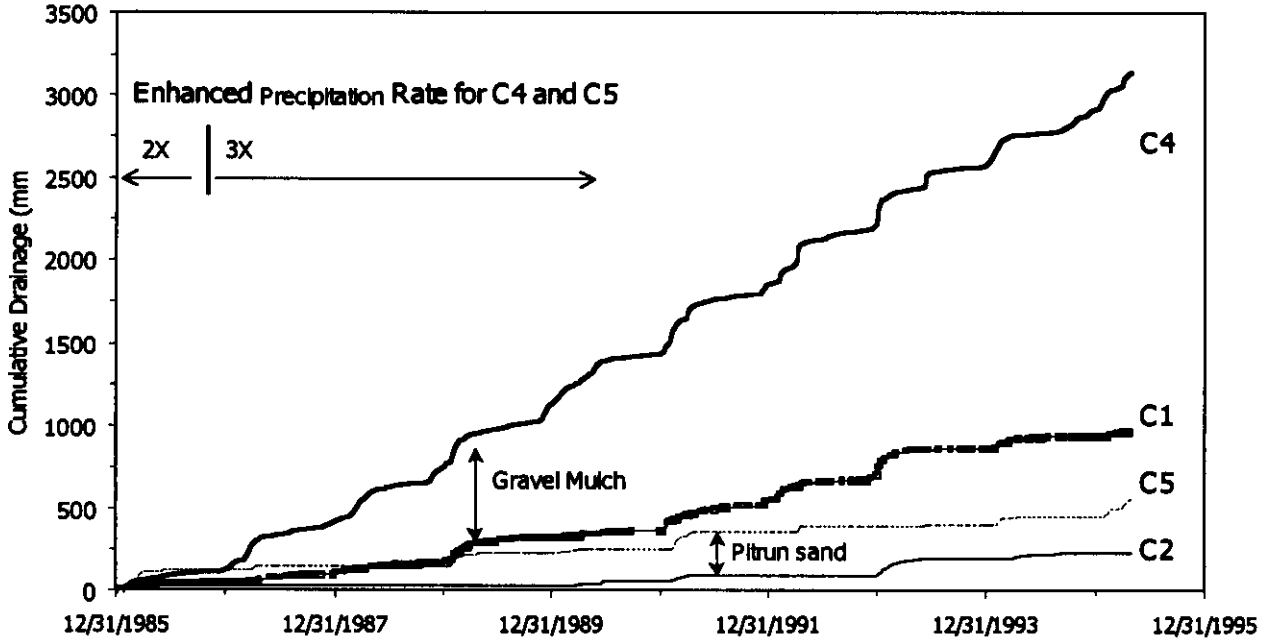

Figure A.13. Cumulative Drainage from the Clear Tube Lysimeters

Figure A.13 shows that the gravel mulch lysimeters had much more drainage than the pitrun sand lysimeters. From February 8, 1990, through February 11, 1998, drainage rates averaged 104 and 332 mm/yr for the ambient (C1) and enhanced precipitation (C4) treatments, respectively. These drainage rates represented 52 and 72%, respectively, of the total amount of precipitation and irrigation received from 1990 to 1998. Two factors that explain the higher drainage relative to the pitrun sand test are the lack of vegetation and the suppression of evaporation by the gravel mulch. The suppression occurs because water that infiltrates into the sand beneath the gravel can only evaporate by the slow process of diffusion up through the gravel mulch layer. The other mechanism for water to move upward is for water to flow directly in the liquid phase up through the gravel. Such flow is essentially negligible because of the extremely low hydraulic conductivity of unsaturated gravel.

A.4.1.8 Vegetation

Vegetation was planted on the lysimeters in November 1987 for the first three tests. Bunchgrasses and sagebrush seedlings were dug at McGee Ranch, which has a shrub-steppe plant community growing on silt loam (Gee et al. 1989). McGee Ranch was the borrow area for the silt loam that was placed in the lysimeters. Species included *Poa sandbergii* (Sandberg's bluegrass), *Oryzopsis hymenoides* (Indian rice grass), and *Artemisia tridentata* (sagebrush). Although *Bromus tectorum* (cheatgrass) was present at McGee Ranch, no attempt was made to transplant it. Gee et al. (1989) assumed that cheatgrass seed was present in the transplant soil masses as well as in the plant community surrounding the FLTF and that cheatgrass would have no difficulty occupying the lysimeter surfaces.

The record of vegetation measurements and observations is sparse. Phenology observations were made in the spring of 1988 only. Phenological stages were delayed about 1 month relative to stages observed in natural settings, possibly because of the wet initial conditions in the lysimeters (Gee et al. 1989).

In May 1989 and the spring of 1992, individual plant height, width, areal coverage, and location within the lysimeters were measured. The main observation was that irrigation caused significant increases (by a factor of 2 to 3) in total plant biomass. Indian rice grass decreased in all lysimeters between 1989 and 1992 but the cause was never determined (Gee et al. 1993a).

Root behavior was observed with the minirhizotrons and reported only once (Campbell et al. 1990). The data, in the form of root counts, suggested higher root density under the enhanced precipitation treatment.

Root observations were also made using the clear tube lysimeters. Sagebrush roots grew downward through the silt loam in lysimeter C6 at an average rate of 2 cm/d, and sometimes at rates as high as 5 cm/d (Campbell and Gee 1990; Campbell et al. 1990). The downward growth rate may have been a function of the constrained rooting volume because the lysimeter diameter was only 0.3 m. When the roots reached the sand filter layer, they penetrated no more than 1 cm presumably because the sand held very little water. In the sandy soil of lysimeters C2 and C5, the downward root growth rate averaged 1.4 and 0.9 cm/d, respectively. All of these lysimeters were moist prior to transplanting. In lysimeter C3, which was not irrigated, roots grew down to the existing wetting front within the silt loam layer and stopped. The sagebrush on this lysimeter died in 1989 and was not replaced. The hypothesis is that the water available in this small lysimeter was insufficient to support the plant.

The sagebrush on C6 died in 1991, despite receiving the enhanced precipitation treatment. Although cheatgrass remained, lysimeter C6 became noticeably wetter in the next two years. By early 1993, the filter layers and basalt riprap were visibly wet. In March 1993, a sagebrush seedling was planted on C6. By late May, a few roots had penetrated the sand filter layer and entered the gravel filter layers. By late July, a few roots appeared to be at the 2-m depth. These observations indicated that gravel layers are not root impediments, or barriers, as long as water is available (Gee et al. 1993a). Between 1993 and 1998, the sagebrush in C6 died and no attempt was made to plant a replacement.

On four dates in late 1998 and early 1999, the FLTF was surveyed to identify the existing plant species and monitor changes in areal coverage. Sagebrush and Sandberg's bluegrass still remained. Indian rice grass was no longer present. A new species was observed on several lysimeters: *Agropyron cristatum* (crested wheatgrass). Cheatgrass was present on most of the vegetated lysimeters. Individuals of eight other species were present. The most notable of this group was *Salsola kali* (tumbleweed), which has a deeply penetrating taproot that allows the plant to extract water stored deep within the profile.

Since 1987, one of the most difficult tasks in operating the FLTF is maintaining the no-vegetation status of those lysimeters that were supposed to be bare. Our experience has been that these lysimeters must be weeded every two weeks in the spring and monthly during the remainder of the year. On several occasions, a one-month hiatus in weeding during the spring resulted in an extensive crop of plants,

usually tumbleweeds but also sagebrush seedlings, cheatgrass, and other species. The implication is that a non-vegetated condition (e.g., due to fire, disturbance, etc.) will probably not persist for silt loam surface barriers for more than a couple of months, and certainly not for more than 1 year.

A.4.2 Results of the Eleven Tests

We used the FLTF data (primarily the drainage data) to draw conclusions for each of the eleven tests. For the barrier tests, we compared the drainage data to the design standard of 0.5 mm/yr (Wing 1994). For our evaluations, we assumed natural conditions, with no disturbance by humans.

Hanford Barrier. For periods ranging from 6.5 to 11 years, there has been no drainage from the lysimeters containing the Hanford Barrier configuration (1.5 m of silt loam above sand and gravel layers) with plants. For Hanford Barrier lysimeters without plants, there has been no significant drainage (i.e., greater than 0.5 mm/yr) under ambient precipitation and under 3 years of 2x normal precipitation. Drainage from these non-vegetated lysimeters eventually occurred, but only after 3 years of 3x normal precipitation. Based on our experience of keeping these lysimeters plant-free, we predict that Hanford Barriers receiving 3x normal precipitation will not remain plant-free for more than a few months at most. Based on all of the data collected to date, we expect that the Hanford Barrier will perform as designed for the conditions envisioned for the ILAW Disposal Site.

Hanford Barrier with Gravel Admix. The two lysimeters containing this configuration with plants and receiving the ambient precipitation treatment showed no drainage after 6.5 and 10 years, respectively. The gravel admix did not appear to impair the ability of the Hanford Barrier to prevent drainage. We did not see any recognizable differences in plant community compared to the tests without gravel admix. Although there were no treatments involving enhanced precipitation, we expect that a Hanford Barrier with gravel admix and receiving enhanced precipitation will prevent drainage as designed.

Eroded Hanford Barrier. The two lysimeters (containing 1.0 m of silt loam above sand and gravel), with plants, and receiving the ambient precipitation treatment showed no drainage after 10 years. This configuration is similar to the modified RCRA Subtitle C cover. The results suggest that the modified RCRA cover will perform as well. A test of the actual design has been initiated (see below). The single lysimeter receiving the enhanced precipitation treatment was set up and started in May 1998. With a data record less than 1 year long, this test is not complete. However, we expect that it will be just as successful as the ambient treatment in preventing drainage.

Gravel Mulch. The two small lysimeters used for this test generated a significant amount of drainage in 8 years: 104 mm/yr (52% of received water) for the ambient treatment and 332 mm/yr (72% of received water) for the enhanced precipitation treatment. These results may be useful for describing an upper limit to deep drainage in tank farms. The gravel mulch used at the FLTF contains very few finer particles (except what the wind deposits). Tank farms, in contrast, have 50% or more sand particles (Figure 3 of Smoot et al. 1989). Of all the tests, the clean gravel mulch without plants resulted in the highest deep drainage rates.

Pitrun Sand. The two small lysimeters used for this test generated a measurable amount of drainage, although not consistently in every year. In an 8-year period, drainage rates averaged 23.6 mm/yr (12% of received water) for the ambient precipitation treatment and 52.4 mm/yr (11% of received water) for the enhanced precipitation treatment. These lysimeters are vegetated, mostly with grasses. Several attempts were made to establish sagebrush, but the plants did not survive for more than a few years. Thus, these deep drainage results are probably higher than for a similar sand with a shrub-steppe plant community.

Basalt Sideslope. The two lysimeters used for this test generated a significant amount of drainage in 4 years: 87.1 mm/yr (36% of received water) for the ambient treatment and 256 mm/yr (53% of received water) for the enhanced precipitation treatment. As a percentage of total water input, drainage was 36 and 53% for the ambient and enhanced precipitation treatments. These lysimeters had no vegetation, so the drainage rates should be viewed as upper limits. A field-scale test of this sideslope with no vegetation is occurring at the Hanford Prototype. The results after 3 years indicated drainage rates of 22 to 34% of the precipitation (Ward et al. 1997).

Sandy Gravel Sideslope. The two lysimeters used for this test generated a significant amount of drainage in 4 years: 130 mm/yr (54% of received water) for the ambient treatment and 345 mm/yr (72% of received water) for the enhanced precipitation treatment. As a percentage of total water input, drainage was 54 and 72% for the ambient and enhanced precipitation treatments. These lysimeters had no vegetation, so the drainage rates should be viewed as upper limits. A field-scale test of this sideslope, with vegetation (albeit limited), is occurring at the Hanford Prototype. The results after 3 years indicated drainage rates of 20 to 30% of the precipitation (Ward et al. 1997). The lysimeter and Hanford Prototype results may be useful for describing deep drainage in tank farms. However, we have no measure of the particle size distribution of the sandy gravel used in the tests.

Hanford Prototype Barrier. The two lysimeters used for this test had no drainage in 4.5 years, even under 3x normal precipitation. In addition, matric potentials were always below the tensiometer range, indicating dry soil. We expect that the Hanford Prototype Barrier will perform as designed for the conditions envisioned for the ILAW Disposal Site.

Hanford Barrier Erosion/Dune Sand Deposition. The four lysimeters used for this test have been monitored for 1.5 years. The matric potential data indicate that the silt loam is wetting under both precipitation treatments. Drainage has not occurred for the ambient precipitation, but has been significant for the 3x normal precipitation treatment. After 1 to 2 more years, we suspect that drainage may begin from the ambient treatment. Vegetation on the lysimeters is limited to shallow-rooted species, primarily cheatgrass. The combination of dune sand and cheatgrass was intended to mimic a serious but plausible degradation of the cover. In the first year, the cheatgrass cover was not measured because it was sparse to non-existent. By November 6, 1998, one year after the test began, there was no live cheatgrass on D5 and 25% coverage on D12. Because of the limited cheatgrass cover during the first year, the drainage results may more accurately be said to reflect an unvegetated state. Cheatgrass was much more prevalent in spring 1999. It may be that several years are required for vegetation to establish itself in the lysimeters of this test. Till then, we make no predictions except to say that sand deposition on a surface cover has the potential to degrade performance relative to preventing drainage.

Sand Dune Migration. The two lysimeters used for this test were started in July 1998, so the length of record is short. By March 31, 1999, no drainage had occurred from the lysimeter receiving ambient precipitation. However, the lysimeter receiving 3x normal precipitation already generated significant drainage. Like the erosion/deposition test above, vegetation is supposed to be shallow-rooted species like cheatgrass. However, plant activity was marginal, so the results are more nearly like an unvegetated test. It may be that several years are required for shallow-rooted vegetation to establish itself. Till then, we make no predictions except to say that a sand dune on a surface cover has the potential to degrade surface cover performance (relative to preventing drainage) and to increase recharge rates in the immediate vicinity of the cover.

Modified RCRA Subtitle C Cover. The two lysimeters used for this test were started in February 1999. It will take several years of data to reach conclusions, but we expect that this cover will perform as designed for the conditions envisioned for the ILAW Disposal Site.

A.5 Conclusions

The data collected at the FLTF have shown how soil type, barrier design, vegetation, and precipitation can impact deep drainage rates. One of the significant results from the FLTF is that the Hanford Barrier described by Wing (1994) worked much more successfully than expected. In concert with vegetation, the barrier reduced drainage to zero (compared to the design goal of 0.5 mm/yr). This performance occurred under ambient and 2x precipitation, with or without plants. Even under 3x precipitation, the vegetated Hanford Barrier prevented drainage. The only condition that resulted in drainage through a Hanford Barrier was when plants were purposefully kept off for three consecutive years under 3x precipitation. All indications are that plants will never be absent for more than a few months and that precipitation will not exceed 128% of modern levels, which is far below the 3x precipitation rate that caused drainage.

A second barrier design, the Hanford Prototype Barrier, also reduced drainage to zero. Data are just starting to be collected for a third design, the Modified RCRA Subtitle C barrier. Two lysimeters with a similar design (i.e., 1 m of silt loam) had zero drainage in 10 years under ambient precipitation conditions. Therefore, we expect the modified RCRA Subtitle C design will work just as well at preventing drainage.

The addition of gravel admix to the surface silt loam layer of the Hanford Barrier did not impact barrier performance, nor did the loss of 0.5 m of silt to erosion. In both cases, there was no drainage. The dune sand test is beginning to show an increase in water storage. Although the length of record is short and there is already measurable drainage under the 3x precipitation treatment. The lysimeters in this test had a sparse cover of shallow-rooted cheatgrass and none of the deep-rooted plants of a shrub-steppe community that might reduce drainage considerably. Without a deep-rooted shrub-steppe plant community, deposition of wind-blown sand on the cover is a concern.

The sideslope tests showed how poorly these materials prevented drainage. The sandy gravel material drained 54% of the ambient precipitation, while the basalt drained 36%. These tests were not vegetated, so the results represent an upper limit to drainage through such sideslopes.

Because the cover systems performed much better than the design goal of 0.5 mm/yr, we propose using a rate of 0.1 mm/yr for the 2001 ILAW PA. The data clearly support this lower rate. We would have proposed a lower rate if we understood the seasonal drainage observations more fully. The possibility of seasonal water vapor movement downward from the surface cover indicates a need to understand the temperature effects.

Appendix B

Recharge Estimates Using Environmental Tracers at the Immobilized Low-Activity Waste (ILAW) Disposal Site

B.1 Introduction

This appendix summarizes the analyses of sediments collected from boreholes located in the 200 East Area of the Hanford Site for tracer measurements. This area is a proposed location for the burial of low-level waste encapsulated in glass and is referred to as the Immobilized Low-Activity Waste (ILAW) Site (Figure B.1). In this area, vegetation and, to a lesser degree, heterogeneity in the stratigraphy control the downward movement of water.

Naturally deposited atmospheric tracers were used to determine the rate of water movement through the vadose zone. The natural tracer method based on chloride mass balance (CMB) is one of the simplest, least expensive, and most useful for determining long-term recharge in arid climates (Allison et al. 1994). Recharge is often used interchangeably with deep drainage flux. Technically, recharge is the amount of water over time reaching the water table. Deep drainage flux is the water flux below the evapotranspiration zone, or alternatively, the water flux at a point where the chloride concentration is measured (Phillips 1994). Using the CMB method, recharge is determined by applying a mass balance argument on the

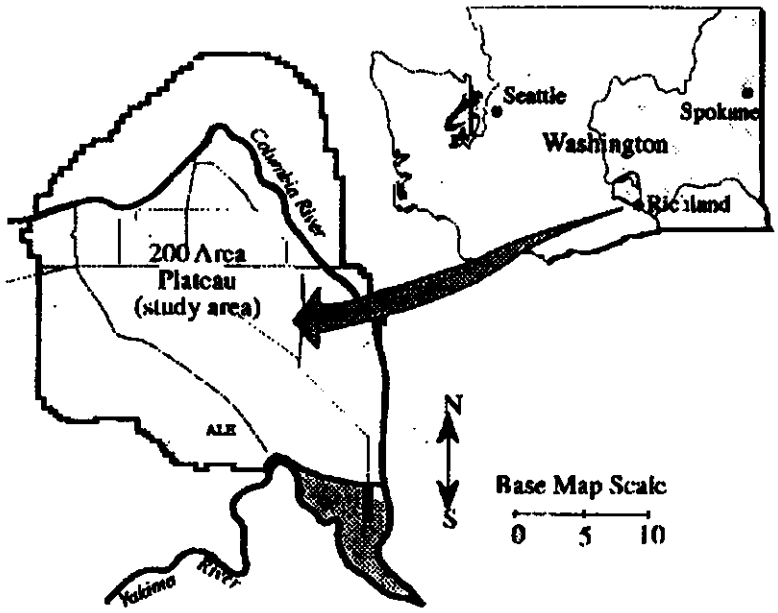

Figure B.1. Washington State Map and Location of Study Area at the Hanford Site

chloride ion in which the difference between the chloride concentration in the soil water and the atmospheric input concentration is due to evapotranspirative enrichment.

Environmental tracers give site-specific estimates of deep drainage flux below the evapotranspiration zone. Therefore, this technique is ideal for investigating the effect of spatial variations in vegetation and stratigraphy on recharge. At the proposed ILAW Disposal Site, spatial variations in vegetation and stratigraphy can occur at distances ranging from a meter to tens of meters. Interpretation of chloride profiles at the proposed ILAW Disposal Site suggests that prior to the establishment of a dense sagebrush community, atmospheric tracers such as chloride did not accumulate in the sediment profiles. This indicates rapid water flux through these medium sand sediments. The impact of vegetation and its absence have been demonstrated elsewhere (e.g., Allison 1988). Stratigraphy, in particular the occurrence of silt lenses, impacted the spatial distribution of moisture content across the proposed ILAW Disposal Site. Variations in peak concentrations of chloride in the different boreholes suggest differences in the history of vegetative establishment during the Holocene.

In this appendix we compare information from two exploratory boreholes drilled in 1995, a trench dug in 1995, and four boreholes (B8500 series) drilled in 1998. The objectives of the exploratory drilling in 1995 were to demonstrate the feasibility of collecting continuous cores in these largely sandy sediments and to determine the location of the chloride profiles for recharge estimates. Large volume samples were collected from the trench to develop a profile for the bomb-pulse tracer ^{36}Cl. An additional objective of the sampling at the B8500 boreholes in 1998 was to provide estimates of natural recharge using tracer methods and to assess the variability in recharge rates across the proposed ILAW Disposal Site.

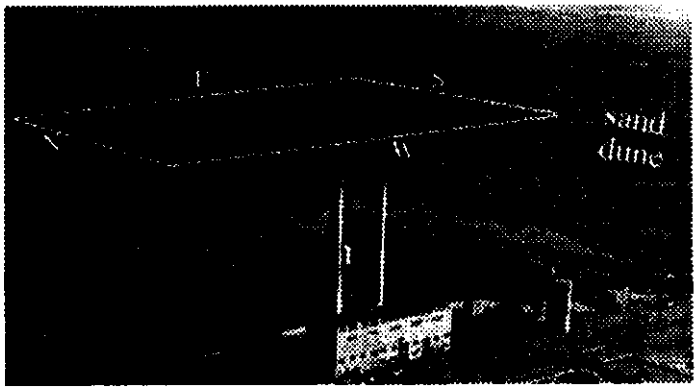
The application of tracer methods ideally requires the collection and analysis of continuous cores from the surface to below the root zone (approximately to a depth of 15 m at the proposed ILAW Disposal Site). Nearly continuous cores were collected at two previously undisturbed sites in March 1995 using a hollow stem auger with split-tube wire-line sampling. In September 1995, a trench was dug south of the exploratory boreholes to a maximum depth of approximately 5 m. In the spring of 1998, one deep borehole (B8500, also designated 299-E17-21) and two shallow boreholes (B8501 and B8502) were drilled near the proposed ILAW Disposal Site. Unlike previous exploratory drilling in 1995, the drilling for the B8500 series boreholes was not controlled by the researchers who were collecting the data. As a result, many of the standard drilling procedures at the Hanford Site conflicted with or negated the research goals. This impact was most severe on the investigation into recharge mechanisms that are largely controlled by near-surface processes.

Core sediments were not collected above 3 m at B8500, which precludes this borehole being used to estimate recharge with atmospheric tracers. Near-continuous sediment cores were collected from B8501 and B8502. Preliminary results indicate that the near-surface recharge processes at B8501 may have been affected by disturbances associated with the construction of a drilling pad and the standard practice of drilling *through* the gravel pad (as opposed to drilling off the side of the pad in undisturbed sediments). In addition, some of the sediment cores from B8502 were affected at the drill site by storage in ice chests containing standing water. In some cases a wetting front was observed in the core sediment. In other cases, droplets of water were found between the Lexan liner and the duct tape that was used to seal the

ends of the cores. It cannot be determined whether the highly variable moisture profiles at the shallow holes are 1) natural, 2) an artifact of the drilling pad, or 3) lack of end caps and blue ice for sealing and storing the cores. However, in some profiles there is a distinct correlation between increased moisture content and the spatial distribution of silt lenses.

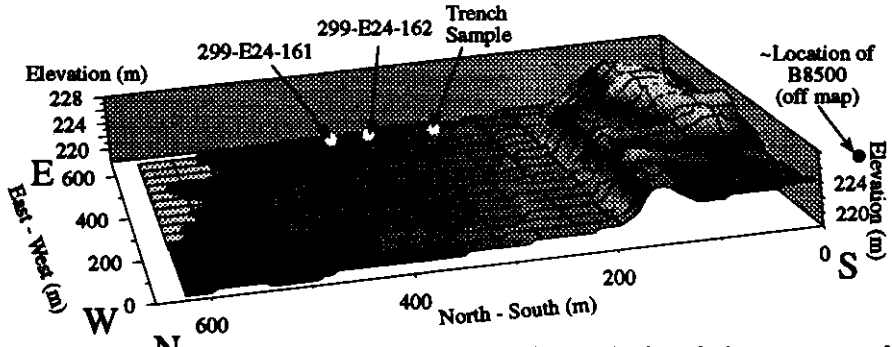
The problems associated with drilling the B8500 boreholes limit the information that can be used from these cores. Except for borehole B8503, which was drilled in undisturbed sediments, the moisture profiles, sediment characterization, and bulk densities should be disregarded in the upper 2 to 3 m of the B8500 boreholes.

B.2 Site Description



The proposed ILAW Disposal Site is located on the south side of the Cold Creek bar, a depositional bar left in the lee of the Umtanum Ridge during Pleistocene cataclysmic flooding. This bar is dominated by gravel on the north side (closest to the main flood channels) grading to fine sand on the south side.

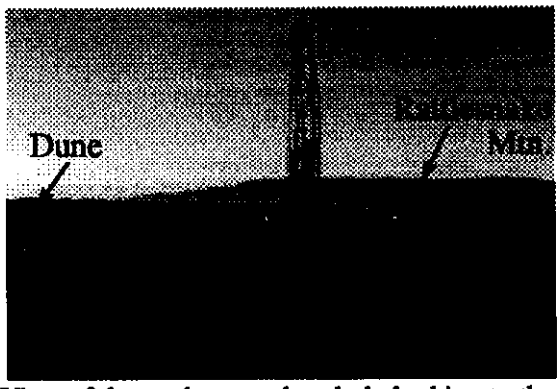
The proposed ILAW Disposal Site lies along the northern margin of a giant dune field (Appendix D). A long, stabilized dune lying in an east-west direction can be seen along the southern portion of the proposed ILAW Disposal Site in the photograph at the top of Figure B.2. The existence of the dune field appears to be controlled by wind moving from west to east, down the adjacent Dry Creek and Cold Creek valleys and across the expansive Hanford plains toward the Columbia River. Most dunes are stabilized by vegetation and are not actively growing or migrating. The closest point of active dune formation to the proposed ILAW Disposal Site is approximately 3 km south of this area (Gaylord and Stetler 1994). The presence of a dune at the proposed ILAW Disposal Site indicates a history of sand dune development in this area since the last cataclysmic flood (~13,000 years yBP). Appendix D discusses this eolian activity in more detail.



B.3 Borehole Descriptions

Table B.1 summarizes the six boreholes that have been drilled and used to collect sediment samples for tracer analyses. Two boreholes (designated 299-E24-161 and 299-E24-162) were drilled in 1995 to a depth of approximately 18 m. The stratigraphy consisted of a thin layer of sand, 0.3 to 0.6 m thick, resting on top of the Hanford formation. From 0.6 m to about 4.3 m are gravelly sands, reflecting the strength of the flood currents carrying gravel across the bar. The remainder of the sediments encountered (from 4.3 to 18.0 m) are sands with occasional minor gravel. To minimize surface disturbance, drilling pads were not constructed at these boreholes.

The sand-dominated layers of the Hanford formation were deposited during the late Pleistocene cataclysmic flooding (13,000 to 30,000 years ago). Pedogenic calcium carbonate (Stage 1) forms a partial rind on the underside of some gravel clasts in sediments from 0.3 to 1.2 m deep. No other calcic zones were encountered. Sand grain size is primarily coarse to medium (1 to 0.25 mm in diameter), with more than 70% of the sand consisting of those sizes. This reflects a calmer depositional environment than the north side of the bar, where boulders are up to 0.3 m in diameter. A thin sand layer, formed from reworking of flood deposits, overlies the Hanford formation.



View of ILAW site from north-east. Power plant is in the foreground. The rectangle represents the approximate location of the surface plot below.

NA	B8503	N134909	E574127	~May 1998

The drill pad for the B8500 boreholes was on the western end of the windward side of a dune oriented in an east-west direction. The near surface sediment (apart from the imported sediment fill and drill pad) is primarily the sediment composing the sand dune. Below this dune material the sediments are coarse to medium sands characteristic of the Hanford formation (Reidel and Reynolds 1998).

Many tracer methods rely on accurately measuring the depth below surface of the tracer profiles. To ensure this accuracy, the surface elevations were surveyed using a ground-positioning satellite (GPS) system before the gravel drilling pad was constructed and after the drilling was completed (Table B.2). The natural surface sediments were graded in preparation for the gravel layer as indicated by the large mounds of natural sediments along the northeast edges of the gravel pad. Without GPS readings after grading and prior to application of gravel, it would be difficult to determine the amount of natural sediment that was removed under the existing drilling pad. The sediments under the pad were compacted and visibly wetter than the undisturbed sediments.

Table B.2. Pre- and Post-Pad Elevations by Ground-Positioning Satellite

Well ID	Pre-Pad Elevation ft (m)	Post-Pad Elevation ft (m)	Difference ft (m)
B8500 (2-E17-21)	734.9 (223.39)	735.7 (224.24)	+0.8 (+0.85)
B8501	739.5 (225.40)	741.1 (224.88)	+1.6 (+1.49)
B8502	734.9	737.8	+2.9

B.4 Results

The analyses of the borehole samples followed procedures outlined by Murphy et al. (1991) and Murphy et al. (1996). Tables B.3 to B.9 contain the results for every sample analyzed. These results are discussed below.

(a) Background-corrected ratios are calculated using the measured ratio for a blank sample.

(b) Uncertainty in the $^{36}Cl/Cl$ is the combined uncertainties in the sample measurement and in the standard measurements used for normalization. The final value reported is the weighted mean of the individual measurements of the sample. Two uncertainties are calculated from this weighted mean: 1) the internal error is the propagated uncertainty in the weighted mean, where the weighting factors are the uncertainties in the individual measurements calculated as stated above; and 2) the external error is the population standard deviation of the individual measurements of the weighted mean. The reported error is the larger of the internal and external error and represents the uncertainty in the final measurement.

Note: BD = below detection.

Sun River Electric and Watts Construction started construction of the drilling pad on February 12 and completed work on February 17, 1998. The site is extremely sandy and a bulldozer was used initially to clear the vegetation and level the area. Gravelly sediments were taken from a borrow pit in the 200 West Area that was used to burn sagebrush. Approximately 15 cm of this material was laid down, and then a large vibratory roller was used to compact the material. This compaction can easily affect the first two feet of sediment. Approximately 7.5 cm of crushed gravel was then laid down and the vibratory roller compaction was repeated. Drilling began on April 6, 1998, at B8500, April 24, 1998, at B8501, and April 27, 1998, at B8502. The gravel drill pad is a very effective structure for reducing evaporation, which increases the movement of water deeper into the profile. Precipitation totaled 22.1 mm between construction and drilling. Our concern is that some of this water may have affected the upper samples.

B.4.1 Physical Properties

B.4.1.1 Stratigraphy

Stratigraphic columns were constructed from available geologic information (Figure B.3). In 1995, the columns were reconstructed from geologic notes taken at the drill site. A more thorough analysis was done in 1998 when the split cores were examined in detail in the laboratory.

Distinct layering was evident from the exposed trench wall. This layering was primarily gravels, medium to fine sands, and silts. The structured horizontal layering (seen in the lower portion of the trench photograph in Figure B.3) results from layers of fine and coarse sands and silts, usually on the order of a few centimeters thick. These layers are part of the upper flow regime of the plane-laminated sand facies of the Hanford formation.

B.4.1.2 Grain Size Analyses

Grain size distributions were determined by sieving according to the Wentworth scale; the amount of silt and clay was determined by sedimentation using a hydrometer (Figure B.4). There is a striking difference between the grain size distributions of the boreholes north of the east-west sand dune compared with the B8500 series boreholes that were located just outside the southern boundary of the proposed ILAW Disposal Site. The exploratory boreholes (299-E24-161 & -162) show less clay and silt and much less layering than the B8500 boreholes. In general, the exploratory boreholes had more uniform grain sizes with depth.

Among the B8500 series of boreholes, borehole B8503, which was drilled in undisturbed sediment, provided the most accurate grain-size distribution in the upper 2 m. The grain-size distributions in the upper 3 m of B8501 and B8502 were likely impacted by the fill sediment and gravel that was used to construct the drill pad.

Although the sediments are predominantly sand, some gravel and silt layering is evident in B8503, similar to what was observed at the exposed face of the trench dug in 1995. At some depths a high gravimetric moisture content correlates well with silt layers as shown in Figure B.5 for borehole B8502. This is in contrast to the labeling on the stratigraphy column of areas of clay-rich silt to silty sand. The

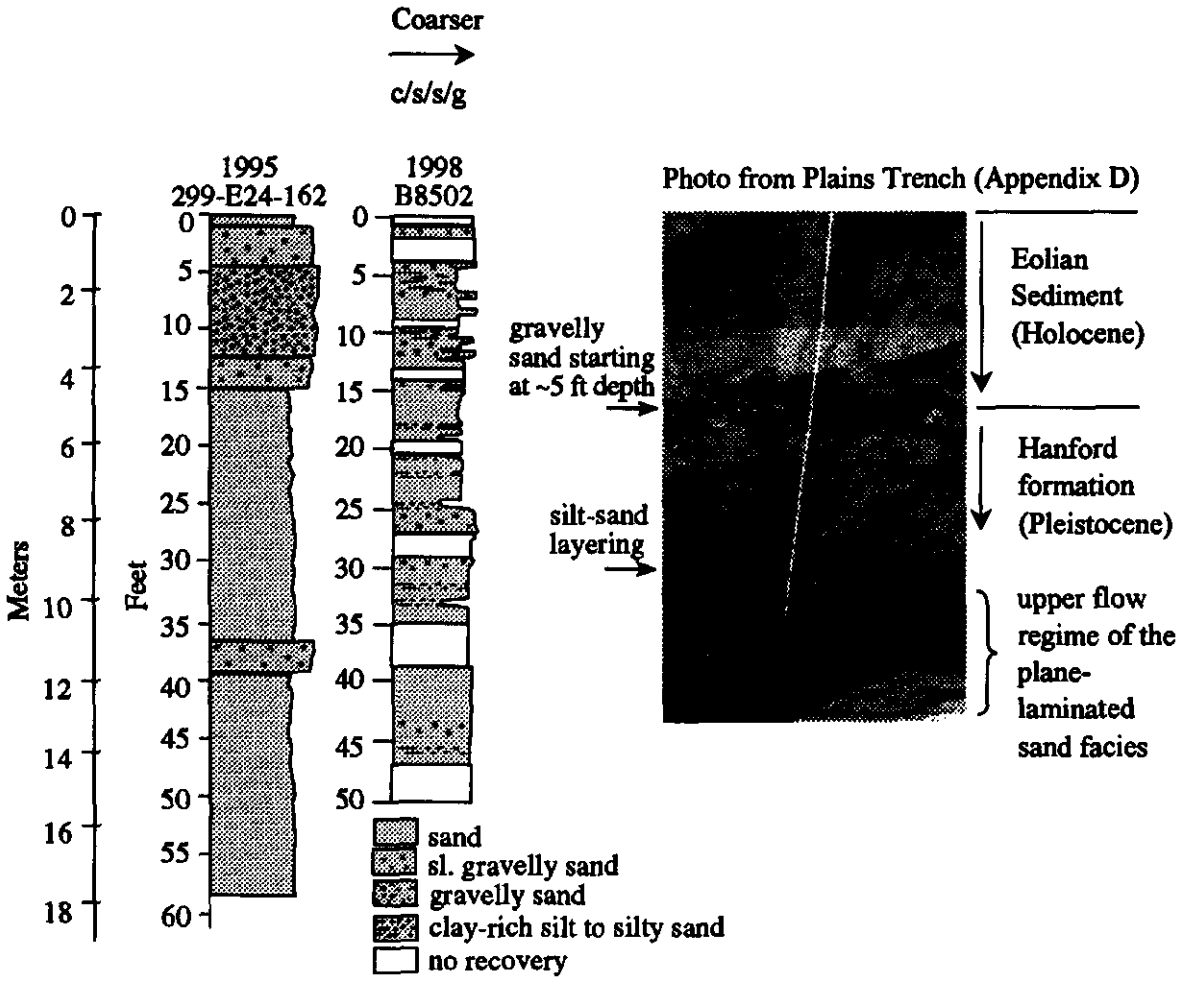

Figure B.3. Stratigraphic Columns Constructed from Drill-Site Geologic Logs and a Photograph Taken from the Trench Excavation in 1995

hydrometer methods indicated a fairly uniform low concentration of clay, ranging between ~5 to 10%. Sieve analyses indicated highly variable concentrations of silt in the sediment column. Therefore, the correlation of moisture with specific layers in the profile is likely due to the concentration of silt and not a clay-rich region in the profile.

B.4.1.3 Gravimetric Moisture Content

Gravimetric moisture contents varied between ~0.01 to 0.13 g/g with the higher values generally in the top 3 m of sediment. The moisture contents of sediments collected from two exploratory boreholes drilled in March 1995 are shown in Figure B.6a along with moisture contents from the B8500 series boreholes (April 1998, Figure B.6b). The 1995 exploratory boreholes (161 and 162) were 35 m apart and were drilled during the same week. The B8500 series boreholes were all within ~22 m and were drilled

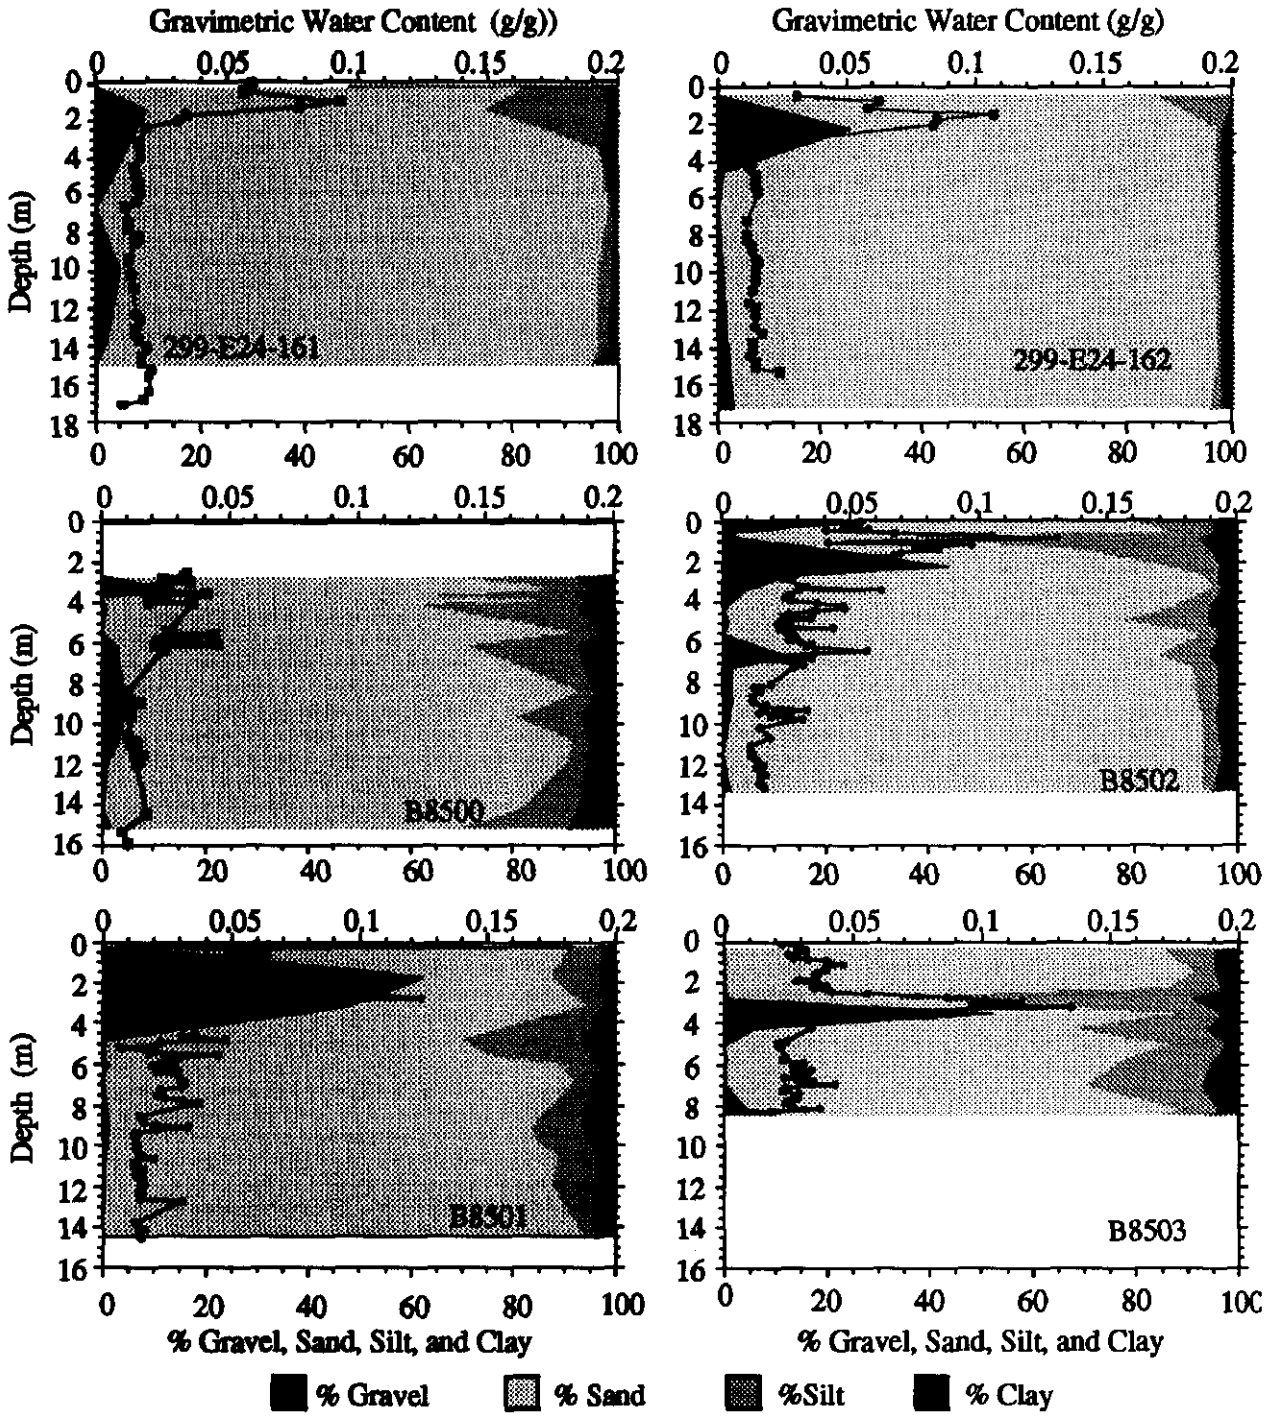

Figure B.4. Gravel, Sand, Silt, and Clay Percentages in the B8500 Series Boreholes. The data points show the corresponding gravimetric water content with depth. The lower x-axis of each graph is the percentage for the grain size distribution, while the upper x-axis of each graph is the gravimetric water contents (g/g).

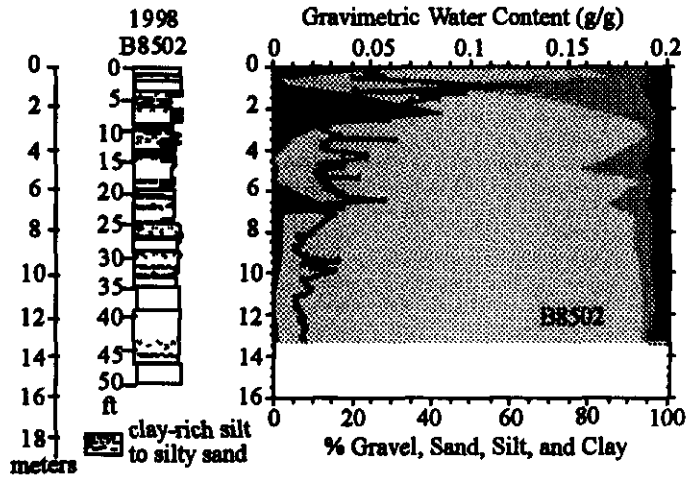

Figure B.5. Comparison of Stratigraphy with Particle Size Distribution for Borehole B8502

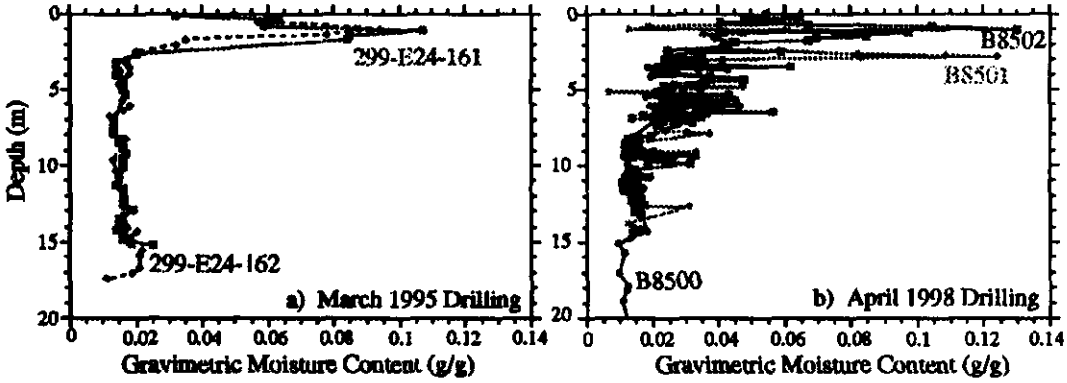

Figure B.6. Gravimetric Moisture Content Profiles from 1995 Exploratory Drilling (a) and Profiles from B8500, B8501, and B8502 (b)

The 1995 exploratory holes showed greater consistency in moisture content, which may be due to greater uniformity in the stratigraphy and surface vegetation compared to the B8500 site or handling problems associated with the B8500 sampling. When there was an obvious wetting front in the core sample (due to improper handling), the sediment was not sampled. The resulting moisture profile for the B8500 boreholes show greater variability than the wells drilled in 1995; however, the moisture contents were within the range typically found for Hanford sediments. Although we cannot assess the impact of the drilling pad construction and fill material on the moisture profiles, we can suggest that the more pronounced silt layering in the B8500 boreholes has a direct impact on the moisture variability with spikes in the moisture content generally associated with silt layers (see Figure B.4).

The other primary difference between the exploratory borehole site and the B8500 site is the surface vegetation. The exploratory boreholes were located on the lee side of the sand dune in a dense stand of mature sagebrush. In contrast, the B8500 boreholes are located on the windward side of the sand dune. The vegetation here was much smaller and sparse. The dense, mature vegetative cover at the exploratory

boreholes may promote the greater uniformity seen in the moisture contents. In these profiles, the predominant moisture was confined to the root zone. Below the root zone, the sediments were extremely dry, ranging from 0.01 to 0.02 g/g gravimetric water content. The B8500 moisture profiles showed greater variability and somewhat higher moisture contents at depths below the root zone.

B.4.1.4 Dry Bulk Density

Dry bulk density measurements were performed on all samples that were used for tracer analysis. The chloride mass balance approach uses this measurement to estimate recharge. Similar to the moisture content, the dry bulk densities were more variable in the B8500 series boreholes when compared to the 1995 exploratory holes (Figure B.7). A correlation was not evident when moisture content was plotted against dry bulk density.

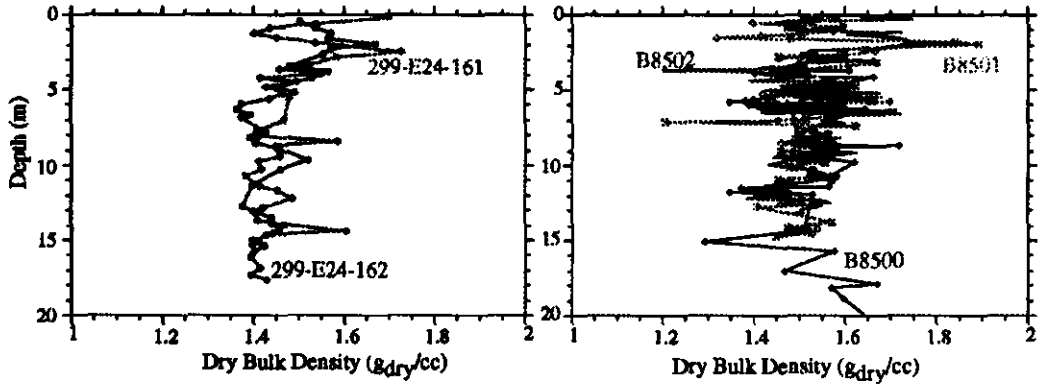

Figure B.7. Dry Bulk Density Comparison Between 1995 Exploratory Boreholes (a) and B8500 Series Boreholes (b)

B.4.2 Tracer Results and Discussion

Unsaturated flow processes have been investigated using indirect physical measurements (e.g., water balance and Darcy flux measurements), direct physical measurements (e.g., lysimetry), and environmental tracers (e.g., Cl, ^{3}H, and ^{36}Cl). Allison and others (Allison 1988; Allison et al. 1994) concluded that the indirect physical measurements were the least successful in arid regions and the tracer methods were the most successful. However, Phillips (1995) cautioned that "unless considered in the context of a thorough evaluation of the physical hydrogeology, tracer results are of generally limited value. Conversely, isotopic and environmental tracers can usually provide very useful constraints on interpretations of subsurface flow regimens."

The application of environmental tracers generally yields a site-specific, long-term recharge estimate (where recharge is defined as the net deep drainage flux when measured below the root zone). This section details the results of the environmental tracers, ^{36}Cl, chloride, and Cl/Br ratios.

B.4.2.1 Bomb-Pulse ^{36}Cl

^{36}Cl (half life approximately 301,000 years) was produced indirectly during atmospheric nuclear weapons testing by thermal neutron irradiation of chloride in sea water. Thus, only the explosions carried out by the United States in the South Pacific between late 1952 and mid-1958 activated chloride in sea-water and produced the worldwide ^{36}Cl signal (Bentley et al. 1986). The peak in the ^{36}Cl fallout occurred in 1955 (Phillips et al. 1988). Water fluxes are estimated for bomb-pulse ^{36}Cl from the depth of the center of mass of the ^{36}Cl profile. The amount of water in the profile above the center of mass is equal to the water flux over the time period since the ^{36}Cl was deposited on the soil surface.

Archived samples were processed for ^{36}Cl. These samples had been collected in 1995 at the ILAW Disposal Site (previously known as the Low Level Glass Site) in the 200 East Area. Large quantity samples were collected from a trench with a backhoe. Depth measurements were made before each sample was collected. The samples were sealed in plastic buckets and processed for leachable chloride in late 1997 to early 1998. The samples were analyzed for $^{36}Cl/Cl$ by tandem accelerator mass spectrometry (TAMS) at Lawrence Livermore National Laboratory. Blind sample splits were included to determine TAMS measurement variability. The results with measurement error bars are plotted against sample depth in Figure B.8. The samples and sample-splits were processed in two different runs approximately a month apart. The sample splits showed little variability considering the TAMS runs were a month apart.

A sharp $^{36}Cl/Cl$ peak occurs in the trench profile (see Figure B.8) with a center of mass at approximately 1.5 m. The peak is still well within the root zone at this site. When the bomb-pulse $^{36}Cl/Cl$ is located in the root zone, one can infer that the water flux at this site is extremely low (Scanlon et al. 1997). Much of the water in the root zone is eventually removed by evapotranspiration; therefore, estimates of water fluxes by tracers in the root zone will overestimate the amount of net deep drainage flux below the root zone by several orders of magnitude (Tyler and Walker 1994). These types of estimates would also be affected by seasonal moisture variations in the root zone. Recharge is defined as the net deep drainage flux *below* the root zone (e.g., that water that has escaped evapotranspiration processes and can therefore contribute to recharge of the unconfined aquifer).

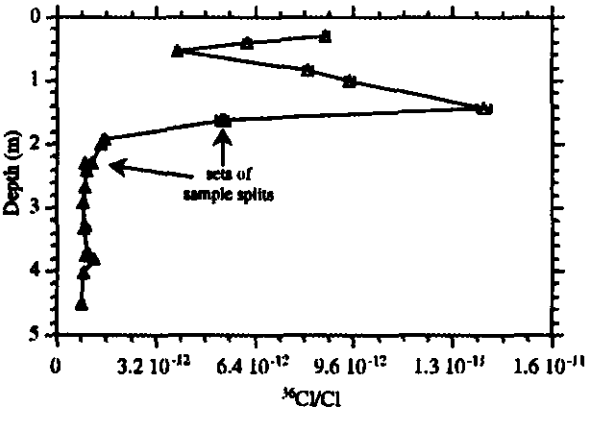

Figure B.8. Bomb-Pulse ^{36}Cl Profile from Samples Collected in the Plains Trench at the ILAW Disposal Site

The shape of the $^{36}Cl/Cl$ pulse in Figure B.8 is significant because it suggests that the center of tracer mass is moving by piston flow through the root zone. Piston-type flow is an underlying assumption in most unsaturated flow models and in methods used to estimate recharge by atmospheric tracers. Deviations from piston flow can occur when there is preferential flow through root channels and macropores created by natural soil activities. Although there is no evidence to indicate that this piston-type flow can persist below the root zone, absence of a strong preferential flow component in the root zone suggests that this mechanism may dominate in these sandy sediments. The ratio $^{36}Cl/Cl$ may not indicate preferential flow if chloride concentrations are high because small variations in ^{36}Cl can be overwhelmed by the high chloride. We did not measure the chloride concentrations of these samples, but nearby boreholes indicated the chloride concentrations could be as high as 4000 mg/L.

B.4.2.2 Chloride Mass Balance

The natural tracer method based on CMB is one of the simplest, least expensive, and most useful for determining recharge in arid climates (Allison et al. 1994). In this mass balance approach, water entering the soil column contains meteoric chloride that is treated as an inert tracer. As water percolates downward through the root zone, evapotranspiration removes water, thus enriching the chloride concentration with depth through the root zone. This increase in chloride concentration quantitatively reflects the corresponding reduction in water flux from the infiltration flux to the deep drainage flux beneath the evapotranspiration zone. The CMB method is especially applicable to arid and semiarid regions where evapotranspirative enrichment of the pore water produces a distinct chloride profile in the unsaturated zone.

Application of the CMB method typically involves the following simplifying assumptions regarding transport: 1) flow is vertically downward of piston type at constant water content and 2) the precipitation and the accumulation rate of atmospheric chloride are steady over the relevant period. An additional assumption of steady state water flux throughout the column is often invoked, but as shown by Ginn and Murphy (1997) this assumption is not required in application of CMB. Recharge or net deep drainage flux is determined by the relationship

$$J_R = \left(\frac{Cl_o}{Cl_{sw}}\right) P \qquad \text{(B.1)}$$

where J_R = net downward deep drainage flux (mm/yr)
Cl_o = average atmospheric chloride concentration in local precipitation and dry fallout (mg/L or equivalent units of g/m^3)
Cl_{sw} = average chloride concentration in the soil water (mg/L)
P = average annual precipitation (mm/yr).

Cl_o can be expressed as the total chloride mass deposited at ground surface q_{Cl} (q_{Cl} - units of mg $m^{-2}yr^{-1}$) divided by the precipitation (160 mm/yr at Hanford). Values for q_{Cl} can be measured,

calculated, or obtained from the literature. For the ILAW site, q_{Cl} was determined using the approach outlined by Phillips et al. (1988) and Scanlon et al. (1990):

$$q_{Cl} = \frac{{}^{36}Cl_o \left(atoms\, m^{-2} s^{-1}\right)\left(31.56 \times 10^6\, s/yr\right)\left(35.5 \times 10^3\, mg/mol\right)}{\left({}^{36}Cl/Cl\right)_m \left(6.023 \times 10^{23}\, atoms/mol\right)} \quad \text{(B.2)}$$

where ${}^{36}Cl_o$ = calculated natural fallout of 18.8 atoms $m^{-2}s^{-1}$ for 46°N geographic latitude (Andrews and Fontes 1992)

$({}^{36}Cl/Cl)_m$ = ${}^{36}Cl/Cl$ ratio in the soil water excluding the anthropogenic ${}^{36}Cl$ peak.

Over the Holocene the geographic latitude represents a long-term average of the frequent fluctuations in the geomagnetic latitude (Merrill and McElhinny 1983). Below the bomb pulse, the average ${}^{36}Cl/Cl$ ratio between depths 2.4 and 4.8 m was 911 x 10^{-15}. The values ranged from 810 x 10^{-15} to 1160 10^{-15} and had a median value of 887 x 10^{-15}. Ratios at other sites at Hanford fall within this range (Murphy et al. 1996; Prych 1998). Using the average ratio of 911 x 10^{-15} in Eq. B.2, we calculated a q_{Cl} value of 38.4 mg/m^2/yr. This value is consistent with previously reported values for the 200 area plateau, which range from 32.7 to 49.4 mg/m^2/yr (Murphy et al. 1996).

Figure B.9 shows the chloride profiles (concentration of chloride in the pore waters) for the two exploratory boreholes in 1995 and the four B8500 boreholes drilled in 1998. The exploratory boreholes both show a peak in chloride starting at approximately 1.5-m depth and ending at approximately 4-m depth (center of mass is approximately 2.5 to 3 m). As can be seen in Figure B.9b, only the bottom portion of the chloride pulse was recovered from borehole B8500. The drilling contractor was not prepared to collect continuous core and did not attempt to collect core above approximately 3 m. The depth of the bottom of the B8500 profile was consistent with the location of the chloride profiles in 1995. By 5 to 6 m the chloride concentration in the porewater has returned to background levels.

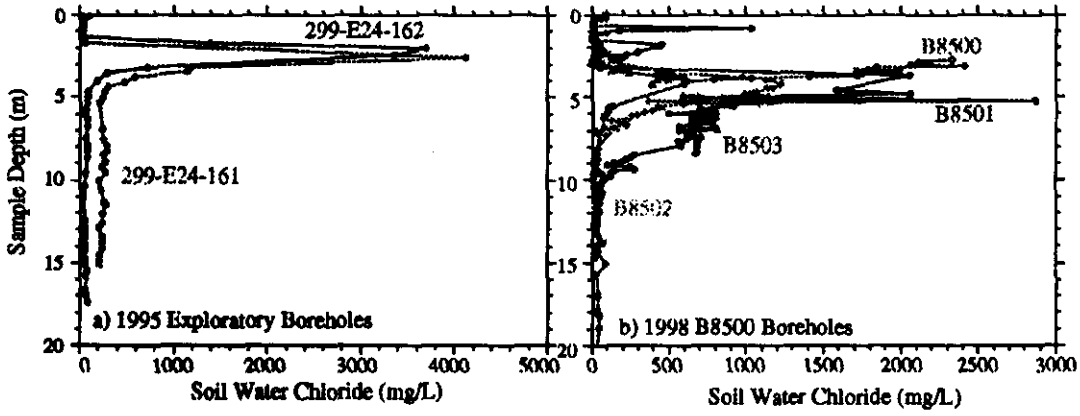

Figure B.9. Comparison of Chloride Profiles from B8500, B8501, and Exploratory Boreholes Drilled in 1995

The chloride profile for B8501 is more complete, but much more irregular than what we typically find at undisturbed sites (Figure B.9b). The chloride peaks near the surface (0 to 3 m) are most likely artifacts of the fill dirt/gravels that were deposited at this location and therefore should be disregarded. For example, B8503 is located directly adjacent to B8501, a meter off of the drill pad where the surface was undisturbed. There are no significant peaks in the chloride in the top 3 m of the B8503 profile. The secondary peak of chloride in the B8501 borehole between a depth of 6 to 9 m suggests a past period of lower recharge rates, possibly due to changes in the surface vegetation. It is possible that the B8503 profile may have mimicked the chloride profile in B8501; however a critical portion of the B8503 core, where the peak chloride concentration would likely occur, was not recovered between 4 and 5 m. The chloride profile from the B8502 borehole is deeper than the peaks detailed in the 1995 exploratory boreholes and has a broader peak, suggesting higher recharge rates at this location.

The CMB method for estimating recharge relies on an accurate accounting of the mass of this tracer. If chloride mass is removed by grading or added by applying gravel/fill to the surface, then the mass balance approach will be compromised. So little of the chloride pulse is defined in B8500, that we are unable to determine the peak concentration and cannot estimate recharge using the chloride mass balance method for this particular borehole. In addition, incomplete recovery of the B8503 chloride profile precludes using this profile for estimating recharge rates.

The net downward deep drainage flux can be estimated with the conventional CMB method (Equation B.1). A value for Cl_{pw} is determined by plotting cumulative chloride content with depth against cumulative water content at the same depth (Figure B.10). The slopes of the straight-line segments represent a period over which the precipitation and atmospheric chloride deposition conditions were approximately constant. The recharge rates ranged from 0.013 to 0.016 mm/yr at the 1995 exploratory boreholes (Figure B.10a). Somewhat higher rates were found at the B8500 site, ranging from 0.03 to 0.065 mm/yr; however, these estimated rates are still quite low. The recharge rates are consistent with the differences in surface vegetation at the two locations. Two recharge rates are calculated for B8501, one corresponding to the initial chloride peak and the other corresponding to the secondary bulge in chloride below the initial peak (Figure B.10b).

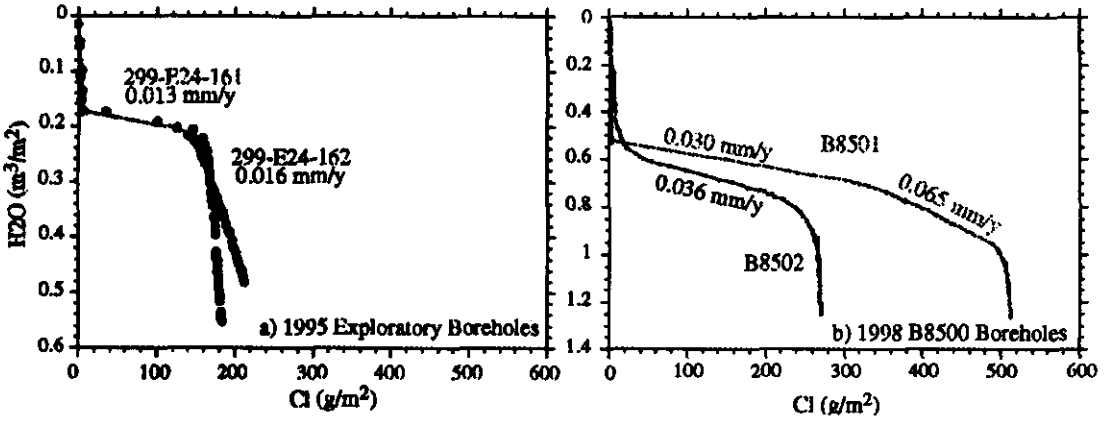

Figure B.10. Cumulative Water Versus Cumulative Chloride in the Sediment Profiles

The cumulative masses of chloride are different for the boreholes shown in Figure B.10. In particular, borehole B8501 had more total chloride than the other boreholes. If we assume that the large peak starting at approximately 3 m was not contaminated by fill material, then there are two possible processes that could lead to the differences in total chloride mass: 1) spatial and temporal differences in the extraction rate of water over time, and 2) variable input of chloride at the soil surface.

The variable total masses of the chloride in the different boreholes is most likely caused by spatial and temporal variations in the extraction rate of water over time. The extraction rate is a function of the type and density of the vegetation at a particular location and also is affected by the seasonal timing of precipitation. The two borehole locations were both subjected to repeated flooding during the late Pleistocene, which would have erased the pre-Holocene chloride signal (Murphy et al. 1996). The post-flood depositional history at the two ILAW drilling locations, however, is quite different as evidenced by their stratigraphy. The B8500 boreholes were located on the tail of a long dune lying in an east-west direction, while the 1995 exploratory boreholes were located approximately 300 m north of the dune. At the exploratory boreholes the eolian sands represent the top 0.5 m of the profile followed by the flood deposits of the Hanford formation. Using the accumulation of chloride mass at the exploratory boreholes as a measure of the time of evapotranspirative enrichment, vegetation capable of extracting pore water such that chloride is accumulated was likely established around 5,000 yBP at this site. This timing is consistent with the end of a period of maximum aridity that occurred between 8,000 and 5,500 yBP (Chatters and Hoover 1992; Gaylord et al. 1991) and transition to higher precipitation rates that would have been conducive to the establishment of vegetation.

The stratigraphy at the B8500 location is much more complex. The occurrence of a paleosol at 3 m in B8501 and 1.5 m in B8502 (Reidel et al. 1998) may reflect a time period early in the Holocene (approximately 8,000 to 10,000 yBP) when a grass-steppe vegetation dominated (Chatters and Hoover 1992; Mehringer 1985). This paleosol was also encountered at a backhoe trench that was attempted on the north (leeward) side of the dune in 1995 (the Dune Trench in Appendix D). The entire sequence exposed to approximately 4 m in this trench consisted of eolian sand. The flood deposits of the Hanford formation were not encountered before the trench collapsed at 4 m. However, a dark yellowish brown silty fine sand was found just below 3 m in the trench. Several peat-like clasts consisting of dense, partially decomposed mats of root hairs were located at this depth indicating past establishment of vegetation at this location. The dune lying in an east-west direction at the southern end of the proposed ILAW Disposal Site overlies this paleosol and may have been deposited during a period of maximum aridity, between 8,000 and 5,500 yBP. Therefore, it is possible that the lower chloride bulge in B8501 contains chloride accumulated in the early Holocene (10,000 to 8,000 yBP), followed by an arid period of dune formation (8,000 to 5,500 yBP), followed by establishment of vegetation again in the late Holocene (approximately 5,000 yBP to present). The more recent period is represented by the sharp chloride peak at 4 to 5 m.

In addition to a variable history in extraction rate, spatially variable atmospheric deposition of chloride could lead to differences in the total mass of chloride in the sediment profiles. It is highly unlikely that the atmospheric deposition of chloride would be spatially variable over such a small area (22 m horizontal separation between B8501 and B8502). Non-meteoric sources of chloride, such as

chloride leaching from basalt grains or anthropogenic sources of chloride, may lead to spatially varying masses of chloride in the sediment profile and will be discussed in more detail in the next section.

B.4.2.3 Cl/Br Ratios

Ratios of ions are often used as tracers in hydrologic studies to determine the origin or evolution of waters or to quantitatively evaluate the mixing of different sources of water. If the two ions used have similar properties, then their ratio should remain relatively constant. In a recent article, Davis et al. (1998) reviewed information on the chemistry, characteristics, and concentrations of chlorine and bromine in nature. We have adopted the terminology of Davis et al. (1998) and have expressed Cl/Br as a ratio of the mass of each element.

Ratios of Cl/Br were analyzed to evaluate non-meteoric sources of chloride (Figure B.11). At the proposed ILAW Disposal Site, non-meteoric sources might include chloride leaching from basalt sand grains and chloride deposited from anthropogenic sources such as fly ash from a nearby power plant or other processing facilities within the 200 East Area. The ratios of potential sources of chloride were either measured or extracted from published reports. The basalt sands in the Hanford formation originate from the Columbia River basalt, which consists of multiple basalt flows that include the Grande Ronde, Saddle Mountain, and Wanapum flows. Flanagan (1973) measured a Cl/Br ratio of 333 for the Grande Ronde basalt. Ratios of Cl/Br in an additional 14 basalt samples ranged from 184 to 500 (Yoshida et al. 1971). The meteoric ratio of Cl/Br is somewhat more difficult to evaluate because approximately 60% of the chloride deposition occurs in dry fallout, while the remaining 40% is associated with precipitation events. The anion ratios may be quite different for wet and dry deposition. However, to evaluate the meteoric source, we need the combined ratio of wet and dry atmospheric deposition. In an extensive survey, Davis et al. (1998) found that most Cl/Br ratios in precipitation were less than 200. They suggested that Cl/Br ratios in precipitation vary geographically between 130 and 180 near the coast, to

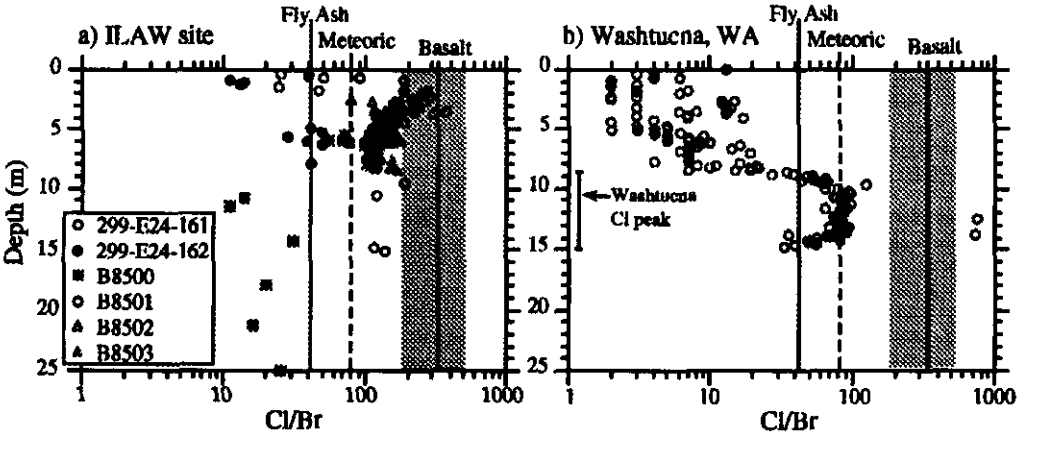

Figure B.11. Cl/Br Ratios of Pore Water Extracts from the ILAW Site (a) and the Washtucna Site in the Palouse Region of Eastern Washington State (b). The dashed line represents the meteoric Cl/Br ratio. The solid line represents the Cl/Br ratio of Grand Ronde basalt.

between 75 and 120 several tens to a few hundred kilometers inland, to as low as 50 several hundred kilometers inland. Berg et al. (1980) measured a Cl/Br ratio of 80 in the lower stratosphere at northern latitudes, which represents the total concentration of these anions in air. In the absence of specific measurements of meteoric Cl/Br in the Pasco Basin, shallow porewater ratios should reflect the combined wet/dry fallout ratio of meteoric Cl/Br. As can be seen, however, at the proposed ILAW Disposal Site (Figure B.11a) the Cl/Br ratios in the first few meters of the profile were the most variable, ranging from 10 to over 100. Surface evaporation alone should not affect this ratio.

In all of the boreholes examined to date, the Cl/Br ratio was low in the shallow portion of the borehole, increased to a maximum at the depth of the chloride peak, and then declined again below the chloride peak in the lower regions of the profile (Figure B.11). The increase in Cl/Br shifts the ratio closer to the ratio found in basalt. However, the increase in the ratio is not correlated with the basalt composition of the sediments (Murphy et al. 1996) nor is there sufficient chloride in basalt to impact the mass of this peak. The increase in the ratio also is not consistent with fly ash from the power plant located next to the proposed ILAW Disposal Site. Leaching of an 11-cm-deep sample of fly ash yielded a Cl/Br ratio of 41 (Table E.3, Appendix E), somewhat lower than the meteoric signature of 80 reported by Berg et al. (1980). In contrast to the shallow fly ash sample, a deeper sample (61 cm) yielded a Cl/Br ratio of 382. Although based on only two samples, the wide range of Cl/Br ratios in the fly ash may make it difficult to demonstrate a correlation with the ratios observed in the boreholes.

Finally, the ratios from the proposed ILAW Disposal Site are compared to the ratios collected from a borehole in the Palouse region of eastern Washington State (Figure B.11b, Washtucna, Washington). This site is not located near a power plant and is in a region of eolian deposition of fine sand and silt. The precipitation and recharge rates are much higher at the Washtucna site (Ginn and Murphy 1997). The Cl/Br ratios above the chloride peak are much lower than values at the proposed ILAW Disposal Site. It is not known whether these lower Cl/Br ratios reflect the relative distances of the sites from the ocean (approximately 350 kilometers for ILAW versus approximately 450 km for Washtucna) or other atmospheric patterns which might affect the meteoric ratio (Davis et al. 1998). The maximum Cl/Br ratios occurred concurrent with the depth of the chloride peak and then declined below this zone of evapotranspirative enrichment. Plotting the Cl/Br ratio against the chloride concentration in the pore water showed the relationship of an increasing ratio with increasing concentration of chloride (Figure B.12). The chloride and bromide peaks in the ion chromatograph were sufficiently separated that this relationship was not due to analytical interference at high chloride concentrations. We were also unable to find any bias in the ratios with low bromide measurements.

Davis et al. (1998) found a similar relationship of increasing Cl/Br with increasing concentration of chloride in precipitation samples and in groundwater samples. These authors also provide insight into a possible mechanism that leads to higher Cl/Br ratios in the zone of evapotranspirative enrichment of chloride. Chlorine is generally 40 to 8000 times more abundant than bromine. Therefore, a relatively small change in the total mass of bromine will give rise to a large change in the Cl/Br ratio. Additionally, bromide is much more soluble than chloride. McCaffrey et al. (1987) noted that during the evaporation of seawater, the residual brine is enriched in bromide due to bromide's higher solubility. Finally, some researchers have suggested that surface vegetation may concentrate bromine (Gerritse and George 1988; Shotyk 1997).

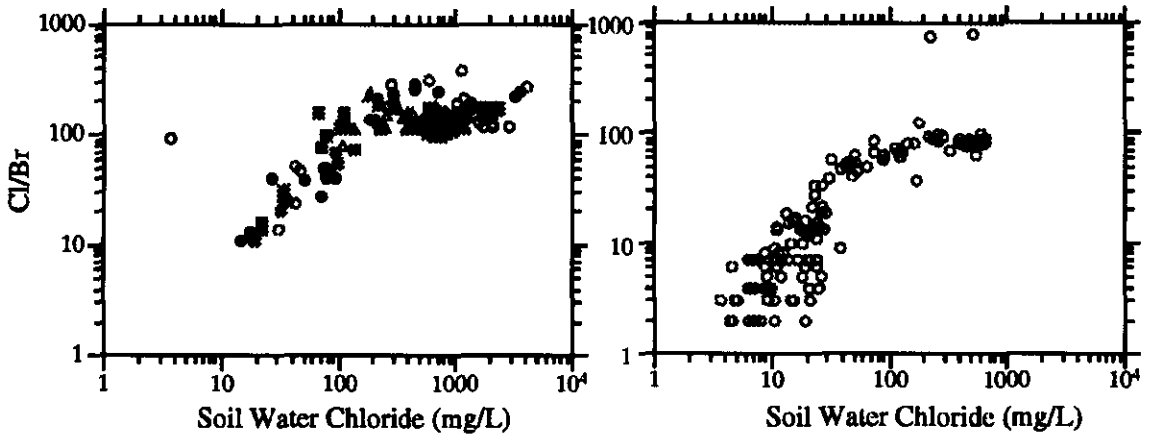

Figure B.12. Relationship Between the Soil Water Chloride Concentration and the Cl/Br Ratios at the ILAW Site (a) and the Washtucna Site in Eastern Washington State (b)

Two possible mechanisms could result in greater Cl/Br ratios in the zone of evapotranspirative enrichment: differential solubility and selective plant uptake. The highest soil water chloride concentrations generally range from 1000 to 4000 mg/L at gravimetric moisture contents as low as 0.02 g/g. Theoretically, plants could reduce the water content in the sediment. Under this condition, chloride is more likely than bromide to precipitate out of solution, leaving the soil solution enriched in bromide. As the plants take up soil water, the more soluble bromide will be removed in quantities greater than chloride, because a higher proportion of bromide mass will be in solution. When sediments are processed with distilled water to extract dissolved species, both the precipitated and solution chloride are recovered. Because bromide concentrations are so much lower than chloride to start with, any removal of the more soluble bromide by the plants will produce lower total bromide mass in the evapotranspiration zone. This precipitation mechanism is not likely, however, because the solubility concentration limit of chloride salts is ~220,000 mg/L. In the example above, the plants would have to reduce the water content from 0.02 g/g to the unrealistically low value of 0.0004 g/g for precipitation to occur. The selective plant uptake of bromide relative to chloride remains a viable mechanism.

This process could be tested by 1) extracting the pore water directly from the sediments without adding distilled water, and/or 2) by measuring the ratios of Cl/Br in the plant biomass for direct comparison with the ratios in the zone of evapotranspirative enrichment. Rickard and Vaughan (1988) measured chloride and bromide in two samples of sagebrush leaves, which yielded Cl/Br ratios of 100 and 196. These values bound the limits found in the zone of evapotranspirative enrichment at the proposed ILAW Disposal Site. Ideally, a direct comparison of the Cl/Br ratios in the sediment profile should be made with the plant biomass at the same site.

If the Cl/Br ratios are altered in the zone of evapotranspirative enrichment, then the Cl/Br ratios may be much more useful in tracer studies than just identifying non-meteoric sources of chloride. The Cl/Br ratios may provide an understanding of the recharge mechanisms taking place in the Hanford vadose zone. For example, all of the profiles at the proposed ILAW Disposal Site show the characteristic

increase in the Cl/Br ratio in the zone of evapotranspirative enrichment (Figure B.11a). Most of the profiles show a decline in the Cl/Br ratio below this zone, suggesting that little water is escaping the root zone. In one of the 1995 exploratory boreholes, 299-E24-161, high Cl/Br ratios persist at depth and somewhat higher total chloride mass. On a mass basis, approximately 5% of the chloride may be displaced below the chloride peak. There are two possible mechanisms that may lead to this displacement of chloride from the peak: 1) preferential flow, or 2) displacement of sands during drilling. Although preferential flow cannot be ruled out, we might expect to see some indication of chloride mass displacement in the shape of the chloride peak (e.g., multiple peaks). The chloride peak at this site is extremely sharp. In addition, the ^{36}Cl profile, which was evaluated in nearby, similar sediments, also does not indicate preferential flow processes. The depth affected by elevated chloride mass cannot be assessed because the borehole did not extend beyond 15 m and the depth to groundwater at this location is 100 m. The other mechanism that may result in a small amount of the chloride mass displaced below the zone of evaporative enrichment is simply displacement of sands during drilling. The sands are extremely dry below the root zone and can "flow" during the drilling process. This makes sediment recovery difficult and can easily lead to cross-contamination along the vertical borehole.

B.5 Conclusions

Tracer measurements are effective in providing direct estimates of recharge in the natural environment. This approach can yield a range in recharge rates that often reflect the spatial heterogeneity in stratigraphy, surface land forms, and vegetation, as well as the temporal history at a particular site. Tracer measurements and physical characteristics were evaluated at two different locations at the proposed ILAW Disposal Site. In 1995, two exploratory boreholes were drilled within the ILAW boundaries. In 1998, one deep and three shallow boreholes (B8500 series) were drilled just outside the southern boundary of the proposed ILAW Disposal Site. The fine-scale stratigraphy at the two locations is quite different, which is not unusual for the Hanford formation. At the B8500 location, the shallow stratigraphy (0 to 15 m) shows slightly higher clay contents (5 to 10%) and higher and more variable silt contents. These variations lead to more pronounced horizontal layering at the B8500 site and greater fluctuations in water content and bulk density along the vertical profiles than was evident in the profiles from the exploratory boreholes. The mature and dense sagebrush vegetation at the exploratory boreholes would also contribute to the more uniform (and low) gravimetric moisture profiles at this site.

Although drilling is relatively easy in the predominantly sandy sediments found at the proposed ILAW Disposal Site, core recovery is quite difficult. The depth of the bottom of the root zone was defined operationally as the depth of the zone of evapotranspirative enrichment of chloride. At and below this depth the sediments were extremely dry, loose, and uncompacted, and it was sometimes impossible to keep the sediment within the split tube samplers. The chloride mass balance method was applied to samples from those boreholes that had relatively continuous core recovery within the critical zone of evapotranspirative enrichment of chloride. Recharge rates were estimated for two exploratory boreholes (299-E24-161 and -162) and two shallow boreholes (B8501 and B8502). In all cases the tracer measurements showed relatively low long-term averages of recharge, ranging from 0.013 to 0.036 mm/yr. At one borehole, B8501, a secondary chloride bulge below the initial peak suggests a past period of recharge (possibly in the early Holocene) with an average rate of 0.065 mm/yr.

The variable total masses of the chloride in the different boreholes is most likely caused by spatial and temporal variations in the extraction rate of water over time. The two borehole locations were subjected to repeated glacial-outburst flooding during the late Pleistocene, which would have erased the pre-Holocene chloride signal (Murphy et al. 1996). The stratigraphy at the different locations suggests early Holocene establishment of vegetation at the B8500 location followed by a period of dune formation in the mid-Holocene, and then vegetation establishment again in the late Holocene. The exploratory borehole stratigraphy, north of the sand dune, shows no evidence of establishment of vegetation in the early Holocene. It is likely that no evapotranspirative enrichment of chloride occurred prior to the establishment of vegetation approximately 4,000 to 5,000 yBP. Without vegetation, the movement of water through the vadose zone would be rapid.

A bomb-pulse ^{36}Cl peak was measured in samples excavated from a trench with a backhoe. A sharp peak at a depth of 1.5 m showed that this tracer was still in the root zone and, therefore, could not be used to estimate recharge. Scanlon et al. (1997) suggested that the presence of ^{36}Cl near the surface indicates little or no water flux below the root zone. The sharp ^{36}Cl profile suggests that the water is moving by piston flow through the root zone. If preferential flow is occurring in a particular sediment, we would expect to see evidence of this process in the root zone where old root channels and macropores are common. However, the chloride concentrations are too high to draw firm conclusions.

Ratios of Cl/Br were also used as a tracer in this study to investigate non-meteoric sources of chloride input. These ratios, which were consistently elevated in the zone of evapotranspirative enrichment of chloride, may be due to preferential uptake of bromide into the plant biomass. Although the Cl/Br ratios do not quantify recharge, the ratios have the potential to suggest invalidation of some recharge estimates. At the ILAW Disposal Site, the Cl/Br evidence does not contradict the recharge estimates from other methods.

Appendix C

Simulation Estimates of Recharge Rates for the Two ILAW Disposal Sites

M. J. Fayer

Appendix C

Simulation Estimates of Recharge Rates for the Two ILAW Disposal Sites

C.1 Introduction

Lockheed Martin Hanford Company (LMHC) is designing and assessing the performance of disposal facilities to receive radioactive wastes that are currently stored in single- and double-shell tanks at the Hanford Site. The preferred method of disposing of the portion that is classified as immobilized low-activity waste (ILAW) is to vitrify the waste and place the product in near-surface, shallow-land burial facilities. The LMHC project to assess the performance of these disposal facilities is known as the Hanford ILAW Performance Assessment (PA) Activity, hereafter called the ILAW PA. Acceptance of ILAW disposal at the Hanford Site depends on demonstrating that public health and the environment are adequately protected. Achieving this goal will require predictions of contaminant migration from the facility. To make such predictions will require estimates of the fluxes of water moving through the sediments within the vadose zone beneath and around the disposal facility. These fluxes, loosely called recharge rates, are the primary mechanism for transporting contaminants to the groundwater.

Mann (1999) indicated that two disposal sites will be considered: the ILAW Disposal Site (located southwest of the PUREX Plant) and the Existing Disposal Site (the former Grout Vaults). For each, recharge rate estimates are needed for a fully functional surface cover, its sideslope, and the immediately surrounding terrain. In addition, recharge estimates are needed for degraded conditions and for the case of irrigated farming directly on the cover. Mann (1999) indicates that the temporal scope of the 2001 ILAW PA is 10,000 years, but could be longer as some contaminant peaks occur after 10,000 years.

Pacific Northwest National Laboratory (PNNL) assists LMHC in their assessment activities. One of the PNNL tasks is to provide defensible estimates of recharge rates for current conditions and long-term scenarios involving the shallow-land disposal of ILAW (LMHC 1999). A major goal of the PNNL task is to collect sufficient data for the conditions and scenarios deemed to be important for evaluating the performance of the disposal facilities. These rate estimates will be provided using lysimetry, tracer studies, and modeling studies.

The recharge task uses a numerical recharge model to estimate the recharge fluxes for scenarios pertinent to the ILAW PA for which data do not currently exist. Because of the long time periods involved, data do not exist for many of the scenarios. Therefore, the model is used to extend the observations and to estimate recharge rates for potential future scenarios. This appendix summarizes the process used to provide LMHC with recharge estimates for scenarios identified for the 2001 ILAW PA.

C.2 Methods

PNNL used a one-dimensional numerical model to estimate recharge rates for the two proposed ILAW disposal locations—the ILAW Disposal Site and the Existing Disposal Site. Figure C.1 shows where the two sites are located within the 200 East Area. Two soil types (Rupert sand and Burbank loamy sand) occupy both sites (Hajek 1966). Much of the proposed ILAW Disposal Site is covered by a relatively undisturbed shrub-steppe plant community. A shrub-steppe community existed at the Grout Vault Site at one time, but it was removed to construct the four existing vaults and place the spoils pile (located to the east). Most elevations at the proposed ILAW Disposal Site range from 219 to 222 m. The dune along the southern edge rises above the surrounding terrain by as much as 9 m, with a peak elevation of about 229 m. Elevations at the Existing Disposal Site are slightly lower, ranging from 204 to 206 m.

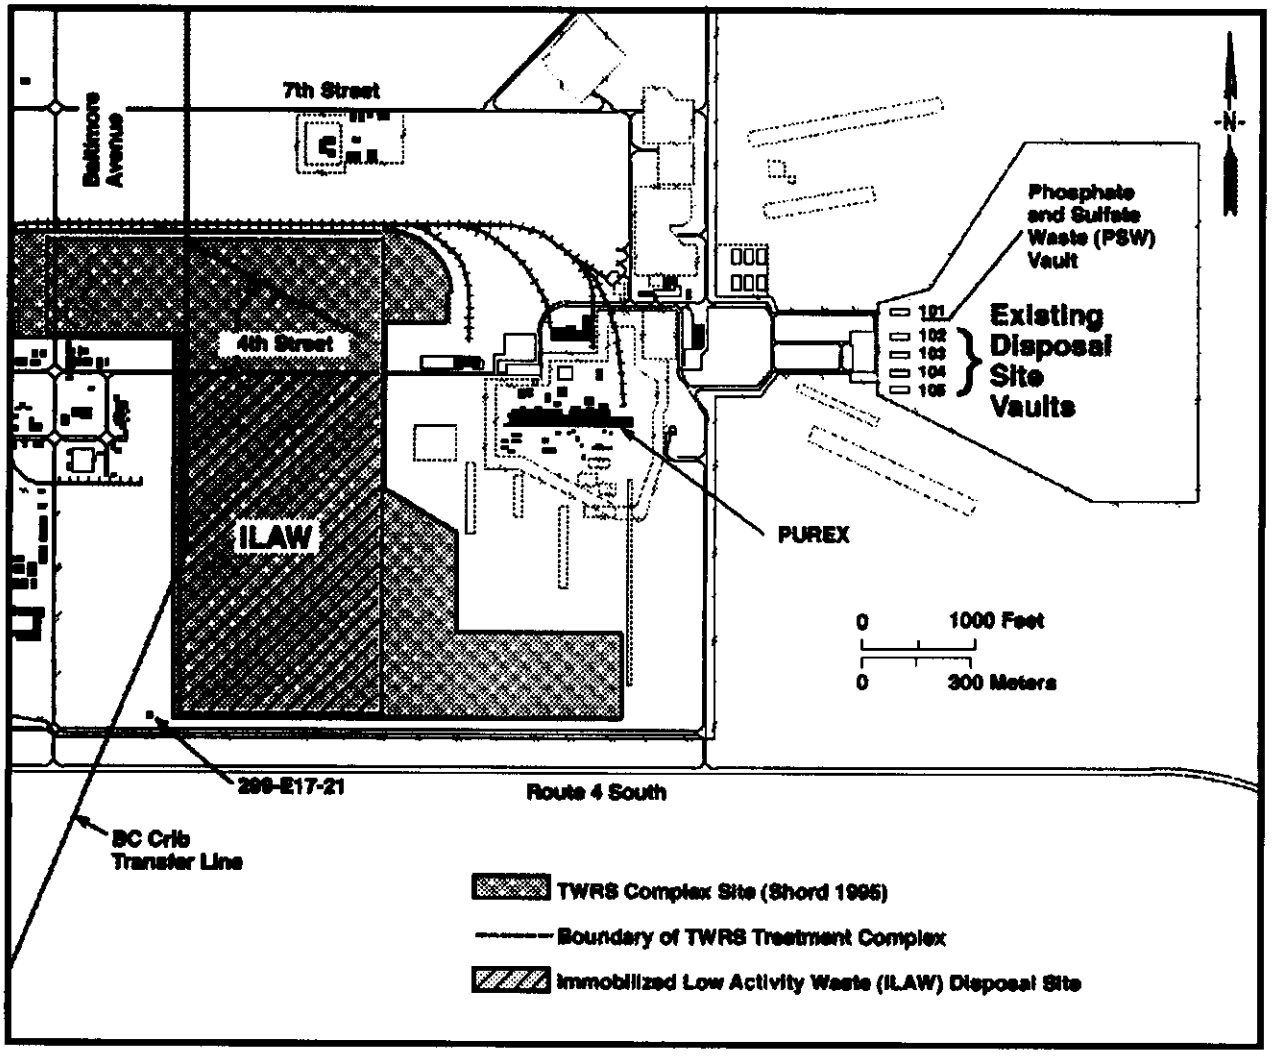

Figure C.1. Locations of the ILAW Disposal Site and the Grout Disposal Vaults

Based on this information, three scenarios were identified for simulation: the surface cover, Rupert sand, and Burbank loamy sand. Two additional scenarios were included to address two types of surface cover degradation. The sideslope component of the cover was not evaluated here. The simulation cases and associated model parameters are described in the following sections. The purpose of the surface cover is to store water and promote evapotranspiration rather than promote lateral flow. Thus, the one-dimensional UNSAT-H model is appropriate.

C.2.1 Simulation Cases

Table C.1 shows the five scenarios that were evaluated to estimate the response of recharge rates to variations in several variables, including climate, vegetation, soil properties, and irrigation. The first three scenarios addressed functional disposal facility features: the proposed surface cover and the two soil types found in the surrounding terrain. The fourth scenario addressed the impacts of dune sand deposition on the surface cover. The fifth scenario addressed the impact of erosion of a portion of the surface cover. All five scenarios were evaluated for current climate conditions and for the future climate possibility most likely to promote recharge (i.e., increased precipitation and decreased temperature, denoted P↑T↓ symbolically).

Table C.1. Scenarios and Variables Tested with Simulations Using the Isothermal, Non-Hysteretic Mode of UNSAT-H and a Shrub-Steppe Plant Community (unless noted otherwise)

		Scenario				
Variable	**Condition**	**Modified RCRA Subtitle C Cover**	**Rupert Sand**	**Burbank Loamy Sand**	**Dune Sand on Cover**	**Eroded Surface Cover**
Climate	Current	√	√	√	√	√
	P↓		√			
	P↑		√			
	T↓		√			
	T↑		√			
	P↓T↑		√			
	P↑T↓	√	√	√	√	√
Vegetation	Cheatgrass		√			
	No plants	√	√	√	√	√
	No plants, future climate (P↑T↓)		√	√		
Shrub Leaf Area Index	High (0.4 vs. 0.25)		√			
	Low (0.1 vs. 0.25)		√			
Rupert Sand Properties	Higher $K(h)$ vs. Rupert sand		√			
	Lower $K(h)$ vs. Rupert sand		√			
Complete Areal Plant Coverage	Cheatgrass		√			
	Sagebrush		√			
Irrigation Efficiency	75%	√	√			
	100%	√	√			

Plant community composition will likely change in response to climate changes. Wing et al. (1995) reported that the plant communities in the Columbia Basin have fluctuated between sagebrush-dominated shrub-steppe and bunchgrass-steppe in the Holocene. Also, there is modern evidence of invasive plant species supplanting native species. Finally, the modern record clearly indicates that fires occur regularly, removing vegetation in the short term and altering the composition of the plant community for years after a fire.

C.2.2 Model Description

Simulations were conducted using the UNSAT-H computer code (Fayer and Jones 1990). UNSAT-H was accepted for use at Hanford via the Tri-Party Agreement process (DOE 1991). The ILAW project has used this code for several years specifically to calculate recharge rates. In FY 1998, the code was updated to include new features such as hysteresis and the ability to simulate multiple years with one input file.

The UNSAT-H code has been tested with lysimeter data. Fayer et al. (1992) and Martian (1994) compared predicted and measured water storage values for lysimeters at Hanford. Both found that calibration of several parameters improved the match of predicted to measured values as determined by the root-mean-square (RMS) error. For a 1.5-year test of a lysimeter receiving an enhanced precipitation treatment, Fayer et al. (1992) calculated a RMS error of 0.8 cm after calibration (versus 2.2 cm without calibration). Martian (1994) looked at a much longer time period (5.5 versus 1.5 years) and found the RMS error was higher—about 1.8 cm for the calibrated model. The analysis was not done for the uncalibrated model. Martian determined the correlation coefficient for the comparison of measured and simulated soil water storage was 0.94, which is quite good. Fayer and Gee (1997) extended the comparison to 6 years. The data were collected from a non-vegetated weighing lysimeter containing 150 cm of silt loam over sand and gravel. They found that the RMS error for water storage predictions was about 2.3 cm regardless of whether the model was calibrated or whether it included heat flow or hysteresis. Fayer and Gee (1997) extended the comparison to matric potential and drainage. They found that the simulation with hysteresis was far better at predicting matric potentials throughout the 6-year period and it was the only simulation to predict drainage (52% of the measured amount, with timing that matched the observations). Fayer and Gee (1997) concluded

- UNSAT-H can reasonably predict the water balance components of a capillary-break type cover.
- The inclusion of heat flow has only a minor effect on surface evaporation and vapor flow within the soil (the impacts of heat flow on snow accumulation and melt and on soil freezing were not evaluated).
- A calibrated model will not necessarily apply well outside of the calibration period.

Khire et al. (1997) tested UNSAT-H for simulating water movement in surface cover test plots in a semiarid setting in Washington and a humid setting in Georgia. They tested the model using a 3-year record of data that included overland flow, soil water storage, evapotranspiration, and percolation. Time series plots of the data and predictions showed that UNSAT-H generally mimicked the seasonal trends.

The authors noted several conceptual features that were important to the Washington site but were not included in the model: snow cover, snow melt, and freezing soil. These features are scheduled for inclusion starting in FY 2000 (LMHC 1999).

The UNSAT-H code has been used at the Hanford Site to estimate the areal distribution of recharge rates (Fayer et al. 1996). The code has also been used elsewhere to evaluate infiltration through surface covers (Magnuson 1993) and surficial sediments (Martian and Magnuson 1994).

C.2.3 Model Domain and Discretization

The model domain for the surface cover extended to the base of the gravel filter layer, which was located at a depth of 130 cm. We would have extended it to the base of the gravel drainage layer, but the hydraulic properties of this material were too difficult to simulate using the standard hydraulic functions. Fortunately, our experience has shown that neglecting the additional thickness of gravel has only a minimal impact on the results. Differences in drainage caused by variations in filter gravel thickness were less than 0.1 mm/yr. For the other simulation cases, the model domain was extended to 400 cm. The node spacing in all simulations started at 0.2 cm at the soil surface and gradually increased with depth. At material interfaces, the node spacing was decreased to 2 cm. Changes in node spacing from node to node were limited to less than 50%. Time step sizes were allowed to range from 10^{-10} to 1 hour, depending on the mass balance error.

C.2.4 Soil Hydraulic Properties

Soil hydraulic properties consist of the soil water retention function and the hydraulic conductivity model. For all materials in this report, soil water retention was described with the van Genuchten function and hydraulic conductivity was described with the Mualem conductivity model. Three soil models were considered: modified RCRA Subtitle C Cover, Rupert sand, and Burbank loamy sand. Table C.2 lists the parameters for the materials making up each soil model. We did not address possible changes in soil hydraulic properties in response to soil development.

Martian (1994) simulated the performance of the modified RCRA Subtitle C Cover by accounting for all five materials that reside above the asphalt layer: silt loam/gravel admix, compacted silt loam, filter sand, filter gravel, and drainage gravel. For this report, the sand and gravel parameters were described using the Martian (1994) parameters without modifications. In contrast, some of the silt loam parameters were modified to accord with known relationships and/or measurements. The silt loam admix parameters were derived using the parameters for silt loam reported by Martian (1994) and correcting for a gravel content of 15% by weight using relationships in Bouwer and Rice (1983). The gravel and silt loam particle densities were assumed to be equal (i.e., 2.72 g/cm^3). The gravel correction changed θ_s, θ_r, and K_s. The parameters α and n were not changed from the Martian (1994) values because no known relationship with gravel content exists.

The values of the compacted silt loam parameters θ_s and K_s differ from the values reported by Martian (1994). θ_s was calculated to be 0.353 cm^3/cm^3 based on the uncompacted bulk density

Table C.2. Parameters Used to Describe Soil Hydraulic Properties in the Simulations. The van Genuchten parameter m was set equal 1-1/n. The pore interaction term was specified using the standard value of 0.5.

Soil Type (depth interval, cm)	θ_s cm^3/m^3	θ_r cm^3/m^3	α 1/cm	n –	K_s cm/h
Modified RCRA Subtitle C Surface Cover					
Silt Loam Admix (0 to 50)	0.422	0.0042	0.0163	1.37	2.64
Compacted Silt Loam (50 to 100)	0.353	0.111	0.0077	1.78	0.0049
Filter Sand (100 to 115)	0.445	0.01	0.0726	2.8	392
Filter Gravel (115 to 130)	0.419	0.005	4.93	2.19	1260
Drainage Gravel (130 to 145)	0.4	0.005	10.0	3.0	3600
Rupert Sand					
BWTF Sand (0 to 400)	0.433	0.0381	0.106	1.78	35.3
Sensitivity Case 1 (0 to 400)	0.357	0.007	0.155	1.72	21.6
Sensitivity Case 2 (0 to 400)	0.408	0.035	0.0355	2.04	21.6
Burbank Loamy Sand					
BWTF Sand (0 to 41)	0.433	0.0381	0.106	1.78	35.3
Loamy Sand, 45% gravel (41 to 76)	0.279	0.0160	0.0292	1.35	2.44
Loamy Sand, 85% gravel (76 to 89)	0.0760	0.0040	0.0292	1.35	0.519
Sandy Gravel (89 to 400)	0.0833	0.0084	0.0061	1.52	0.572

(1.37 g/cm^3), compacted bulk density (1.76 g/cm^3), and particle density (2.72 g/cm^3). The K_s value was set equal to the value 0.0049 cm/h based on measurements of compacted silt loam reported by Skelly (1994).

The Rupert sand is very deep sand (Hajek 1966; also called Quincy sand by USDA 1971). The hydraulic properties of this sand were represented using parameters describing the sand in the lysimeters at the Buried Waste Test Facility (Fayer and Gee 1992). The values of θ_s, θ_r, and K_s were used directly. Because Fayer and Gee (1992) used the Brooks-Corey (BC) function, two parameters had to be converted for use in the van Genuchten (VG) function used for this report. The BC parameter h_e was inverted to yield the VG α parameter and the BC parameter b was transformed into the VG n parameter using the relationship $n = 1+1/b$.

Ward et al. (1998)[(1)] conducted a field infiltration test at the proposed ILAW Disposal Site. They collected water content and matric potential data for five depth increments in the upper 1.5-m of soil for six different infiltration fluxes. Ward et al. then used the data collected in situ to fit parameters for the van Genuchten retention function. The resulting five functions were similar and appeared to bracket the Rupert sand function determined above, supporting the use of a single function to represent Rupert sand.

(a) Ward AL, RL Clayton, and JC Ritter. 1998. "Hanford Low-Activity Tank Waste Performance Assessment Activity: Determination of in situ hydraulic parameters of Hanford Sediments," Letter Report to Fred Mann, Fluor Daniel Northwest, Richland, Washington, August 31, 1998.

The Burbank loamy sand consists of loamy sand from the soil surface to 41 cm, gravelly loamy sand (45% gravel) from 41 to 76 cm, very gravelly loamy sand (85% gravel) from 76 to 89 cm, and sand and gravel below 89 cm (USDA 1971). The hydraulic properties of the surface layer of loamy sand were described using the properties for Rupert sand. The properties of the second and third layers were obtained by scaling the properties of Sample 25 C (a loamy sand from Rockhold et al. 1993) using the gravel percentages of each layer. The properties of the fourth sample (a sandy gravel) were assigned those from the 4.1-m sample from Well 216-B-61-A (p. A-55 of Connelly et al. 1992). This sample was referred to as sandy gravel, and the particle size distribution (p. A-56 of Connelly et al. 1992) shows it to contain 76% gravel. Therefore, the hydraulic properties were scaled to account for the gravel.

The hydraulic properties of the soil profiles described in Table C.2 are shown in Figures C.2 to C.4. In addition to Rupert sand, Figure C.3 shows the retention functions determined for five soil depths with an infiltration test at the proposed ILAW Disposal Site (Ward et al. 1998).[a] The retention properties for two of those depth ranges (0.0 to 0.25 m for sensitivity case 1and 0.75 to 1.0 m for sensitivity case 2) were used to show the impact of variations in the Rupert sand properties. The K_s value for these depths was set to 21.6 cm/h, which represent the median of 29 surface measurements distributed across the proposed ILAW Disposal Site (Fayer et al. 1996).[1]

C.2.5 Initial Conditions

All simulations were started using the weather data for 1957. Initial matric potential values were not available for any of the scenarios, so the initial conditions were specified as -10^3 cm. This value is wetter than some measured vadose zone potentials (e.g., Prych 1998), so early drainage could reflect this initial water if recharge rates are lower for the given scenario. However, this limitation was overcome by repeating the 41-year sequence until the beginning and ending water storage values were within 0.1 mm of each other. This procedure uncoupled the results from the impact of using arbitrary initial conditions. The implicit assumption is that the 41-year weather record, when repeated, is representative of much longer periods.

C.2.6 Boundary Conditions

Boundary conditions describe the water inputs and outputs at the top and bottom of the model domain. For this report, these conditions are the weather data that affect the calculation of evapotranspiration, precipitation, and the drainage rate from the bottom of the profile. The weather data were derived from the meteorological data collected at the Hanford Meteorological Station (HMS) for the years 1957 to 1997 (Table C.3 shows typical 30-year variations in some of the annual values). The HMS is located about 6 km west-northwest of the proposed ILAW Disposal Site at an elevation of 223 m (Hoitink et al. 1999). This elevation differs by less than 10 m from the elevations of the two disposal sites so that topographic differences in weather between the HMS and the proposed disposal sites should be negligible.

(b) Fayer MJ, JL Downs, BN Bjornstad, and K Mahan. 1996. "Integrated recharge assessment: Summary of FY 1995 Activities," Letter report to Fred Mann, Fluor Daniel Northwest, Richland, Washington, April 1996.

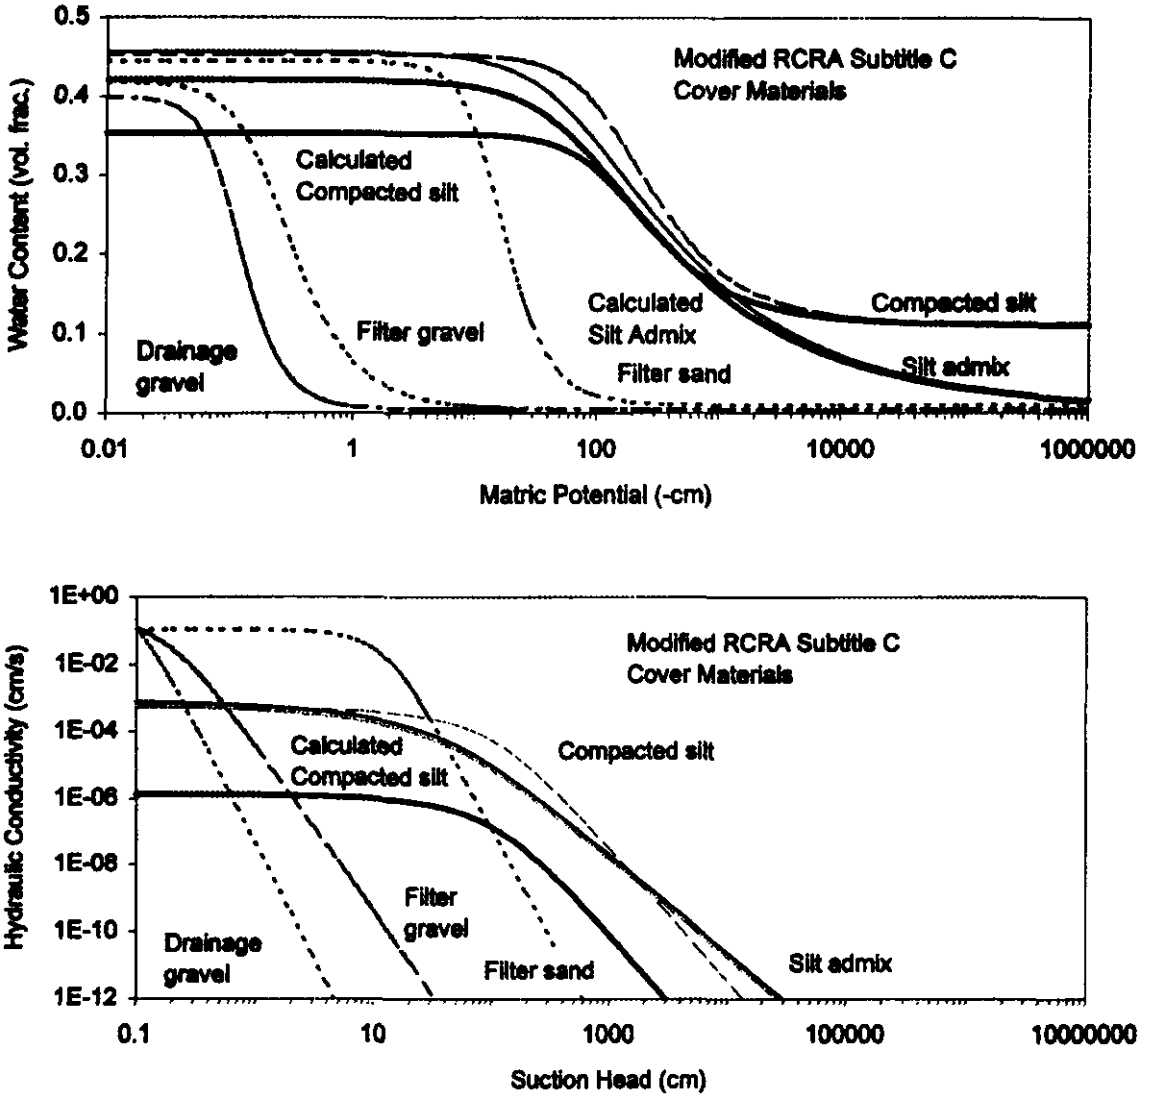

Figure C.2. Hydraulic Properties of the Materials Composing the Modified RCRA Subtitle C Cover

The current climate conditions were represented using the daily weather data. Measured hourly precipitation rates were used to describe the water inputs. Snowfall was treated as an equivalent rainfall at the time it occurred. Weather data such as wind speed, cloud cover, relative humidity, solar radiation, and maximum and minimum air temperature were used to calculate potential evaporation using the Penman Method (Doorenbos and Pruitt 1977).

Future climate conditions were represented by scaling the current temperature and precipitation data to match paleoclimate observations derived from pollen data. Whitlock and Bartlein (1997) described a 125,000-year paleoclimate record constructed from the pollen record in cores taken from Carp Lake, near Goldendale, Washington. Carp Lake is located about 175-km southwest of the Hanford Site, at an

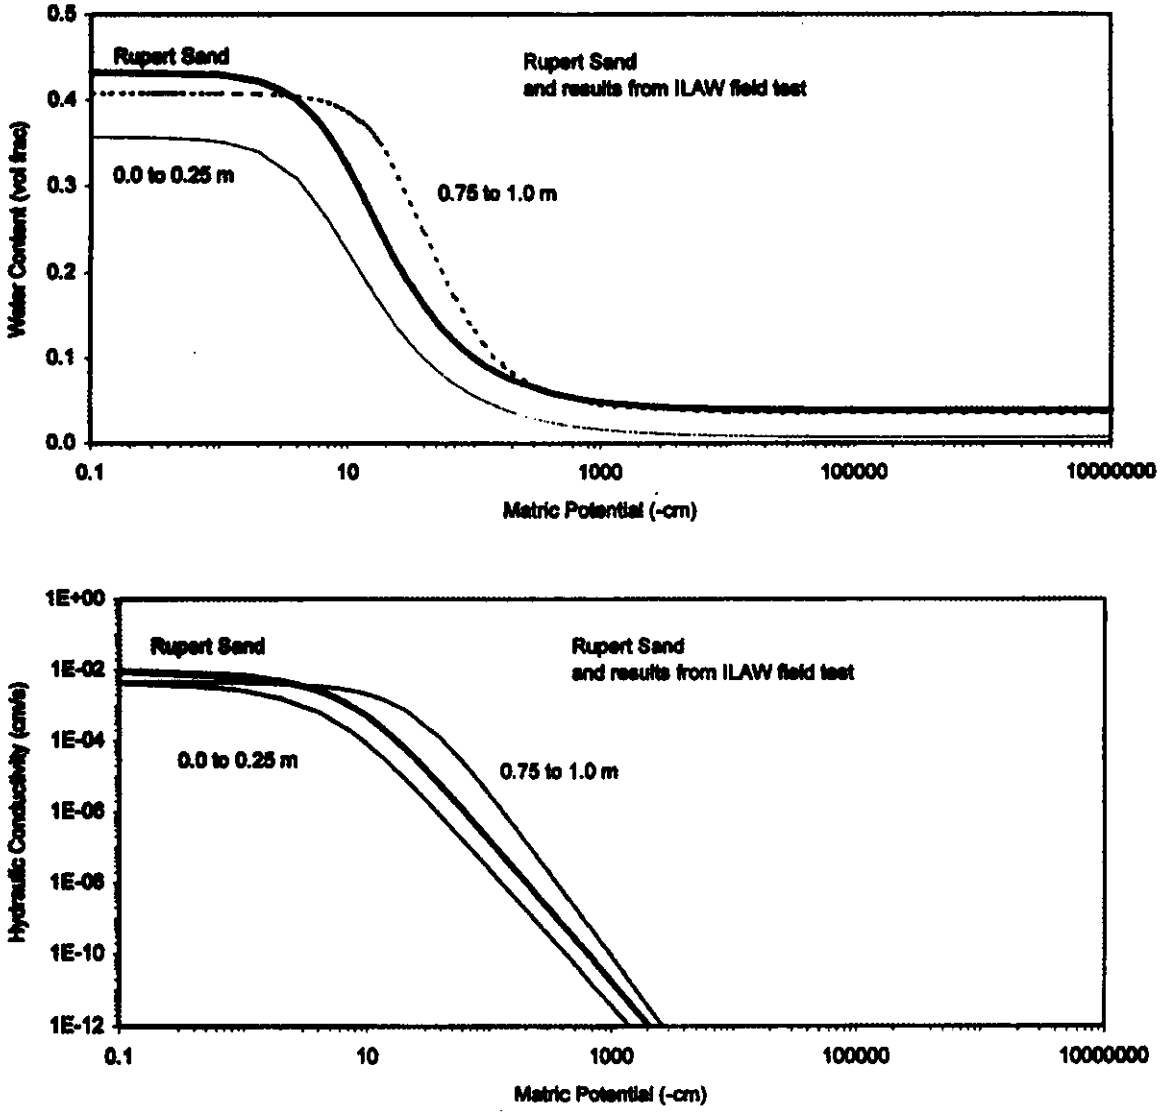

Figure C.3. Hydraulic Properties of the Rupert Sand

elevation of 714 m. Similar pollen records at the Hanford Site were eliminated during the glacial flooding 13,000 years ago. Thus, Carp Lake provides a proxy for paleoclimate information. Wing et al. (1995) described the Carp Lake pollen interpretation relative to precipitation and temperature. For the entire Holocene (i.e., the last 10,000 years), the data suggest that annual temperatures and precipitation ranged from 0 to 2.8°C warmer and 0 to 50% drier compared to modern climate. During the glacial period prior to the Holocene, annual temperatures ranged from 0.2°C warmer to 2.5°C cooler and precipitation ranged from 75 to 128% of modern levels. In summary, for the last 100,000 years, annual precipitation ranged from 50 to 128% of modern levels and annual temperatures ranged from -2.5 to 2.8°C (-4.5 to 5°F) of modern levels.

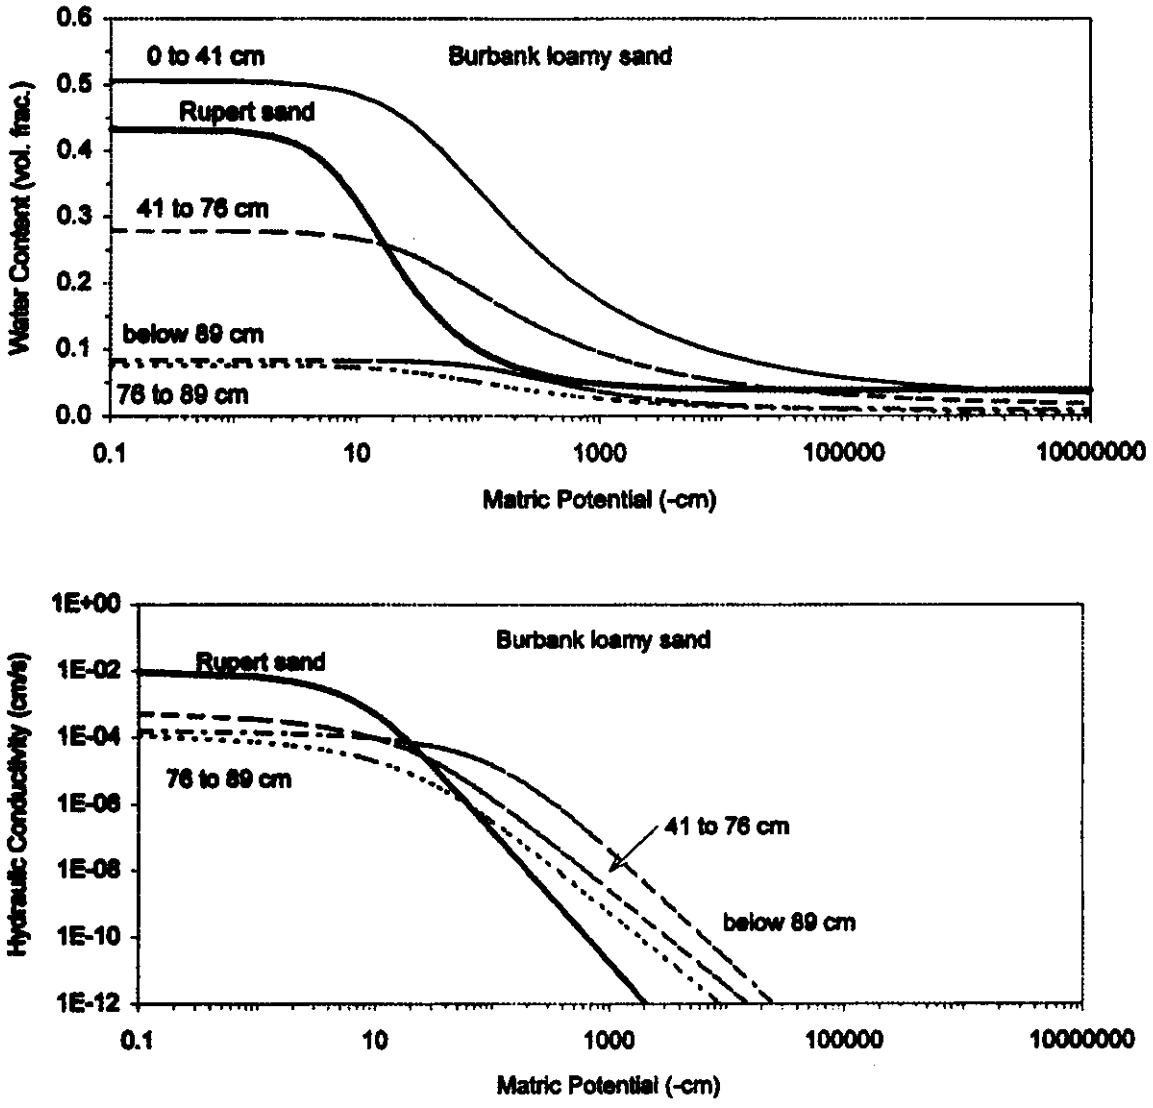

Figure C.4. Hydraulic Properties of the Burbank Loamy Sand

Table C.3. HMS Weather Statistics for 1961 to 1990 (* indicates a daily value)

Weather Variable	Period of Record	Annual Values		
		Average	Minimum	Maximum
Precipitation, mm (in.)	1961-1990	163 (6.26)	75.9 (2.99)	313 (12.31)
Air Temperature, °C (°F)	1961-1990	11.8 (53.3)	9.8 (49.6)	13.6 (56.4)
Dewpoint Temperature, °C (°F)	1950-1997	1.3 (34.4)	-0.3 (31.5)	3.2 (37.7)
Wind at 15.2 m (50 ft), kph (mph)	1945-1997	12.2 (7.6)	10.0 (6.20)	13.5 (8.4)
Solar Radiation, W/m^2 (ly/d)	1953-1997	172 (355)*	4.4 (9)*	406 (838)*

To represent future climate conditions with weather information, the Hanford weather record for 1957 to 1997 was used as the base data. From that base, future precipitation conditions were constructed by linearly scaling the current data. Future temperature conditions (daily maximum and minimum air temperatures) were constructed by adding or subtracting the projected temperature change. Changes in dewpoint temperature (humidity), solar radiation, wind speed, and cloud cover were not addressed. Seasonal changes implied by the pollen record will be addressed in subsequent work for the 2003 PA. Also not considered here are possible short-term changes caused by increased carbon dioxide. To date, the suggested carbon dioxide-induced changes fall within the range of climate changes inferred from the pollen record and so were not considered any further.

For the irrigation simulations, we modified the precipitation input files to include irrigation events. If a precipitation event coincided with an irrigation event, the two were added to yield a single water application event. Irrigation was applied between the hours of 0600 and 1200 once every 8 days. James et al. (1989) estimated the total crop irrigation requirement of about 81 cm for potatoes grown on silt loam in Richland, assuming 100% irrigation efficiency. This requirement was met using an hourly irrigation rate of 0.75 cm/h. If the efficiency dropped to 75%, James et al. (1989) estimated the irrigation requirement would increase to 108 cm for the season. This requirement was met using an hourly irrigation rate of 1.0 cm/h.

The bottom boundary was represented with a unit-gradient condition. This condition is generally acceptable when the boundary is well below the deepest plant roots, which were at 2 m in this report, and the drainage rate exceeds 1 mm/yr. For lower drainage rates, temperature cycling can have a significant effect on overall water movement via the temperature effect on vapor flow. In these cases, heat flow modeling can be used to examine total flux rates (such modeling was not done for this report).

C.2.7 Plant Information

The plant community is an important component of the disposal facility. The two major functions performed by the plants are the efficient removal of water stored in the near-surface soil (thus minimizing recharge) and protection of the soil surface from wind and water erosion (thus protecting the integrity of the surface cover). By minimizing recharge and protecting the integrity of the surface cover, plants help to ensure the successful long-term protection of the disposal facility.

The majority of simulations performed for this report included a shrub-steppe plant community, which is the dominant community in and around the 200 Areas. As indicated earlier, Holocene pollen records indicated that plant communities in the Columbia Basin have alternated between shrub-steppe and bunchgrass-steppe. Recently, non-native species such as cheatgrass have been shown to compete successfully with native species and, in some cases, can dominate disturbed areas for years. Finally, range fires and industrial and waste management activities can eliminate vegetation for short periods of time. To address some of these alternate conditions, supporting simulations were conducted in which the plant community was either cheatgrass or no plants. A bunchgrass-steppe community was not included in this analysis; we assumed its impact would fall between that of shrub-steppe and cheatgrass. Finally, an irrigation scenario was evaluated using a potato crop.

To simulate plants with UNSAT-H Version 3.0 requires the following information:

- the method of partitioning potential evapotranspiration (PET)
- the active season
- the bare fraction
- the root length density
- the maximum rooting depth during the year
- the effectiveness of plant water withdrawal as a function of matric potential.

UNSAT-H allows only one plant to be simulated at a time. For this report, the shrub-steppe was simulated using shrub parameters and the cheatgrass community was simulated using cheatgrass parameters. In both cases, other species that might be present were not considered (e.g., shrub understory species). Table C.4 shows the parameters that were chosen based on literature parameters or reasonable estimates of parameters. The plant parameters were held constant for each simulation year. Not addressed by this study were the potential plant community responses to yearly precipitation and temperature variations, fire, diseases, nutrient cycling, grazing, and land use changes.

For shrubs and potatoes, the leaf area index (LAI) method was used to partition potential evapotranspiration into potential evaporation and potential transpiration. Figure C.5 shows the shrub leaf area variation throughout the year. Link et al. (1990a) reported a maximum LAI value of 0.25 for sagebrush for 4 years in a sagebrush-bunchgrass community growing on a silt loam soil on the Fitzner/Eberhardt Arid Lands Ecology (ALE) Reserve. Our preliminary measurements at the proposed ILAW Disposal Site are showing similar LAI values. The maximum potato LAI was 2.5. Although not shown in Figure C.5, the variation throughout the year was similar to that of the shrub. For cheatgrass, the PET-partitioning method used was the cheatgrass model in UNSAT-H. This model was developed by Hinds (1975) using field data from a 2-month cheatgrass experiment.

Table C.4. Plant Parameters for UNSAT-H Simulations (see text for descriptions)

Parameter Description	Parameter Value		
	Shrub	**Cheatgrass**	**Potatoes**
PET Partition Function	LAI	Cheatgrass	LAI
Active Days of the Year	Mar 1 to Nov 30	Mar 1 to May 31	April 9 to Sep 16
Bare Fraction	0.27	0.27	0.0
Maximum Rooting Depth (m)	2.0	0.6	0.6, Surface cover 0.9, Rupert sand
Root Density Coefficients			
a =	0.217	1.17	1.17
b =	0.0267	0.131	0.131
c =	0.0109	0.0206	0.0206
Plant Uptake Potentials (-MPa)			
h_n =	0.003	0.003	0.003
h_d =	0.1	0.1	0.04
h_w =	7.0	2.0	1.6

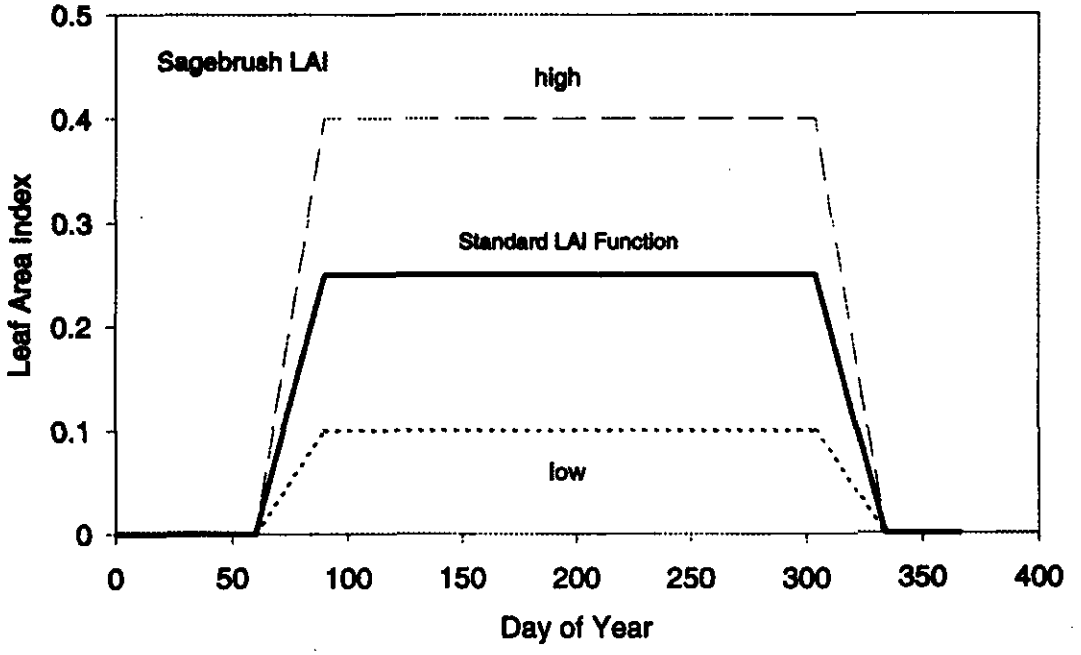

Figure C.5. Leaf Area Index for Sagebrush

The start and end dates of plant activity determine when during a growing season to calculate transpiration and root growth. Rickard and Vaughan (1988) reported that many plant species generally become active around March 1 in a normal year on the ALE Reserve. This start date coincides with the onset of air temperatures in excess of 3°C, a temperature suggested by Hanson et al. (1987), as the minimum needed for positive shrub and cool-season grass activity. Both shrubs and cheatgrass were started on March 1. Potatoes were started on April 9. This date was set 30 days prior to the initiation of irrigation, which was determined by air temperature. Irrigation was initiated on May 9, which is the average date when the 30-day running average of air temperature equals or exceeds 12.8°C (55°F) (James et al. 1989).

Because shrubs maintain LAI throughout the year, this minimum temperature was used to determine when shrub activity ceased in the fall. Based on the average temperatures reported by Hoitink et al. (1999), shrubs were allowed to be active until November 30. The end date for cheatgrass is earlier than that for shrubs. An ending date of May 31 was chosen for cheatgrass based on observations of cheatgrass at the Grass Site in 1986 and 1987 (Link et al. 1990b). The end date for irrigated potatoes was 130 days after the start date for irrigation (James et al. 1989).

The bare fraction represents the fraction of the soil surface devoid of vegetation. This value is used to scale the potential transpiration, which was calculated assuming a 100% plant cover. Roots from plants around the bare areas may (and likely do) penetrate some of the bare area. However, the one-dimensional nature of the UNSAT-H model does not allow it to represent multidimensional root behavior. Thus, reducing potential transpiration based on the bare fraction may underestimate transpiration. For the simulations with a shrub-steppe component, the bare fraction was set to 0.69. This value was derived

from preliminary measurements at the proposed ILAW Disposal Site and the Existing Disposal Site (Downs and Kahn 1998).[1] A slightly lower value of 0.577 was used for the cheatgrass simulations based on data from Downs and Kahn. Reductions to potential transpiration caused by bare areas are added to potential evaporation. Two additional simulations were conducted in which the bare fraction was set to zero for both the cheatgrass and shrub cases; a bare fraction value of zero represents 100% plant cover. A full canopy was assumed for the potato simulation; thus the bare fraction was set to zero.

Root parameters were obtained directly from the simulations reported by Fayer and Walters (1995). They used root length density data from Mayer et al. (1981) to fit the root density function

$$rld = a \exp(-bz) + c \qquad (C.1)$$

where rld = root length density (cm roots/cm soil)
z = soil depth (cm)
a, b, and c = fitting parameter.

The resulting parameters are shown in Table C.4. Maximum rooting depths were 2.0 m for shrub and 0.6 m for cheatgrass. The roots of shrubs were considered to be at their maximum depth throughout the growing season. Being an annual, cheatgrass roots were assumed to have a uniform growth rate of 1 cm/d for their entire growing season. Potatoes were simulated using the same rooting parameters as cheatgrass.

The plant water uptake parameters in Table C.4 were obtained directly from the simulations reported by Fayer and Walters (1995). There is some support for the wilting point values (h_w), which are the lowest matric potentials at which plant water withdrawal becomes zero. Sagebrush was reported to operate in soils with potentials as low as -7.0 MPa (Fernandez and Caldwell 1975; Branson et al. 1976). Cline et al. (1977) showed that cheatgrass could remove water at potentials as low as -1.5 MPa. In their first year of measurements at the proposed ILAW Disposal Site, Downs and Khan (1998 Letter Report to F Mann) have observed the lowest plant potentials in shrubs (values as low as -2.5 MPa). The parameter h_d represents soil water potential below which plant uptake decreases below the potential water uptake rate. The parameter h_n represents the soil water potential above which plant water is zero because of anaerobic conditions. Between h_n and h_d plant water uptake is set to its potential rate. For rangeland simulations, Hanson et al. (1987) suggested that plant water uptake was reduced by half when the soil potential was -0.64 MPa. Using the parameters in Table C.4, the potentials corresponding to halving the uptake rate are -0.84 and -0.45 MPa for shrubs and cheatgrass, respectively. These values are in line with the value suggested by Hanson et al. (1987). Plant water uptake parameters for potatoes were obtained from Feddes et al. (1978).

C.3 Results

Each 41-year simulation took approximately 2 hours of dedicated time to run on a UNIX workstation. In most cases, repeating the weather sequence just once was enough to establish a condition indicative of

(a) Downs JL and FO Khan. 1998. "Brief status report: FY 1998 vegetation field studies on the LLTWDS Site," Letter report to Fred Mann, Fluor Daniel Hanford, Richland, Washington, September 1998.

the long-term average. In several cases, three to four repetitions of the weather sequence were required for the profile to achieve a condition indicative of the long-term average. In some cases, one sequence was enough to establish that the soil profile was drying and that further repetition of the weather sequence would dry out the profile even more.

Table C.5 shows the average long-term deep drainage rate for all simulations conducted. The average rate was calculated for all 41 years of the last simulation sequence. For those simulations that indicated drying, the rate was assigned a value of < 0.1 mm/yr. The less than symbol was used to indicate the uncertainty of specifying such a small rate, especially given the types of assumptions used (e.g., constant plant communities and isothermal flow).

The results in Table C.5 indicate that the surface cover will perform better than the design goal of 0.5 mm/yr. This performance occurred even in the absence of plants. When the cover was exposed to the future climate state most conducive to drainage, the simulation results still indicated a drainage rate of < 0.1 mm/yr.

(a) na = not analyzed

The results in Table C.5 indicate that the two soils, under shrub-steppe vegetation, have long-term drainage rates of 2.2 and 5.2 mm/yr., respectively. When plants were removed, the drainage rates jumped by a factor of 10 to 20. Under the future climate state most conducive to drainage, the drainage jumped by factors of 7 and 12, respectively.

Two cover degradation cases were evaluated. In the first, dune sand was deposited on the cover to a depth of 20 cm. The results in Table C.5 indicate that the cover still had drainage rates < 0.1 mm/yr under the shrub-steppe vegetation. When shrubs were removed to leave just cheatgrass, simulated drainage increased dramatically to 18.4 mm/yr. Clearly, deeper rooted plants like shrubs are needed to prevent drainage under these conditions. When all plants were removed, the cover drainage rate jumped to 32.7 mm/yr. The simulated increase in drainage is consistent with lysimeter data (e.g., Sackschewsky et al. 1995).

Under the future climate state most conducive to drainage, the drainage went from zero to 16.9 mm/yr. These results indicate that barrier performance in limiting drainage could be significantly degraded by the deposition of wind-borne sand. Efforts are under way to collect data on this case at the Field Lysimeter Test Facility under a separate ILAW task.

The second degradation case was an eroded surface cover, in which 20 cm of the surface silt layer was removed. The results in Table C.5 indicate that cover performance in limiting drainage was not impaired, even for the case without plants.

The simulation results in Table C.5 demonstrate that irrigation and its efficiency can have a large impact on recharge. Reducing the efficiency from 100 to 75% increased recharge on the cover from 0.1 to 26.7 mm/yr. The same reduction of irrigation efficiency for Rupert sand increased recharge from 30 to 58 mm/yr.

The sensitivity of long-term drainage rates was evaluated using the Rupert soil primarily because this soil yielded reportable rates. The rates for the surface cover were too low to be effective for this evaluation. Table C.6 shows that decreasing precipitation led to nearly zero drainage regardless of the temperature conditions. For modern precipitation conditions, drainage was inversely related to temperature. If temperatures rise in the near future in response to rising carbon dioxide levels, we can

Table C.6. Comparison of Rupert Sand Drainage Rates for Various Future Climate States (data from Table C.5)

	Long-Term Deep Drainage Rates (mm/yr)		
	Precipitation		
Air Temperature	Low (50% of modern)	Modern	High (128% of modern)
Low (modern - 2.5°C)	< 0.1	7.5	27.0
Modern	< 0.1	2.2	13.2
High (modern + 2.8°C)	< 0.1	0.6	5.2

expect a decrease in drainage rates. If an ice age recurs, the decreasing air temperatures will lead to an increase in deep drainage rates. At the high precipitation level, drainage rates will increase for all temperature conditions. The magnitude of the increase will be more than four times greater for the high temperature versus the low temperature condition.

Table C.7 shows that the median annual drainage rate is much less than the average rate. The large difference is indicative of a non-normal distribution, where many years of drainage are punctuated by just a few years with very high rates. In all cases, the standard deviation was roughly one-half to one-third of the average rate. Figure C.6 shows the annual drainage rate for two of the cases in Table C.7. For the Rupert sand under the current climate, there was only one time in the entire 41-year period when significant drainage occurred.

Additional simulations were conducted to highlight sensitivities to three parameters: hydraulic properties, shrub LAI, and the fraction of bare ground. Two alternative sets of hydraulic properties for Rupert sand were derived from a field infiltration experiment at the ILAW Disposal Site. The alternative properties resulted in drainage rates of 2.7 and 3.3 mm/yr under shrub-steppe vegetation. These rates are not much different than 2.2 mm/yr predicted using the original properties for Rupert sand.

The second set of simulations compared different shrub LAI values selected to encompass the range of values measured at the ILAW Disposal Site in 1998 (Appendix F). For LAI values ranging from 0.1 to 0.25 (the original LAI value) to 0.4, the predicted drainage rates were 5.6, 2.2, and 1.6 mm/yr, respectively, for Rupert sand. These results show that recharge is sensitive to this plant parameter.

The third set of simulations assessed the impact of the fraction of bare ground. For cheatgrass, reducing the bare fraction from 0.577 to 0.0 reduced drainage from 33.2 to 26.6 mm/yr, which is still a high drainage rate. For the shrub-steppe, reducing the bare fraction from 0.69 to 0.0 reduced the drainage rate from 2.2 to < 0.1 mm/yr.

An alternative method for characterizing drainage rates for the heterogeneous shrub-steppe plant community is to weight the predicted drainage rates for the different conditions according to their areal

Table C.7. Statistical Summary of Annual Drainage Rates Beneath a Shrub-Steppe Plant Community Under Two Climate States (n = 41)

	Simulated Long-Term Drainage Rates (mm/yr)									
	Current Climate					Climate Extreme (P↑T↓)

Figure C.6. Predicted Annual Recharge Rates for Rupert Sand, Shrub-Steppe Plant Community, and Two Climate States: Current and High Precipitation/Low Temperature

coverage. Based on FY 1998 data from the proposed ILAW Disposal Site, shrub coverage is 31%, grass coverage is 42.3%, and bare ground accounts for 26.7%. Assuming plant coverage is 100% within each zone, the lumped predicted recharge rate is (0.31*0.0 + 0.423*26.6 + 0.267*44.3 =) 23.1 mm/yr. This value is biased high because the method assumes there are no plant roots penetrating adjacent bare areas, which we know not to be the case. Work is ongoing to document the lateral extent of these roots. It may be possible to adjust the effective area covered by the shrubs to provide a more realistic estimate of recharge for these types of plant communities.

C.4 Conclusion

A set of simulations was used to estimate recharge rates for scenarios pertinent to the 2001 ILAW PA. The scenarios included the surface cover and two surrounding soil types, as well as two types of surface cover degradation. The simulations were conducted using a 41-year sequence of weather collected at the Hanford Site from 1957 to 1997. This sequence was repeated until the results remained unchanged to uncouple results from assumed initial conditions.

The low LAI value was tested for two other cases on Burbank loamy sand, lowering LAI sand on cover from 0.25 to 0.1 increased recharge from 5.2 to 15.2 mm/yr. On the surface cover with dune sand, lowering LAI increased recharge from <0.1 to 4.1 mm/yr.

The simulation results indicated that the surface cover limits drainage to < 0.1 mm/yr, which is much better than the design goal of 0.5 mm/yr. The cover maintained this performance level when plants were removed, when the climate became wetter and cooler, and when 20 cm of the silt loam layer was eroded. The cover also maintained this performance when windblown sand was deposited, but significant drainage (32.7 mm/yr) occurred when plants were removed. Under a wetter, cooler climate, the cover had 16.9 mm/yr of annual drainage even though shrub-steppe vegetation was present.

Drainage rates in the two surrounding soils were 2.2 to 5.2 mm/yr under shrub-steppe vegetation. Additional simulations highlighted model sensitivities to variations in climate, soil hydraulic properties, plant parameters, and irrigation.

Appendix D

Eolian Activity at the ILAW Disposal Site, Central Hanford Site

B. N. Bjornstad

Appendix D

Eolian Activity at the ILAW Disposal Site, Central Hanford Site

D.1 Introduction

The U.S. Department of Energy is planning to vitrify the low-activity waste from single- and double-shell tanks. This immobilized low-activity waste (ILAW) will then be disposed in a near-surface burial facility at Hanford. Lockheed Martin Hanford Company is designing and assessing the performance of this disposal facility. An issue of concern is the possibility of sand dunes forming on or around the surface cover and affecting recharge rates. For example, active sand dunes at the Hanford Site lack vegetation, which could lead to an increase in the rate of natural recharge (Gee et al. 1992). An increase in natural recharge would increase water contact with the waste as well as transport through the vadose zone to the groundwater.

In 1995, three trenches were excavated at Hanford to collect samples for tracer analyses of recharge and to look for datable soil horizons to determine the approximate age of surface soil and sand dune formation. This appendix describes sand dune formation and age at the Hanford Site and reports the results of trench studies.

D.2 Dunes at Hanford

The proposed ILAW Disposal Site is located in the south-central portion of the 200 East Area. Figure D.1 shows that the disposal site lies along the northern margin of a giant dune field that extends from the northeastern flank of Rattlesnake Mountain to the Columbia River (a distance of 27 km) and southward to the boundary of the city of Richland. The existence of the dune field in this area appears to be controlled by wind moving, from west to east, down the adjacent Dry Creek and Cold Creek valleys and across the central Hanford Site toward the Columbia River. Most dunes are stabilized by vegetation and are not actively growing or migrating, except locally within a narrow 3.2 to 4.8-km-wide area that extends westward from the natural wind gap created by Ringold/Koontz Coulee (Gaylord et al. 1991). The northern limit of dune formation lies in the southern portion of the 200 East Area and consists of stabilized dunes that occupy part of the proposed ILAW Disposal Site. Presently, the point of active sand dune formation that is closest to the proposed ILAW Disposal Site is ~3.2-km south of the 200 East Area (Figure D.1).

Although eolian features are generally not present elsewhere in the 200 East Area and the Hanford Site, there is still a significant amount of wind energy available. Apparently, in these areas the material available is too coarse grained making it unsuitable for transport and dune development; or the surface is

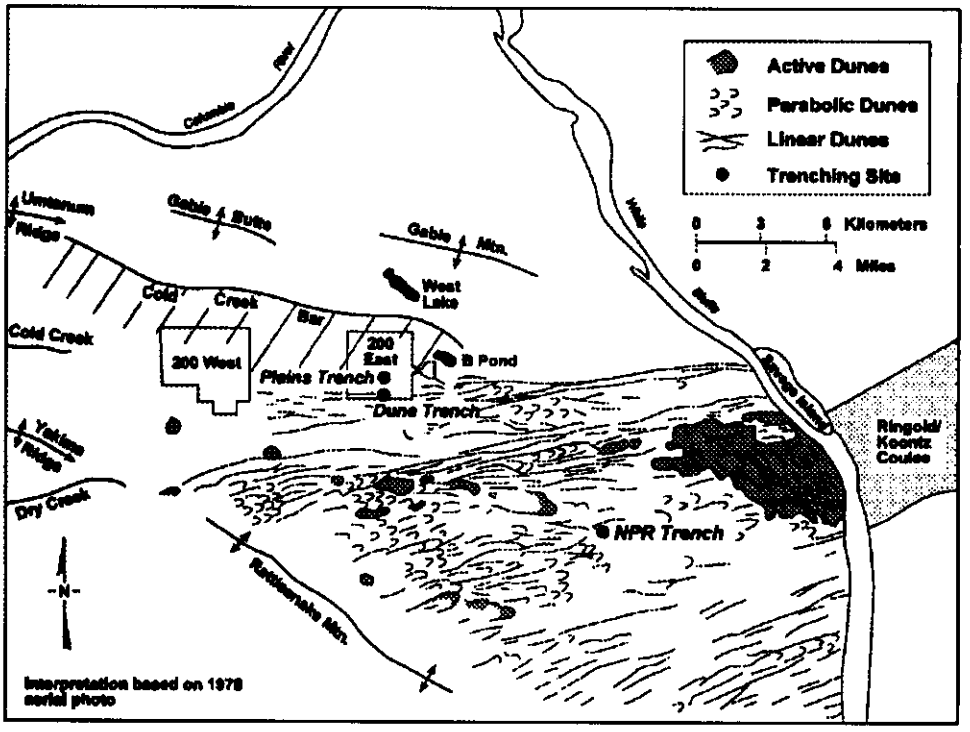

Figure D.1. Locations of the Sand Dune Features at the Hanford Site and the Trenching Studies Conducted in 1995

stable, which inhibits dune formation (Kasper and Glantz 1987). Dune formation and migration is complex and the result of the interaction between time, topography, climate, and man-related activities such as fire or construction.

D.2.1 Dune Types/Wind Directions

Figure D.1 shows that the most predominant eolian bedforms (i.e., the shapes of wind-formed sediment deposits) on the Hanford Site are linear sand ridges aligned in the direction of the strongest winds (southwest to northeast). This is particularly true where dunes are stabilized by vegetation. In some cases, the same ridge can be traced for miles with little or no discontinuity. In other cases, ridges may divide in two or end at a parabolic dune in the downwind direction. Linear sand ridges are reported to form in variable wind regimes (Brookfield 1984). The predominant wind direction at Hanford is from the northwest (Glantz et al. 1990). The strongest winds blow out of the southwest, although less frequently than the northwest. Based on recent meteorological data, winds capable of moving sand-sized particles occur ~40 days/year at the Hanford Site (Gaylord and Stetler 1994).

Where dunes are active or dune blowouts occur, parabolic dunes are the predominant bedform. Parabolic dunes are convex in the downwind direction with arms that point in the upwind direction. From aerial photographs (the basis of Figure D.1), it appears that linear ridges result from the migration of the parabolic dunes. In these situations, the arms become anchored with vegetation while the central part of the dune continues to migrate forward. Linear ridges can also result from the interaction of winds coming

from two directions (i.e., northwest and southwest), but the evidence of linear dunes parallel to the predominant high-wind direction does not support this mechanism. In areas where dunes are extremely active and void of any vegetation, a wide range of bedforms has developed, including transverse, parabolic, and complex barchanoid bedforms. This is the case for the very active dune field that is present immediately west of Ringold/Koontz Coulees (Figure D.1).

D.2.2 Volcanic Time Markers

At least three distinct volcanic ash layers may be associated with Quaternary age sediments at the Hanford Site. These provide key time markers from which to perform regional stratigraphic correlation. The layers of volcanic ash are recognized by their white color and gritty texture. The oldest Quaternary-age volcanic layer observed at the Hanford Site is the Mount St. Helens "set S" layer. This layer was dated at 13,000 years ago using a technique that relates time to the reference year 1950 (Mullineaux et al. 1978). All subsequent time estimates are relative to this reference year. This layer occurs as a couplet; the upper layer is about 2.5-cm thick while the lower layer is often barely visible and is about 0.16-cm thick. When observed, this ash layer lies near the top of the cataclysmic flood sequence and thus forms a lower stratigraphic marker for identifying eolian and other post-cataclysmic flood deposits at the Hanford Site. The second volcanic layer that may be observed also occurs as a couplet and is related to the two closely spaced eruptions from Glacier Peak around 11,200 years ago (Mehringer et al. 1984). Where found within the Pasco Basin, the combined thickness of the Glacier Peak ash couplet is about 8 cm. The third volcanic layer that may be observed is from an eruption 6,850 years ago of Mount Mazama commonly known as Crater Lake (Bacon 1983). Where preserved, Mount Mazama ash usually has a pink cast and may be 30- to 90-cm thick, especially where it has been eroded and redeposited. The latest Quaternary ash layer, from the May 18, 1980, eruption of Mount St. Helens, is preserved in the extreme northern portion of the Pasco Basin. It is not found in the southern part of the basin, including the proposed ILAW Disposal Site. We can obtain information to determine the time and rate of eolian deposition by observing the relationships between these volcanic layers and adjacent eolian deposits.

D.2.3 Age of Sand Dunes at Hanford

Sand dunes found at the Hanford Site appear to be late Pleistocene to Holocene in age. The maximum age of the dunes is limited to 13,000 years ago, the age of the last cataclysmic flood from glacial Lake Missoula (Mullineaux et al. 1978). Petrologic and petrographic analyses demonstrate Hanford dune sands were derived primarily from reworking of Pleistocene Missoula flood deposits (Gaylord et al. 1991). While eolian activity occurred prior to this time, wind-related deposits were probably either buried beneath younger flood deposits or eroded away during subsequent flooding. Due to erosion and deposition that occurred during flooding, most of the area below 366-m elevation in the vicinity of the Hanford Site was probably void of vegetation immediately following the floods (Baker et al. 1991). Without the anchoring effects of vegetation, the bare ground would have produced abundant sedimentary material for eolian transport. For this reason, a significant amount of eolian transport may have occurred immediately following the floods, slowly tapering off over time as vegetation took hold. It is likely the sand dunes at the proposed ILAW Disposal Site formed soon after the last flood. Smith (1992) estimated that sand transport was most active prior to 4,400 years ago, at which time they had become mostly stabilized. On the other hand, Gaylord et al. (1991) reported that the dune sands they

examined appear to have developed since volcanic ash from Mount Mazama was deposited 6,850 years ago. Dunes are presently active in the central and eastern portions of the dune field (Figure D.1). It is not certain whether these areas have been continuously active since the late Pleistocene or whether they have been reactivated due to range fire or some other natural event.

D.3 Trenching Results

Three trenches were excavated at the Hanford Site on September 28-29, 1995. Trenches as deep as 4.6 m were dug with a backhoe. The purpose of the trenches was to collect samples to determine moisture content and to estimate recharge via chlorine-isotope analysis. Another purpose of the trenches was to look for datable horizons in the soil column that could be used to determine the approximate age and rate of deposition. Samples were collected every 0.15 to 0.3 m from the surface to the bottom of the trench. Two trenches, referred to here as the Plains Trench and the Dune Trench were dug within the proposed ILAW Disposal Site. A third trench was dug about 13 km to the southeast, near the Wye Barricade. This site, which is referred to as the New Production Reactor (NPR) Trench (Figure D.1), was chosen to provide a contrast to the proposed ILAW Disposal Site trenches. It also lies within the zone of stabilized sand dunes. Descriptions of the three sites are presented in the following sections.

D.3.1 Plains Trench

The Plains Trench was dug to a depth of ~4.3 m. The sediments within this trench consisted of essentially two stratigraphic units. The upper unit was composed of 1.2 m of a structureless, loose, light gray, silty sand. This unit, consisting of eolian material, contains reworked windblown sand deposited since the last cataclysmic flood less than 13,000 years ago. The lower unit consisted of a stratified coarse-grained, basaltic sand and gravel from 1.2 m to the bottom of the trench. This unit contains deposits known as the Hanford formation that were laid down during the last cataclysmic flood(s). No buried soil horizons were observed in this trench, suggesting the flood deposits are probably entirely late Wisconsin 13,000 to 18,000 years in age. There were no volcanic layers or other datable horizons observed in this trench. The absence of the thick Mazama ash layer indicates significant wind reworking of sediments as recently as 6,850 years ago.

D.3.2 Dune Trench

The Dune Trench was excavated just south of the Plains Trench, on the north (leeward) side of a prominent east-west linear sand ridge (Figure D1). The trench was oriented north-south, perpendicular to the axis of the sand ridge (Figures D.2 and D.3). This aspect of the sand ridge was chosen for the trench because it was believed this is where volcanic layers or other marker horizons would most likely be preserved. The maximum depth of the trench was 4.0 m. The entire sequence exposed within the trench appeared to consist of eolian sand; no cataclysmic flood deposits of the Hanford formation were observed. The absence of flood deposits is not surprising because the 6.1- to 9.1-m-high sand ridge is an eolian feature that developed since the last flood. Thus, flood deposits probably lie at depths well below the bottom of the trench.

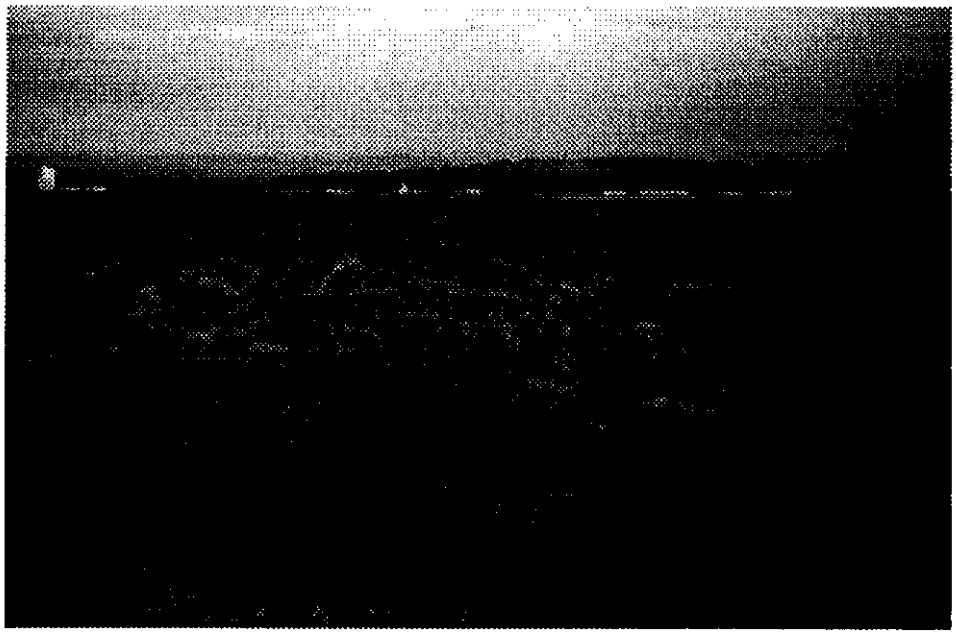

Figure D.2. Looking North from the Dune Trench Overlooking Old-Growth Sagebrush of the Proposed ILAW Disposal Site. The Plains Trench is located about 600 m north along the dirt road. Facilities in the distance are about 900 m north.

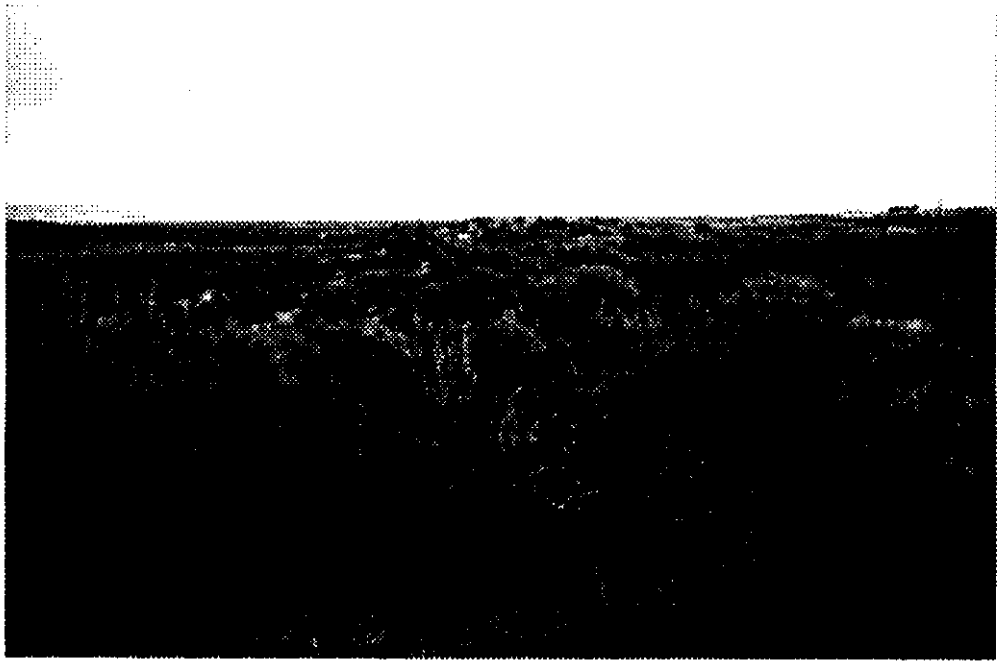

Figure D.3. Looking East from the Dune Trench Over Old-Growth Sagebrush and Parallel to the Axis of the Dune

Figure D.4 shows several contrasting layers within the eolian sequence. The upper 2.4 m consisted of a relatively uniform, structureless, loose, brown (10YR5/3) silty fine sand. Of this 2.4 m, the uppermost 0.6 m is slightly darker in color (Figure D.5) due to staining and weathering associated with surficial soil processes. From a soil development viewpoint, the upper 0.6 m would probably be classified as a weakly

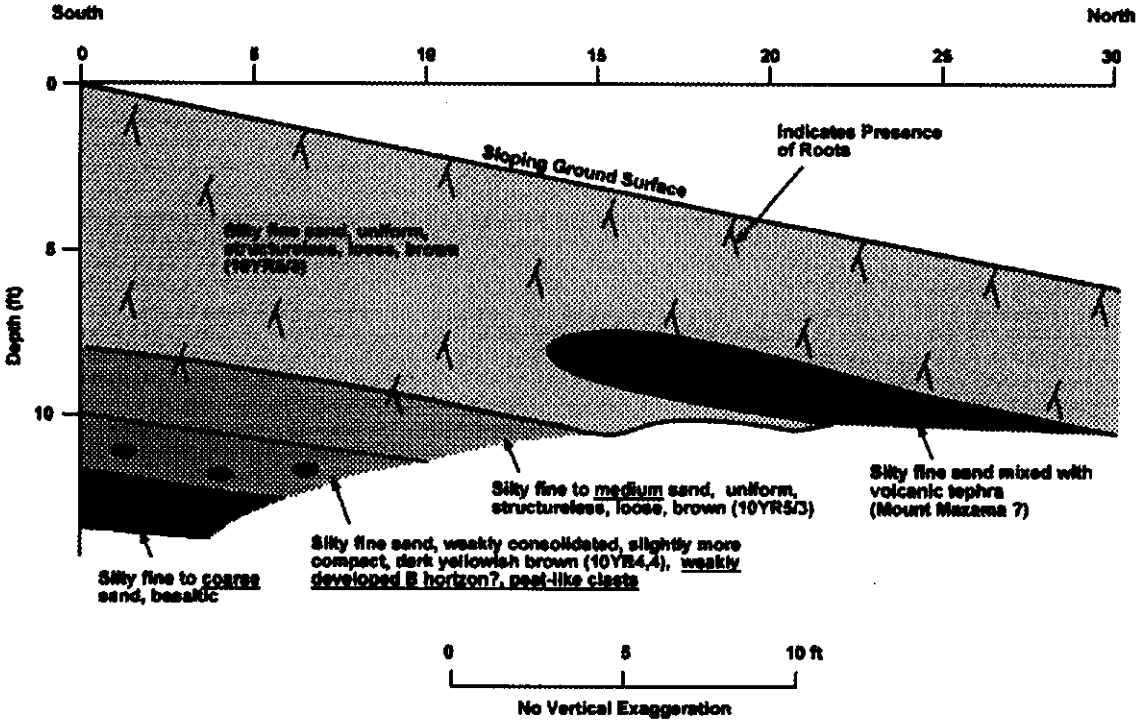

Figure D.4. Cross Section View of the Dune Trench Showing the Approximate Location of the Possible Tephra Layer

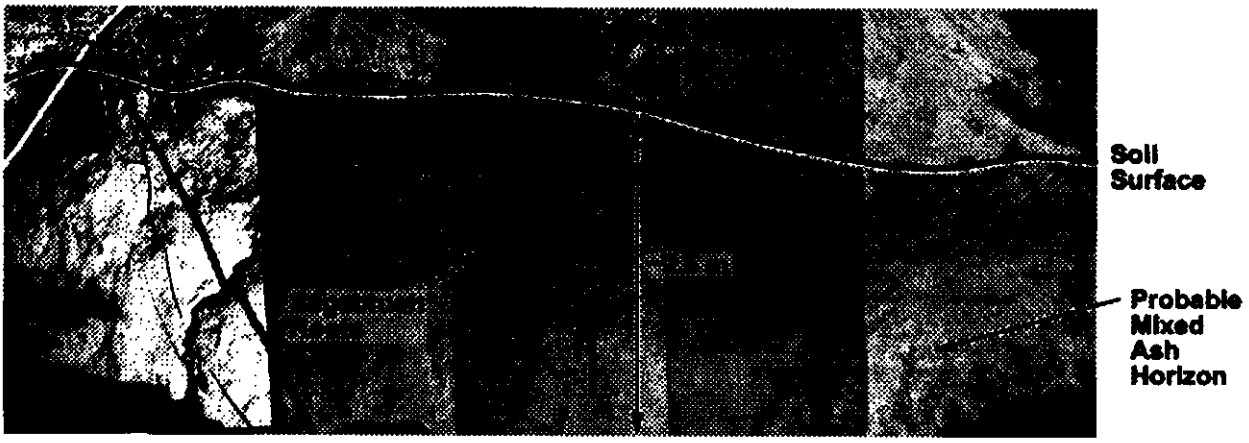

Figure D.5. Profile of the Dune Trench Showing the Lighter Colored Horizon Suspected of Containing Reworked Ash from the Mt. Mazama Eruption that Occurred 6,700 Years Ago

developed A or B horizon. Modern roots appeared to penetrate to a depth of about 2.4 m. Between 2.4 and 3.0 m is a slightly coarser layer of silty fine to medium-grained sand (Figure D.4). Underlying this layer was 0.45 m of weakly consolidated, slightly more compact, dark yellowish brown (10YR4/4) silty fine sand. This layer of finer-grained material may represent possibly a weak B paleosol horizon. Several peat-like clasts, consisting of a dense, partially decomposed mat of root hairs were collected for carbon-14 dating from this layer. At the very bottom of the excavated trench was a coarser textured layer of fine to coarse sand. Mineral grains in the coarse sand fraction were composed of about 50% basalt.

After attaining the maximum depth (~4 m) the equipment would allow, the backhoe was relocated downhill to extend the length of the trench to about 9.1 m. Soon after moving the backhoe downhill the trench caved, and it was no longer possible to keep the trench open to more than 2.4 to 3.0 m deep. About 4.6 m from the beginning of the trench and around a depth of ~1.2 to 1.5 m, there was a lighter colored layer 0.3 m or more thick, that appeared to be soil mixed with what appeared to be light-colored volcanic ash (Figure D.4). The ash is probably from Mount Mazama. This implies that the upper 1.2 to 1.5 m must be ≤ 6,850 years old and that at least 3.0 m of eolian sediments were deposited between 6,850 and 13,000 years ago.

D.3.3 NPR Trench

The NPR Trench was excavated to a depth of 4.4-m (Figure D.6). The stratigraphy was similar to that observed at the Plains Trench, which consisted of a thin layer of eolian sand over flood deposits. Overall, the exposed sedimentary sequence became finer grained nearer the surface. The eolian material at the surface was limited to about 0.15 m of pale brown, structureless, silty fine sand (Figure D.7). Immediately below this was another 0.15 m of silty medium to coarse basaltic sand, which represents the top of the cataclysmic flood deposits (Hanford formation). This layer of sand was moderately cemented with calcium carbonate (i.e., near-surface calcic-soil development) and displayed well-developed cross bedding to the east. This is consistent with the west-to-east paleocurrent direction associated with cataclysmic floods in this area. From the 0.3- to 1.5-m depth was a layer of gravelly medium-to-coarse basaltic sand that displayed low angle cross bedding. From 1.5 m to the bottom of the trench, the sediments consisted of a poorly sorted, gravelly coarse sand to sandy gravel typical of the Hanford formation. There were no volcanic layers or other datable horizons observed in this trench. The absence of the thick Mazama ash layer indicates significant wind reworking of sediments as recently as 6,850 years ago.

D.4 Conclusion

The existence of eolian sand dunes at the proposed ILAW Disposal Site demonstrates the potential for sand dune development, at least under the conditions of the early-to-middle Holocene period. Lack of a Mount Mazama ash layer in the Plains Trench and NPR Trench suggests significant wind reworking of sediments at these sites as recently as 6,850 years ago. A mixed ash/sediment layer in the Dune Trench suggests that 1.2 to 1.5 m of eolian sand has been deposited there in the last 6,850 years. Deposition rates like this will have to be considered when interpreting hydrologic and tracer data from these sites. Modern

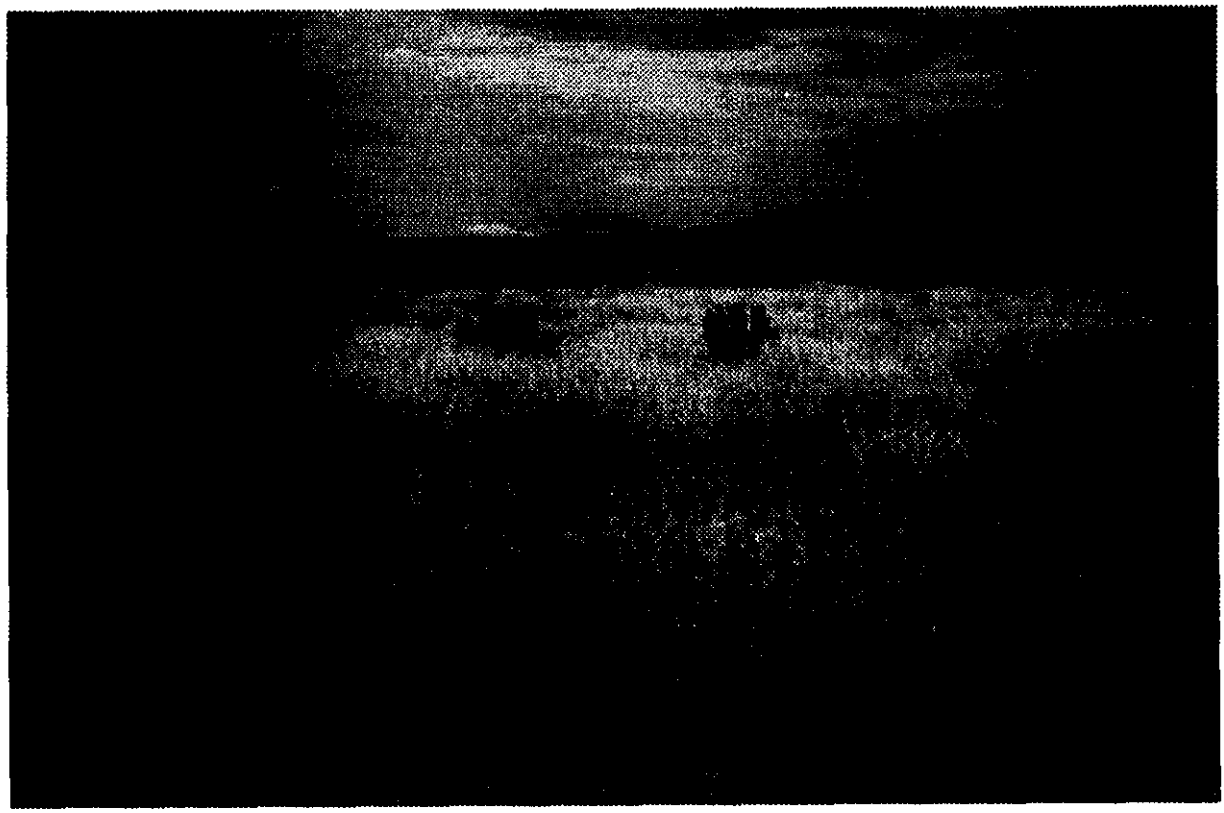

Figure D.6. View to the North of the NPR Trench. The vegetation is primarily big sagebrush, Sandberg's bluegrass, and cheatgrass. The nearest shrub in the photograph is about 10 m from the trench.

land use patterns may preclude any major sand dune formation or movement in the near future. However, the potential for some sand deposition still exists and its impact on facility performance needs to be considered.

Evaluation of Anthropogenic Chloride Deposition at the ILAW Disposal Site

C. W. Lindenmeier, R. J. Serne, M. J. Fayer, and R. E. Clayton

Appendix E

Evaluation of Anthropogenic Chloride Deposition at the ILAW Disposal Site

E.1 Introduction

As part of the performance assessment under way to evaluate the suitability of the unsaturated zone of the Hanford Site for Immobilized Low-Activity Waste (ILAW), Pacific Northwest National Laboratory (PNNL) conducted a preliminary site investigation to determine if human activities in years past may influence data used for the determination of recharge rates. Because the natural recharge rate is a key parameter needed to perform calculations of the transport of water and contaminants through the vadose zone and into the groundwater, several methods are currently being employed to estimate the long-term recharge rate. One method under consideration is the chloride mass balance (CMB) method described by Murphy et al. (1991, 1996). This method uses chloride as an environmental tracer to estimate natural recharge rates. However, one concern about using this method is the potential for excess chloride deposition in the region of investigation due to anthropogenic activity. Excess chloride that is not accounted for in the calculations would change the mass balance ratios and subsequently bias the calculated recharge rate lower than the actual value.

The proposed ILAW Disposal Site is located in the 200 East Area (Figure E.1) just southeast of the 284-E Power House and Steam Plant (Figure 7.1). The site contains a relatively undisturbed old growth sagebrush area and has two predominant sediment types: Burbank loamy sand, and Rupert sand (Hajek 1966). Because this site is near a formerly active coal-fired power plant, we focused on examining the assumption that this power plant could have been a potential source of chloride deposition. This assumption is supported by the premise that the predominant form of chlorine released during the combustion of coal is an HCl aerosol that would have high affinity for particulates released in the stack of the plant. Additionally, we expected that deposits from stack emissions would correlate with prevailing wind patterns, readily determined from meteorological data. Wind data collected from the 60-m tower in the 200 Area between 1986 and 1998 (Hoitink et al. 1999) suggest that the proposed ILAW Disposal Site is downwind of the power plant.

E.2 Objective

The objective of this task was to develop and implement a quick and inexpensive chemical screening technique that would be sufficient to indicate whether or not emissions from the 284-E coal-fired power plant may have contributed excess chloride into the sediments at the proposed ILAW Disposal Site. The

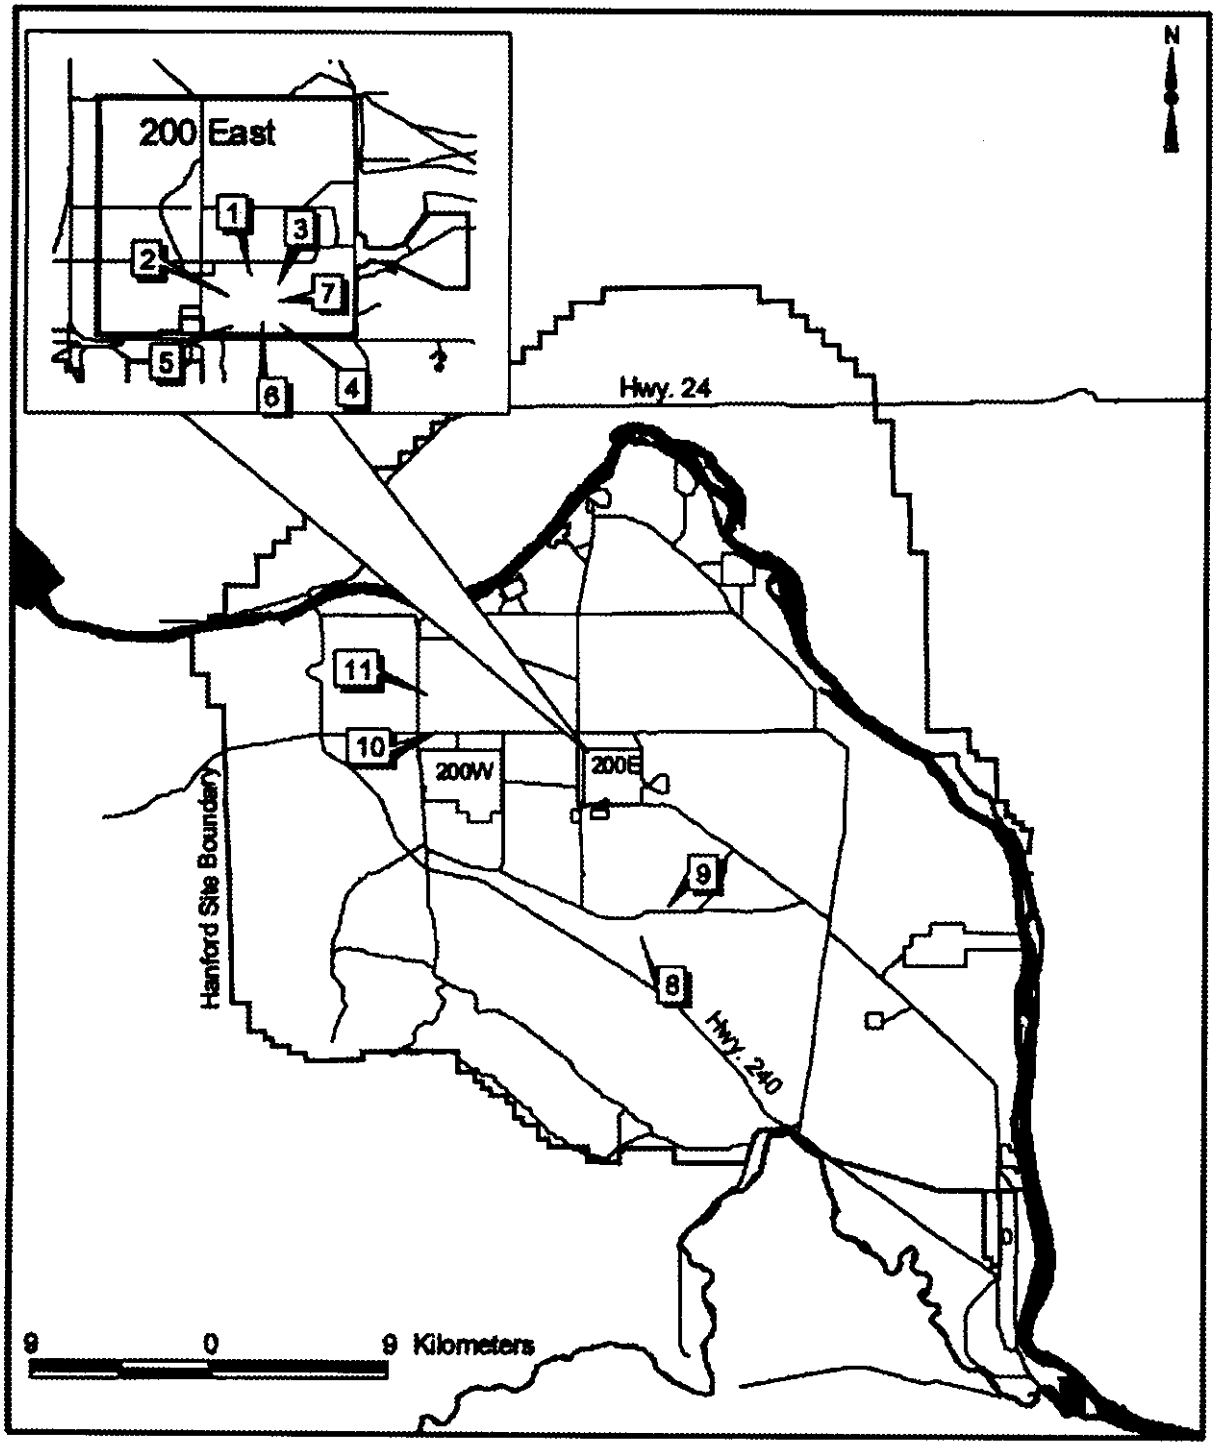

Figure E.1. Sampling Location Map

coal power plants at the Hanford Site began operation in 1945 and did not use emission control devices until 1980 (Fayer et al. 1996).[1] Coal power plants without emission controls are known to emit large quantities of nitrous oxides, sulfur oxides, and particulates, as well as a suite of trace metals such as arsenic, cadmium, chromium, or manganese. First we sought to determine if a chemical "fingerprint" could be identified from analyses of coal and fly ash materials found near the proposed ILAW Disposal Site. This fingerprint would be used to compare surface and below surface sediment samples removed from the proposed ILAW Disposal Site along with representative background sediment samples collected at various locations on the Hanford Site. X-ray fluorescence analysis of surface sediments was used to determine metal and trace metals. Ion chromatography (IC) analysis was used to determine major anions in water from leached sediments.

E.3 Methods

As shown in Table E.1, sample cores were collected from

- the top of the coal ash pile (Station 1)
- the remaining coal pile (Station 12)
- locations southwest of the proposed ILAW Disposal Site (Stations 8 and 9)
- locations northwest of the proposed ILAW Disposal Site (Stations 10 and 11)
- locations within the proposed ILAW Disposal Site boundaries (Stations 2, 3, 4, 5, 6, and 7).

Our rationale for sampling at these stations was based on the need to collect screening data that would be fairly representative of the entire site. Thus core samples were collected from the four corners of the proposed ILAW Disposal Site, a sample from a large sand dune laying along a southern, east-west transect, and two internal locations that were selected in part because they were accessible with the sampling truck. Additionally, for Stations 3 and 7, sample cores were removed from two separate locations—one an area clear of sagebrush, and the other under the canopy of living sagebrush. Dual sampling at Stations 3 and 7 was done to determine if different vegetation conditions might create significant variability and thus be a factor to consider when assessing the data. Background sampling stations were selected by a combination of visual examination, using sediment charts (Fayer and Walters 1995) that identified similar sediments associated with the proposed ILAW Disposal Site, and using a minimum distance of 5 km from the proposed ILAW Disposal Site. The 5-km distance was selected by using a calculated deposition rate for chloride as a function of distance as reported by Fayer et al. (1996).[a] Based on their simple model, at 3.4 km from the point source, deposition rates for chloride would essentially equal the natural rates. A 5-km point source distance minimum was thought to be both conservative and practical for selecting representative background sediments.

For most of the sampling, 5.08-cm-diameter cores were collected to an average depth of 152 cm using aluminum pipe (Type 6061-T6 with 5.08 cm OD x 0.12 cm wall) and a motorized impact driver (Bosch Rotary Hammer). The coring was accomplished by driving one segment of pipe to a depth of 76.2 cm to

91.4 cm. A second segment was driven down as far as possible usually resulting in a recovery of approximately 50.8 additional cm. The second core was partially hand dug out of the ground to facilitate removal. In one case at Station 3, a third segment of pipe was used allowing for the recovery of an additional 10.2 cm. After reaching the desired depth, the tubes were extracted by hand or with pipe wrenches. Excess tube length was removed and the cores were labeled and taped for transport to the lab. This method helped minimize material loss from the end of the pipe and reduced core shrinkage due to compaction. Depth measurements were taken from the hole and compared to the actual core material collected in each pipe segment. We noted an average of 5.08 to 10.2 cm shrinkage in both segments inside the pipes compared to the open hole. Following the completion of core removal, a flagged fence post was placed at the location. One exception to our collection protocol occurred when we attempted to collect the background samples for the Burbank sediment. We were successful only in obtaining shorter cores—a 25.4-cm depth in one case and 40.6-cm depth in the other.

Samples were identified using the station number as the first number followed by a dash; a second number representing the core number followed by a lowercase letter identifying the hole at a specific station. Thus a sample such as 3-3a represents Station 3, the third core removed at hole 'a.' Sub-samples sent for analyses followed this notation with the addition of a depth value. The cores were then transported to PNNL's Sigma 5 Building and placed in cold storage for sub-sampling at a later time. Actual sampling locations were recorded using a Trimble Geoexplorer2 Geographical Positioning System (GPS) unit. The GPS locations collected from each station were downloaded to a computer and corrected by differential correction for real-time data. The locations were then mapped on a Hanford Site map (Figure E.1).

The screening method selected to determine total chemical composition and chlorine extraction measurements (x-ray fluorescence analysis and water leach followed by chlorine analysis by ion chromatograph) involved separating the core into 25-g aliquots beginning at the surface and continuing until we reached the 10-cm depth. Each 25-g portion was sealed in a 30-mL glass bottle; a 10-g portion was then removed from each of the first surface samples and the last samples near 10-cm depth. These

10-g portions were stored in other 30-mL glass bottles and delivered to Ron Sanders (KLM Analytical) for x-ray fluorescence analysis.

Preliminary IC and pH analyses were performed using a 2:1 ratio water to sediment extract (Methods of Soil Analysis. Part 2; 62-1.3.2.2) with the remaining 15 g of sediment from the sample taken at the 10-cm depth, and 15 g of sediment taken from the bottom of the last core removed from a given sampling site (ranging from 119 to 178 cm deep). Each 15-g sediment sample intended for IC and pH analyses was then combined with 30-mL of deionized water in a 50-mL Nalgene centrifuge tube and gently agitated for 24 hours, centrifuged at 2500 rpm for 20 minutes, decanted into a syringe, and passed through a 0.2 μm membrane filter into a 30-mL glass bottle. The filtrate was then submitted for IC and pH analyses. In addition, a 10-g sample from the 11- to 12-cm depth was carefully weighed and placed in an oven at 105°C for 24 hours to determine moisture content.

E.4 Results and Discussion

Table E.2 shows the moisture content and 2:1 extract pH data of all sub-sampled depths for each core. Anion data from IC analysis are shown in Table E.3, and metals data from x-ray fluorescence analysis are shown in Tables E.4, E.5, and E.6.

Our preliminary assessment of the data does not offer a conclusive answer to the question of whether or not chloride data obtained from the proposed ILAW Disposal Site and used in recharge calculations may be compromised by operation of the 284-E power plant. It was our hope that by using trace metal analysis from the coal-ash and coal materials, a clear fingerprint could be identified. This fingerprint could then be readily compared to sediments within the proposed ILAW Disposal Site and sediments used for background comparison. This does not appear to be the case when reviewing the x-ray fluorescence data. The x-ray fluorescence analyses were performed only on near-surface samples because we expected the trace metals to be sorbed near the surface. However, if emission controls began in 1980, then the majority of deposition likely occurred prior to 1980. In the 20 years since then, precipitation could have leached trace metal deeper in the soil. Therefore, x-ray fluorescence analyses of deeper samples are warranted.

The ion chromatograph sulfate data, however, suggest that atmospheric deposition resulting from power plant emissions may have occurred. Specifically, sample 3-3a at the 142-cm depth shows a sulfate concentration of 182 ppm, sample 3-2b at the depth of 120 cm shows a sulfate concentration of 144 ppm, sample 6-2a shows a sulfate concentration of 35 ppm, sample 7-2a at the depth of 170 cm shows a concentration of 11 ppm, and sample 7-2b at the depth of 152 cm shows a concentration of 38.6 ppm. Sulfate concentrations at each of these sites are at least 3 times greater, and in one case, as much as 46 times greater than the highest background sulfate value from a comparable depth. These high sulfate values are at depths far below x-ray fluorescence analyses. If the high sulfate values represent deposition of coal emissions, then trace metals (if present and relatively weakly adsorbing) are likely much deeper than the 10-cm samples analyzed during this task.

In reviewing Environmental Protection Agency (EPA) data associated with sulfur dioxide emissions from coal-fired plants (EPA 1998), it could be assumed that the sulfur dioxide emitted over the life of the

E.5 Conclusions

To resolve the issue of where coal emissions might be within the profile, we recommend additional analyses of the entire core from at least two stations—one from the proposed ILAW Disposal Site and one from a representative background site. Preferably, these would be Stations 3 and 9. As reported, Station 3 has the highest indication of being potentially affected, and its location is well within the prevailing wind pattern located on the northeast corner of the proposed ILAW Disposal Site. X-ray fluorescence data appear to indicate that Station 9 is reasonably representative of background sediment. Profiling should involve sub-sampling each of the cores at a minimum of 20-cm intervals for 2:1 extract IC analyses, and sediment x-ray fluorescence analysis along the entire length of each core. Additionally it is recommended that, using stable isotope ratio mass spectrometry, an effort should be made to determine if a chemical fingerprint for isotopic sulfur could help determine the source of the sulfate.

Vegetation Data Summary for Supporting Recharge Estimates - FY 1998 and FY 1999

J. L. Downs and F. O. Khan

Appendix F

Vegetation Data Summary for Supporting Recharge Estimates - FY 1998 and FY 1999

F.1 Introduction

Pacific Northwest National Laboratory (PNNL) manages the "PNNL Geotechnical Support of Hanford Immobilized Low-Activity Waste (ILAW)" project to assist Lockheed Martin Hanford Company (LMHC) in designing and assessing the performance of a disposal facility for radioactive wastes currently stored in single- and double-shell tanks at the Hanford Site. A major challenge in assessing long-term performance of buried waste disposal facilities involves characterizing and understanding the distribution of mean recharge rates across the heterogeneous landscape at Hanford. Location-specific recharge rates are determined by site-specific climate, soils, and topography (aspect and slope), as well as the disturbance or land use history (fire, erosion, grazing), soil properties, and vegetation properties.

The overall objective of the recharge task is to provide defensible estimates of recharge rates for current conditions and long-term scenarios involving the shallow-land disposal of low-level waste at the Hanford Site (WHC 1995). Rockhold et al. (1995) outlined the conditions and scenarios that could impact the disposal facility and provided estimates of recharge rates from existing lysimeter and tracer data for four conditions. However, for most of the conditions and scenarios identified by Rockhold et al. (1995), very limited data were available with which to estimate recharge rates. Thus, a major goal of the recharge task is to collect sufficient data to enable estimation of recharge rates for the conditions and scenarios deemed to be important for evaluating the performance of the disposal facility.

This letter report outlines the vegetation studies accomplished during FY 1998 and 1999 to support the prediction of recharge rates over the lifetime of the disposal facility. Under Subtasks 2c, 2d, and 2e of the recharge task, PNNL has gathered and compiled vegetation data from the literature and at the proposed ILAW Disposal Site for use in predicting the long-term water balance and recharge. The information gathered addresses data gaps (previously identified in the letter report, Review of Existing Vegetation Data for Performance Assessment Modeling of the ILAW Disposal Site) to the extent possible given current funding levels. PNNL modeling staff have been and will continue to be consulted to prioritize data collection and interpretation. Field data are summarized and presented, along with a discussion of how these data meet future modeling requirements.

F.1.1 Background and Study Objectives

The plant community existing at a site of interest influences a number of factors that determine recharge rates for that site. Vegetation can influence the surface-water runoff, the infiltration of precipitation in the soil, the amount of water stored in the soil, and even the amount of precipitation that

reaches the soil surface. The greatest effect of vegetation on surface-water budgets is in the transpiration fraction of the total evapotranspiration. Plants growing in arid systems may actually remove all water stored in the soil column, depending on the rooting depth, plant phenology and form, and the soil type; thus, plants can effectively reduce drainage and subsequent recharge (Gee et al. 1992, 1994; Link et al. 1994).

In general, models used to estimate recharge rates for different conditions will require certain vegetative parameters including estimates of plant transpiration and plant water status (leaf water potential) that can be correlated with soil water potentials. Knowledge of rooting depths, root densities, and root distributions are also required for modeling efforts to accurately simulate sequential removal of water from different depths within the soil profile. Depending on surface, vegetation, and soil conditions, recharge rates at Hanford can range 1000-fold: from less than 0.01 cm/yr under a complete cover of shrubs to more than 10 cm/yr under graveled surfaces without vegetation (Murphy et al. 1996; Gee et al. 1992).

Because vegetation is a function of the physical environment, differences in environmental conditions such as soil depth or soil type are readily reflected by differences in the plant community composition and structure across the landscape. The density and canopy cover of mixed shrub and grass communities can vary greatly across relatively short distances. Changes in soil type and/or slope and aspect can create sharp delineations between community types or change the abundance of a particular species. Understanding the patterns of plant distribution—both above- and belowground—is key to understanding plant water use and its impact on recharge rates.

The objectives of the vegetation subtasks are to provide the descriptive information and data that are needed to better understand and predict recharge rates at the proposed ILAW disposal facility on the Hanford Site. These data will aid in understanding how and to what extent plants may control recharge at the Site and be used to develop the appropriate ranges and distributions of plant parameters that can be used in computer modeling efforts to assess recharge. In FY 1998, field data collected under these subtasks included information concerning the existing and potential plant community structure: plant canopy cover, species diversity, shrub density and distribution of size classes, plant root spatial distribution and biomass, total leaf area and biomass, and determination of leaf area index. In FY 1999, our objectives were to collect physiological and life history information over a 7-month period from November 1998 through May 1999.

Our investigation concentrated on defining water relations for three dominant plant species on the site: big sagebrush (*Artemisia tridentata*), cheatgrass (*Bromus tectorum*), and Sandberg's bluegrass (*Poa sandbergii*). The FY 1999 study focused on defining plant water status with respect to soil water status for each of the species of interest during winter and spring months. We conducted the following studies throughout the year:

- documentation of plant phenology
- measurement of leaf (xylem) water potential through winter until late spring
- concurrent measurement of leaf-level conductance as feasible
- concurrent measurement of soil water content

- finalizing measurements of root distribution and biomass of shrubs and grasses.

We also sampled plants for leaf area index (LAI) to compare with the 1998 leaf area and biomass data and to refine the community level estimates for LAI. To the extent feasible, measurements were made to document seasonal changes in LAI.

F.2 Methods

The field study area is located at the proposed ILAW Disposal Site in the 200 East Area of the Hanford Site (Figure F.1). The current plant community can be classified as either *Artemisia tridentata/Bromus tectorum* (Big Sagebrush/Cheatgrass) or *Artemisia tridentata/Poa Sandbergii* (Big Sagebrush/Sandberg's bluegrass) depending on the extent to which cheatgrass has replaced bluegrass as the understory grass species. Soils of the ILAW site are predominantly sands and loamy sands (see Section 3.0 of the main report). The topography of the ILAW site to the south and west of the plutonium-uranium extraction (PUREX) facility is relatively flat with the exception of a stabilized dune running in

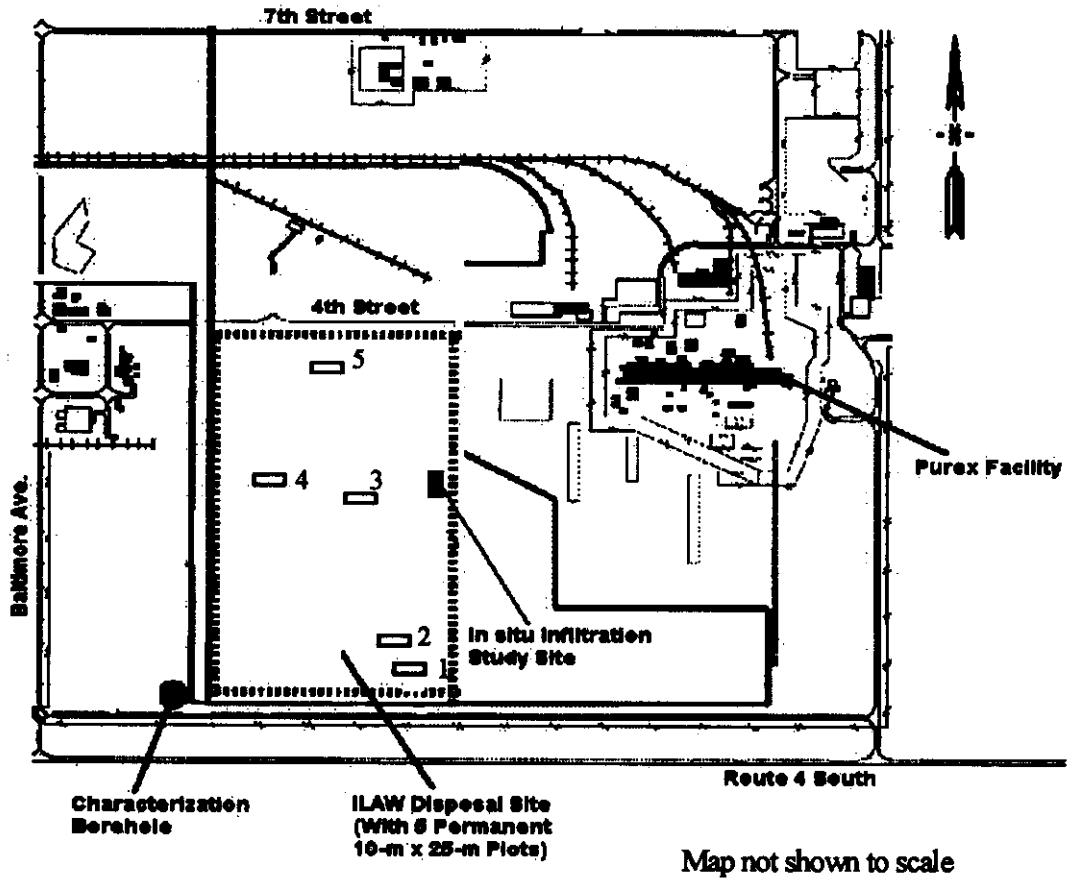

Figure F.1. Map of the Immobilized Low Activity Waste Disposal Site in the 200 East Area Displaying the Five Permanent Vegetation Monitoring Plots

an east-west direction along the southernmost edge of the site. The general climate at the Hanford Site is best described as semiarid with hot dry summers and cold, wet winters. During the 1998-1999 measurement period, winter temperatures were warmer than the long-term averages for the site. November was 5.3°F above the normal monthly average (40.2°F), December was 5.4°F above the normal monthly average (31.4°F), January was 1.6°F above the normal monthly average (31.3°F), and February was 3.7°F above the normal monthly average (38.0°F).

Efforts in FY 1998 were focused on characterizing two types of plant communities that might establish on the ILAW disposal facility: the existing sagebrush-steppe type community currently occupying the proposed disposal area, and abandoned fields that represent the unaided establishment of vegetation after construction or possible successional stages following fire. Characterization efforts included measurements of plant canopy cover, shrub density and height, species diversity, leaf area and biomass. In addition, root distributions were sampled to a depth of 1 m on the in situ infiltration test plot.[a] Leaf-level conductance, leaf water potential growth and phenology, and concurrent soil water status were measured from November 1998 through May 1999.

F.2.1 Species Diversity and Canopy Cover of Herbaceous Plants

Five 100-m transects were randomly established in 1998 at the ILAW Disposal Site and three 100-m transects at the Existing Disposal Site to determine plant diversity, abundance, and canopy cover by species for the sagebrush-steppe community. On each 100-m transect, three 10-m x 10-m plots were established along the transect at 25, 50, and 75 m. In each 10-m x 10-m plot, shrub height, widest diameter (d_1), and diameter (d_2) perpendicular to the first diameter measurement were recorded. Shrub canopy cover was calculated using this plot data. An ellipsoidal area was calculated for each shrub

$$Area = \pi\left(\frac{d_1 d_2}{4}\right) \tag{F.1}$$

and the total shrub area was summed for each plot and expressed as a percentage of ground area to determine percent canopy cover. These were averaged for each transect and a mean canopy cover was determined for each site (ILAW, n = 5; Grout, n = 3). Understory canopy cover by species was visually estimated in 0.2 x 0.5-m plots using a modification of Daubenmire's (1959) method. These 0.1-m quadrants were systematically placed along the transect to provide 25 to 30 samples of plant cover and compostion along each transect. Species lists were compiled for the area adjacent to each transect. Where feasible, percent bare ground and percent of ground covered by biotic crust was also estimated.

Data were also gathered in a similar fashion from five additional transects established randomly on abandoned fields on fine-textured soils on the Hanford Site (two transects at McGee Ranch, two transects at Lower Snively field, and one transect at Benson Ranch). No shrubs were found on abandoned field

(a) Ward AL, RL Clayton, and JC Ritter. 1998. "Hanford Low-Activity Tank Waste Performance Assessment Activity: Determination of in situ hydraulic parameters of Hanford Sediments," Letter Report to Fred Mann, Fluor Daniel Northwest, Richland, Washington, August 31, 1998.

transects, so no 10-m by 10-m plots were established on those transects. These data are compared with data obtained from the ILAW Disposal and Existing Disposal Sites.

F.2.2 Leaf Area Index and Shrub Biomass

During February 1998, all sagebrush plants were harvested from a 2-m x 10-m plot on the borehole site, southwest of the PUREX facility, and in April 1998 from the 5-m x 8-m in situ infiltration test plot, including its borders and measured for canopy cover, LAI, and shrub biomass. At the same time, herbaceous groundcover was harvested for leaf area determination from eight 1-m^2 plots at the borehole site (February 1998) and from six random 0.1-m x 0.5-m plots at the in situ infiltration test plot (April 1998). All leaves were separated from each plant and a total leaf area for that shrub obtained using a LI-COR 3100 Area Meter. Leaves and stems were dried and weighed for a total biomass of each shrub. For each harvested understory plot, all live herbaceous plant material was separated from litter and a total leaf area obtained using a LI-COR 3100 Area Meter. Equations were developed to relate sagebrush volume to leaf area and sagebrush leaf biomass to leaf area. These relationships are used with shrub density and size measurements to evaluate variability in leaf area across the assessment site.

Nine additional shrubs were harvested in spring 1999 in the ILAW Disposal Site for LAI values and shrub biomass measurements. Shrubs harvested were selected in three categories, three of each; small, medium, and large, and all plants were measured for height and diameter before harvesting. At the same time, herbaceous groundcover was harvested for leaf area determination from six random 0.1-m x 0.5-m plots at the site. These data have not been summarized for this report, but will be included at a later date.

All sagebrush in 14 randomly selected 10-m x 10-m plots across the site were measured in 1998 to obtain average shrub size, shrub density, and canopy cover. Measurements were also obtained from nine additional 10-m x 10-m plots near the Existing Disposal Site for comparison.

Root distribution sampling was conducted before excavation of the in situ permeability plot during July 1998. Approximately 75 core samples of soil 0.05 m x 1 m deep were removed in sections (>450 subsamples) for processing. Root samples were washed of soils and oven dried. Dried roots were weighed to determine root biomass. Samples were grouped for analysis according to distance from the main stem of sagebrush plants in the area.

F.2.3 Plant Phenology and Growth

Five large (10-m x 25-m) permanent plots were established in November 1998 across the proposed ILAW Disposal Site to monitor phenological changes and growth of the dominant grass species (cheatgrass and Sandberg's bluegrass) during FY 1999 (Figure F.1). Two of the five plots are located in the southeastern corner of the site adjacent to each other. One plot was established on each of two slopes located on the site: a north-facing slope and a south-facing slope. The location of these plots will enable us to monitor plant growth and development under different exposure to sunlight and rainfall determined by aspect. The other three plots were randomly located across the ILAW Disposal Site so that data collected will represent vegetation characteristics sitewide.

Within each of the five large permanent plots, ten subplots (0.5-m x 0.2-m) were established to monitor phenological changes of the two grass species of interest during the growing season. Subplots were equally apportioned either beneath shrubs or in inter-shrub spaces. Five shrubs within each 10-m x 25-m plot were chosen randomly to establish the sub-plots: five sub-plots close to or beneath the shrub canopy (one plot per shrub), and five sub-plots located in inter-shrub space.

From November 1998 through May 1999, growth and development were observed monthly in the winter and bi-weekly in the spring in each subplot, when the grasses were most active. Estimated canopy cover and growth stage for both grass species of interest were recorded at each observation period. Grass height of each species was measured at the same time through March. Growth was also measured for each of the five marked shrubs in each permanent plot. Initial height and diameter measurements were taken in November 1998 when the plots were established and a second set of similar measurements was taken in the spring 1999.

F.2.4 Leaf Water Potential and Conductance

Seven individuals of both juvenile and mature sagebrush (14 individual plants) were selected randomly on the ILAW site from outside the permanent plots and marked for measurement. Leaf water potential and stomatal conductance measurements were taken on these plants. Seven randomly selected sites in the vicinity of the marked shrubs were established for similar measurements for cheatgrass and Sandberg's bluegrass. Leaf water potential of sagebrush and cheatgrass was determined by a series of replicated measurements during the winter and spring months. These measurements were conducted monthly in the winter months (November, December, January, February, and March) and bi-weekly in the spring months (April and May) during peak growing season. Leaf water potential of Sandberg's bluegrass was measured only during April and May 1999, when the size of the leaves was large enough to allow measurement. Pre-dawn and midday leaf water potential measurements were conducted during the same day using the pressure chamber technique as described by Koide et al. (1989).

Two measurements were conducted on each shrub and grass site during each sample period. Because the entire cheatgrass plant was used for each measurement, the area of sampling was permanently marked and consecutive sampling was conducted as close to the original sample as possible. Because Sandberg's bluegrass is a bunchgrass, the bunch in each selected site was marked and samples were obtained from that bunch for each measurement. In cases where the size of the selected bunch was not adequate, bunches of bluegrass close to the original sample were used for measurements.

Stomatal conductance was measured for sagebrush and the two dominant understory grasses using standard porometry methods (Pearcy et al. 1989). A LI-COR 1600 Steady State Porometer was used for these measurements. Peak (midday) conductances were determined for sagebrush from February 1999 to May 1999, for cheatgrass from March 1999 to May 1999, and for Sandberg's bluegrass in May 1999. Because of its size, we were unable to conduct any conductance measurements on Sandberg's bluegrass until May. These measurements were taken in concert with leaf water potential measurements. Data collected were summarized to evaluate the magnitude and variability of seasonal changes in leaf water potential and conductance.

F.2.5 Soil Moisture

Soil samples were obtained at the same time as leaf water potential measurements to determine water content of the soil in the area of the plants being measured. Samples were obtained in two locations, under shrub canopies and in inter-shrub space, at depths from surface to a maximum of 1.5 m; 0 to 10 cm, 10 to 20 cm, 40 to 50 cm, 90 to 100 cm, and 140 to 150 cm. Where feasible, two or three sets of samples (near shrub and inter-shrub space) at different locations were obtained for accuracy. Soil water content (weight %) was determined by the gravimetric technique.

F.3 Results And Discussion

Work done during the 1998 fiscal year resulted in significant progress in characterizing existing plant community characteristics and defining the variability and condition of the shrub community at the ILAW site. Sampling and data analysis in FY 1999 presented here provide important information concerning the water relations of dominant species and phenology and life history information for the winter to spring growth period.

F.3.1 Plant Community Structure

The density and canopy cover of big sagebrush found on the two disposal sites vary slightly (Table F.1) and are representative of cover values reported for big sagebrush/Sandberg's bluegrass associations (average cover, 24%; range, 8 to 35%; Franklin and Dyrness 1988). It is interesting to note that although shrub canopy cover is nearly equal at the two locales (ILAW = 32% and Existing Disposal Site = 29%), the density of shrubs at the ILAW site is about 1.5 times the sagebrush density found on the Existing Disposal Site area. The overall age of shrubs in the two study areas appears to be similar with large spreading shrubs common at both sites. However, at the ILAW site, very dense patches of sagebrush are scattered across the northern and center portion of the site. Some of these patches are distinguished by multiple stemmed plants with relatively small canopy diameters that represents a slightly unusual growth form for big sagebrush in this vegetation association.

Table F.1. Summary of Sagebrush Characteristics Measured Across The ILAW Site and Existing Disposal Site

Location	Average Density Shrubs/Hectare	Average Height of Shrubs (cm)	Height Range Low - High (cm)	Average Canopy Cover (%) of Shrubs
ILAW Disposal Site	4000	101	7 - 225	32.0
Existing Disposal Site	2590	89	10 - 175	29.6

Table F.2 indicates that total plant cover on the Existing Disposal Site is also lower than that found on the ILAW Disposal Site (64% versus 83%). Native grass cover (principally Sandberg's bluegrass) and

native forb cover are higher on the ILAW site than on the Existing Disposal Site. This difference is also reflected in the higher species diversity found on the ILAW site. The percent bare ground and percent biotic crust cover were also estimated on a subset of the transects. Estimates of bare ground were 19.9% at the ILAW site and 34.8% at the Grout Site; biotic crust estimates were 8.3% at the ILAW site and 12.6% at the Existing Disposal Site.

Table F.2. Summary of Species Diversity and Canopy Cover Data

Location	Plant Form	Native Species	Alien Species	Totals	Average Native Species Cover (%)	Average Alien Species Cover (%)	Total Average Cover (%)
ILAW Disposal Site	Forbs	12	5	17	7.0	1.40	8.4
	Grasses	2	1	3	13.6	28.6	42.2
Total Herbaceous		14	6	20	20.6	30.0	50.6
	Shrubs	1	0	1	32.0	0	32
Total		15	6	21	52.6	30.0	82.6
Existing Disposal	Forbs	8	4	12	2.2	0.9	3.1
Site	Grasses	1	1	2	4.0	26.8	30.9
Total Herbaceous		9	5	14	6.3	27.7	34.0
	Shrubs	1	0	1	29.6	0	29.6
Total		10	5	15	35.9	27.7	63.6
Abandoned Fields	Forbs	6	5	11	4.1	13.2	17.2
	Grasses	1	2	3	1.3	63.7	65.0
Total		7	7	14	5.4	76.9	82.0

Communities on abandoned (disturbed) agricultural fields were evaluated as analogs to unaided vegetation development on a constructed cover. Mean canopy cover of all plant functional types on the abandoned fields was about the same as total cover at the ILAW site, but was greater than the total mean canopy cover found on the Existing Disposal Site. However, 77% of the total cover on abandoned fields is composed of alien grasses (64% canopy cover), specifically cheatgrass. Alien grass cover on abandoned fields is more than twice that found on shrub-dominated sites. Fewer native species (which are more likely to be deeper-rooted perennial plants) are found on the abandoned fields than in shrub-dominated communities. No shrubs were encountered along transects placed in abandoned fields. Although shrubs may be present in abandoned fields, canopy cover is less than 1% and considered negligible.

F.3.2 Phenology and Growth

Cheatgrass is a winter annual, and although most seeds germinate in the fall after sufficient rainfall, a second recruitment of seedlings in early spring months also occurs. Sandberg's bluegrass is a '*cool-season*' perennial grass that is senescent and dormant during the dry hot summer and becomes green and active after fall rains. Both species maintain green leaves and are assumed to lie quiescent

when temperatures become cold over the winter months. Observations of phenology and growth of the two dominant grass species at the ILAW site from November 1998 through May 1999 indicated that both species were active throughout the winter months. Warmer than normal winter temperatures during the measurement period (see study site description) must be taken into consideration when evaluating these data. Nighttime temperatures in December and January fell to the low- to mid-20s F, but daytime temperatures were often in the upper 30s to low 40s (Hanford Meteorological Station data for 1998 and 1999).

Plant growth as evidenced by changes in canopy cover of dominant grasses at the ILAW site was estimated over the 7-month period (November 1998 through June 1999) and is shown in Figures F.2 and F.3. Canopy cover of the grasses more than doubled between October and February, indicating the grasses were not quiescent; growth and development continued throughout the winter, as weather allowed. Direct measurements of plant height for the two species over the winter months also provide evidence of growth and plant activity during the winter (Table F.3). Measurements of big sagebrush on the fire plots indicated increases in shrub canopy between November 1998 and April 1999. On average, canopy increased by about 5 cm and the two diameters (d_1 and d_2) increased by 7 and 5 cm.

Measurements of plants in different microhabitats showed significant differences in plant growth determined by spatial and structural relationships with the shrub component of the plant community. Plants of both grass species showed greater growth and canopy cover under shrubs than plants in inter-shrub spaces. This increased growth under the shrub canopies may be a result of several factors. The microclimate under shrubs may be more favorable for growth than that found in more open areas. Also, soil nutrient levels may be higher underneath shrub canopies, which can act to create "islands of fertility" within semiarid systems (Allen 1991).

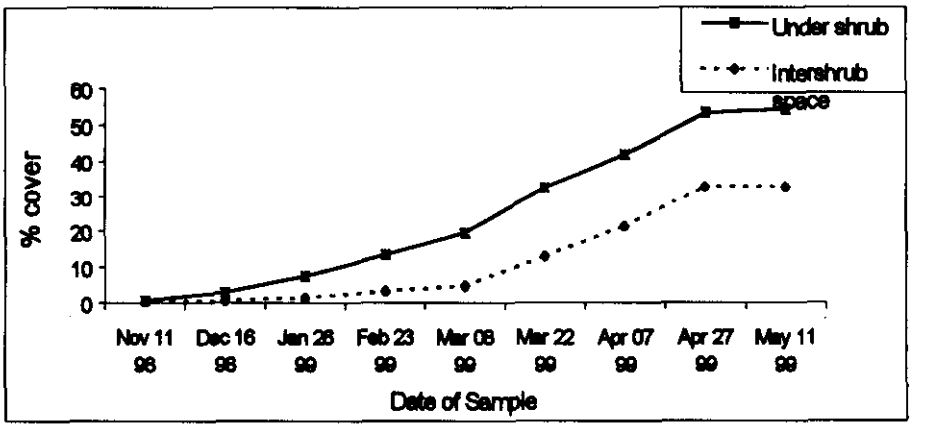

Figure F.2. Mean Percent Canopy Cover for Cheatgrass at the ILAW Site Throughout the Measurement Period

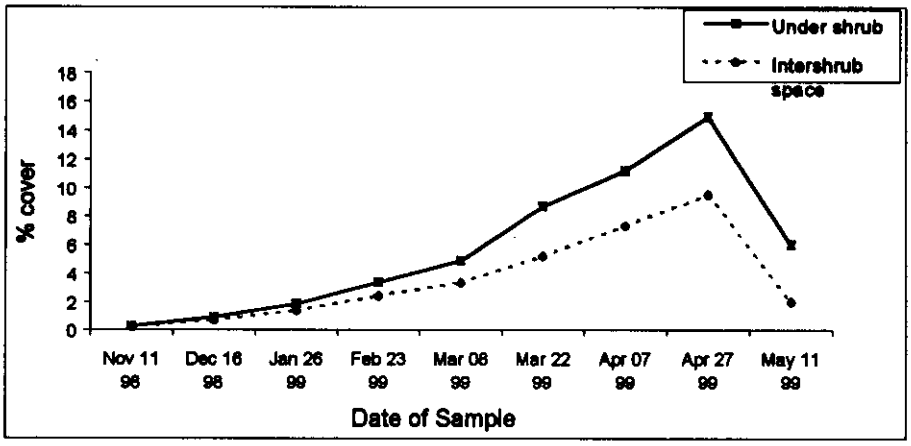

Figure F.3. Mean Percent Canopy Cover for Sandberg's Bluegrass at the ILAW Site Throughout the Measurement Period

Cheatgrass developed two to three times greater mean canopy cover than Sandberg's bluegrass at the proposed ILAW site, depending on the microhabitat. In Figure F.3, we can see that the peak canopy cover of Sandberg's bluegrass occurred at the end of April at the ILAW site and that the bluegrass began to senesce by early May. Cheatgrass maintained green canopy for approximately 2 weeks longer than Sandberg's bluegrass, although total canopy cover did not change significantly between April 27 and May 11.

Phenological stages recorded from November through May (shown in Figure F.4) indicate that both species initiate floral structures very early in the spring, about mid-March. These data along with the canopy cover estimates indicate that growth and development of these two cool season grasses occurs very early during the growing season. Observations in this study indicated that cheatgrass initiated floral structures about 1 week earlier than Sandberg's bluegrass. In contrast, previous study of phenology for these species on the Hanford Site (Link et al. 1990) found that Sandberg's bluegrass initiated floral structures approximately three weeks before cheatgrass.

Table F.3. Grass Height (cm) Measured at the Proposed ILAW Site During Winter 1998-1999

Species	October	November	December	January	February	March
Cheatgrass	2	3	4.5	5	6	7.5
Sandberg's Bluegrass	2	3.5	6	8	8.5	10

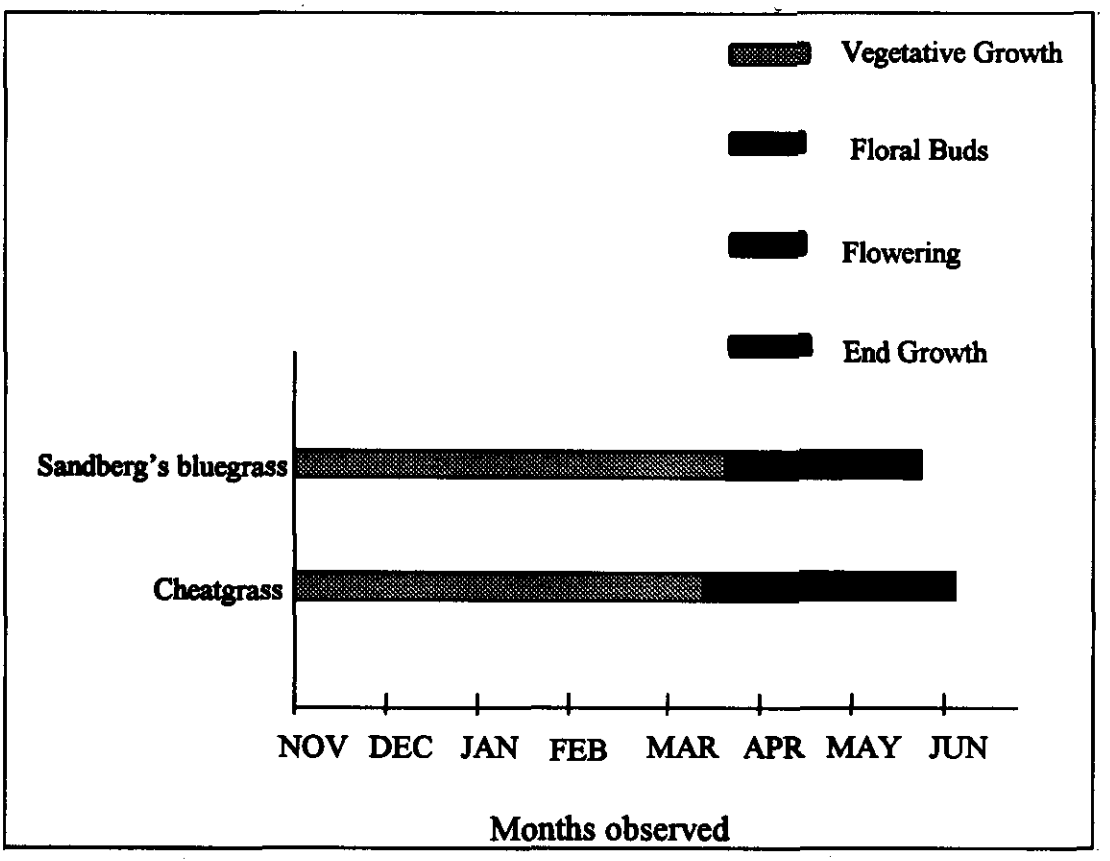

Figure F.4. Phenological Stages of Cheatgrass and Sandberg's Bluegrass at the ILAW Site Over the Measurement Period (Nov. 1998 – June 1999)

F.3.3 Leaf Area and Biomass Measures

Data collected on shrub and understory leaf area in 1998 and 1999 were compiled to provide an estimate of LAI at near peak biomass (Tables F.4a and F.4b). These values were developed using both measured leaf area indices and relationships developed from morphometric measurements of shrubs. Regression relationships were developed to relate leaf biomass to leaf area and to relate calculated shrub volume to leaf area for two different time periods: February and April (Figures F.5 and F.6). The equation describing the relationship between leaf biomass and leaf area shows a reasonable fit to the data

Table F.4a. Estimated Leaf Area Index for Shrubs Measured in 1998

Month	Location	LAI
February	ILAW Site	0.102
April	ILAW Site	0.204
June[a]	ILAW Site	0.282
July[a]	Grout Site	0.140
(a) Values estimated using morphometric and plot data.		

Table F.4b. Estimated Leaf Area Index for Understory Plants Measured in 1998 and 1999

Date	Location	LAI
February 1998	ILAW Site	0.118
April 1998	ILAW Site	0.904
May 1999	ILAW Site	0.395

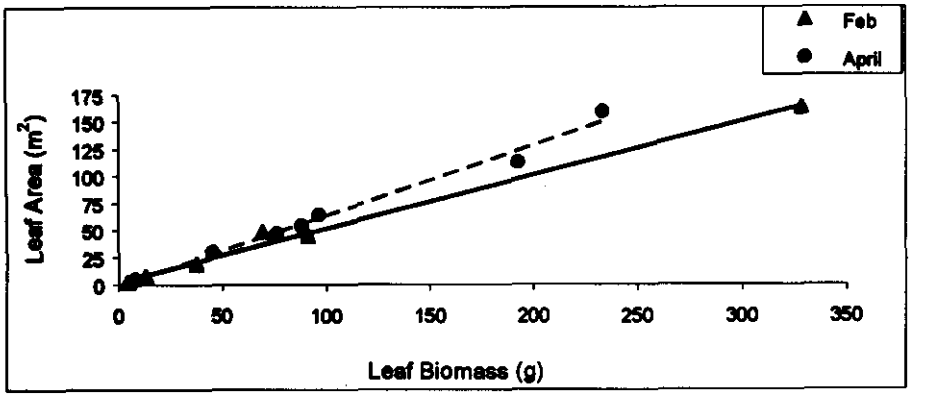

Figure F.5. Regression Relationship of Leaf Area to Biomass for Shrubs Measured in February and April 1998

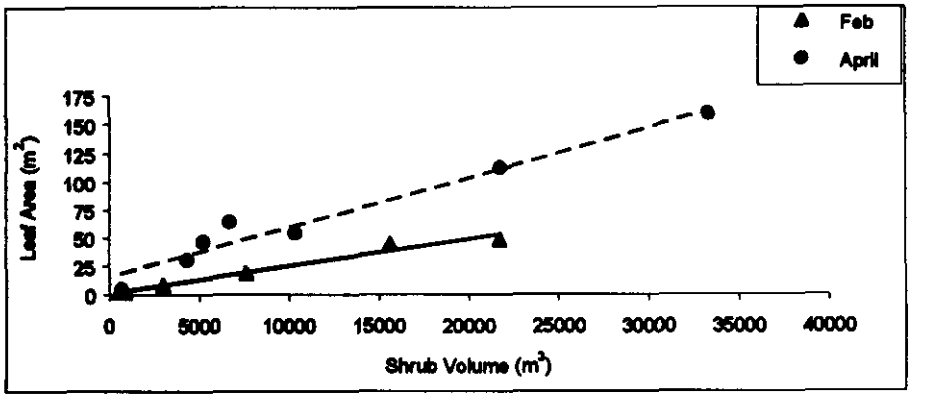

Figure F.6. Regression Relationship of Leaf Area to Volume for Shrubs Measured in February and April 1998

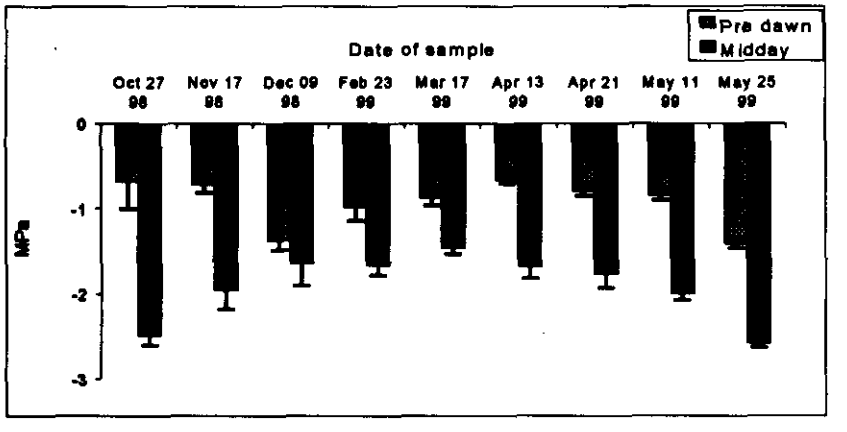
for both measurement time periods. Leaf area is not predicted as well by calculated shrub volumes. However, biomass data for entire shrubs or over large spatial areas are seldom available. Using a leaf area relationship developed on morphometric measurements allows us to estimate the spatial variability in

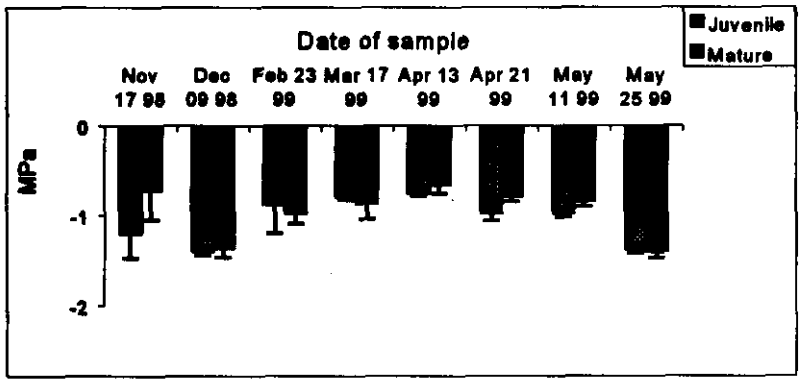
shrub leaf area through nondestructive measures of shrub size and canopy extent. The difference between the February and April relationships can be explained by the increase in shrub and grass leaf area during the spring growth period.

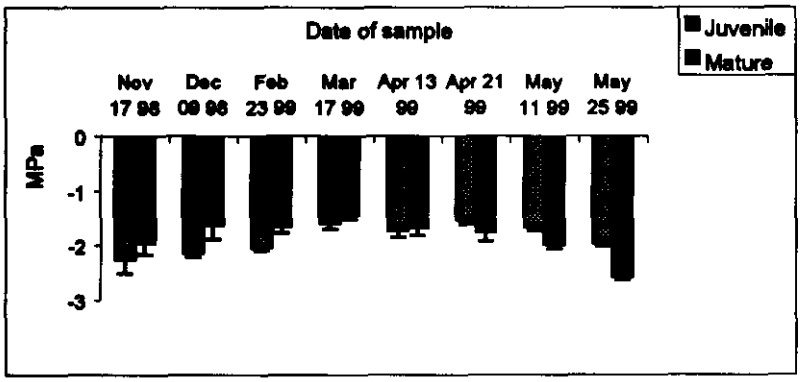
F.3.4 Plant Water Status

Predawn and midday water potentials were measured for mature sagebrush during the 7-month period from October 1998 to May 1999. Leaf water potential of plants varies on a diurnal schedule: as the plant goes through a daily cycle of photosynthesis and transpiration, leaf water potentials become increasingly negative because the plant loses water faster than the root system and vascular system can absorb and transport water to the leaf. At night when photosynthesis and transpiration are not occurring in C-3 plants, leaf water potentials become less negative as water is taken up from the soil and plant water potentials equilibrate with soil water potentials (Kramer 1983). Measurements of predawn leaf water potential should closely represent the soil water potential integrated over the plant's rooting zone. Differences between predawn and midday water potential indicate water use or water loss through plant transpiration. The leaf water potential differences in Figure F.7 show clearly that sagebrush were active during the winter months of the 1998-1999 season.

Leaf water potential data for different size classes of shrubs (juvenile less than 50 cm, and mature greater than 75 cm) indicate significant differences in patterns of water use at different points in time. Although predawn leaf water potential measurements (Figure F.8a) initially indicated that juvenile plants might be more stressed, the data are highly variable (November measurement), and no significant difference is found for the measurement period. A pattern occurs where the midday leaf water potential of juvenile plants appears to be more negative during November, December, and February; whereas, the same plants appear less stressed (less negative leaf water potential) during April and May (Figure F.8b). Figure 8c more clearly shows this pattern as the difference between mean predawn and mean midday values for the two size classes of shrubs.







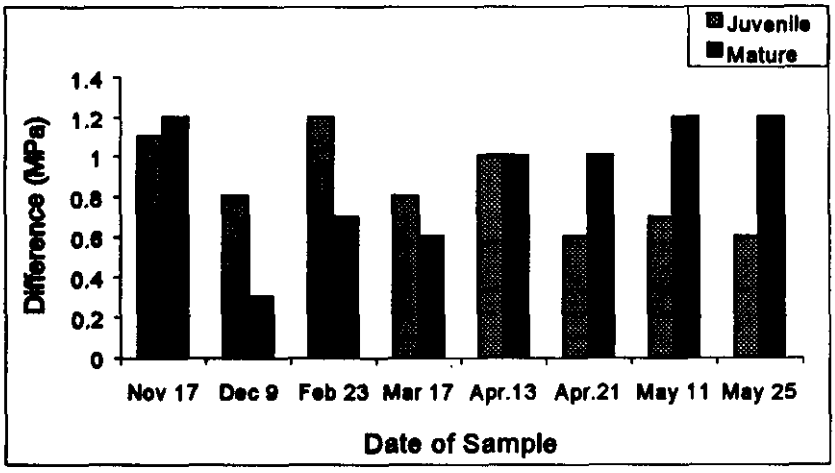


Figure F.7. Measured Leaf Water Potential for Mature Big Sagebrush: Predawn and Midday Measurements (error bars are ± one standard error)

(a)

(b)

(c)

Figure 8. Measured Leaf Water Potential for Juvenile and Mature Big Sagebrush: a) Predawn, b) Midday, and c) Predawn Minus Midday (error bars are ± one standard error)

Mean values for predawn and midday leaf water potentials for cheatgrass over the past 8 months indicate that the understory plant is less active during the winter months in terms of water use than big sagebrush. Very small differences occurred in predawn and midday leaf water potentials during the months of November, December, January, and February (Figure F.9). In contrast, the differences between predawn and midday values during March, April, and May are large, indicating significant water loss to transpiration during the spring growing season.

Although plant cover data indicate significant plant activity during the winter season for Sandberg's bluegrass, we were unable to obtain leaf water potential measurements due to the small size of leaves and equipment used. Leaf water potential information obtained for the spring season indicates that predawn values were consistently low (approximately -0.7 MPa) for the three measurement periods and midday values were significantly lower (-2.0 to -3.0 MPa) indicating significant transpirational water loss during the daylight hours (Figure F.10). In contrast to the low predawn leaf water potentials for Sandberg's bluegrass, at early April measurement periods, cheatgrass was able to obtain predawn xylem potentials of about -0.3 MPa. This may reflect that the greater rooting depth of cheatgrass allows this species to equilibrate predawn potentials with soil water potentials in deeper, wetter portions of the soil profile. The root zone of Sandberg's bluegrass generally is limited to the top 30 to 45 cm of the soil profile, whereas cheatgrass may develop roots below 75 cm (Link et al. 1990).

Leaf-level conductance data obtained during the spring months for big sagebrush were highly variable and apparently lower than values reported previously in the literature (Figure F.11) (Evans et al. 1991). Sagebrush conductance values measured previously by the author during the spring months under different soil conditions were approximately 2 to 3 times greater than values measured at the ILAW site. Although the porometer was factory calibrated before any measurements were taken, we consider these

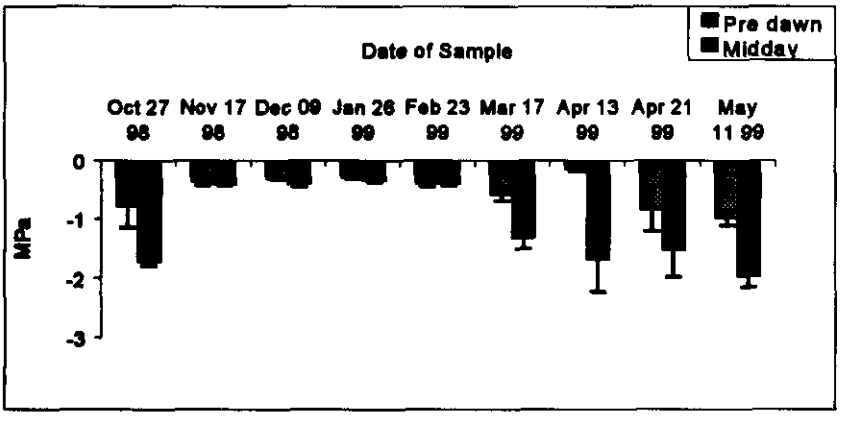

Figure F.9. Measured Leaf Water Potential for Cheatgrass at Predawn and Midday (error bars are ± one standard error)

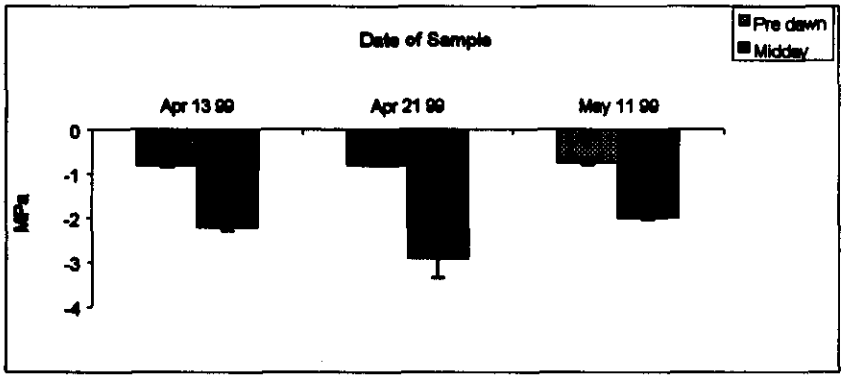

Figure F.10. Predawn and Midday Leaf Water Potentials for Sandberg's Bluegrass (error bars are ± one standard error)

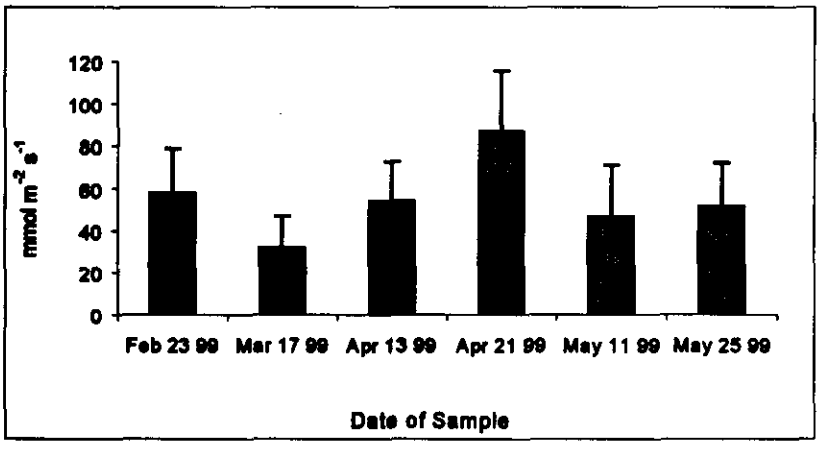

Figure F.11. Leaf-Level Conductance Data for Sagebrush (error bars are ± one standard error)

data suspect and will test the porometer system against a small-chamber gas-exchange system during the summer months. Conductance values measured for cheatgrass (Figure F.12) are also suspiciously lower than those reported previously (Link et al. 1990; Downs and Link 1993). Another possible explanation is that low conductance values could be a result of the combination of relatively low soil water availability along with cool springtime temperature.

F.3.5 Soil Water and Root Characteristics

Soil water contents of the profile measured at each measurement period (Figures 13a-e) illustrate storage of water in the soil profile throughout the winter and early spring. Initial measurements in October, November, and December show the increase in water content at depths to 20 cm. The wetting

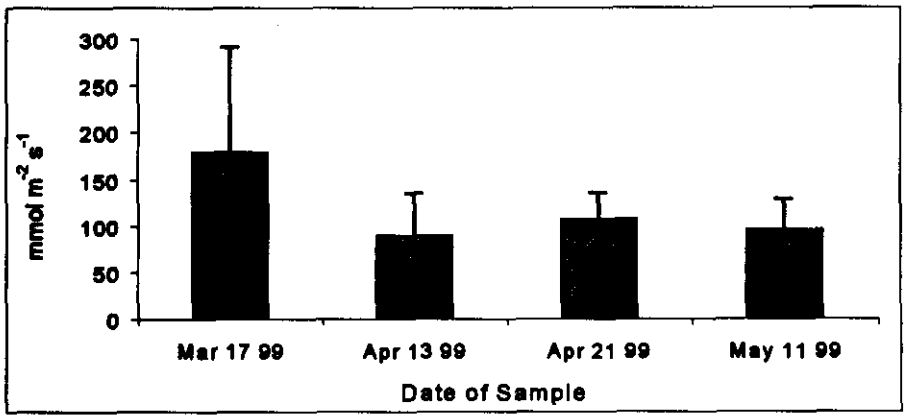

Figure F.12. Leaf-Level Conductance Data for Cheatgrass
(error bars are ± one standard error)

Figure F.13 (b). Soil water content (%) at 10 to 20-cm depth

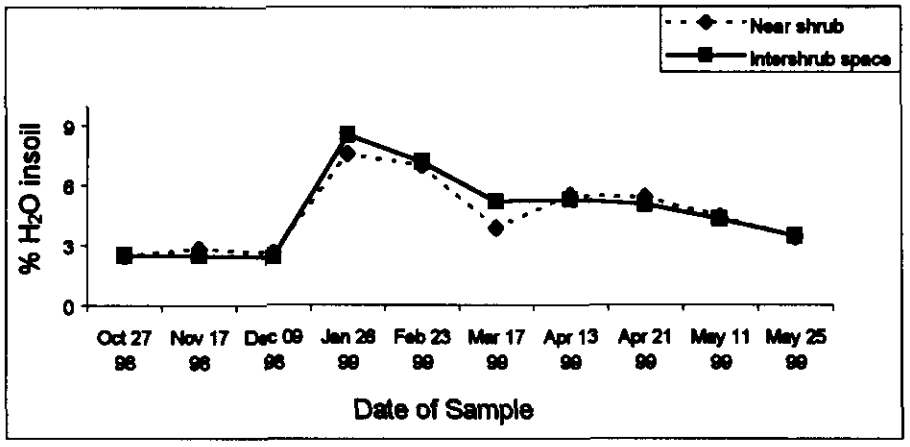

Figure F.13 (c). Soil water content (%) at 40 to 50-cm depth

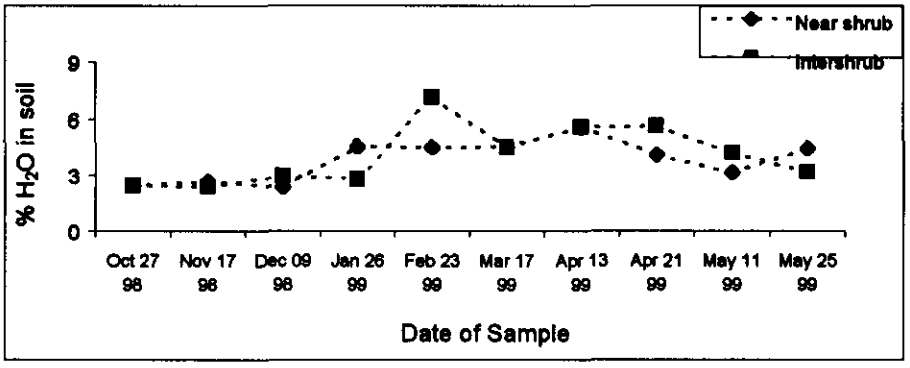

Figure F.13 (d). Soil water content (%) at 90 to 100-cm depth

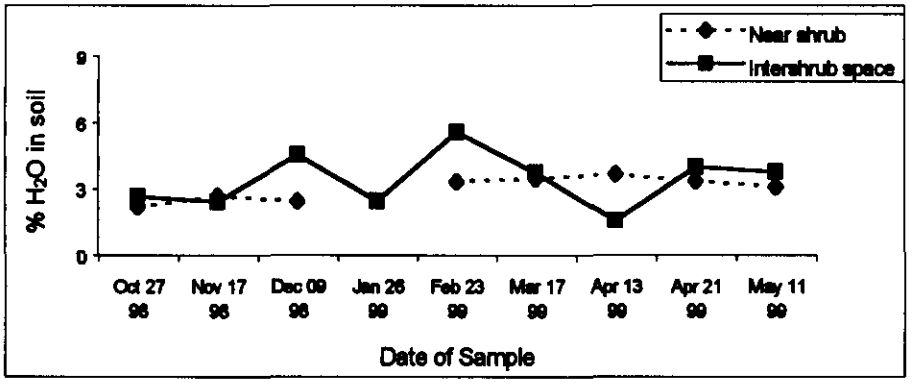

Figure F.13 (e). Soil water content (%) at 90 to 100-cm depth

front resulting from fall and winter precipitation does not reach the 50-cm and 100-cm depths until January. Soil water contents of the top 50-cm of the profile begin to decline in February with the onset of significant plant activity and growth.

Small differences in water storage may occur between areas occupied by shrubs and areas between shrubs. Soils at the 100-cm and 150-cm depths below inter-shrub spaces appear to be more variable with regard to soil water content. Although the data are based on few samples, the soil water content appears to be slightly lower at both the 100-cm and 150-cm depth near shrubs in April and May. This spatial difference in soil water content may be related to water use by the deeper-rooted shrubs. These sampling efforts were not intended to fully describe the soil water conditions on a seasonal basis, but to provide supplemental information for interpretation of plant parameters. Further investigation of soil water dynamics is needed to adequately quantify soil water availability for transpiration or drainage at the proposed site.

Data collected to describe rooting density through the top meter of the profile show considerable variability in root distribution (Figure 14). Root density (g/cm^3) is highest near the surface in the top 30-cm regardless of where the sample was collected. However, at a distance of greater than 60 cm from the main trunk of the shrub, rooting density at the surface is less than that found closer to the shrubs, and also appears to be less variable. Because we could not separate live from non-functional roots, rooting densities reported here may likely overestimate the amount of functional root system in each category. Root separation and determination of functionality is very difficult for plants growing in arid systems and little to no information is available for turnover rates of roots in shrub-steppe systems.

Figure F.14 also depicts an apparent increase in root density between 60 and 90 cm below the surface regardless of distance from shrubs. This increase may be related to a change in soil texture noted at approximately that depth. Drill logs for two of the boreholes located in the proposed ILAW site describe a change in texture between 60 cm and deeper depths.

Figure F.14 (e). Plot of Mean Root Density of all Samples >60 cm from Shrubs

F.3.6 Implications for Recharge Estimation

Data collected to this point indicate that several of the assumptions generally used for plant parameters in recharge estimation may need to be revised. Current modeling simulations estimate the evapotranspiration component of recharge based only on a single species. Improvements to the model to include multiple species or multiple plant functional types (shrub, grass, and forb) would greatly improve the evapotranspiration component. The differences in timing and phenology of the multiple species likely to be present on the disposal site need to be represented in the recharge modeling efforts. Both leaf water potential and growth data indicate that all three of the dominant species, big sagebrush, cheatgrass, and Sandberg's bluegrass carry out photosynthesis and transpiration during the winter months. The current evapotranspiration component of the model also assumes that the lateral distribution of roots is uniform. Data collected under this task indicate that root distributions are highly variable, and may well be influenced by community structure.

More sophisticated modeling efforts could incorporate critical temperatures for plant growth, LAI, stomatal conductance under non-limiting soil water availability, leaf water potentials, and even values for root resistance to water uptake and transport. Determining the relationship between soil/air temperatures and plant activity and growth would allow us to better quantify seasonal evapotranspiration and provide a realistic driving force for simulations of plant water use.

Appendix G

Quality Assurance and Safety

Appendix G

Quality Assurance and Safety

All laboratory and field experiments are conducted under PNNL quality assurance (QA) requirements as described in the guidance provided in PNNL's Standards Based Management System (SBMS) and as specified in the Project QA Plan. Significant modifications to the QA plan are made in accordance with the guidance in the SBMS.

Project staff members are qualified and receive any training needed to carry out their assigned responsibilities.

Staff use equipment of known accuracy for data collection. For measurements necessary to substantiate test results, staff ensure that standards used for calibration are traceable to nationally recognized standards. Measuring and Test Equipment (M&TE) lists are generated by each task and maintained in the project files applicable to the specific task. M&TE used is identified in the laboratory record books or other data recording location to provide traceability to instrument calibrations.

Test procedures and methods are documented and deviations noted. New methods developed during the course of this work are documented and reviewed. All test procedures, data processing software, and supporting documentation undergo independent technical review by qualified PNNL staff.

Staff maintain records necessary to substantiate results and processes of research activities. After activities are completed, records are filed and maintained per the project Records Inventory and Disposition Schedule (RIDS).

All precautionary measures are taken in accordance with standard PNNL safety procedures to ensure that field work is conducted in a safe manner. No hazardous wastes have been generated during the conduct of work described in this report.

This document was too large to scan as a single document. It has been divided into smaller sections.

SUMMARY

This data package functions to document the input data that will be used for simulations of the immobilized low-activity waste disposal system with the Subsurface Transport Over Reactive Multiphases (STORM) code. The STORM code will be used to provide the near-field radionuclide release source term for a performance assessment to be issued in March of 2001 and to provide the Department of Energy with an earlier (August 2000) assessment of confidence in meeting performance objectives for the ILAW disposal system. The STORM code requires input of two main general classifications of data: 1) multiphase flow, and 2) reactive transport. Multiphase flow input will principally be defined in the near-field hydraulic properties data package or the far-field hydraulic properties data package. All input related to conducting reactive transport calculations used to compute contaminant release rates will be defined within this data package. This includes a complete set of chemical reactions and supporting thermodynamic data that will make up the reaction network in the simulations. The majority of these data were extracted from the thermodynamic database package shipped with the geochemical code EQ3/6. However, several secondary reaction products identified from laboratory tests with prototypical BNFL, Inc. glasses were not included in this database, nor are the thermodynamic data available in the open literature. One of these phases, herschelite, was determined to have a potentially significant impact on the release calculations and so a solubility product was estimated for this phase.

Because of the continuing rapid evolution in glass development underway by BNFL, Inc., this data package is still in a very preliminary stage and must be viewed as a work in progress. The available laboratory testing data for several prototypic BNFL, Inc. waste glasses covering a wide range of potential glass formulations are discussed. However, base case calculations for the 2001 ILAW PA will focus on one prototypic ILAW glass, LAWABP1. Consequently, more extensive testing and analysis regarding this glass formulation are provided in this data package. Frequent updates to this data package are to be expected as new data are developed.

1.0 INTRODUCTION

The Hanford Low-Activity Tank Waste Disposal Program is planning to issue a performance assessment (PA) in March of 2001. The major goals of the performance assessment activity are to:

- support the design of disposal facilities
- provide the technical basis for the Department of Energy (DOE) to authorize construction of disposal facilities
- obtain approval to dispose of immobilized low-activity Hanford tank waste in those facilities
- provide a technical basis for final closure of the disposal facilities.

However, another critical near-term goal is to provide an early assessment of confidence in meeting performance objectives for the ILAW disposal system. This assessment has been requested by management at DOE-ORP to help support a decision in August of 2000 to award a contract to BNFL, Inc. for construction of a vitrification plant for low-activity waste.

A critical component of the PA will be to provide quantitative estimates of radionuclide release rates from the engineered portion of the disposal facilities (source term). Computer models are essential for this purpose because impacts on groundwater resources must be projected out to time periods of 10,000 y and longer. Details on the recommended technical strategy for developing this source term have been published [1] and have undergone review by an international panel of experts. The computer model selected for modeling the radionuclide source-term is the Subsurface Transport Over Reactive Multiphases (STORM) code [2]. The required inputs to this code will be derived from literature sources and from laboratory experiments with ILAW glasses. This report, therefore, functions to document the input data that will be used for STORM simulations. The STORM code requires input of two main general classifications of data: 1) multiphase flow, and 2) reactive transport. Multiphase flow input will principally be defined in the near-field hydraulic properties data package or the far-field hydraulic properties data package [3]. However, we will list the constants needed for STORM simulations. All input related to conducting reactive transport calculations will be defined within this data package.

For those data supplied by this activity, the values and supporting justification are described. Values are needed for (at a minimum) the best estimate case, an uncertainty case, and a reasonable bounding case. However, it must be recognized that because of the continuing rapid evolu-

tion in glass development underway by BNFL, Inc., this data package must be viewed as a work in progress. Frequent updates to this data package are to be expected as new data are developed. However, at the outset, we will attempt to bound the glass composition region currently anticipated by BNFL Inc. with the intent to reasonably bound the expected performance of their product.

Laboratory testing provides the majority of the key input data required to assess the long-term performance of ILAW glasses with the STORM code. Test data from four principal test methods, called out by McGrail et al [1], are discussed in this data package including the single-pass flow-through test (SPFT), pressurized unsaturated flow (PUF) test, product consistency test (PCT), and vapor hydration test (VHT). Test results using each of these techniques are provided in Chapter 2.0, Laboratory Testing. The different test methods focus on different aspects of the glass corrosion process. Linkages between the test methods, their principal function, and the data they provide for modeling are provided in Table 1. The interested reader is encouraged to consult reference [1] for additional details regarding these test methods and their use in evaluating long-term glass performance.

Table 1. Overview of Test Methods Discussed in this Data Package

Test Method	Temperature Range	Duration	Data Provided	Purpose
SPFT	25-90°C	14-28 d	Dissolution rate as a function of temperature, pH, and solution composition	Parameterization of kinetic rate law for glass dissolution
PUF	40-100°C	Months to years	Effluent chemical composition and dissolution rate as a function of temperature and flow rate, secondary phases, hydraulic property changes.	Highly accelerated test for glass screening, secondary phases for STORM reaction network, validation of STORM code.
PCT	20-100°C	Weeks to years	Solution composition and dissolution rate as a function of S/V ratio and temperature, secondary phases.	Glass screening, secondary phases for STORM reaction network, calibration of reaction network with EQ3/6 code.
VHT	70-300°C	Days to years	Rough estimate of dissolution rate as a function of temperature, secondary phases	Highly accelerated test for glass screening, secondary phases for STORM reaction network. Cannot be used for evaluating glass corrosion models.

2.0 LABORATORY TESTING

The results from laboratory testing of a large number of prototypic ILAW glasses are discussed in this chapter. It is organized in accordance with the four principal test methods, 1) Single-Pass Flow-Through (SPFT), 2) Product Consistency Test (PCT), 3) Vapor Hydration Test (VHT), and Pressurized Unsaturated Flow (PUF), specified in the strategic plan [1] for assessing the long-term performance of ILAW glasses.

2.1 PRELIMINARIES

The interested reader should consult McGrail et al. [1] for a thorough discussion of how each of the tests described in this Chapter fit into an overall strategy to evaluate the long-term performance of ILAW glasses. All testing work reported in this data package was conducted in accordance with PNNL's Quality Management System Description and associated Quality Assurance Program Documents (QAPD), which are maintained electronically as part of the Standards Based Management System or under an equivalent QA Program at Argonne National Laboratory (ANL). All instrument calibrations and materials are traceable, test procedures and associated training activities are documented in detail, and test methods comply with established plans and procedures. Computer Software and Database Control procedures are being followed for data analysis software being used to store, sort, and reduce data.

All staff members contributing to the work specified in this Test Plan received proper technical and quality assurance training in accordance with QAPD Training and Qualification for Staff. Equipment is either calibrated periodically or at the time of use and the calibration status of each piece of equipment is documented through a Material and Test Equipment sheet (M&TE), which is maintained as a part of the QA file. The M&TE sheets specify the required calibration methods, usually include a calibration procedure, and document the status of the equipment. All equipment requiring calibration prior to its use will be so labeled.

Documented procedures were used for sample preparation, test performance, and sample analysis. Operations not specifically covered in a documented procedure were documented in a Scientific Notebook. Comments regarding the test performance and test activities are contained in a Scientific Notebook associated with each test.

2.2 GLASS FORMULATIONS

The test results presented in the following sections will reference seven different ILAW glass compositions. These are provided in Table 2 for reference. It should be noted that LD6-5412 glass is a "high-temperature" glass formulation and has been included here because of the long history of studies with this glass. LRM-1 is an analytical reference standard glass developed at ANL [4]. LAWA23, LAWA33, and LAWABP1 are prototypic of ILAW glasses under development by BNFL, Inc.

Table 2. Composition (Mass%) of Selected ILAW Glasses

2.3 SINGLE-PASS FLOW-THROUGH TEST RESULTS

The SPFT test is an open system test where a solution at a known flow rate and constant temperature flows through a reaction cell that contains the sample. The configuration precludes recirculation of a portion of the effluent and so makes a "single-pass" through the reaction cell. Many different SPFT apparatuses have been developed, but these can all be classified as three basic types: 1) well-mixed batch, 2) packed bed, and 3) fluidized bed. The well-mixed batch type of apparatus was used for all test data reported here.

We have quantified the dissolution kinetics of LAWA33 and LAWABP1 glass compositions through the use of single-pass flow-through (SPFT). Because vitreous materials are metastable substances, and since dissolution reaction rates are slow, the glass-aqueous solution system cannot reach chemical equilibrium with the environment. Therefore, to understand the reactivity of potential waste glass candidates in subsurface environments, a complete knowledge of the dissolution kinetics of these vitreous materials is necessary. Although static (such as the PCT and MCC) tests are widely used to determine the behavior of glass-aqueous solution systems under repository conditions, SPFT experiments are ideal for elucidating the kinetic rate law parameters that will be used to model release rates into the geosphere. The usefulness of SPFT experiments stems from the system reaching a steady-state condition between the glass and the aqueous solution. Steady-state conditions ensure that the system is maintained at constant chemical affinity and the effluent is at a constant value of pH.

Over the last few decades, a general rate equation has been fashioned to described the dissolution of glass (and more ordered materials) into aqueous solution:

$$k_i = \overset{\mathrm{v}}{k} \nu_i a_{\mathrm{H}^+}^{-\eta} e^{\frac{-E_a}{\mathrm{RT}}} \left[1 - \left(\frac{Q}{K} \right)^{\sigma} \right] \prod_j a_j \qquad (1)$$

where: k_i = dissolution rate, g/m²/d
$\overset{v}{k}$ = intrinsic rate constant, g/m²/d
v_i = the stoichiometric coefficient of element i in the glass (dimensionless)
a_{H^+} = hydrogen ion activity
a_j = activity of the j^{th} aqueous species that acts as an inhibitor or as a catalyst of dissolution
E_a = activation energy, kJ/mol
R = gas constant, kJ/mol·K
T = temperature, K
Q = ion activity product
K = pseudoequilibrium constant
η = pH power law coefficient
σ = Temkin coefficient.

Although this equation is useful, there is still considerable debate in the scientific community regarding the identity and values of the above parameters. For example, it is well established that dissolution rates increase with an increase in the activity of the hydroxyl ion (i.e., pH), but it is not clear if other aqueous species inhibit or catalyze reaction rates. It is generally recognized, for example, that aluminum in solution causes a decrease in reaction rates of aluminosilicate materials [5], yet there is disagreement over how this effect should be taken into account in Equation (1). For example, some investigators advocate that the activity of aluminate and even silicic acid should be represented as an inhibitor term [6] like the hydrogen ion activity. Other investigators have proposed that the aluminate activity should be part of the pseudoequilibrium constant, along with the activity of silicic acid [7]. An additional uncertainty rests with the nature and value of the Temkin coefficient, σ, which represents the net reaction order of the dissolution rate. Investigators have reported values of σ ranging between 0.4 and 1 whereas others have recommended that σ should be ignored in the above equation.

Findings of our SPFT experiments to date will be presented with the data can be grouped into three separate sections: First, we discuss the effects of varying the ratio *q/s* (the flow-through rate divided by the surface area of the sample) on dissolution rates. Second, we elucidate the effects of adding Si and Al into the input solution. Third, we quantify the dependence of the dissolution rate on the pH of the solution. From these data, we are able to determine the values of the pseudoequilibrium constant for a glass, K_g, the intrinsic rate constant, $\overset{v}{k}$, the power law coefficient for solution pH, η. Values of other parameters, such as the activation energy, E_a, and the Tem-

kin coefficient, σ, can be reasonably estimated, as discussed below. Finally, we illustrate how SPFT data can be used to extract Na ion-exchange rates.

2.3.1 Description of the Experiments

SPFT experiments utilize Teflon reactor vessels that are connected to lines that transport aqueous solutions from the input reservoir and lines that carry solution to the collection vials, as illustrated in Figure 1. Computerized syringe or infusion pumps precisely control flow of aqueous solutions into the reactors. Reactors are housed in constant temperature ovens and powdered samples (typically the 75 to 150 μm size fraction) react with the volume of solution within the vessel. Effluent samples are collected continuously and aliquots are periodically retained for analysis. Concentrations of the elements are determined by precision ICP-AES and ICP-MS methods. Input solutions are made by combining deionized water, THAM (tris hydroxymethyl aminomethane), and nitric acid in variable amounts to yield solutions buffered at pH values of 2 to 10. Variable amounts of LiOH, stabilized by LiCl, make up solutions with pH values to 11. Currently, experimental data with variable pH conditions are limited to LAWA33 glass at 40°C; experiments utilizing LAWABP1 glass are so far restricted to pH=9. The effect of variable silicon (up to saturation with respect to amorphous silica) and aluminum (up to 500 ppb Al) were used to explore the effects of solution composition on reaction rates of both LAWABP1 and LAWA33 glasses. All input solutions are continuously sparged by nitrogen gas to prevent deviations from the initial pH values.

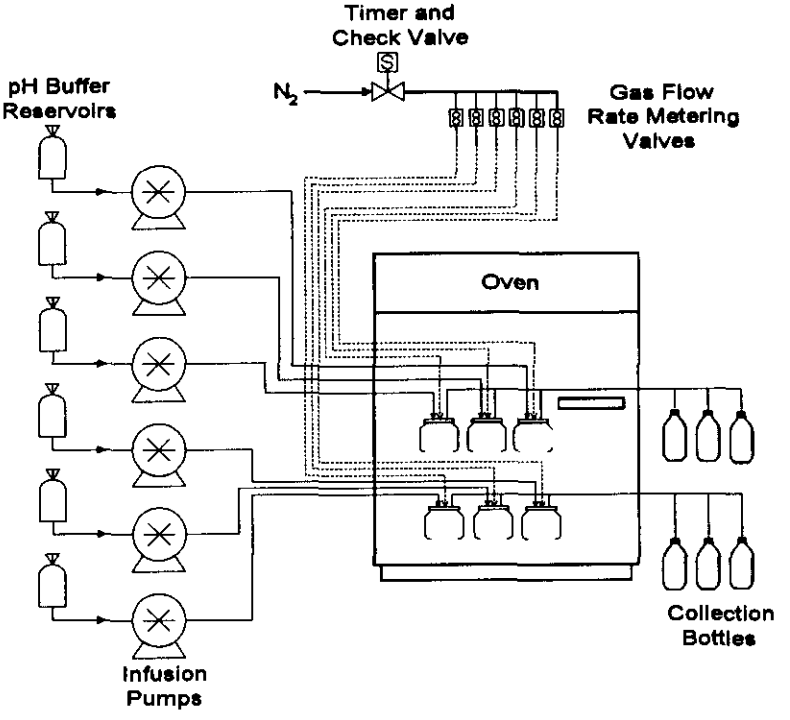

Figure 1. Schematic of Batch Flow-Through Reactor

Apparent dissolution rates are calculated from the expression:

$$rate_i = \frac{(C_i^{out} - C_i^{in})q}{f_i S} \quad (2)$$

where

$rate_i$ = the apparent dissolution rate of the glass sample as indexed by element i (g m^{-2} d^{-1})
C_i^{out} = concentration of the element of interest in the effluent (μg/L)
C_i^{in} = concentration of the element of interest in the feed solution (μg/L)
q = solution flow-through rate (L/d)
f_i = mass fraction of the element in the glass (dimensionless).
S = surface area of the material (m^2).

Blanks (effluent samples run through the system without glass powders) establish concentrations of elements of interest in the input solution. Apparent dissolution rates are calculated from steady-state concentrations of the elements of interest. 'Steady-state concentrations' refer to concentrations of the element of interest that are invariant with respect to time.

2.3.2 Results

The steady-state concentrations of elements in SPFT experiments are internally consistent, as evident by the figures discussed below. In brief, concentrations of elements of interest, especially B, Na, Al, and Si, when converted into dissolution rates by Equation (2), indicate only a small experimental uncertainty. Typically, dissolution rates based on multiple elements exhibit small differences, typically ≤0.2 log units (or ~1.6X). In some cases, particularly when low flow-through rates are used, the apparent dissolution rates between sodium and boron, for example, may be large. The reasons for this dispersion of data are rather easily rationalized, as discussed in the upcoming section. In a similar vein, duplicate experiments yield virtually no difference between the calculated dissolution rates. Typically, replicated experiments agree within 0.1 log units (or ~1.3X). There are, however, some notable exceptions to this generalization, as we discuss below. In summary, the experiments behave according to expectations and we have amassed a large amount of dissolution data that are discussed in the next several sections.

2.3.2.1 Effects of Variable q/s

Apparent dissolution rates increase with increasing ratio of *q/s* as illustrated in Figure 2. On this figure, $\log_{10}$ apparent dissolution rate is plotted against $\log_{10}$ *q/s* (m s^{-1}), where *q* is the flow-through rate (m^3 s^{-1}) and *s* is the surface area of the solid material (m^2). Thus, as the ratio of *q/s* increases (from left to right on the diagram), the apparent dissolution rates, based on concentrations of Si, Al, B, Mg, Na, and K, increase. At small values of *q/s* (left-hand side of the diagram), note that the apparent dissolution rates display a relatively wide range of values. For example, dissolution rates based on Al are systematically slower than rates calculated from boron concentrations. On the other hand, apparent rates based on sodium are faster compared to boron. As *q/s* increases, the apparent dissolution rates for the various elements converge toward a single value, so that for values of *q/s* $\geq 10^{-8}$ (m s^{-1}) rates based on Si, Al, B, Na, and K are indistinguishable. The systematics discussed above can be rationalized in the following way. For experimental conditions in which flow-through rates are low, concentrations of elements increase to the point where the system becomes saturated with respect to crystalline or amorphous phases. Aluminum is likely to reside in such phases, which keeps its concentration in the solution low and consequently artificially suppresses the apparent dissolution rate. On the other hand, sodium is released into solution by both matrix dissolution and ion exchange with hydrogen species in solution. Under conditions where glass matrix dissolution is slow due to high solute loading at low flow-through rates, the ion exchange mechanism dominates. Therefore, sodium release into solution is high and the apparent dissolution rates will have artificially high values. Boron is neither harbored in secondary phases nor is it leached to the extent that alkalis are. Accordingly, dissolution rates based on boron concentrations lie between the extremes manifested by Al and Na. With higher values of *q/s*, the convergence of dissolution rates towards a single value represents conditions in which the glass dis-

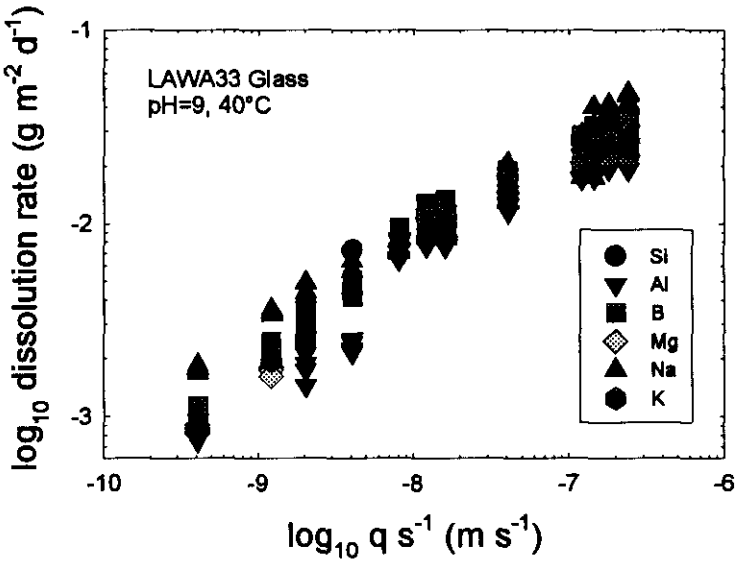

Figure 2. Plot of $\log_{10}$ q/s (Flow-through Rate/Surface Area) versus $\log_{10}$ Dissolution Rate of LAWA33 Glass, pH(25°C) = 9, T = 40°C

solves more congruently. Note also on this diagram that at the higher values of *q/s* ($\geq 10^{-7}$ m s^{-1}) that dissolution rates appear to become independent of *q/s*, although more experiments are needed to confirm this with certainty.

For the LAWABP1 glass, varying *q/s* values at 90°C yields results similar to those for LAWA33 glass at 40°C. Figure 3 illustrates that the dissolution rate (based on boron) becomes independent of flow-through rate above log *q/s* values of 6×10^{-8} (m s^{-1}). Therefore, the maximum dissolution rate under these experimental conditions (90°C, pH(25°C)=9) is ~0.14 g m^{-2} d^{-1}. Note that the relationships between rates based on Al, B, and Na displayed in Figure 3 are similar to those discussed above: at low values of *q/s*, the apparent rates based on Na are faster than those for the other elements. At higher values of *q/s*, the rates for all elements converge, indicating congruent dissolution.

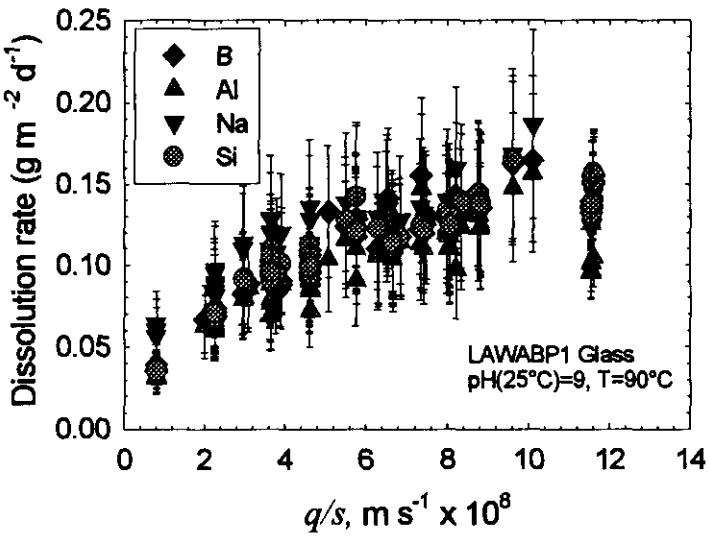

Figure 3. Plot of $\log_{10}$ q/s (Flow-through Rate/Surface area) Versus $\log_{10}$ Dissolution Rate of LAWABP1 Glass, pH(25°C)=9, T=90°C

The formal means of discussing the dependence of dissolution rate on flow-through rate is by the chemical affinity term. Succinctly, chemical affinity is a measure of a system's displacement from equilibrium; it is equivalent to the free energy of reaction as a function of reaction progress. Therefore, a small value of chemical affinity is equivalent to a small free energy value; i.e., the system is close to equilibrium with respect to a solubility-limiting phase. Conversely, a large value of chemical affinity is equivalent to a large free energy difference and the system is far from equilibrium. Accordingly, small values of log q/s (on the left-hand side of Figure 2 and Figure 3) are characterized by small chemical affinities and are closer to equilibrium. Larger values of $\log_{10}$ *q/s* (on the right-hand side of the above diagrams) are characterized by larger values of chemical affinity (dilute solutions) and the dissolution rates are predicted (and do) become independent of flow-through rates. The concept of chemical affinity is important in that it is tied to Equation (1) by the term: $1-Q/K$. As we discuss more fully below, the nature of the value of K, whether it is solely a

function of silicon activity or not, is an important concern for predicting the corrosion resistance of waste glass.

2.3.2.2 Effects of Variable Solution Composition

In Equation (1), the dissolution rate of a glass is inversely proportional to the ratio of the activity product, Q, divided by the psuedoequilibrium constant, K_g, assumed to be related to a solubility limiting phase that controls the glass dissolution kinetics. As the value of the activity product approaches that of K_g, the value of the term $1\text{-}Q/K_g$ approaches zero, suggesting that the dissolution rate should also go to zero. This is not strictly true since glass is a metastable substance and therefore cannot come to equilibrium with solution. Nevertheless, Equation (1) predicts that the dissolution will decrease as Q/K_g approaches unity.

As a starting point, K_g is represented by the equilibrium constant of amorphous silica, whose value is well understood in terms of temperature [8]. Below we address the question of whether the amorphous silica equilibrium constant is appropriate for vitreous materials other than SiO_2. To determine the relationship between silicon concentration of the solution and dissolution rate, we performed a series of experiments in which the concentration of silicic acid was varied from zero to near saturation with respect to amorphous silica. Figure 4 is a plot of dissolution rate (boron) for LAWA33 glass versus silicon concentrations in the effluent. Clearly, the dissolution rate decreases with the addition of silicon in the feed solution. It is also evident that the decrease in dissolution rate is linear over the solution compositions studied. Note also that these data can be used to compute values of k_o, K_g, and the concentration of silicon at saturation (C_{sat}); we will forgo further discussion of these parameters until a later section.

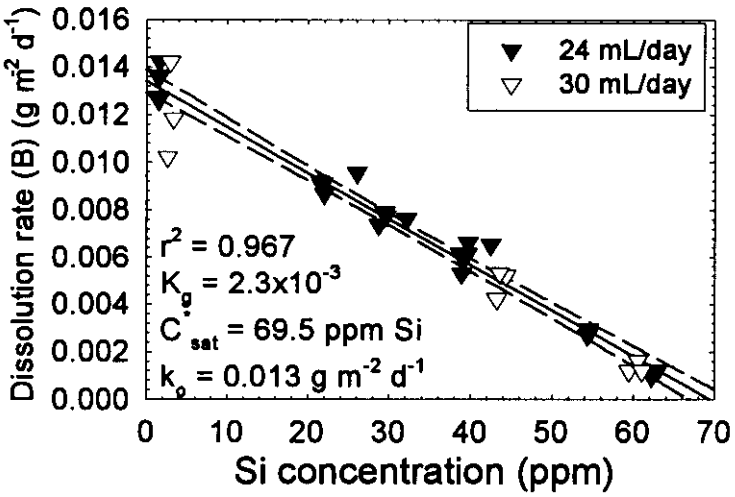

Figure 4. Plot of Dissolution Rate Versus Si Concentration of Effluent Solution, LAWA33 glass, pH=9, T=40°C. Solid line is the best fit and the dashed line is the 95% confidence interval.

The linear decrease in rate with Si concentration is interesting because it appears to validate the hypothesis of Grambow [9], which states that the dissolution of glass is rate-limited by the rupture of the Si—O bond, and so glass dissolution rate should vary linearly with the activity of silicic acid. If this relationship holds true for all glass compositions, then the task of predicting the dissolution rate with solution composition would be relatively simple.

Dissolution rate values based on elements other than boron also follow a similar linear trend as silicon is added to solution. For example, rates based on Al and Na concentrations are compared with the rates obtained for boron concentrations as a function of flow-through rate (Figure 5). In experiments with flow-through rates of 24 mL d^{-1}, apparent rates are fastest for sodium and slowest for aluminum with boron in between. These apparent discrepancies are due to the following. In the case of sodium, the rates are faster compared with boron, especially with greater silicon content of the solution. The release of sodium into solution is due to two distinct phenomena: Matrix dissolution and exchange of Na in glass for hydrogen species in solution. In the situation in which Si concentrations approach saturation with respect to amorphous silica, ion exchange is the dominant mechanism for the release of sodium into solution [10]. Accordingly, apparent sodium rates will appear to be faster compared to boron rates. In the case of Al, the rates are relatively slower with respect to boron. As previously discussed, this is due to retention of aluminum in solid phases when the solution approaches saturation. It is therefore evident that LAWA33 glass dissolves incongruently at 24 mL d^{-1}.

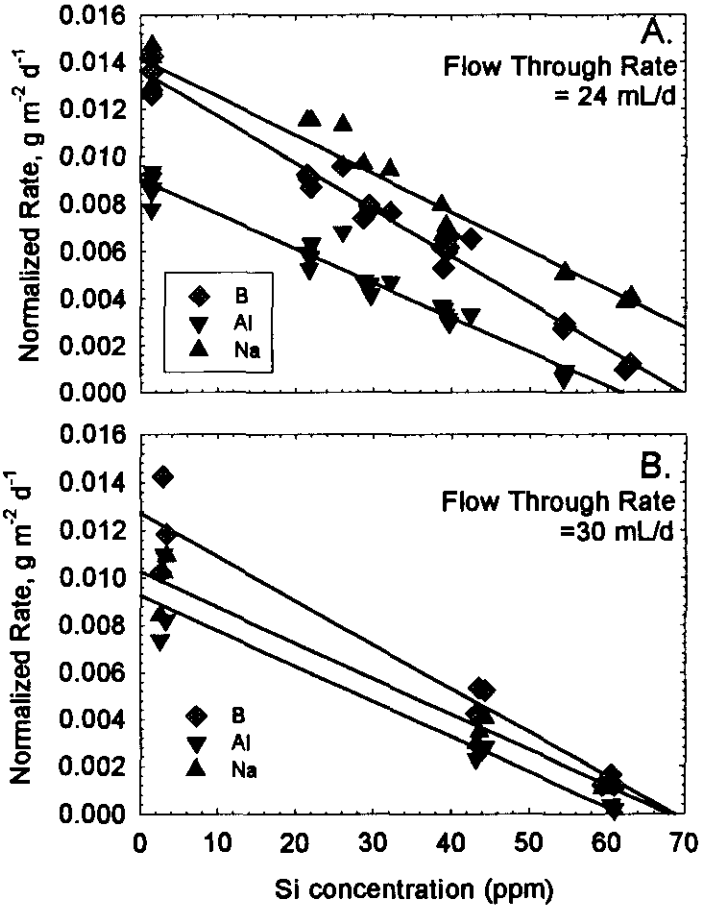

Figure 5. Plot of dissolution rate versus silicon concentration for LAWA33 Glass at 40°C and pH = 9.

In contrast, the results for experiments with flow-through rates at 30 mL/d are more consistent with congruent dissolution. Apparent rates for Na, Al, and Si

are approximately the same, within experimental error. These results again attest to the importance of the control of chemical affinity on the dissolution rate.

If dissolution of glass followed the rate law proposed by Grambow [9], it would be easy to predict the corrosion resistance of any vitreous waste products once knowledge of the chemistry of contacting solution is calculated (see Section 3.0). However, the rate law proposed by Grambow appears to fail under a potentially important set of circumstances, as described below. In addition, a number of investigators showed that dissolution rates are not linearly dependent on Si concentrations. These investigators proposed that glass dissolution is governed by the activities of aluminum and silicon in solution [7,11,12]. Gin [7] advocates a mixed Al-Si activity product formulation for the affinity term:

$$K_g = a[\mathrm{Al(OH)_4^-}]^{\nu_{Al}} a[\mathrm{SiO_2(aq)}]^{\nu_{Si}} \qquad (3)$$

where a denotes the activities of the species {$Al(OH)_4^-$ and $SiO_2(aq)$ are the dominant species in the pH-range investigated}, and ν_{Al} and ν_{Si} represent the mole fraction of aluminum and silicon in the glass, respectively. However, as pointed out by McGrail et al. [13], this assignment is strictly arbitrary and may not be consistent with the fundamental mechanisms controlling glass dissolution. The following discussion is an attempt to determine which of these formulations is appropriate for the glass compositions that we studied.

Figure 6 illustrates the relationship between dissolution rate and the concentration of Si in solution in experiments with LAWABP1 glass. This figure clearly indicates the non-linearity of the data. Therefore, the rate law proposed by Grambow [9] appears to be inappropriate for this glass composition.

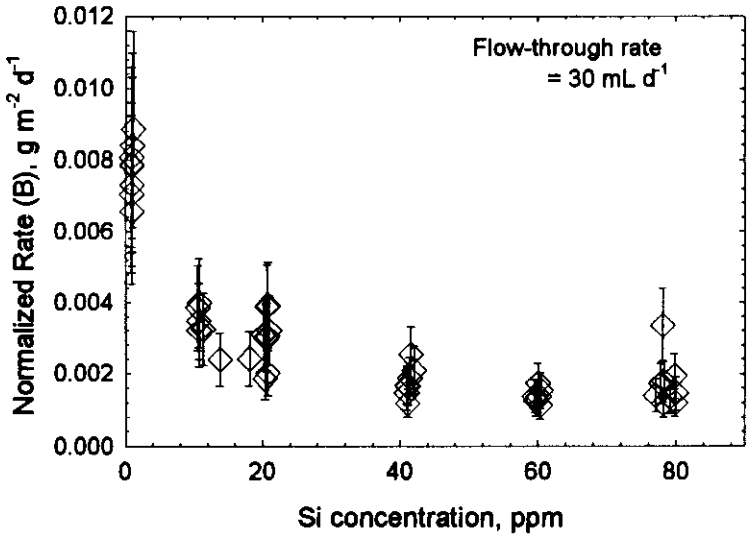

Figure 6. Plot of Dissolution Rate (Boron) Versus Silicon Concentration for LAWABP1 Glass at 40°C and pH(25°C)=9.

One possible explanation for the failure of Grambow's model is that aluminum is not accounted for in the affinity term. Accordingly, we plot in Figure 7 the dissolution rate of LAWA33 and LAWABP1 glass versus the mixed activity product term discussed above [Equation (3)]. The data for LAWA33 glass show a somewhat nonlinear relationship with the mixed Al-Si activity term. The Si sweep data in Figure 7b for LAWABP1 glass show a good linear trend but for experiments where we added Al to the input solution (labelled "Al sweep" on the diagrams), the trend of the data are in the direction opposite to that required by Equation (3).

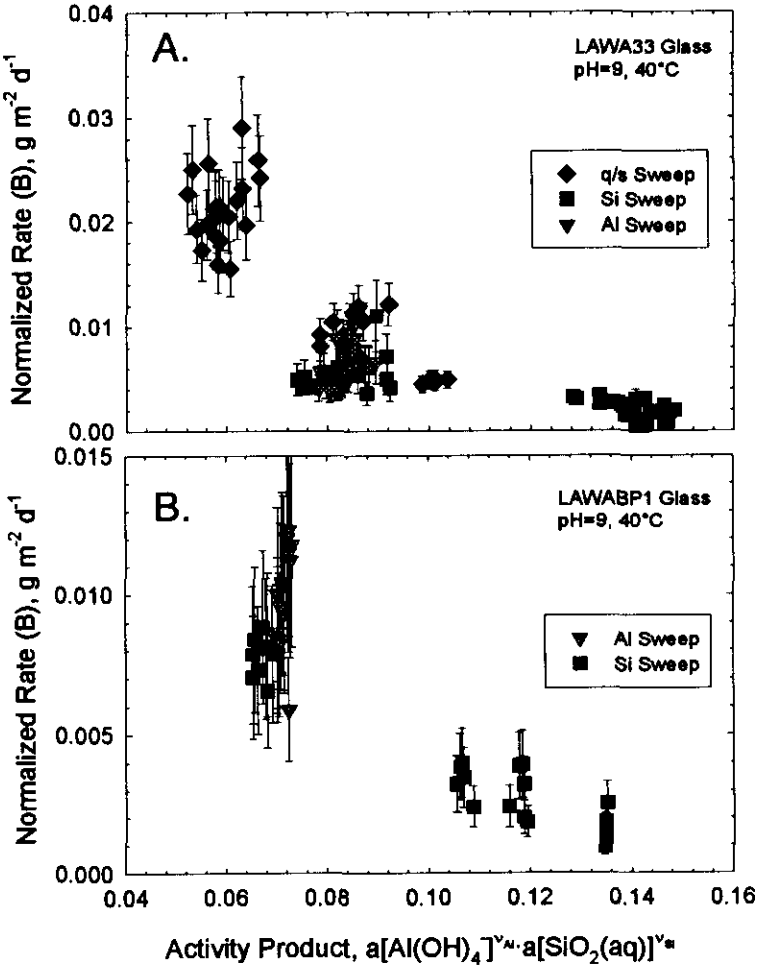

Figure 7. Plot of dissolution rate (boron) versus the mixed Al-Si activity product for (A) LAWA33 and (B) LAWABP1 glass, pH=9, T=40°C. Activities of Al and Si are raised to mole fraction of the element in glass (see text).

One potential flaw of the rate model proposed by Gin [7] is that there is no fundamental reason to raise the activities of the Al and Si species to the mole fraction of the element in glass. If the amorphous layer that develops on the surface of glass during reaction controls the chemical affinity term, there is no reason to use mole fractions of elements in glass. This is because the chemical compositions of the glass and the amorphous layer are distinctly different. In Figure 8, we plot the dissolution rate of LAWABP1 glass at 90 and 40°C as a function of the activity product K_g = $a[Al(OH)_4^-]\cdot a[SiO_2(aq)]$. Expressing the affinity term this way enhances the effect of the aluminate ion on the dissolution rate as compared with Equation (3). Although the correlation is not ideal, the overall fit to the data is much better. Consequently, we conclude that a simple activity product term best explains the entire set of data for LAWABP1 glass, although future mixed activity formulations

may prove to be better. From the x- and y-intercepts of a linear regression to the data, the forward rate constant (k_o) and K_g are obtained, as shown in Figure 8.

2.3.2.3 Effects of pH on Dissolution Rates.

Dissolution rates increase on both ends of the pH scale relative to near-neutral solutions. This is due to hydronium (H_3O^+) and OH- ions that increase reaction rates on the low and high ends of the pH scale, respectively. In basic solutions, the OH^- anion participates in a nucleophilic attack on the Si–O–Si framework bonds. In acid solutions, H_3O^+ readily exchanges with alkali ions in non-bridging oxygen sites and can also directly hydrolyze Si–O–B bonds [14]. Accordingly, most aluminosilicate glass compositions exhibit relatively fast reaction rates under acid and basic conditions and relatively slow rates at near-neutral pH conditions. Results from SPFT experiments with LAWA33 glass reveal the expected amphoteric behavior, as displayed in Figure 9A. Note that this figure depicts the dissolution rates based on multiple elements (B, Na, and Al), which are, for the most part, internally consistent. Because the solution percolating through the ILAW glass repository is anticipated to be basic, the results between pH values of 7 to 11 are especially relevant (Figure 9B). The slope of the line through these data points yields the power law coefficient, $\eta = 0.5$, for the rate-dependence on hydronium ion activity [see Equation (1)]. Although the LAWA33 and LAWABP1 glass compositions are different, we anticipate that the latter will be-

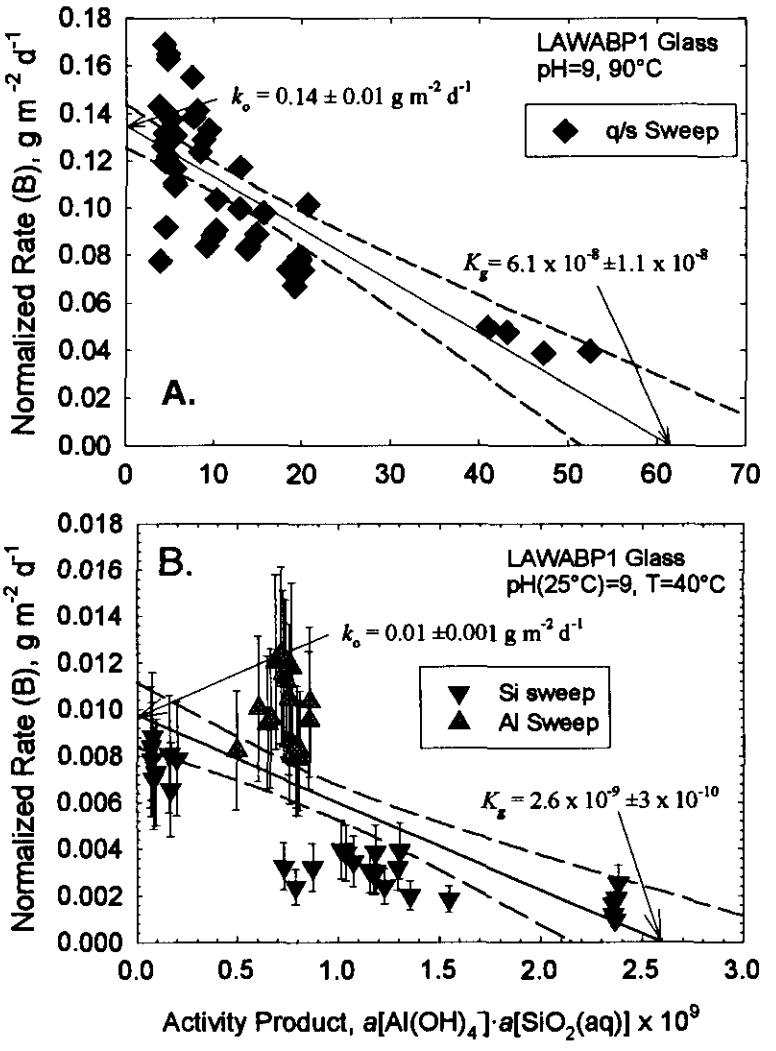

Figure 8. Plot of Dissolution Rate Versus Mixed Al-Si Activity Product for LAWABP1 glass at (A) 90°C and (B) 40°C

have similarly to the former. Accordingly, we recommend the value of 0.5 for the power law coefficient for LAWABP1 glass until the value can be determined experimentally.

2.3.2.4 Remaining Parameters

Two parameters remain from Equation (1) that have not yet been determined, the Temkin coefficient (σ) and activation energy (E_a). In previous carefully done SPFT tests with LD6-5412 glass, McGrail et al. [13] found that $\sigma = 1$ provided the best fit to their data. Furthermore, Lasaga [15] points out that the TST kinetic rate law is not fundamentally valid for $\sigma \neq 1$. Consequently, we will assign $\sigma = 1$ and not consider this "parameter" further. The apparent activation energy, E_a, can also be reasonably estimated from previous work with other glass compositions. Nearly all properly performed glass dissolution experiments yield activation energies of 75 ±5 kJ mol^{-1} and we recommend the temporary use of this value as well.

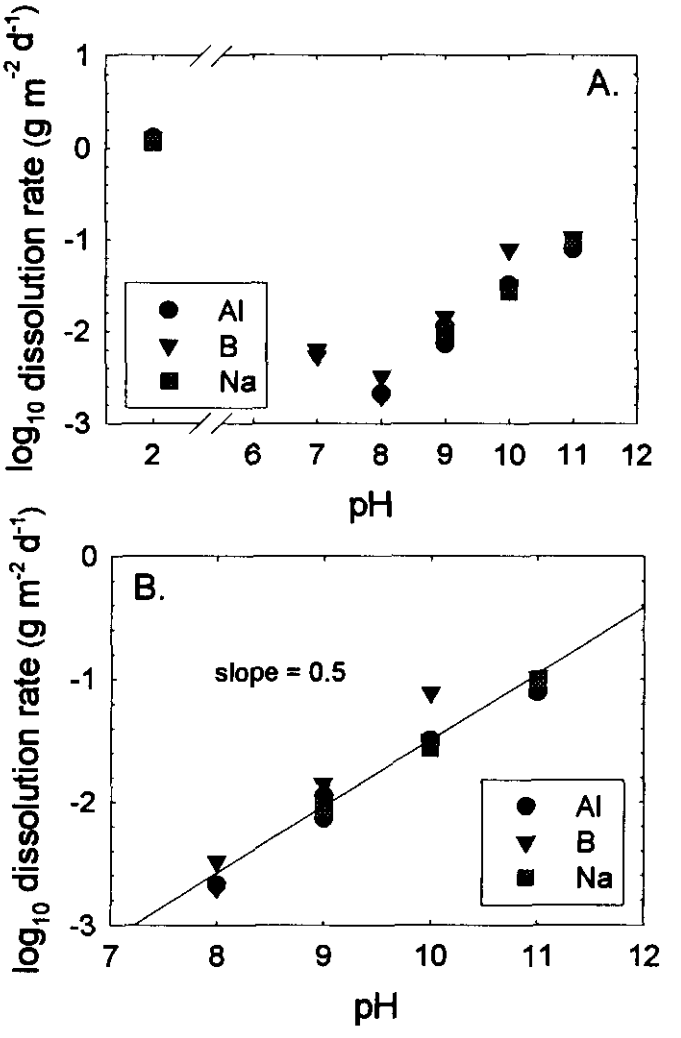

Figure 9. Plot of dissolution rate of LAWA33 glass versus solution pH for (A) full pH range investigated, and (B) alkaline range. T=40°C, flow-through rate = 30 mL d^{-1}

2.3.2.5 Na Ion Exchange

As was discussed in Section 2.3.2.2, as the solution contacting a glass becomes more concentrated with dissolved glass components, the rate of matrix dissolution declines. Under near-saturation conditions when the matrix dissolution rate is very small, a secondary reaction mechanism, alkali ion exchange, becomes the dominant process controlling the glass corrosion rate [10]. Because Na ion exchange can have a significant impact on the calculated release rates from an ILAW disposal facility [16], the Na ion-exchange rate for LAWABP1 glass is needed. Because

secondary phase formation is minimized in SPFT experiments, they provide one of the best means of extracting Na ion-exchange rates.

The rate of Na ion-exchange (r_x) was calculated via

$$r_x = f_{Na}(r_{Na} - r_B) \quad (4)$$

where r_{Na} and r_B are the normalized release rates of Na and B, respectively, and f_{Na} is the mass fraction of Na in the glass. Effectively, Equation (4) provides an estimate of the amount of Na released in excess of the amount contributed from glass matrix dissolution alone. In Figure 10, we plot r_x from SPFT experiments at 90°C at the smallest ratio of q/s tested and at 40°C from the Si sweep experiments with the largest amount of Si added to the influent solutions. These data sets were selected because they provided the smallest chemical affinity (most concentrated solutions) and thus maximized the contribution from the ion-exchange reaction. Because data are currently available at only two temperatures, the activation energy regressed from the data should be considered as tentative. Still, the estimated value of 50.6 kJ/mol is quite reasonable, consistent with a low energy barrier for removal of Na^+ from a non-bridging oxygen site in the glass and/or a transport controlled process (diffusion). Using this activation energy, the estimated Na ion-exchange rate for LAWABP1 glass at 15°C is 3.5×10^{-6} mol/(m²·d).

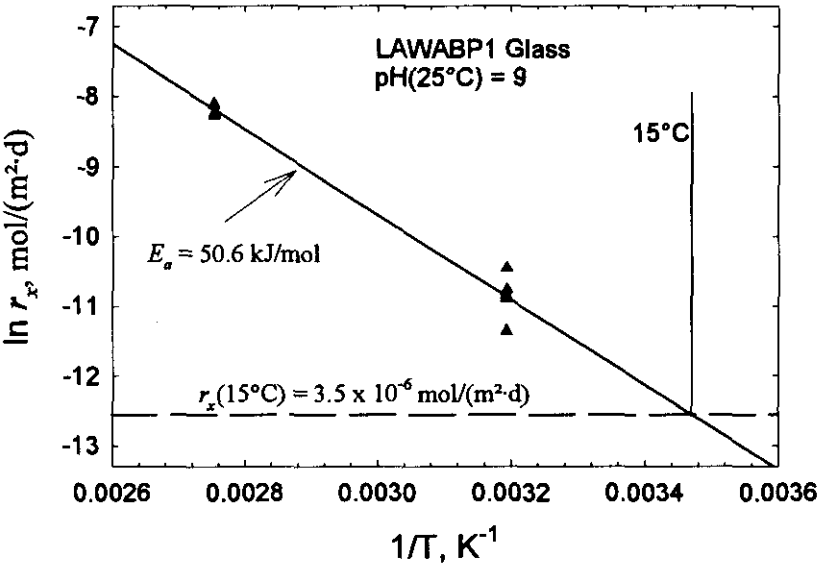

Figure 10. Plot of Excess Na Release via Ion-Exchange as a Function of Temperature From LAWABP1 glass at pH(25°C)=9

2.3.2.6 Future Experiments

The data presented in the foregoing sections demonstrates the utility of SPFT experiments for determining kinetic rate law parameters. Dissolution rate constants, pseudoequilibrium constants, and power law coefficients can all be obtained. Our next set of goals is to determine the dissolution rate as a function of pH and over a series of temperatures so that other parameters, such as the acti-

vation energy, can be obtained. We are also interested in further quantifying the effects of Si and Al in solution, especially over a range of temperatures. These data will allow us to determine the rate parameter values in a number of independent ways, which can then be used to check for internal consistency. We will be able to incorporate these variables into models that will bound the release rates over the expected composition region being considered by BNFL, Inc.

2.4 PRODUCT CONSISTENCY TEST RESULTS

2.4.1 Test Description

The Product Consistency Test (PCT) has been standardized as an ASTM standard procedure [17]. The ASTM standard includes two methods: PCT Method A was developed specifically for verifying process control of vitrified HLW forms and is conducted with specific values of test parameters; PCT Method B does not specify the values of test parameters. Because the PCT Method B encompasses commonly used variations of test parameters, we refer to all static dissolution tests with crushed glass generically as PCTs.

The PCTs are conducted by reacting an aliquot of crushed glass that has been sieved to isolate the desired size fraction with an aliquot of a solution in a sealed vessel at the desired temperature. There are three degrees of freedom for parameter variation in PCTs, temperature, glass surface area to solution volume ratio (S/V), and test duration. The glass surface area (S) is determined either by direct measurement with gas adsorption techniques such as Kr or Ar BET methods or as estimated from the size fraction of the glass [13]. Tests are conducted as batch tests wherein a separate test is run for each test duration. At the end of the test, the solution is analyzed for pH and the concentrations of dissolved glass components. The latter are used to calculate the amount of glass that has reacted and the dissolution rate. The reacted glass surface can also be analyzed to help characterize the reaction mechanism, such as when an alkali-depleted layer or alteration phases form.

2.4.2 ANL Test Results

Several PCTs are being conducted at glass surface/solution volume (S/V) ratios of about 2000 and 20,000 m^{-1} at temperatures of 40 and 90°C. The number of tests being conducted was limited by the amount of glass available. Test conditions were selected to allow direct comparison with test results for other glasses. Test solutions were passed through a 0.45 μm pore size filter, acidified

with nitric acid, then analyzed with inductively coupled plasma mass spectrometry (ICP-MS). Test results with LAWA33 glass are summarized in Table A.2. The results of blank tests give the detection limits for B, Na, and Si. Triplicate 7-day PCTs were conducted at 90°C; the results are compared in Table A.3 with 7-day PCT results with LD6-5412 glass, which was a low-level reference glass tested previously, and with SRL 51 and WV 6 glasses, which are non-radioactive reference glasses for waste forms made at the Defense Waste Processing Facility (DWPF) and the West Valley Demonstration Project (WVDP), respectively. Based on the 7-day PCT results, the LAWA33 glass is less durable than these other glasses. The LAWA33 glass is also less durable than LD6-5412 glass in PCTs conducted for longer durations. Alteration phases were not detected in any PCT with LAWA33. The average dissolution rate in the 7-day PCT is 0.025 g/(m^2·d) based on silicon.

2.4.3 PNNL Test Results

To date, only very limited PCT solution analytical data are available on BNFL, Inc. relevant ILAW glasses. All tests were run in Teflon PFA containers at 99°C. This temperature was selected to be consistent with PUF experiments that are also being run at 99°C. No solids analyses have been completed from these tests. A plot of normalized B release data for these glasses is given in Figure 11. Please see Section 3.2.4 for a discussion on how these data are used to derive input for STORM code calculations.

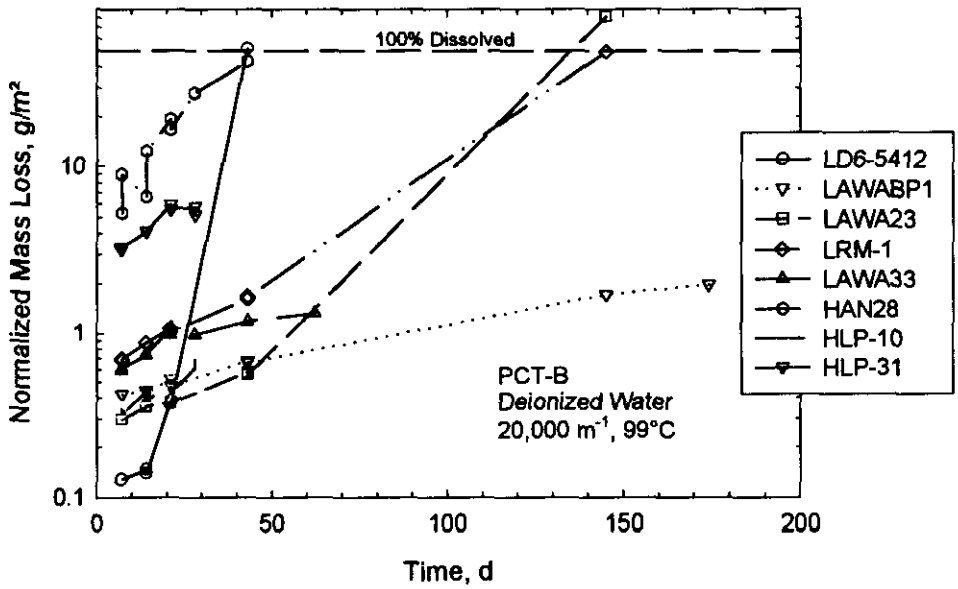

Figure 11. PCT Data for Selected ILAW Glasses

2.5 VAPOR HYDRATION TEST RESULTS

In the vapor-phase hydration test, VHT, monolithic samples are exposed to saturated water vapor at elevated temperatures (typically 100°C to 300°C) in a sealed vessel as shown in Figure 12. At relative humidity (RH) above about 80%, a thin film of water condenses on the sample. The thickness of the film increases with the RH, and it is in this film that the glass corrodes. The thickness of the film determines the effective S/V ratio of the system; for a uniform layer, the S/V ratio is simply the inverse of the thickness of the film. Most VHTs have been performed in 100% relative humidity at temperatures above 100°C, although tests have been conducted at lower humidities and temperatures. At the completion of a test, the sample is removed from the vessel, and the reacted surface is analyzed. Discrete precipitated crystalline phases usually form when the sample corrodes. The solution evaporates from the sample when the test is terminated and is not available for analysis. This precludes using the test to evaluate and test models of glass corrosion behavior, which require detailed measurements of the solution composition in contact with the glass.

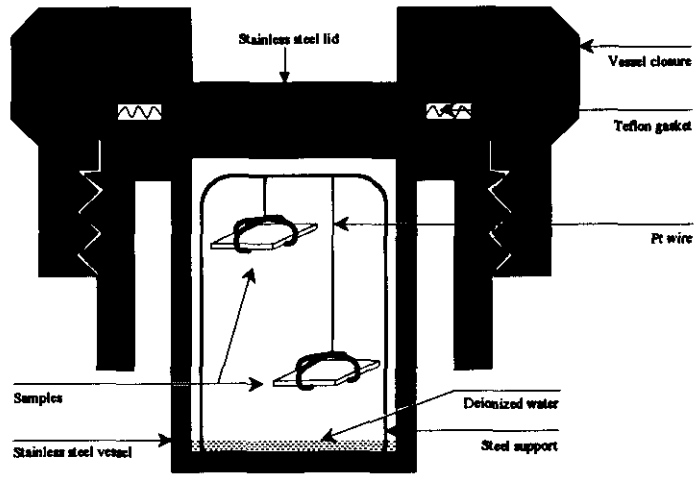

Figure 12. Schematic of Apparatus for conducting Vapor-phase Hydration Test

The VHT environment greatly accelerates the progression of glass corrosion by water. The VHT is the simplest accelerated test used in this testing program because there is only two degrees of freedom in test parameters that can be varied, temperature and test duration (excluding relative humidity). The principal uses of the test are 1) as a screening tool to quickly determine if a glass is likely to corrode at an extreme rate, 2) as a convenient means of generating alteration phases for analysis within a short period, and 3) for a measure of the corrosion rate at elevated temperatures. Vapor hydration has been used by archaeologists to replicate the weathering observed on obsidian artifacts recovered from terrestrial sites [18]. The method has also been used to simulate the long-term weathering of tektite [19] and basaltic glasses [20]. Because the test method produces the same alteration phases that form during the weathering of natural glasses over long periods, the test

has also been used to accelerate the corrosion of waste glasses. High-level waste glasses commonly form clay layers in VHTs. Glasses having compositions relevant to anticipated LAW for Hanford form zeolite phases similar to analcime, gobbinsite, and phillipsite.

2.5.1 ANL VHT Results

A small number of VHTs have been conducted at 150 and 175°C with LAWA33 glass to promote the formation of alteration phases. The tests that have been completed are summarized in Table 3. The glass alters to form a layer of clay (which is probably a smectite clay, based on preliminary analyses) initially and then an assortment of other phases at longer test durations. Analysis of these phases is in progress. Zeolites including analcime and a potassium-bearing analcime appear to be the most abundant phases, besides the clay. Whereas the alteration layers formed on samples reacted for short durations at both temperatures appeared homogeneous, those formed in the longer test durations have a complex microstructures with alteration phases both on top of and within a layer we presume to be clay. The layers and alteration phases are currently being characterized. The approximate thickness of the layers formed under different test conditions are summarized in Table 3. As expected, the glass reacts faster at 175°C than at 150°C, although significant alteration occurs at both temperatures. Not enough tests were conducted to determine the alteration rates after alteration phases formed at these temperatures, although the tests run for the longest durations provide lower bounds to the dissolution rates. Dividing the layer thickness of the 77-day tests at 150°C and the 28-day tests at 175°C by the duration, the minimum rates are 3.9 and 8.9 μm/day at 150 and 175°C, respectively. Assuming the density of the glass is about 2.5 g/cm^3, these rates are 9.8 and 22 g/(m^2·d) at 150 and 175°C, respectively. Assuming an activation energy of 80 kJ/mol, these rates extrapolate to 0.21 and 0.13 g/(m^2·d), respectively, at 90°C. These are lower than the forward rate estimated from the MCC-1 tests and higher than the average rate measured in the 7-day PCTs.

2.5.2 PNNL VHT Results

In addition to the eight glasses discussed in Section 2.4, four additional glasses (HLP-09, HLP-12, HLP-33, and HLP-56) were selected for detailed testing under the ILAW program. As PCT and PUF experiments with these glasses have only just been initiated, details regarding the test results have not been provided in this revision of the Waste Form Release Data Package. However, preliminary VHT results are available and will be discussed in this section. The VHTs were performed according to a PNNL technical procedure.[1] Samples with dimensions 10x10x1.5 mm are prepared from heat-treated glass bars using diamond impregnated saw. All sides are polished to 600 grit surface finish using SiC paper. Samples, stainless steel vessels, lids, and supports are cleaned and samples are suspended from a stainless steel supports on Pt wire. The amount of deionized water needed to saturate the inside of the vessel at given temperature (plus 0.05 ml excess of water, which is allowed to condense on samples surface) is added to the vessel. The sealed vessel is held at constant temperature in a convection oven for a preset time. After the test termination,

[1]Vapor-phase Hydration Test Procedure, GDL-VHT, Rev. 1, Pacific Northwest National Laboratory, Richland, WA (1999)

samples are removed from the vessel and examined for presence of secondary phases first by visual observation and optical microscopy. Amount of glass dissolved is determined by measuring the thickness of remaining unaltered glass as viewed in cross section with an optical microscope equipped with image analysis software. The alteration products are identified with X-ray diffraction (XRD) and scanning electron microscopy (SEM) with energy dispersive spectroscopy (EDS).

A matrix of 55 glasses was developed and tested with the aim to identify the impact of glass composition on the long-term corrosion behavior and to develop acceptable glass composition region [21]. Of the 55 glasses, 45 were designed to systematically vary the glass composition and 10 were selected because of large and growing databases on their corrosion characteristics had accumulated. The testing results of all 55 glasses are reported in detail by Vienna et al. [21]. The results for 12 of these glasses, pertinent to the ILAW testing program, are briefly discussed below.

Corrosion rates for each of the 12 glasses, including apparent activation energy (E_a) are summarized in Table 4. Note that these results represent the current status of testing and some rates/E_a may change significantly as new data become available.

Table 4. VHT Corrosion Rate Summary, (rates in g m^{-2} d^{-1}, E_a in kJ/mol)

	Phillipsite	39-1375	$KCa(Si_5Al_3)O_{16.6}H_2O$

11 Potassium Chloride	77-2121 KCl
12 Sodalite Group	82-1812 $Na_8(AlSiO_4)_6(ClO_4)_2$
13 Sodium Aluminum Phosphate Silicate Hydrate	43-0136 $Na_{13}Al_{24}Si_{13}P_{11}O_{96}\cdot 16H_2O$
14 Sodium Aluminum Silicate	74-1787 $Na_6Al_6Si_{10}O_{32}$
15 Sodium Aluminum Silicate Boron Hydroxide Hydrate	83-0550 $Na_{7.55}(AlSiO_4)_6(B(OH)_4)_{1.685}(H_2O)_{1.97}$
Sodium Aluminum Silicate Hydrate	84-0590 $Na_3Al_3Si_3O_{12}(H_2O)_2$
16 Sodium Aluminum Silicate Hydrate	34-0524 $Na_{5.7}Al_{5.7}Si_{10.3}O_{32}\cdot 12H_2O$
Sodium Aluminum Silicate Hydrate	42-0216 $Na_6[AlSiO_4]_6\cdot 4H_2O$
17 Sodium Titanium Silicate	29-1280 $NaTiSi_2O_6$
18 Zeolite P (Na-exchanged)	80-0699 $Na_{3.552}(Al_{3.6}Si_{12.4}O_{32})(H_2O)_{10.656}$
19 Sodium Calcium Silicate	37-0282 $Na_4CaSi_3O_9$

As is evident from the data in Table 4, glass corrosion rates vary by nearly 3 orders of magnitude in 200°C VHTs for the range of glass compositions tested. HAN28 glass shows the highest corrosion rate, consistent with the results observed in PCTs (Figure 11) and as will be discussed in Section 2.6, PUF tests as well. The best performing glasses in the VHT are HLP-9, HLP-10, and LAWABP1. At the present time, it is not well understood what compositional factors control the long-term corrosion rate of these glasses. The corrosion rate results are essentially a direct measure of the stability of the glass with respect to a suite of alteration phases that form as a consequence of the glass/water reaction. However, because of incomplete or inaccurate thermodynamic data for many of the phases listed in Table 6, predictive modeling of long-term glass stability with geochemical reaction path codes remains limited to much simpler glass formulations than are being considered here.

2.6 PRESSURIZED UNSATURATED FLOW-THROUGH TESTS

The PUF test is a new technique developed at PNNL for testing waste forms [22,23]. The experimental design provides a novel way to study waste form corrosion behavior under unsaturated conditions, subject to open-system flow and transport. Like the SPFT test, the PUF test provides three degrees of freedom for parameter variation: temperature, glass surface area, and flow rate.

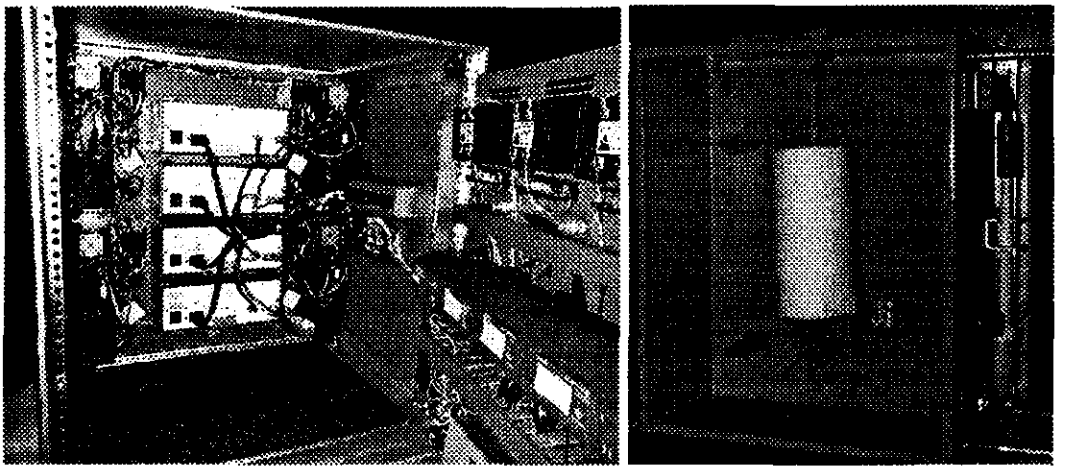

Figure 13. Picture of PUF System Hardware (Patent #5974859)

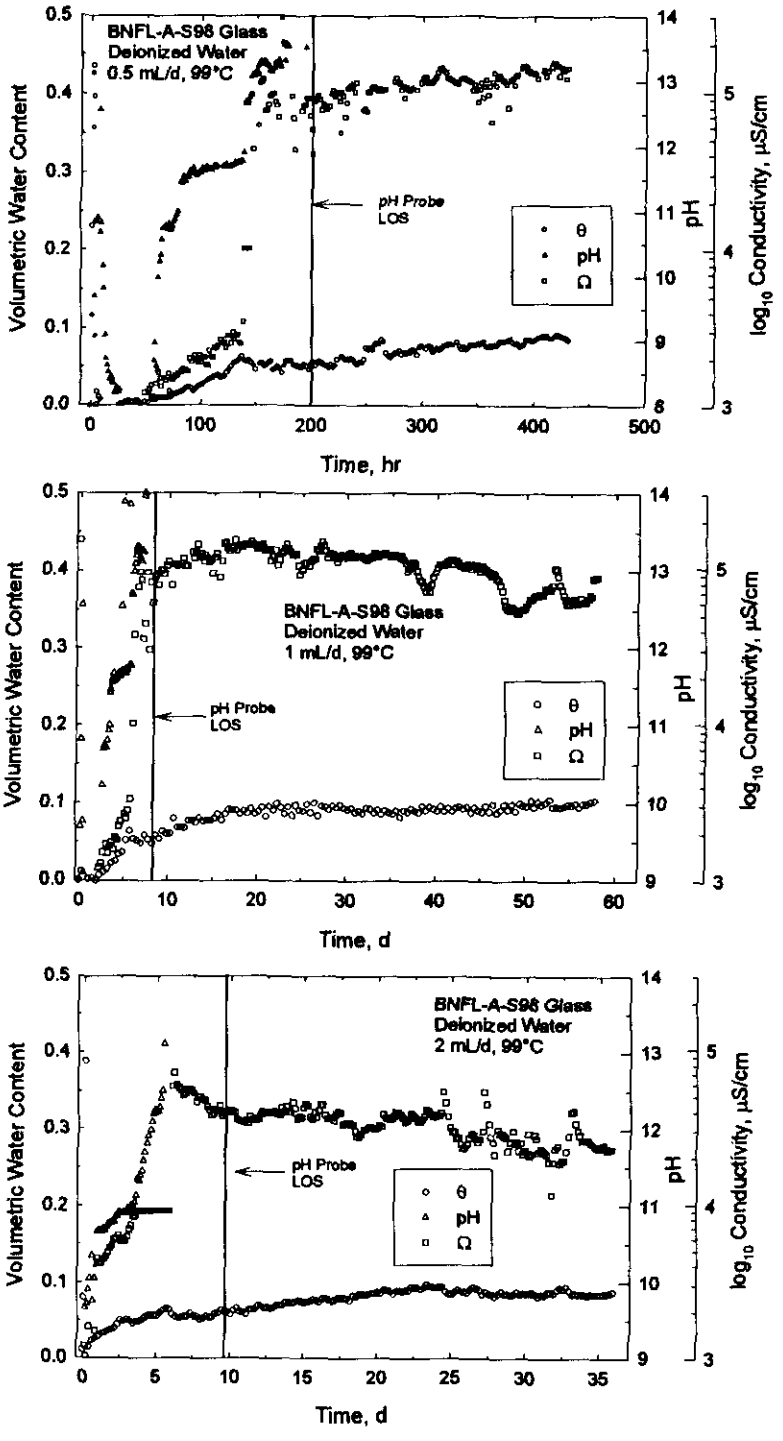
The basic test apparatus consists of a column packed with glass particles (or other material) of a known size and density, and a computer data acquisition and control system (see Figure 13). The column is fabricated from a chemically inert material so that dissolution reactions are not influenced by interaction with the column. A porous titanium plate with nominal pore diameter of 0.2 μm is sealed in the bottom of the column to ensure an adequate pressure differential for the conductance of fluid while operating under unsaturated conditions [24]. Titanium was chosen because it is highly corrosion resistant and has excellent wetting properties. When water saturated, the porous plate allows water but not air to flow through it, as long as the applied pressure differential does not exceed the air entry relief pressure or "bubble pressure" of the plate. The computer control system runs LabVIEW™ (National Instruments Corporation) software for logging test data to disk from several thermocouples, pressure sensors, inline sensors for effluent pH and conductivity, and column weight from an electronic balance to accurately track water mass balance and saturation level.

2.6.1 LAWA23 Glass

Three PUF experiments with LAWA23 glass (known also by the PNNL identifier BNFL-A-S98) have been completed. Details on these tests can be found in McGrail et al. [25]. Figure 14 shows the computer-monitored test metrics. Between 100 and 200 h, all three experiments exhibited a dramatic increase in effluent pH and electrical conductivity. The pH in all three experiments was tracked to values near or exceeding pH 14, whereupon sufficient corrosion of the solid-state pH electrode occurred to cause a loss of electrical signal. The computer-monitored test metrics in all three PUF experiments are now known as characteristic signatures of an autocatalytic acceleration

in glass corrosion rate that occurs after the formation of one or more alteration phases. Although we have observed similar rate excursions with other waste glasses, this was the first time that pH values in excess of 14 were ever monitored in a PUF experiment. The extreme pH values occur after the rate acceleration with BNFL-A-S98 glass because of the high alkali content of glass and the fact that a significant fraction of the SiO_2 in the glass has been replaced with metal oxides that increase solution pH when they dissolve.

XRD and TEM-SAED analysis of reacted solids (see SEM photos in Figure 15) removed from different positions in the PUF column showed diffraction peaks indicative of crystalline phases. Sodium aluminosilicate hydrate ($Na_{3.6}Al_{3.6}Si_{12.4}O_{32}\cdot 14H_2O$) zeolite was the major crystalline phase identified. Calcium silicate hydrate (CSH) was also found along with Na_2ZnSiO_4. The Na_2ZnSiO_4 phase is the round spheres scattered across the surface of the sample in Figure 15b.



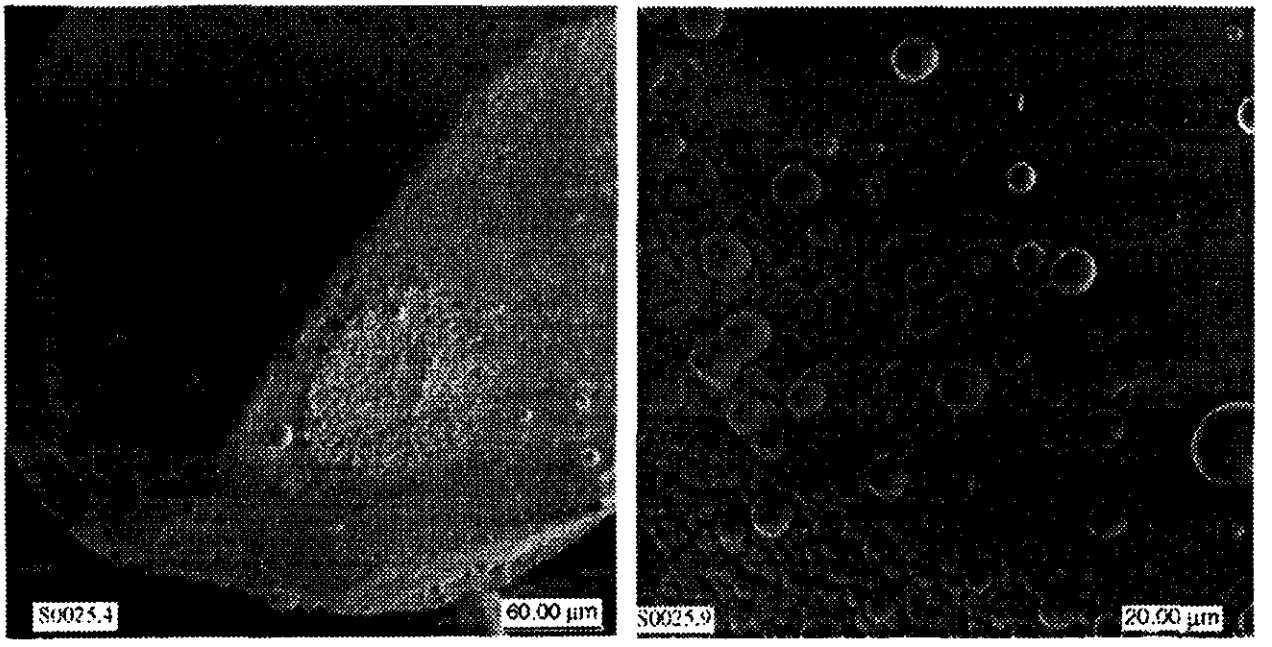


Figure 14. Test Metrics in PUF Tests with BNFL-A-S98 Glass (LOS = loss of electrical signal)

(a) (b)

Figure 15 Particle of BNFL-A-S98 Glass Reacted for 19 d at 99°C in PUF Test

Effluent samples from the same test were analyzed with ICP-MS and the results used to compute normalized release rates for the major glass components (see McGrail et al. [25] for details). The results are shown in Figure 16. The decline in the calculated rate with time is a consequence of the reduction in surface area due to extensive glass corrosion and mass loss after extended periods of time, which was not accounted for in the rate calculation. The calculated rate based on B release is very close to the expected forward rate of reaction of this glass at the test temperature and estimated effluent pH. A complete set of effluent chemical analyses for these tests is provided in Table 7 through Table 9.

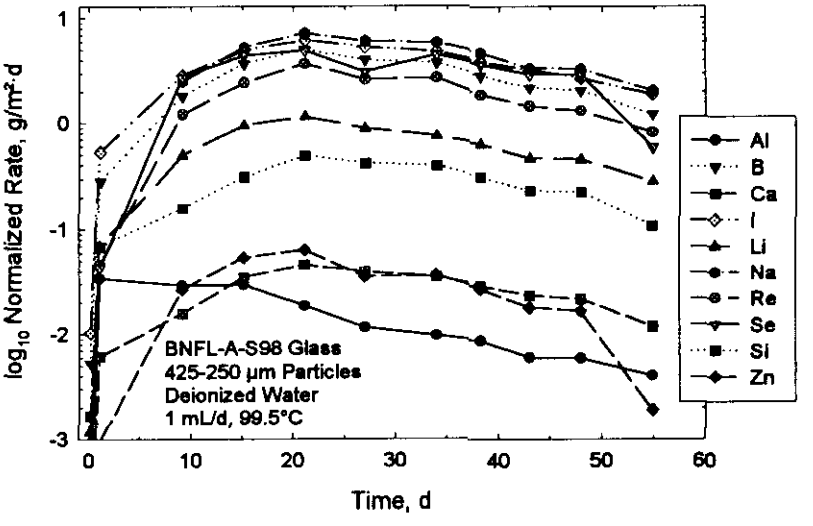

Figure 16. Normalized Release Rates in PUF Test with BNFL-A-S98 Glass

2.6.2 LAWA33 Glass

Given the high reaction rates observed with the LAWA23 glass formulation, a new formulation (LAWA33) was provided by BNFL, Inc. that did not contain Ca, a contributor to zeolite formation that is thought to be the major cause of the reaction rate acceleration. The glass also contained TiO_2 and additional ZrO_2, both of which are considered neutral or stability-enhancing additives. This glass was manufactured and heat-treated according to a cooling curve provided by BNFL, Inc. staff. An examination of the microstructure of this glass in the TEM showed no evidence of phase separation or devitrification as a result of the heat treatment.

Approximately 250g of this glass was prepared but because of poor sample recovery in the size fraction used in the PUF tests, only one experiment was initiated. The results from the computer-monitored test metrics are shown in Figure 17. A problem developed in mass tracking with the electronic balance and so the indicated water content in this test is only approximate. The electrical conductivity and pH traces indicate a fairly rapid increase in the glass corrosion rate. Electrical conductivities reached over 20 mS/cm after only 7 days and after 18 d of reaction, effluent pH values are approaching pH 13. Both of these indicators suggest a rapid rate of glass corrosion in the test. The column became plugged after approximately 100 d of reaction time whereupon the test was terminated.

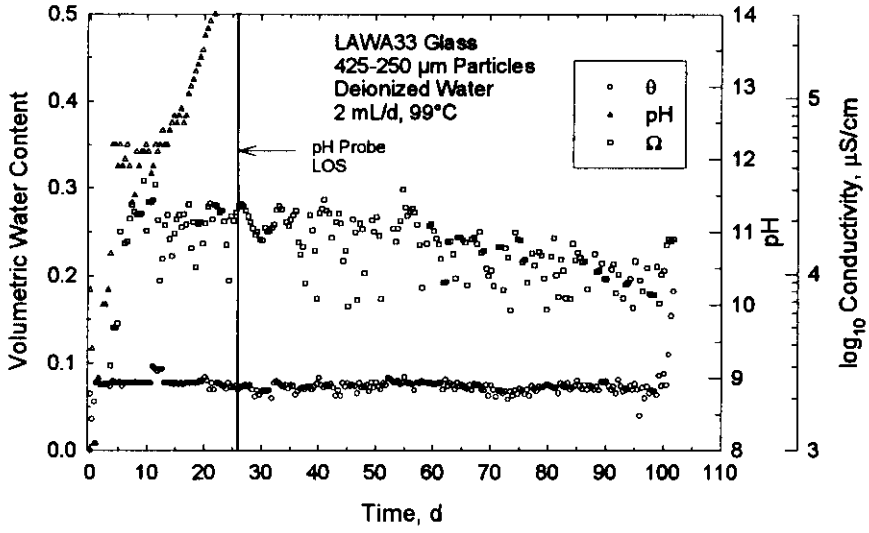

Figure 17. Electronically Monitored Test Metrics in PUF Test with LAWA33 Glass at 99°C and 2 mL/d Flow Rate

ICP-MS analyses of effluent samples were again converted to normalized release rates and the results are shown in Figure 18. The results confirm the high glass corrosion rate, again essentially at the forward rate of reaction at the temperature and estimated pH in the test. XRD and SEM analyses (see Figure 19) of reacted solids from the test showed that the major alteration phase was herschelite, $(Na,K)AlSi_2O_6 \cdot 3H_2O$, a sodium rich zeolite of the chabazite group.

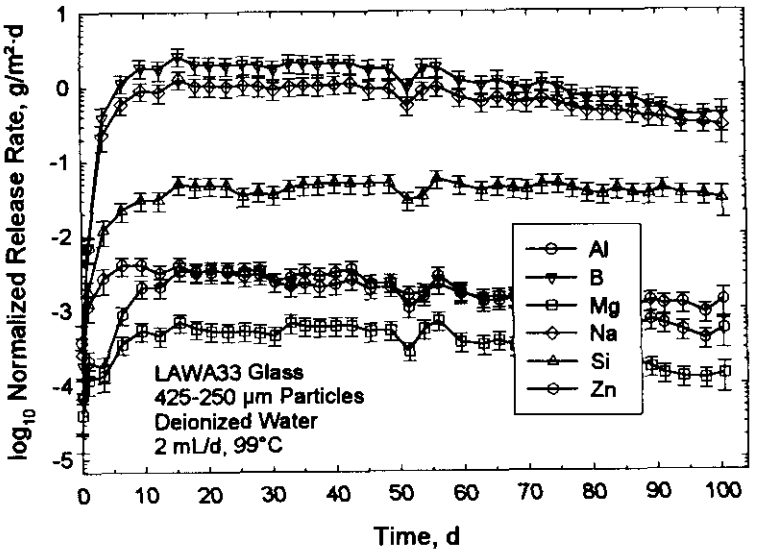

Figure 18. Normalized Release Rates in PUF Test with LAWA33 Glass

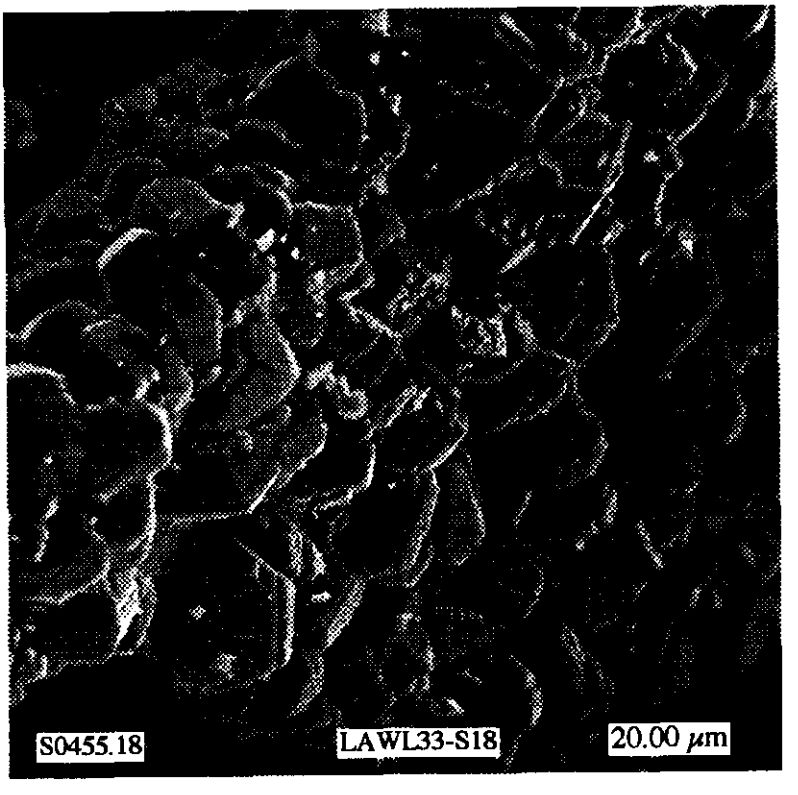

Figure 19. SEM Picture of Reacted Grain of LAWA33 Glass Densely Coated with Large Crystals of Herschelite, $(Na,K)AlSi_2O_6 \cdot 3H_2O$

2.6.3 LAWABP1 Glass

To ascertain whether improved long-term performance could be obtained by adjusting the additives in LAWA33 glass, a glass named LAWABP1 was formulated and manufactured. The composition of this glass is given in Table 2. A PUF experiment at 99°C and 2 mL/d flow rate was initiated with this glass and was terminated after 190 d. The results from the computer-monitored test metrics are shown in Figure 20. The electrical conductivity and pH data show that acceleration of the reaction rate has been delayed approximately three times longer than was observed for both LAWA23 and LAWA33 glasses. More importantly, the rate acceleration appears to be transient, with the rate relaxing back to a nominal value approximately 10X higher than before the acceleration occurred.

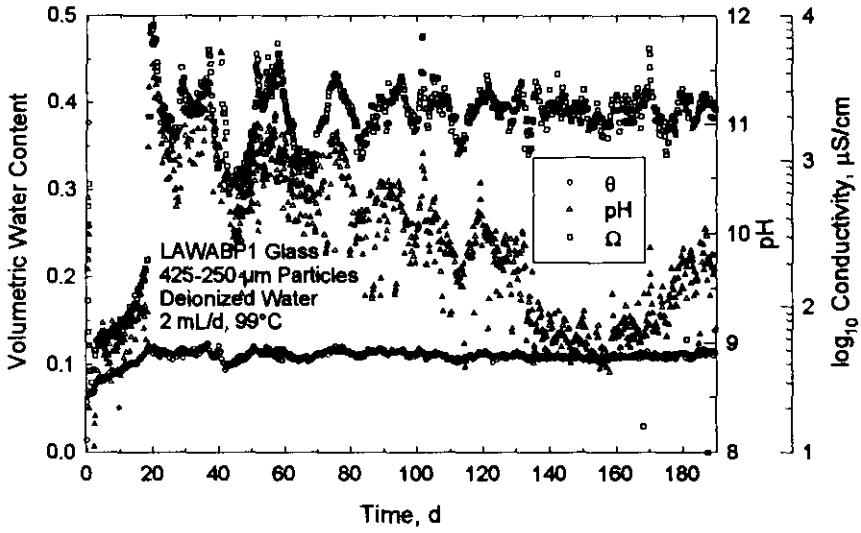

Figure 20. Electronically Monitored Test Metrics in PUF Test with LAWABP1 Glass at 99°C and 2 mL/d Flow Rate

ICP-AES analyses of effluent samples were converted to normalized release rates and the results are shown in Figure 21. There is a five order of magnitude spread in the release rates of the glass components. The soluble elements, such as B and Na, are released at the highest rates whereas highly insoluble elements, such as Ti and Zr, have the lowest release rates. An important difference in the effluent composition

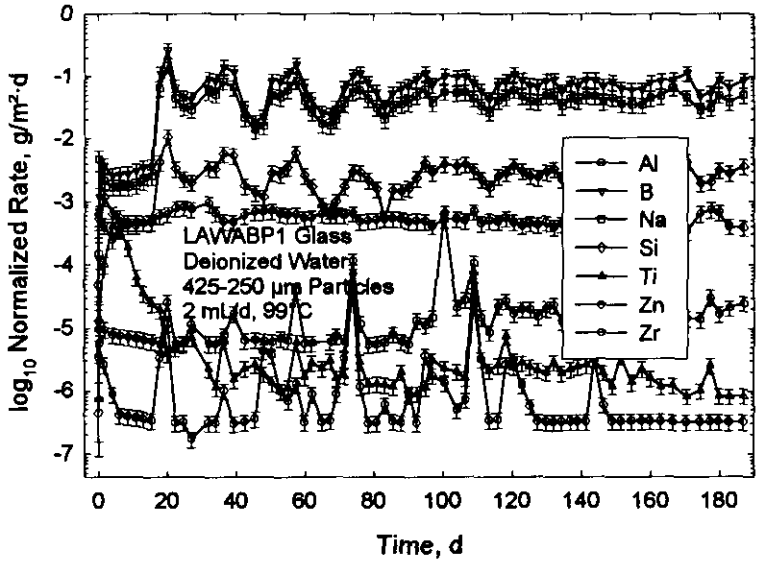

Figure 21. Normalized Release Rates in PUF Test with LAWABP1 Glass

from LAWABP1 glass as compared with LAWA33 glass is the ratio of the normalized B release to the normalized Si release. This value is approximately 60 for LAWA33 glass but only 25 for LAWABP1 glass, indicating that less of the Si is being incorporated into secondary phases, an important factor that slows the corrosion rate relative to LAWA33 glass.

A portion of the reacted solids removed from the LAWABP1 column were dried in glass vials at room temperature in a sealed can with $CaSO_4$ desiccant. Samples were dried until a constant mass was obtained. The observed mass loss was then used to compute the water mass fraction associated with the sample. The results are shown in Figure 22. The first three data points likely represent an imbibition profile as water drips from the fluid inlet onto the top of the porous glass bed. The water content peak observed at sample S9 is indicative of a precipitation front where water mass has accumulated in alteration products. A comparison of optical photo-

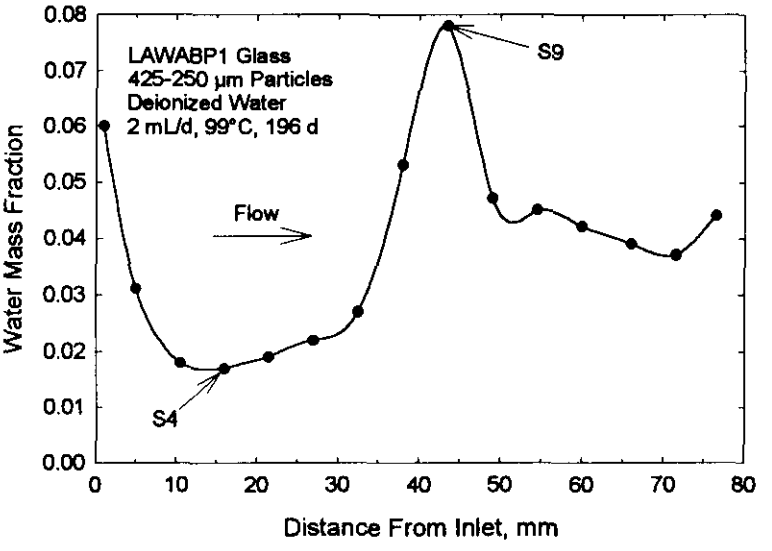

Figure 22. Water Mass Fraction as a Function of Position in Reacted Solids from PUF Test with LAWABP1 Glass. Samples labeled S4 and S9 were selected as representative of minimum and maximum water content samples.

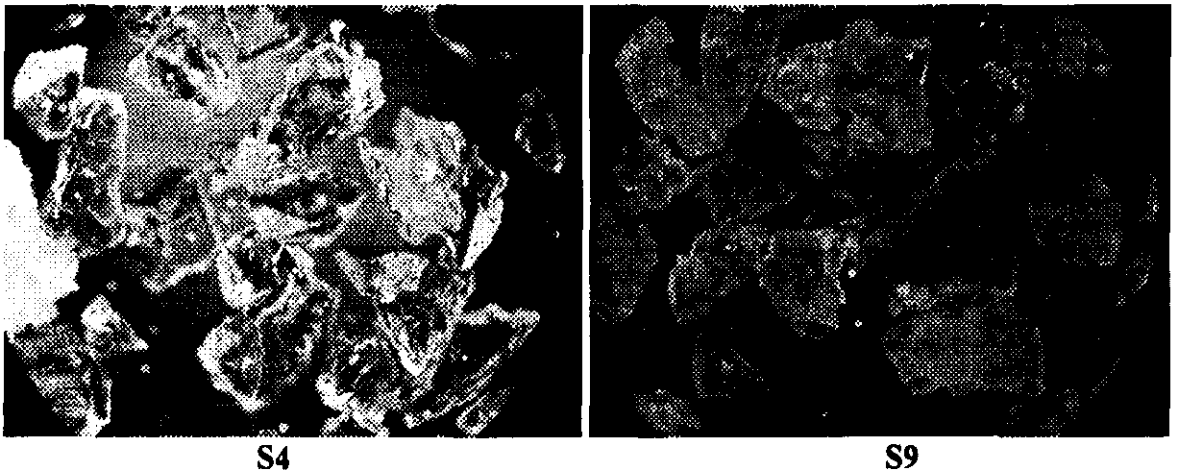

Figure 23. Optical Photos of LAWABP1 Glass Samples S4 and S9 After 190 d of Reaction in PUF Test at 99°C and 2 mL/d Flow Rate

graphs (Figure 23) taken on samples S4 and S9 clearly show this effect as the grains from sample S4 appear almost pristine whereas most of the grains from sample S9 are coated with alteration products.

SEM analyses of sample S9 reveals grains coated with an alteration layer (see highlighted area in Figure 24a) and several crystalline alteration phases. Energy dispersive spectroscopy (EDS) shows that Phase 1 is a mixed Na-K aluminosilicate and the crystal morphology clearly identifies it as herschelite. EDS analysis of Phase 2 shows it to be a pure Na-aluminosilicate and the crystal morphology is consistent with analcime. Phase 3 comprises the bulk of the alteration layer on the glass. EDS analysis indicates that the phase is enriched in Fe, Mg, Zn, and Ti and is most likely a nontronitic clay. Embedded in the clay layer were also small crystals with plate-like morphology (see inset of Figure 24b). This phase is enriched in Ti and Zn compared with the underlying clay layer. More detailed TEM analysis is underway to identify this phase.

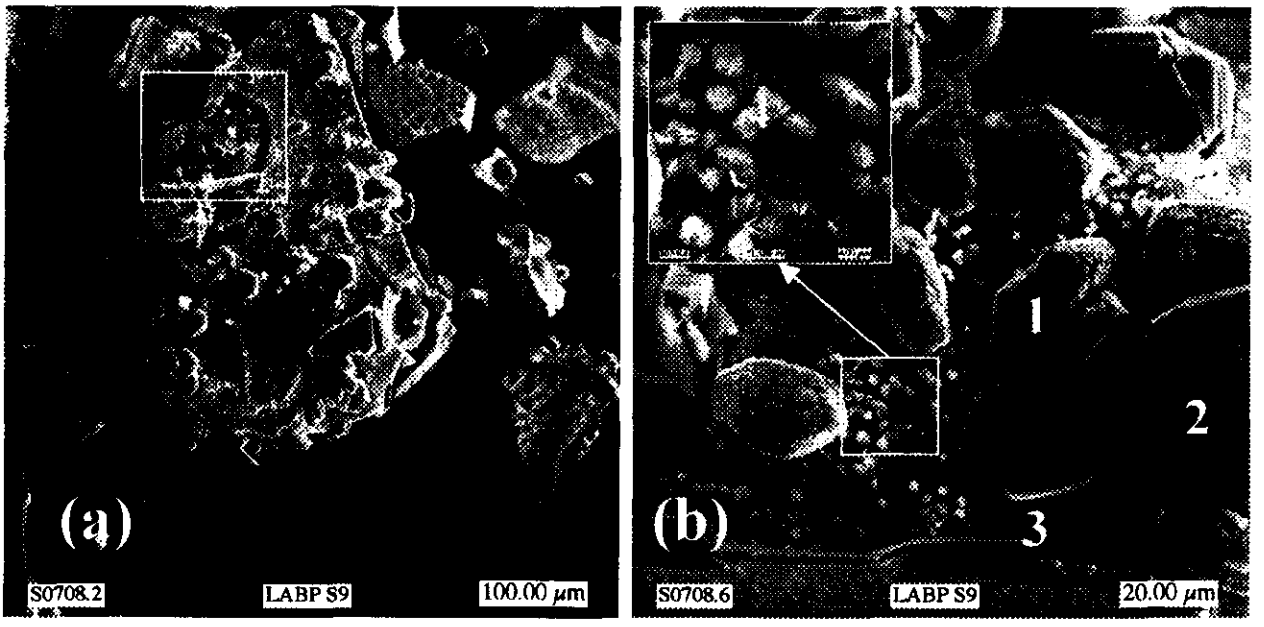

Figure 24. SEM Photos of Reacted LAWABP1 Glass Grains From Sample S9

2.6.4 HLP-10 Glass

The HLP-10 glass was one of two glasses (HLP-10 and HLP-31) selected from a much larger matrix of prototypic BNFL Inc. glasses whose corrosion behavior is being studied via vapor hydration tests [21]. The HLP-10 glass was selected because preliminary VHT data placed it

among the best performing glasses in the matrix while the HLP-31 glass was selected because it ranked as one of the poorer performing glasses in VHTs. The intent here was to ascertain whether similar behavior would be observed in PUF tests with these glasses. PUF tests with these glasses are still in progress at this time so only preliminary results are available.

Results from the computer monitored test metrics for the HLP-10 glass are provided in Figure 25. As was observed for LAWABP1 glass, periodic excursions in pH and conductivity have been monitored after about 20 d test duration. This glass also behaves similar to LAWABP1 in that it does not undergo a sustained acceleration in reaction rate as was observed for LAWA23 and LAWA33 glasses. Results from chemical analysis of the effluent samples are consistent with the data from the inline sensors, as illustrated in Figure 26. A comparison of the B release data for LAWABP1 and HLP-10 glasses suggests that on average, the corrosion rate of HLP-10 is equivalent to or slightly less than LAWABP1 glass under these test conditions.

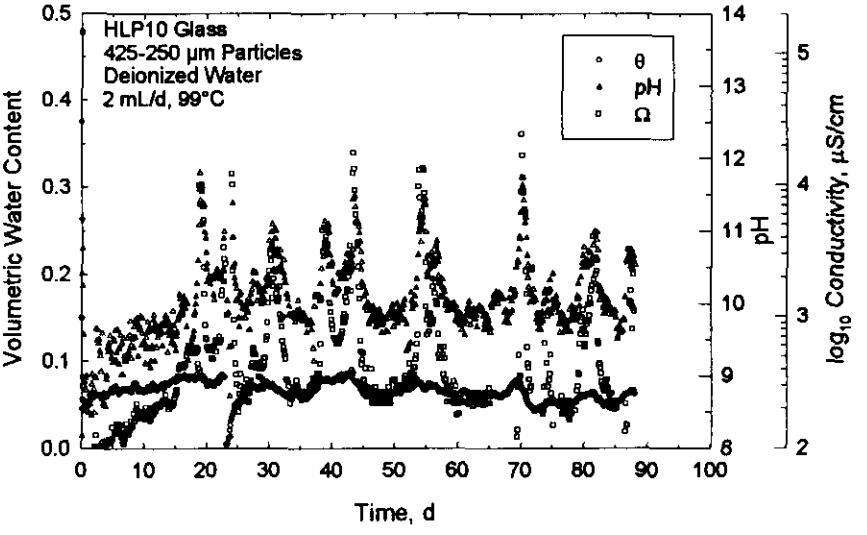

Figure 25. Electronically Monitored Test Metrics in PUF Test with HLP-10 Glass at 99°C and 2 mL/d Flow Rate

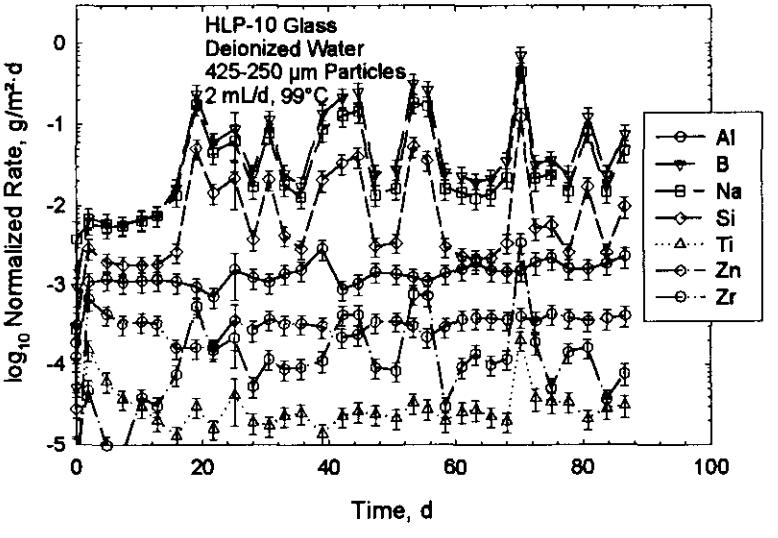

Figure 26. Normalized Release Rates in PUF Test with HLP-10 Glass

2.6.5 HLP-31 Glass

Results from the computer monitored test metrics for the HLP-31 glass are provided in Figure 27. The data show a very complex behavior with rapid swings in effluent pH and electrical conductivity. Volumetric water content also exhibits unstable oscillations that are the most intense we have ever observed in a PUF experiment. The effluent chemical composition again mirrors the data from the inline sensors, at least after approximately 25 days (Figure 28). The excursions are so rapid in first 25 days that the 3 day nominal collection period effectively smooths the data.

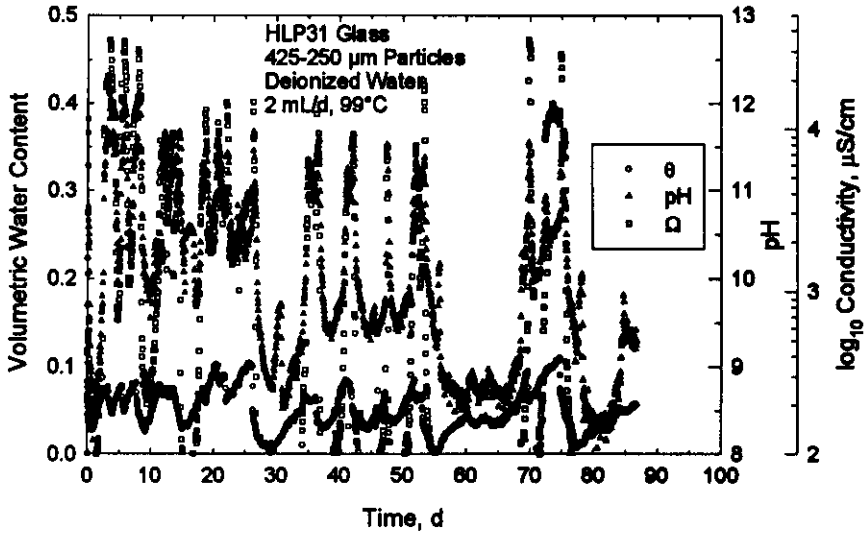

Figure 27. Electronically Monitored Test Metrics in PUF Test with HLP-31 Glass at 99°C and 2 mL/d Flow Rate

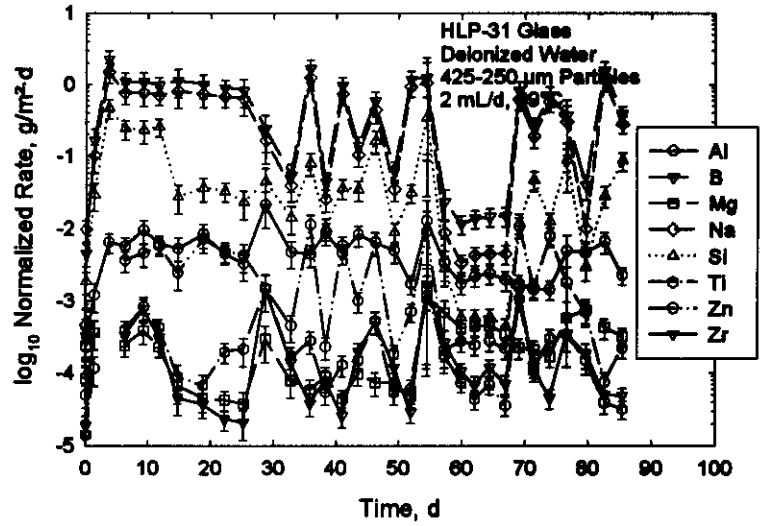

Figure 28. Normalized Release Rates in PUF Test with HLP-31 Glass

Still, the results indicate a very rapid rate of reaction on the order of 1 g m^{-2} d^{-1}, which is approximately a factor of 2-3 less than the expected forward reaction rate of this glass at 99°C and the average pH during the test.

2.7 CORRELATION BETWEEN TEST METHODS

In Sections 2.3 through 2.6, a large data set was presented covering a variety of different test methods and wide range of prototypic glass formulations for low-activity waste. The reader

should be aware that this data set is unique in the world in that it covers more test methods more thoroughly than has ever been done before for any waste form, including borosilicate waste glasses. The purpose of this section then is to examine this data set as a whole to determine what correlations, if any may exist between results from the various test methods.

The SPFT experiments stand alone in this data set as the test method is not designed to elucidate differences in the long-term behavior of glasses, as are the other test methods. As illustrated in Figure 29, the forward dissolution rate among a wide range of glass compositions varies very little. Consequently, the forward reaction rate for almost any reasonable BNFL, Inc. glass can be predicted with confidence. However, considerable uncertainty still exists regarding the form of the affinity term in the kinetic rate law for glass dissolution, especially regarding the role, if any, of Al. Insufficient data exist to draw definitive conclusions at this time except that the aluminate ion does appear to have an important role in regulating the kinetics of the glass corrosion reaction.

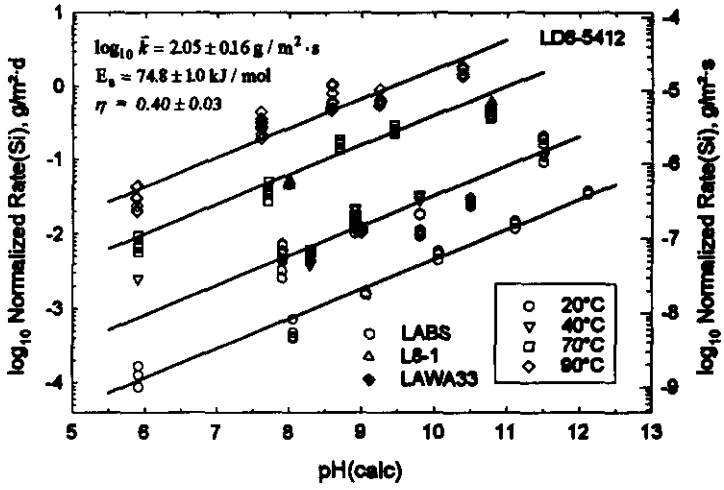

Figure 29. Forward Reaction Rate as a Function of Temperature and Solution pH for Four Different Glass Compositions

In Figure 30, we plot the normalized B and Na release data at 1000 h in the PCT versus the VHT corrosion rate at 200°C for the TFA matrix of 55 ILAW glasses. From the resulting random scatter in the data, we conclude that there is no correlation between the test results. This is not surprising because a 1000 h test duration in the PCT, even at a S/V ratio of 20,000 m^{-1}, is not sufficient to enter an accelerated reaction stage for many glasses, as was clearly demonstrated by the PCT results in Figure 11. Normalized releases prior to rate acceleration remain quite low but this does not mean that the glass will maintain good long-term stability. There are also technical difficulties in assessing normalized release (or glass corrosion rates) with the PCT method. Once a rate acceleration occurs, sufficiently large amounts of glass react that changes in surface area can be significant. Water consumption from hydrolysis of the glass and incorporation into secondary phases results in a time varying and essentially unknown S/V ratio. The stochastic nature

of rate accelerations often means that few data points are available from which to compute a rate once a rate acceleration does occur. For these reasons and the higher degree of acceleration available with the VHT and PUF test methods, they are preferred methods for evaluating long-term glass stability. Qualitatively however, the longer-term PCT data shown in Figure 11 are consistent with the results from PUF and VHT tests. The poorest performing glass is clearly HAN28, which also ranked lowest in VHT and PUF tests, and the best performing glass is LAWABP1. However, PCT data with HLP-31 show high initial release values, which would rank it poorer when compared with LAWA23. This is opposite from VHT and PUF test results with these glasses. Still, at longer test durations in the PCT, a rate acceleration is observed with LAWA23 glass, just as it was observed in PUF tests, which would change its relative ranking.

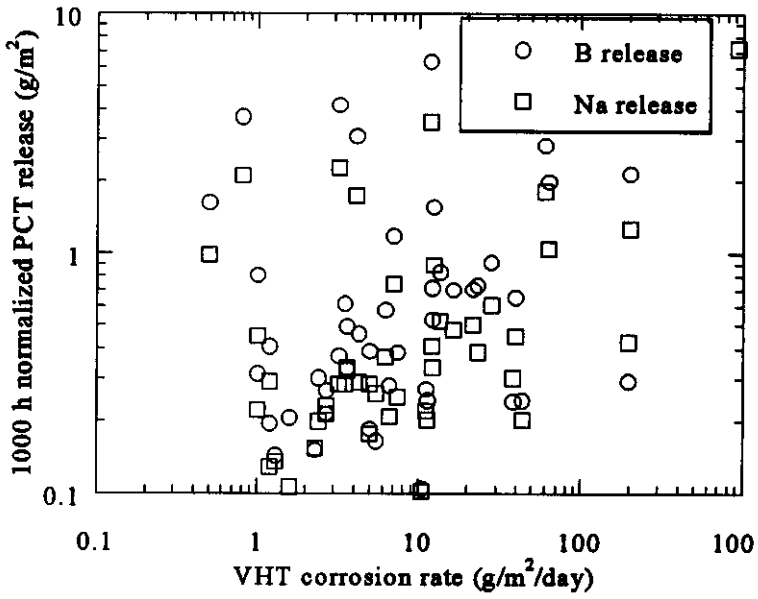

Figure 30. Comparison of 1000 h PCT Normalized Release With 200°C VHT Corrosion Rate

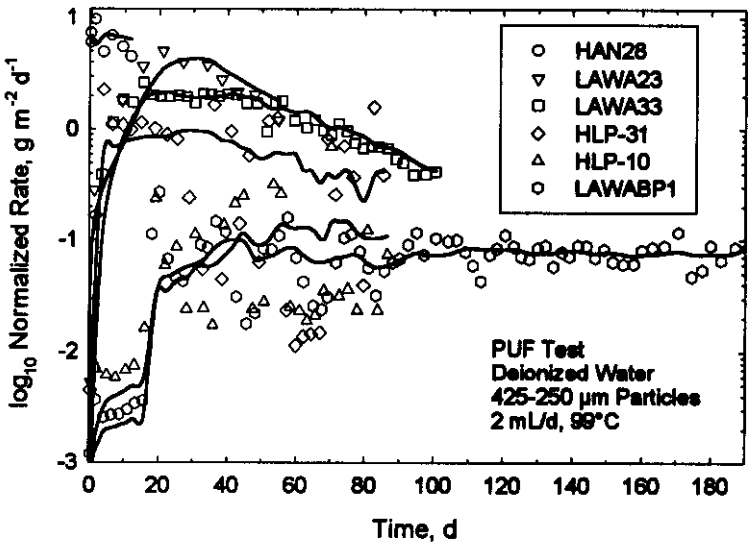

Figure 31. Comparison of Glass Corrosion Rate in PUF Tests at 99°C and 2 mL/d

In Figure 31, the normalized release rate of B in PUF tests with six different ILAW glass formulations are compared (Na was used for HAN28 as this glass does not contain B). The lines on the figure were computed by using a 4-point moving average for the HAN28, LAWA23, and LAWA33 glasses and a 10-point moving average for the HLP-10, HLP-31, and LAWABP1

glasses. The difference in dissolution rate as a function of composition and time become immediately obvious with the order being HAN28>LAWA23>LAWA33≥HLP-31> HLP-10≈LAWABP1.

A comparison of the peak dissolution rate observed in PUF tests versus the dissolution rate estimated in VHTs at 200°C is plotted in Figure 32. The peak dissolution rate was used from the PUF tests because for the glasses with high dissolution rates, the apparent corrosion decreases with time as the total unreacted glass surface area decreases and this is not taken into account in the corrosion rate calculation. The results suggest a good correlation between the VHT and PUF test results ($R^2 = 0.91$). Given that similar secondary phases formed in both types of tests, a correlation between the results from these highly accelerated tests might be expected. We conclude that when the results from all three accelerated test methods, VHT, PCT, and PUF are viewed as whole, a remarkably consistent picture about the long-term performance of ILAW glasses emerges.

3.0 STORM CODE INPUTS

3.1 MULTIPHASE FLOW INPUT

Multiphase flow input data to STORM consists of entries for 1) lithographic units, 2) hydraulic properties, 3) hydraulic initial conditions, and 3) hydraulic boundary conditions. These data are to be principally defined from facility design documents, the near-field hydraulic properties data package, or the far-field hydraulic properties data package [3]. STORM will be used to compute the flow-field in the near-field region based upon hydraulic properties for the materials, specified initial and boundary conditions, and water consumption/release from chemical reactions.

3.1.1 Material Zonation

To establish a consistent framework for overlaying a computational grid on the spatial domain of interest, a set of material zones or lithographic units are established with similar hydrogeological and geochemical properties. These zones are usually related to disposal design components, geologic formations, or geologic facies determined from borehole analyses. However, because limited information is available on physical properties at a given spatial resolution, material zones may also include combinations of materials that are assigned uniform hydraulic and/or chemical properties. Classification of these materials into appropriate zones will be performed as a part of the near-field hydraulics data package [3]. The material zones that will be considered are:

- Waste glass
- Waste package container
- Filler material between waste packages
- Portland concrete
- Back-filled soil
- Glass conditioning layer
- Hanford sands
- Hanford gravels
- Ringold formation

3.1.2 Material Hydraulic Properties

The hydraulic properties for each material zone in the simulation will be determined as a part of the near-field hydraulics data package [3]. For each defined rock/soil type, the following data is needed:

- Nonhysteretic van Genuchten parameters
  - "α" parameter, units (1/m)
  - "n" parameter
  - Minimum saturation
  - "m" parameter
- Particle density
- Porosity
- Specific storativity
- Compressibility
- Tortuosity
- Intrinsic permeability
- Intrinsic permeability function options:
  - Constant
  - Kozeny and Carmen
  - Fair and Hatch
- Aqueous Permeability function options:
  - Constant
  - Mualem or Burdine parameter
  - Van Genuchten "m" parameter
  - Tabular w/ water content
- Gas Permeability function options:
  - Constant
  - Mualem or Burdine parameter
  - Van Genuchten "m" parameter
  - Tabular

3.1.3 Hydraulic Initial Conditions

Initial hydraulic conditions for each material zone will be provided from either the near-field or far-field hydraulics data package [3] as follows:

- Water content
- Water flux
- Dissolved gas content of aqueous phase
- Gas pressure

- Relative humidity of gas phase
- Temperature

3.1.4 Hydraulic Boundary Conditions

The hydraulic conditions of the upper boundary will be determined as a part of the recharge data package [26]. For the base analysis case, the upper boundary will be defined just below the capillary break. Sensitivity cases examining the effects of mass redistribution on the hydraulic properties of the capillary barrier will require setting the upper boundary above the barrier. The following data is needed as a function of time and space along the boundary:

- Water content
- Water flux
- Dissolved gas content of aqueous phase
- Gas pressure
- Relative humidity of gas phase
- Temperature

The side boundaries will be placed at axes of symmetry so that they can be assumed to be no-flow boundaries. The lower boundary will be placed far enough below the waste form so that vertical concentration gradients are small. For hydraulic boundary conditions at this lower boundary, free drainage under gravity will be assumed.

3.2 REACTIVE TRANSPORT INPUT

3.2.1 Lithology

For each material zone, a list of the solid species that comprise that material is required. For each of these solid species in each material zone, the following data is needed:

- Relative volume
- Particle radius

Values for these variables are listed in Table 10 and Table 11. The waste package is assumed to consist of 304L Stainless Steel container filled with LAWABP1 waste glass. For Hanford sands and backfill soil, petrologic and particle size data was obtained from the near-field hydrology data package [3]. The filler material between waste packages is assumed to be quartz sand. The vault concrete is assumed to consist of back-filled soil mixed with 15% Portland cement.

Table 10. Relative Volume of Solid Species in Material Zones

	ILAW Glass	304L SS	Quartz	Albite High	K-Feldspar	Illite	Portlandite
Waste Package	0.99	0.01					
Filler			1				
Vault Concrete			0.34	0.34	0.085	0.085	0.15
Back-filled Soil			0.4	0.4	0.100	0.100	
Hanford Sands			0.4	0.4	0.100	0.100	

Table 11. Particle Radius (m) of Solid Species in Material Zones

	ILAW Glass	304L SS	Quartz	Albite High	K-Feldspar	Illite	Portlandite
Waste Package	5.00E-02	5.00E-02					
Filler			1.00E-04				
Vault Concrete			1.00E-04	1.00E-04	1.00E-04	5.00E-06	1.00E-04
Back-filled Soil			1.00E-04	1.00E-04	1.00E-04	5.00E-06	
Hanford Sands			1.00E-04	1.00E-04	1.00E-04	5.00E-06	

The assumed particle radius values for Hanford sediments and backfill soil are consistent with petrologic and particle size data obtained from laboratory-measured values [27]. The composition of the filler material between waste packages is assumed to be the same as that for the backfill soil. For the Portland cement, we have simply assumed that the material is heavily degraded into a rubble [28] with consistency similar to surrounding soil. Comparatively, the glass is assumed to have an average 500 times larger radius. This is consistent with the expected sparse degree of glass fracturing in the waste package based on prior experience with high-level waste glasses [29,30]. Fracturing is expected to increase the glass surface area a maximum of 10X over geometric.

3.2.2 Aqueous Species

Aqueous species are the cations, anions, or neutral complexes present in the aqueous phase. For each aqueous species, the following data is needed:

- Molecular Weight
- Charge
- Hard core diameter
- Number of elements in aqueous species
- Stoichiometric coefficient of each element

The aqueous species listed in Table 12 were identified by simulating the dissolution of LAWABP1 glass (along with a trace amount of calcite) in deionized water at 15°C with the EQ3/6 code package [31]. All data were obtained from the EQ3/6 data0.com.R8 database [32]. The simulations were not intended to be representative of disposal system conditions. The intent here was only to make use of the EQ3/6 software to extract a subset of aqueous (and solid) species from the large thermodynamic database that were relevant for ILAW simulations. Since LAWABP1 glass contains all of the elements that are currently expected to be part of the final ILAW product produced by BNFL, Inc, and adding calcite caused the software to load Ca species that might be important in a disposal system with a concrete vault, the list of aqueous species given in Table 12 is expected to be reasonably complete. However, for conducting actual disposal system simulations, it will be possible to exclude a number of these species from the simulation because their concentration will be extremely small over the range of chemical conditions anticipated for the ILAW disposal system.

3.2.3 Gas Species

Gas species are compounds such as CO_2 and O_2 that make up the air phase in STORM simulations. For each gas species, the following data is needed:

- Molecular Weight
- Number of elements in gaseous species
- Stoichiometric coefficient of each element

The gaseous species listed in Table 13 are the only ones currently expected to significantly influence the chemical environment in the near and far field. The listed data were obtained from the EQ3/6 data0.com.R8 database [32].

Table 13. Gaseous Species Important for Conducting STORM Code Simulations

Species	*Mol.Wt. g mol^{-1}*	*No. Elements*	*Moles*	*Element*	*Moles*	*Element*
CO2(g)	44	2	1	C	2	O
O2(g)	31.999	1	2	O		

3.2.4 Secondary Mineral Phases

3.2.4.1 Mineral Selection

Secondary minerals are solid phases that precipitate from a supersaturated aqueous solution. For each secondary mineral species, the following data is needed:

- Mass Density (mg m^{-3})
- Stoichiometric coefficient of each element

The mass density is obtained by dividing the molecular weight by the molar volume of the species. A list of potential secondary minerals was identified (see Table 14) by simulating the dissolution of LAWABP1 glass in deionized water at 15°C with the EQ3/6 code package [31] and the data0.com.R8 database [32]. Because LAWABP1 glass contains all of the elements that are currently expected to be part of the final ILAW product produced by BNFL, Inc, the list of secondary phases given in Table 14 is expected to be reasonably complete. However, further testing with BNFL Inc. glasses will likely reveal other secondary phases that will need to be added.

A large number of the phases listed in Table 14 can be eliminated from consideration in STORM simulations because: 1) formation of the phase is kinetically prohibited at the disposal system temperature of 15°C, 2) selection of the phase would violate the Gibbs phase rule, 3) simulations show that allowing the phase to form is inconsistent with a large body of laboratory test data with borosilicate glasses, or 4) the phase is unstable over the range of chemical environments expected for the ILAW disposal system. A final set of phases to be included in STORM simulations with LAWABP1 glass was determined by modeling the solution chemistry observed in PCT experiments with the EQ3/6 code. The results are shown in Figure 33. The agreement with the experimental data is extraordinarily good. The predicted secondary phase paragenesis is provided in Figure 34. However, it was necessary to adjust the log K upward for several of the phases [labeled as amorphous, e.g. $La(OH)_3(am)$] to match the observed solution concentration values. This is a consequence of the fact that amorphous solids rather than their crystalline analogs often form in laboratory experiments with waste glasses. The amorphous solids are typically much more soluble and this is reflected in the equilibrium constant. The final secondary phase reaction network and the associated log K values are provided in Table 15.

Herschelite has been identified as a ubiquitous reaction product in PUF and VHT tests with a large number of BNFL, Inc. glass formulations, including LAWABP1. Because this phase is thought to be principally responsible for dissolution rate accelerations observed during testing, inclusion of this phase in the reaction network is mandatory. However, a solubility product for this phase is not included in the current thermodynamic database for EQ3/6 nor has a measured value been reported. Consequently, it was necessary to estimate a log K for herschelite. The estimation method we used is discussed in the next section.

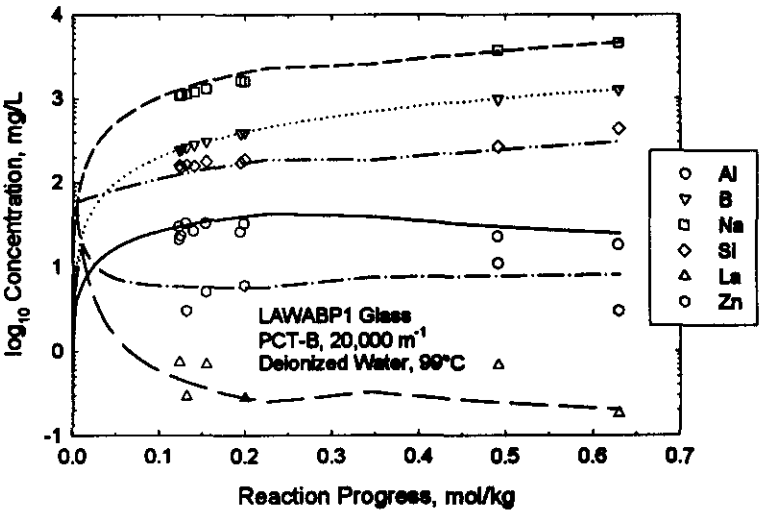

Figure 33. Comparison of PCT Solution Concentration Data with the Solution Composition Calculated with the EQ3/6 Code

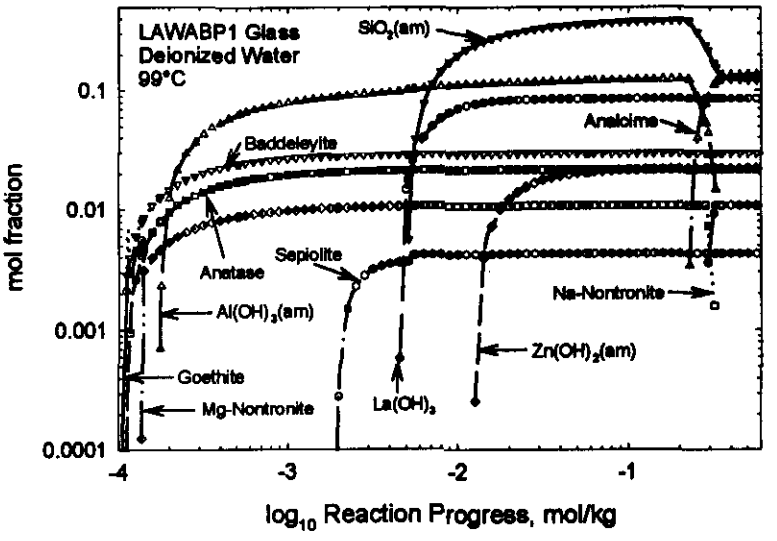

Figure 34. Predicted Paragenetic Sequence of Alteration Phases Formed During the Reaction of LAWABP1 Glass in Deionized Water. PuO_2 and soddyite were also predicted to form. However, they are not shown because of the very small mol fractions associated with these phases.

3.2.4.2 Solubility Product for Herschelite

The composition of herschelite forming from corrosion of a sample of LAWA33 glass was determined using EDS coupled to a SEM. From these data the chemical formula for herschelite was calculated to be $Na_{1.62}K_{0.50}Al_{2.26}Si_{4.00}O_{12.45}$ $6H_2O$. The temperature dependent solubility product was calculated using the approach outlined by Mattigod and Kittrick [33]. In this approach the temperature dependence of solubility of a mineral is expressed in the form:

$$\log K_T = 1/2.303\ R[A \ln T + BT + C/T^2 + D/T + E) \quad (5)$$

where K_T is the solubility product at temperature T (°K), R is the gas constant, $A = \Delta a$, $B = \Delta b/2$, $C = \Delta c/2$, $D = [\Delta a\ T_r + (\Delta b/2)\ T_r^2 - \Delta c/T_r - \Delta S^0\ T_r + RT \ln K_{Tr}]$, and $E = [-\Delta a - \Delta a \ln T_r - \Delta b\ T_r + (\Delta c/2\ T_r^2) + \Delta S^0]$, and Δa, Δb, and Δc are the heat capacity of reaction coefficients from Meier-Kelly equation

$$\Delta C_p = \Delta a + \Delta b\ T + \Delta c/T^2 \quad (6)$$

where ΔS^0 = entropy of reaction
K_{Tr} = solubility product at a reference temperature (298.15 ^{0}K).

The dissolution/precipitation reaction of herschelite is expressed in the form:

$$Na_{1.62}K_{0.50}Al_{2.26}Si_{4.00}O_{12.45}\ 6H_2O\ (solid) + 8.9H^+(aq) = 1.62Na^+(aq) + 0.50K^+(aq) + 2.26Al^{3+}(aq) + 4Si(OH)_4^0(aq) + 2.45H_2O \quad (7)$$

The solubility product for this reaction is expressed as:

$$\log K_T = 1.62 \log Na^+ + 0.50 \log K^+ + 2.26 \log Al^{3+} + 4 \log Si(OH)_4^0 + 8 \log H^+ = 1/2.303\ R[A \ln T + BT + C/T^2 + D/T + E) \quad (8)$$

The sources of thermochemical data used in the calculations are listed in Table 16. The solubility product at reference temperature (298.15 ^{0}K) was calculated from the free energy of formation values listed in Table 1 using the expression

$$\ln K_{298.15} = -\Delta G^o/2.479 \quad (9)$$

where ΔG^o is the free energy of reaction.

Using the data listed in Table 16, the solubility product of herschelite was computed as

$$\log K_T = -11.5438 \ln T + 0.071779T + 8.8225x10^4/T^2 + 1.1881x10^4/T + 15.654 \quad (10)$$

The solubility product for herschelite was calculated at 10 degree temperature intervals starting from 15°C to 95°C. The results are tabulated in Table 2 and graphically represented in Figure 1. The computations showed that the solubility product of herschelite changes by about six orders of magnitude between 15^0 to 95^{0}C indicating significantly higher solubility at higher temperature as compared to its solubility at ambient temperature.

3.2.5 Solute Transport Coefficients

For each gaseous and aqueous species, the following data is needed:

- Aqueous diffusion coefficient (m^2 s^{-1})
- Gas diffusion coefficient (m^2 s^{-1})

The diffusion coefficients will be determined as a part of the near-field hydraulics data package [3].

3.2.6 Solute/Solid Interaction

For each gaseous and aqueous species, the following data is needed:

- Solute/solid partitioning coefficient (m^3 kg^{-1})

This coefficient is related to the distribution coefficients (K_d) being provided by the near- and far-field geochemistry data package [27].

3.2.7 Equilibrium Reactions

For each equilibrium reaction, the following data is needed:

- Stoichiometric coefficient of each aqueous species in each reaction
- Equilibrium constant at a temperature of 15°C.

The equilibrium reactions in Table 18 were identified by simulating the dissolution of *LAWABP1 glass in deionized water at 15°C with the EQ3/6 code package* [31] and the data0.com.R8 database [32]. As discussed in Section 3.2.2, it will be possible to exclude a significant number of these species from the simulations because their concentration will be extremely small over the range of chemical conditions anticipated for the ILAW disposal system. Simulations with the STORM code will be performed to define this range of conditions and to justify elimination of an equilibrium reaction. However, because simulations are required, justification for elimination of an equilibrium reaction must be provided in the ILAW PA and not in this data package.

3.2.8 Kinetic Reactions

For each kinetic reaction, the following data is needed:

- Mass action law type: {full = 1} {reduced = -1} {glass = 0}
- Stoichiometric coefficient of aqueous species in each reaction
- Equilibrium constant at a temperature of 15°C.
- Rate constant of solid reaction

Also, for the glass dissolution reaction only, the following data is needed:

- Stoichiometric coefficient of aqueous species used in equilibrium calculations
- Activation energy of solid reaction
- Exponential factor of solid reaction
- Exponential factor of pH dependence of dissolution reaction

3.2.8.1 Secondary Minerals

A full mass action law type will be used for each mineral except the waste glass. A special glass mass action law type implemented in the STORM code will be used for the glass (see Section 3.2.8.2). Compilations of kinetic rate constants, equivalent to thermodynamic databases for important mineral phases, are not available. Also, the available kinetics data are much more limited as compared with thermodynamic data. For the expected case where kinetic rate constants are not available for an important solid, sufficiently large values will be used to approximate a state of thermodynamic equilibrium with the phase. Alternatively, the specific phase will need to be synthesized and the dissolution/precipitation kinetic rate constants measured. For most instances, we expect to use large enough rate constants to approximate equilibrium conditions, i.e. ensure that the phase will precipitate rapidly if the local chemical environment at a grid node is saturated with respect to the particular phase. This has an additional advantage in that uncertainty in the exact value of a particular rate constant will have little impact on the calculational results.

3.2.8.2 Glass

Because glass dissolution is an irreversible chemical reaction, a special type of mass action law has been implemented in the STORM code to simulate its dissolution [1]. The glass dissolution reaction is written as illustrated for LD6-5412 glass:

$$\text{Glass} + 0.5OH^- + 0.45H_2O = 0.0202K^+ + 0.4208Na^+ + 0.046Ca^{2+} + 0.094BO_2^- + 0.154Al(OH)_3(aq) + 0.2712HSiO_3^- + 0.3348H_2SiO_4^{2-} + 1.6172x10^{-6}TcO_4^{2-} \quad (11)$$

The pH-dependence of the glass dissolution rate is captured with the $0.5OH^-$ term on the left-hand side of Equation (11). The pH dependence for LAWA33 glass was also found to be of order 0.5 from a series of single-pass flow-through experiments, discussed in Section 2.3.2.3. Most glasses exhibit pH-dependence dissolution rates between 0.4 and 0.5 [13]. Consequently, we expect similar behavior for LAWABP1 glass.

The forward dissolution rate constant at 90 and 40°C has been determined by SPFT experiments for LAWABP1 glass (see Section 2.3.2). However, two data points are insufficient to calculate a reliable activation energy. To estimate the intrinsic rate constant at the disposal system temperature of 15°C, we will assume an activation energy of 75 kJ/mol determined by McGrail et al. [13] for LD6-5412 glass and make use of the Arrhenius equation:

$$k_0(T) = \overset{v}{k} 10^{\eta \cdot pH} e^{-E_a/RT} \quad (12)$$

where k_0 is the forward dissolution rate, $\overset{v}{k}$ is the intrinsic rate constant, E_a is the activation energy, R is the gas constant, and T is the temperature. The forward rate constant for LAWABP1 glass at 40°C is 3.4×10^{-3} g m^{-2} d^{-1} (see Section 2.3.2.2) at pH 9. Substituting these values into Equation (12), we find $\log_{10} \overset{v}{k} = 5.54$ g m^{-2} d^{-1}. This estimate for $\overset{v}{k}$ must be considered tentative until sufficient data are available to accurately compute it, as was done for LD6-412 glass shown in Figure 29.

The kinetic rate law formulation in the STORM code uses the above forward rate constant and equilibrium constant for the reaction of the form

$$W_j = A_{m(j)} k_j \left[\prod_{\nu_{ij}<0} (\gamma_i c_i)^{\frac{|\nu_{ij}|}{f_j}} - \prod_{\nu_{ij}>0} (\gamma_i c_i)^{\frac{\nu_{ij}}{f_j}} \Big/ \left(K_j^{eq}\right)^{1/f_j} \right]. \quad (13)$$

SPFT experiments are a relatively new approach for estimating the effective equilibrium constant for waste glasses [11]. In Section 2.3.2.2, preliminary results for LAWABP1 glass were used to estimate a K_g for this glass at 90 and 40°C. These data are plotted in Figure 36. Lacking additional data or a literature precedent for an activation energy associated with K_g, we are forced to rely on only two data points at this time to extrapolate the K_g to 15°C giving $K_g(15°C) = 3.6 \times 10^{-10}$. The apparent activation energy from the plot is approximately 60 kJ/mol, which places it between the E_a for SiO_2(am) of 18 kJ/mol and kaolinite of 100 kJ/mol. We will of course refine the estimated K_g for LAWABP1 glass as additional data become available.

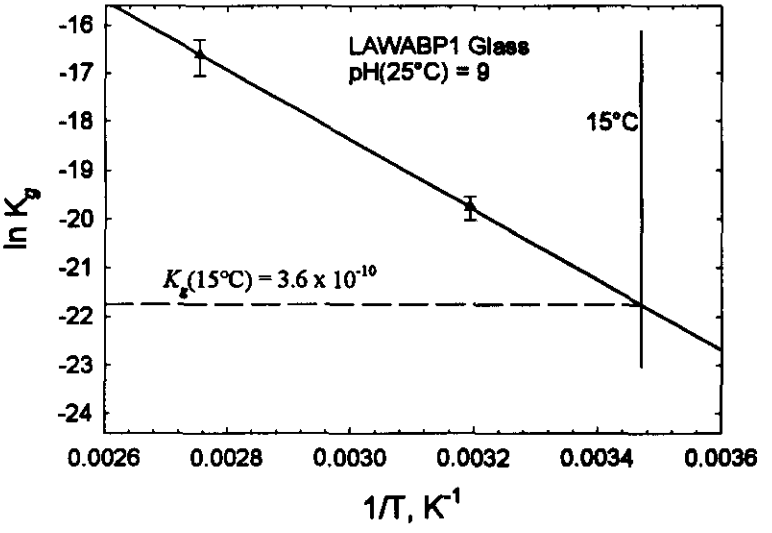

Figure 36. Temperature Dependence of Pseudoequilibrium Constant K_g for LAWABP1 Glass

3.2.9 Initial and Boundary Conditions

For each specified gas species concentration, the following data are needed:

- Partial pressure of gaseous species,

For each specified aqueous species, the following data are needed:

- Specified total concentration
- Stoichiometric coefficient of each aqueous species.

Initial partial pressures of gas species will be specified at typical atmospheric values. Aqueous species concentrations at the upper boundary, and for initial conditions, will be specified as a part of the near-field geochemistry data package [27].

This page intentionally left blank.

4.0 CONCLUSION

In this data package, a large body of data is presented on the corrosion behavior of a wide range of prototypic glass forms for low-activity waste. Four test methods, SPFT, PCT, VHT, and PUF were used in combination to examine the corrosion behavior of these glasses over a wide range of conditions. For one of the glasses, LAWABP1, which performed well in each of the tests, more detailed experiments were conducted to derive the parameters necessary to conduct long-term PA calculations with the STORM reactive transport computer code. A summary of the parameters derived from the laboratory testing is provided in Table 19. Because of the limited data available for LAWABP1 glass, extrapolations in temperature were required in many cases using only a few data points. Consequently, the parameters in Table 19 should be viewed as tentative until significantly more experimental data are available. A large number of experiments with LAWABP1 (and four other glass compositions) are underway. As these data become available, revisions to the parameters in Table 19 will be evaluated along with quantitative estimates of uncertainty.

Table 19. Summary of Best Estimate Parameters for LAWABP1 Glass

Parameter	Meaning	Value	Test Method	Evaluation Method

Summary

Lockheed Martin Hanford Company (LMHC) is designing and assessing the performance of disposal facilities to receive radioactive wastes that are currently stored in single- and double-shell tanks at the Hanford Site. The preferred method for disposing of the portion that is classified as immobilized low-activity waste (ILAW) is to vitrify the waste and place the product in near-surface, shallow land burial facilities. The LMHC project to assess the performance of these disposal facilities is the Hanford ILAW Performance Assessment (PA) Activity. The goal of this project is to provide a reasonable expectation that the disposal of the waste is protective of the general public, groundwater resources, air resources, surface water resources, and inadvertent intruders. Achieving this goal will require prediction of contaminant migration from the facilities. This migration is expected to occur primarily via the movement of water through the facilities and the consequent transport of dissolved contaminants in the pore water of the vadose zone.

Pacific Northwest National Laboratory (PNNL) assists LMHC in its performance assessment activities. One of PNNL's tasks is to provide estimates of the physical, hydraulic, and transport properties of the materials comprising the disposal facilities and the disturbed region around them. These materials are referred to as the near-field materials. Their properties are expressed as parameters of constitutive models used in simulations of subsurface flow and transport. In addition to the best-estimate parameter values, information on uncertainty in the parameter values and estimates of the changes in parameter values over time are required to complete the PA. These parameter estimates and information are contained in this report, the Near-Field Hydrology Data Package.

Acknowledgments

Technical reviews of this report were provided by Dr. John R. Nimmo of the U.S. Geological Survey, Dr. Bridget R. Scanlon of the Texas Bureau of Economic Geology, and Dr. Gary P. Streile of Pacific Northwest National Laboratory. These reviews contributed significantly to the technical soundness and timely completion of this report.

1.0 Introduction

The Hanford Site was established in 1944 as a U.S. Government nuclear materials production facility. During its history, site missions included nuclear reactor operation, storage and reprocessing of spent nuclear fuel, and management of radioactive and hazardous wastes. Today, activities on the site involve environmental restoration, energy-related research, and technology development. Fifty-five years of operations have resulted in the accumulation of significant quantities of radioactive and hazardous wastes as well as their intentional and unintentional release to the environment. Figure 1.1 shows the location of the Hanford Site within Washington State and the proximity of major population centers. Figure 1.2 shows the boundaries of the Hanford Site and the location of the major facilities. The 100 Areas are the sites of reactor facilities. The major processing facilities, waste storage facilities, and waste disposal areas are located in the 200 Areas.

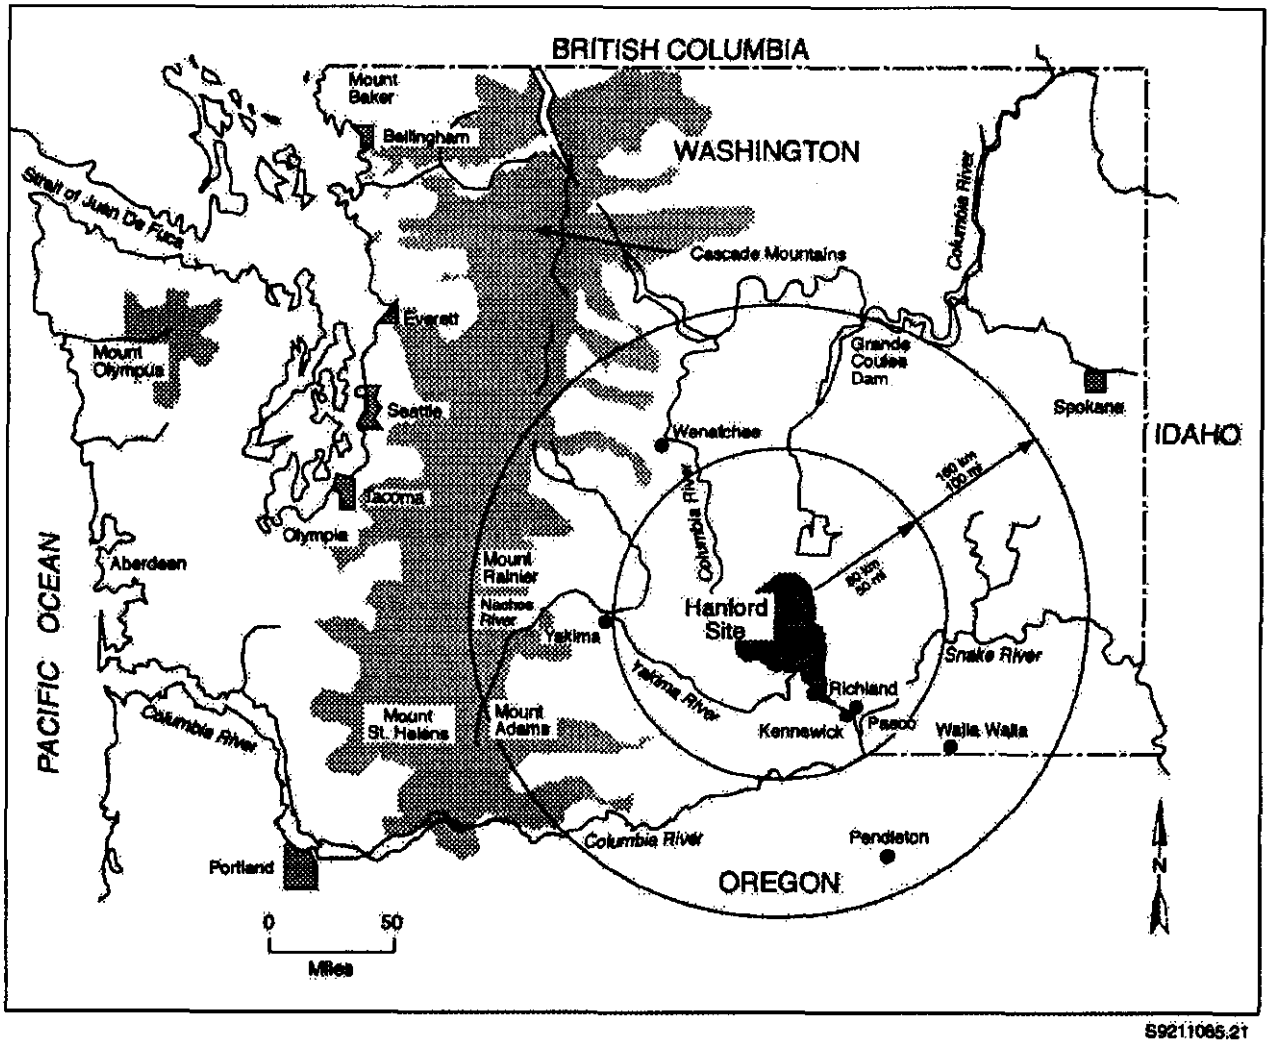

Figure 1.1. Location of the Hanford Site in Washington State

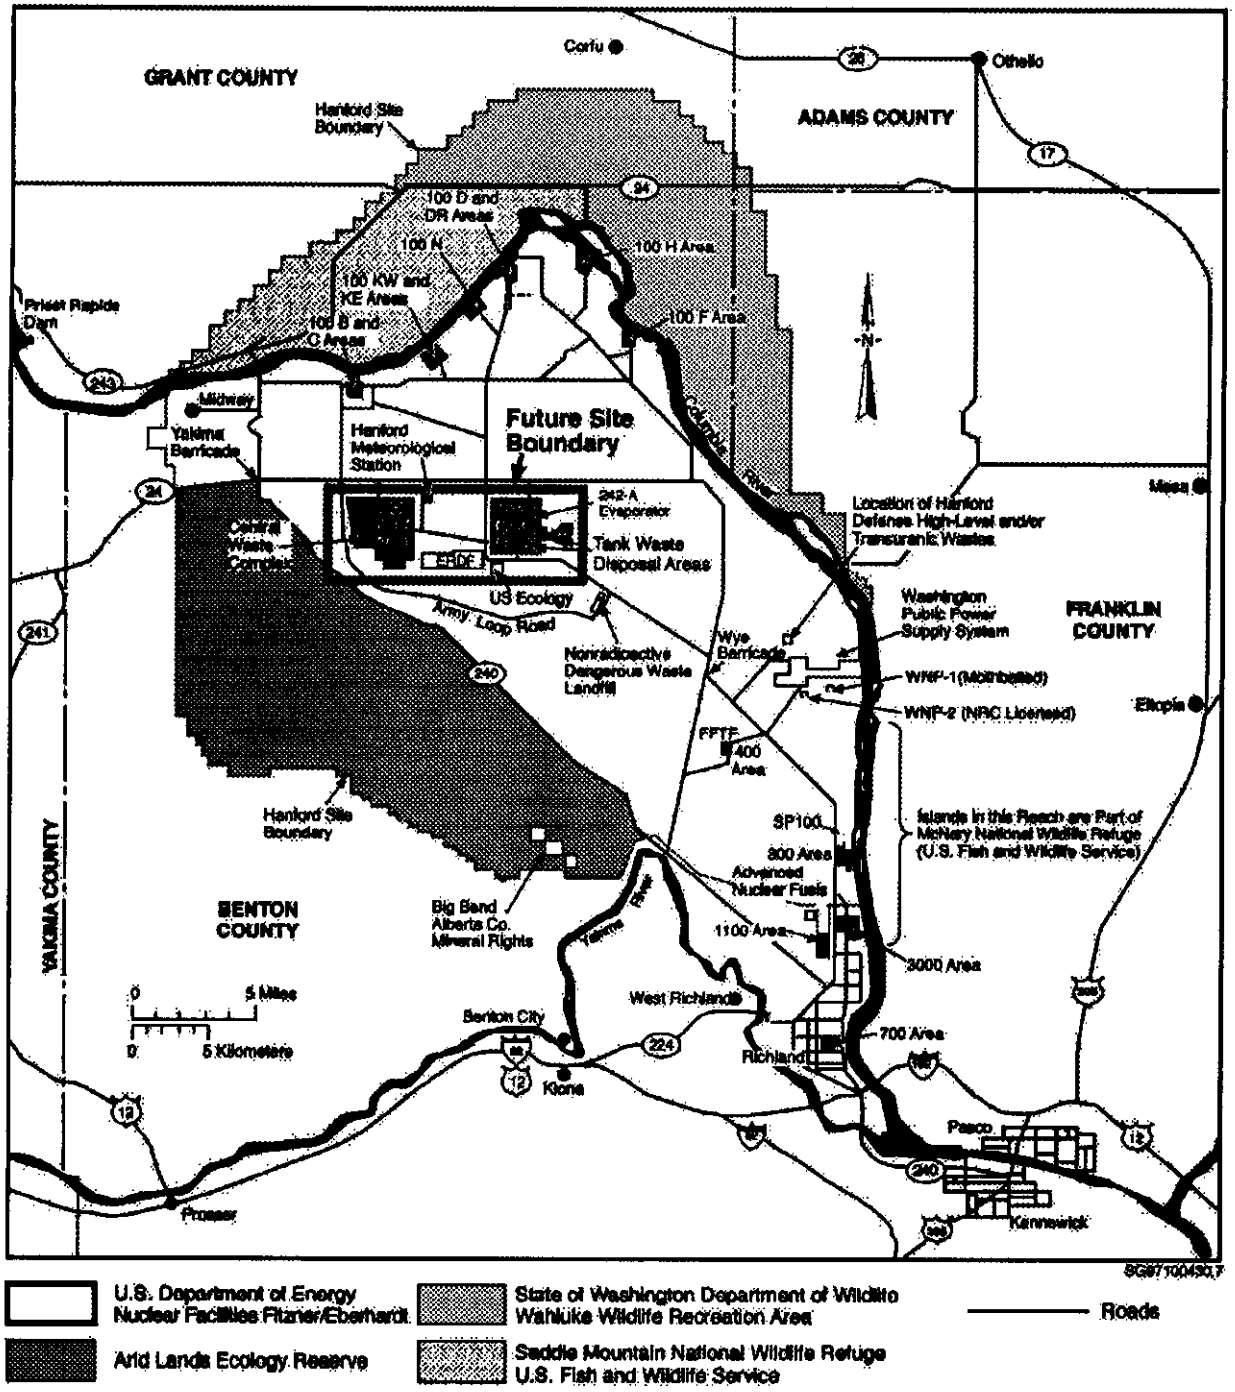

Figure 1.2. Hanford Site Map Illustrating the Locations of Major Facility Areas, Public Roads, Rivers, and the Future Site Boundary

1.1 Source and Destination of ILAW

The legacy of the earlier Hanford missions consists of approximately 204,000 m^3 of radioactive and mixed waste stored in 177 buried single- and double-shell tanks in the Hanford Site 200 Areas. Some of the more important radionuclides in these wastes are ^{3}H, ^{79}Se, ^{90}Sr, ^{99}Tc, ^{129}I, ^{126}Sn, and ^{137}Cs, as well as isotopes and progeny of uranium, plutonium, neptunium, and americium. The current plan for disposal of this waste calls for retrieval of the waste from the tanks, separation of the waste into high-level and low-activity waste streams, and vitrification (incorporation in glass) of each waste stream. Vitrification is intended to immobilize the waste components within the glass matrix. The high-level waste stream will be relatively low in volume, but will contain most of the radionuclides. Vitrified high-level waste will be stored on the Hanford Site until shipped to a federally approved repository. The immobilized low-activity waste (ILAW) will contain the bulk of the material from the tanks, including most of the non-radioactive chemical constituents, but relatively few radionuclides. (This paragraph references information found in Mann, 1999b.)

Current plans for disposal of the ILAW call for the molten glass waste to be placed in steel containers. These containers will be stacked in underground vaults located in the 200 East Area. Existing vaults, constructed for the grouted tank waste disposal program, will be used for the initial production of ILAW. The location of these existing disposal facility vaults is shown in Figure 1.3. The bulk of the waste (approximately 96%) will be placed in newly constructed vaults located to the southwest of the existing vaults, within the area marked ILAW on Figure 1.3 (Mann, 1999b; Burbank and Hohl, 1999). Protective surface covers will be constructed over the vaults prior to closure. Additional details on disposal facility design are given in Section 2.2.

1.2 ILAW Performance Assessments

Lockheed Martin Hanford Company (LMHC) is designing and assessing the performance of the disposal facilities to receive the ILAW. The LMHC project to assess the performance of these disposal facilities is called the Hanford ILAW Performance Assessment (PA) Activity, referred to as the ILAW PA within this report. An interim PA (Mann et al., 1997) and the 1998 ILAW PA (Mann et al., 1998) were the initial efforts to demonstrate the feasibility of safely disposing of ILAW at the Hanford Site. Because the ILAW PA project was in its early stages during the preparation of these PAs, the analyses were conducted using conceptual designs of the facilities and reasonable estimates of material properties without having site-specific and waste-form-specific information. The project has since collected a variety of information including geologic, geochemical, and hydraulic data from a borehole adjacent to the new ILAW disposal site, site-specific recharge data, and geochemical information on contaminant transport through the site sediments. In addition, hydraulic and geochemical information for the expected materials of the disposal facilities and data regarding the behavior of the expected waste form have been and continue to be collected. In addition, various facility design alternatives have been considered and a definitive conceptual design has been proposed for the new ILAW disposal facility. In preparation for a revision of the ILAW PA

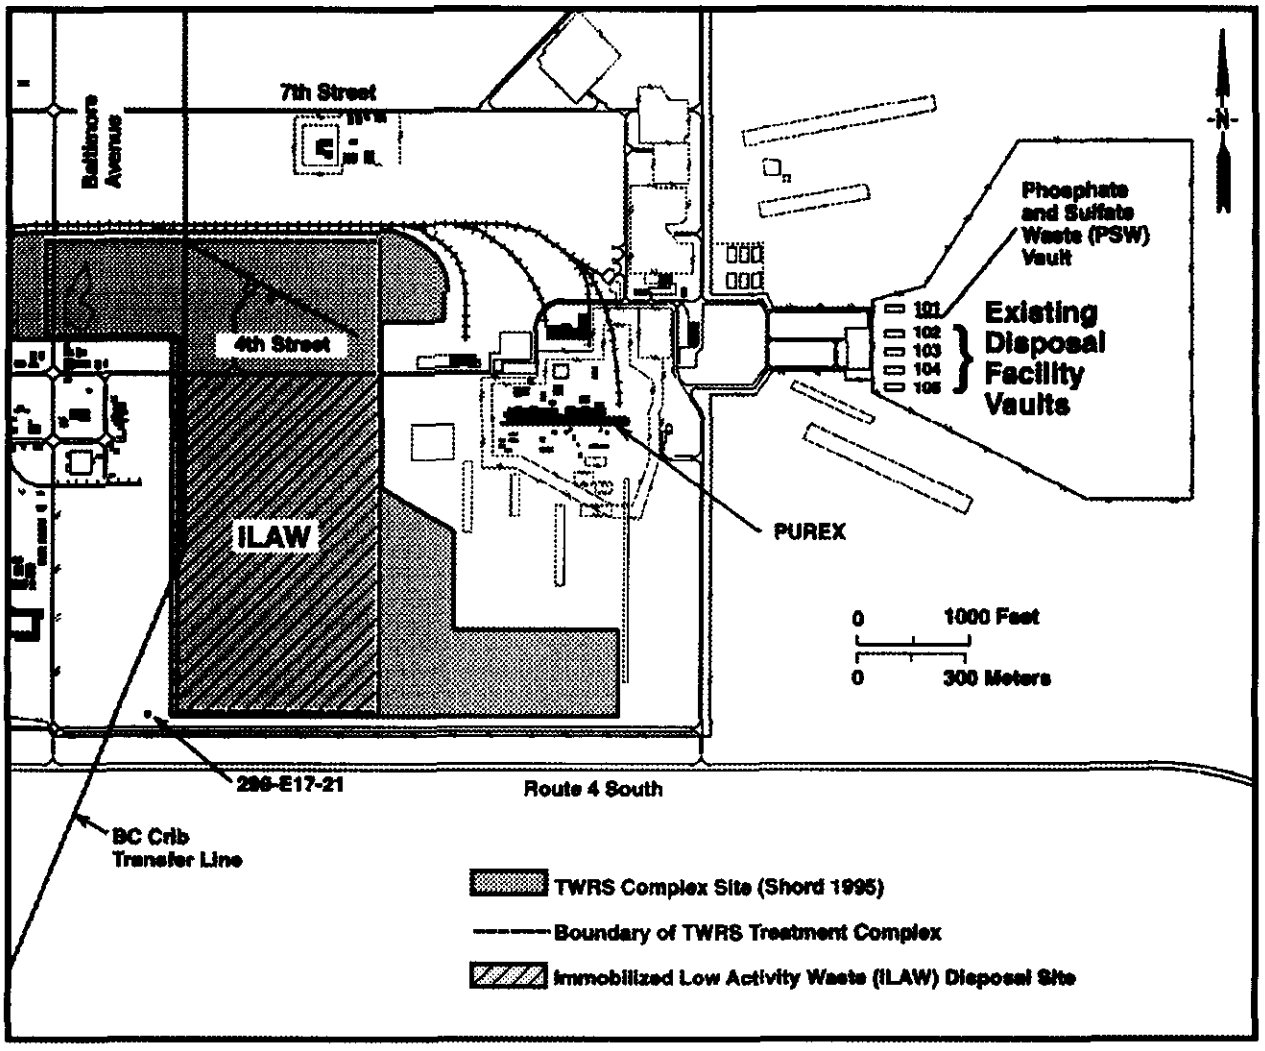

Figure 1.3. Location of the ILAW Disposal Facilities within the Hanford Site 200 East Area: Existing Disposal Facility and New ILAW Disposal Facility (labeled ILAW)

(the 2001 ILAW PA), a number of data packages are being prepared (LMHC, 1998). These data packages will bring together recently collected site-specific ILAW data as well as relevant data collected by other projects. This additional information will be used in the 2001 ILAW PA. These additional data packages include information on geology (Reidel and Horton, 1999), recharge (Fayer et al., 1999), flow and transport in the natural sediments (Khaleel, 1999), geochemistry (Kaplan and Serne, 1999), waste form release (McGrail et al., 1999), and facility design (Puigh, 1999). All data package reports will be included as appendices in the 2001 ILAW PA.

The goal of the PAs is to provide a reasonable expectation that the disposal of the waste is protective of the general public, groundwater resource, air resources, surface water resources, and inadvertent intrud-

ers. Radiological performance objectives and dangerous material (hazardous chemical) performance goals to be used in the 2001 ILAW PA are described in Mann (1999a). The radiological performance objectives include dose limits for an all-pathways scenario and an inadvertent intruder scenario as well as concentration and dose limits in groundwater, surface water, and air. Performance objectives are evaluated for 1,000 and 10,000 years, but are calculated to the time of peak or 10,000 years, whichever is longer. Results from the 1998 ILAW PA (Mann et al., 1998) showed that long-lived radionuclides (e.g., uranium and its daughter products) may produce peak impacts at times significantly greater than 10,000 years after closure.

The specific scenarios to be considered in the 2001 ILAW PA are discussed in Mann (1999b). It is assumed that the main pathway by which exposure will occur involves water movement into and through the disposal facilities, dissolution of the waste, transport of contaminants through the vadose zone to the unconfined aquifer, transport in the aquifer to an extraction well, and human exposure via domestic use of the pumped water. Prediction of subsurface flow and contaminant transport via numerical simulation will be required to complete the 2001 PA. In addition to a base case simulation, sensitivity calculations will be performed to demonstrate that the design for the ILAW disposal achieves impacts that are as low as reasonably achievable (ALARA).

Pacific Northwest National Laboratory (PNNL) assists LMHC in its performance assessment activities. One of PNNL's tasks is to provide estimates of the physical, hydraulic, and transport properties of the materials comprising the disposal facilities and the disturbed region around them. These materials are referred to as the near-field materials. Their properties are expressed as parameters of constitutive models used in simulations of subsurface flow and transport. In addition to the best-estimate parameter values (to be used in the base case simulation), information on uncertainty in the parameter values and estimates of the changes in parameter values over time are required to satisfy the ALARA requirement of the PA. These parameter estimates and information are contained in this report, the Near-Field Hydrology Data Package.

1.3 Quality Assurance and Safety

All laboratory and field experiments are conducted under PNNL quality assurance (QA) requirements as described in the guidance provided in PNNL's Standards Based Management System (SBMS) and as specified in the Project QA Plan. Significant modifications to the QA plan are made in accordance with the guidance in the SBMS.

Project staff members are qualified and receive any training needed to carry out their assigned responsibilities. Staff use equipment of known accuracy for data collection. For measurements necessary to substantiate test results, staff ensure that standards used for calibration are traceable to nationally recognized standards. Measuring and Test Equipment (M&TE) lists are generated by each task and maintained in the project files applicable to the specific task. M&TE used is identified in the laboratory record books or other data recording location to provide traceability to instrument calibrations.

Test procedures and methods are documented and deviations noted. New methods developed during the course of this work are documented and reviewed. All test procedures, data processing software, and supporting documentation undergo independent technical review by qualified PNNL staff. Staff maintain records necessary to substantiate results and processes of research activities. After activities are completed, records are filed and maintained per the project Records Inventory and Disposition Schedule (RIDS).

All precautionary measures are taken in accordance with standard PNNL safety procedures to ensure that field work is conducted in a safe manner. No hazardous wastes have been generated during the conduct of work described in this report.

2.0 Facility Design and Description of Near-Field Materials

A brief summary of the hydrologic and geologic setting of the ILAW disposal facilities is presented in this section. This is followed by a detailed discussion of the current conceptual design of the disposal facilities and the near-field materials to be used in their construction.

2.1 Hydrologic and Geologic Setting

The Hanford Site is located in the semiarid Pasco Basin of the Columbia Plateau in southeastern Washington State, within the rain shadow of the Cascade Mountain Range. The Hanford Meteorological Station, located between the 200 East and 200 West Areas on the Hanford Site, has been collecting climatological data representative of the ILAW disposal sites since 1945 (Hoitink et al., 1999). Precipitation at the Hanford Meteorological Station has averaged 17.4 cm/yr. since 1946, with more than half of the annual precipitation occurring from November through February. Days with more than 1.3 cm of precipitation occur on average less than once each year. Rainfall intensities of 1.3 cm/hr. with a duration of one hour are expected to occur once every 10 years. Rainfall intensities of 2.5 cm/hr. with a one-hour duration are expected to occur once every 500 years. Monthly average snowfall ranges from 0.8 cm in March to 13.7 cm in December. The maximum recorded monthly snowfall is 60 cm; the maximum recorded seasonal snowfall is 142 cm. On average, snowfall accounts for about 38% of precipitation from December through February.

Average daily maximum temperature varies from 2°C in late December and early January to 35°C in late July. On average, there are 52 days during the summer months with a maximum temperature greater than or equal to 32°C and 12 days with a maximum temperature greater than 38°C. From mid-November through early March, minimum temperatures average less than or equal to 0°C. The recorded maximum temperature is 45°C; the recorded minimum is -31°C.

The Hanford Site is characterized as a shrub-steppe ecosystem that is adapted to the region's mid-latitude, semiarid climate (Neitzel, 1998). Such ecosystems are typically dominated by a shrub overstory with a grass understory. Livestock grazing and agricultural production prior to government control of the Hanford Site contributed to colonization by non-native vegetation species that currently dominate portions of the landscape. In addition, summer range fires have tended to eliminate fire-intolerant species and have allowed more opportunistic and fire-resistant species a chance to become established. The dominant non-native species on the site is cheatgrass.

Three soil types occur in the vicinity of the ILAW disposal sites. As described by Hajek (1966), these soils are: Burbank Loamy Sand, a coarse-textured soil usually about 40 cm thick, underlain by a subsoil with a gravel content ranging from 20 to 80 volume percent; Ephrata Sandy Loam, a medium-textured soil underlain by gravelly material; and Rupert Sand, generally characterized as a coarse sand developed under grass, sagebrush, and hopsage in coarse sandy alluvial deposits.

The semiarid climate results in fairly low rates of groundwater recharge. Natural recharge rates across the Hanford Site are estimated to range from 0 to more than 10 cm/yr depending on surface soils, vegetation, and topography (Fayer and Walters, 1995). Minimal recharge rates occur in fine-textured soils where deep-rooted plants prevail. Larger recharge rates are likely to occur in areas with coarse, gravelly surface sediments and little or no vegetation. Fayer et al. (1999) provides estimates of the recharge rates expected to occur on the ILAW disposal sites.

The ILAW disposal sites are located on the Cold Creek bar (commonly referred to as the 200 Areas Plateau), a geomorphic remnant of the cataclysmic floods of the Pleistocene epoch (the Missoula Floods). The stratigraphy in the area consists of basalt flows overlain by the Ringold Formation sediments, Hanford Formation sediments, and surficial deposits. The Ringold Formation consists of clay, silt, compacted mud, fine- to coarse-grained sand and granular to cobble gravel. The Hanford Formation, deposited by the Missoula Floods, consists of pebble-to-boulder sized gravel, fine- to coarse-grained sand, and silt. The fine-grained sediments were deposited under slackwater and backflooded conditions. The surficial sediments consist of alluvial and eolian silt, sand, and gravel deposits that are generally less than 5 m thick. The southernmost 200 m of the new ILAW disposal site (see Figure 1.3) is covered with a stabilized sand dune that is as much as 8 m high (Fayer et al., 1999). Reidel and Horton (1999) provides detailed information on the available geologic information for the ILAW disposal sites (see also Reidel and Reynolds, 1998).

The ILAW disposal vaults will be constructed in excavations within the surficial and upper Hanford Formation sediments. Excavations are likely to be no more than 10 to 15 m deep. Three boreholes drilled near the southwest corner of the new ILAW disposal site in 1998 provide information on the nature of the sediments within the depth of the facility excavations (Reidel et al., 1998). Figure 2.1 contains the detailed geologic logs from the three boreholes for the upper 15 m (50 ft.). Note the generally coarse nature of the sediments and the presence of gravelly layers.

2.2 Facility Design

The existing disposal facility consists of concrete vaults constructed for the grouted waste disposal program (Kincaid et al., 1995). Use of these existing vaults for ILAW disposal will involve removal of the roofs from the vaults and subsequent placement of ILAW waste packages and filler material into the vaults. The vaults will then be sealed with new concrete roofs, and a modified RCRA C cover will be constructed to the original grade. The existing disposal facility vaults will hold about 4% of the anticipated volume of ILAW.

The new ILAW disposal facility will be constructed as described in PHMC (1998) (see also Puigh, 1999). The facility consists of a series of concrete vaults within which the waste packages will be placed. Each vault will be approximately 208 m long, 23 m wide, and 9 m deep and will be constructed within its own excavated trench. Construction of a new vault will take place as each vault is filled. A schematic cross-section of one of the new ILAW disposal facility vaults is shown in Figure 2.2

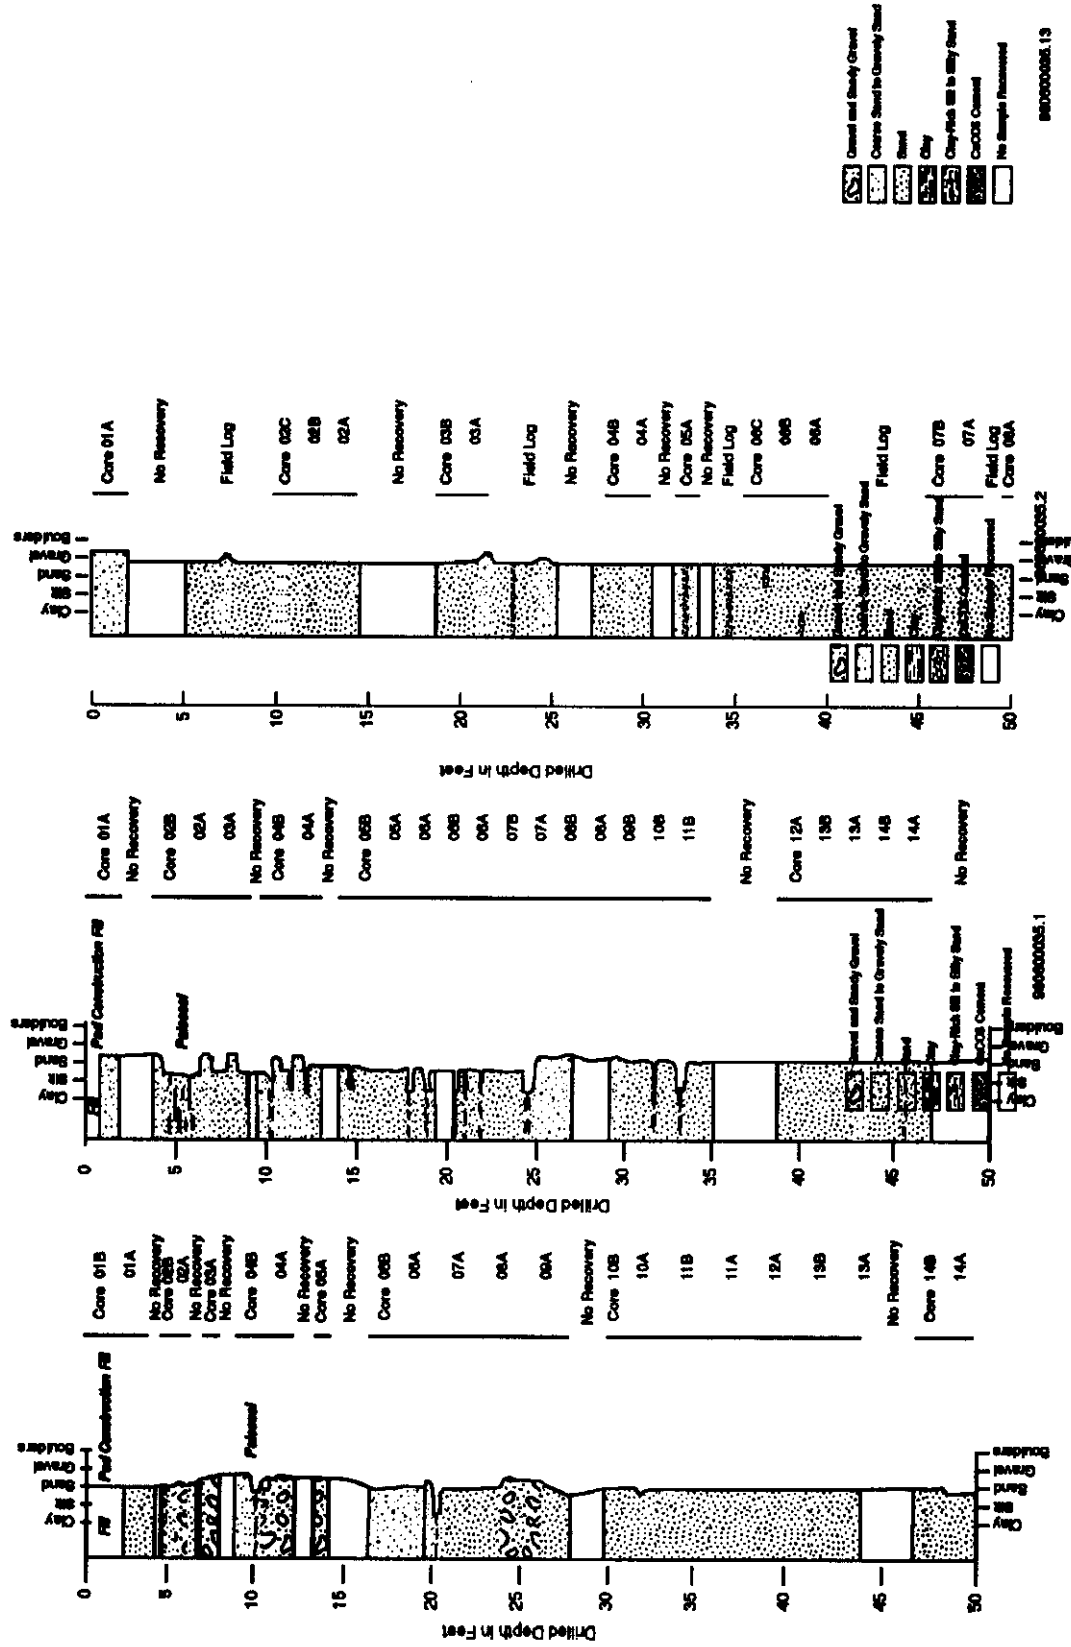

Figure 2.1. Detailed Geologic Logs for Boreholes B8501, B8502, and 299-E17-21 from the Southwest Corner of the New ILAW Disposal Site (after Reidel et al., 1998)

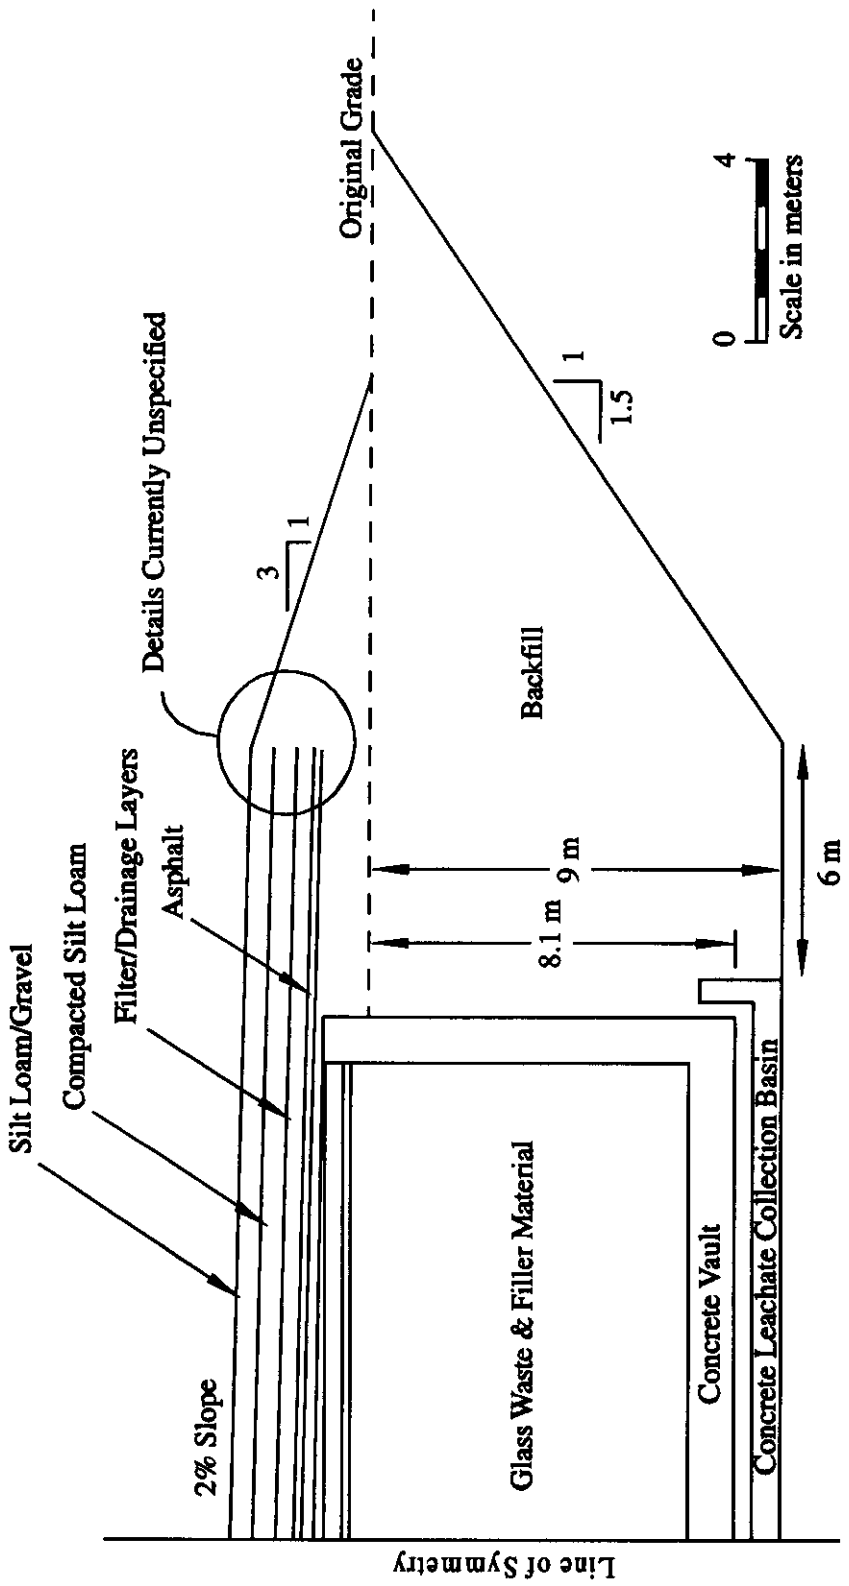

Figure 2.2. Schematic Cross-Section of an Excavation Trench and Vault at the New ILAW Disposal Facility

For both ILAW facilities the waste packages consist of steel containers filled with the glass waste. The space in the vaults between waste packages will be filled with a porous material such as sand. The vaults will be covered with a controlled density fill (defined below) and a layer of concrete to produce a 2% slope. Backfill material will be used to fill in to the original grade. Prior to closure, a protective surface cover will be constructed over the vaults to provide a barrier to water. (Components of the cover will also serve as an inadvertent intruder barrier.) The current conceptual design for the new ILAW disposal facility calls for individual surface barriers to be constructed over each vault. Other design features such as a water conditioning layer and a water diversion layer are not currently specified, but may be included in the final facility design.

For the purposes of hydrologic modeling, the primary differences between the two facilities are as follows.

1. The geometry of the vaults differs.
2. The top of the existing disposal facility vaults are well below grade, whereas the top of the new disposal facility vaults will be approximately at the original grade.
3. High-strength concrete with an asphalt shell was used in the existing disposal facility vault. The type of concrete to be used in the new facility has not yet been specified, but it is anticipated to be a more conventional concrete, with no asphalt shell or coating.

Other than the type of concrete used and the asphalt shell, the near-field materials to be used at the existing disposal site and at the new ILAW disposal site are similar. Because no measurements have been made of the hydraulic properties for the concrete at the existing site, the discussion below of the near-field materials and the parameter values to be presented later in this report should be applied at both sites.

Each material currently specified or that may potentially be used in the ILAW disposal facility is discussed below.

2.2.1 Surface Cover

A Modified RCRA Subtitle C Barrier Design (DOE-RL, 1993) will be used as a surface cover for both the existing and the new disposal facilities. The components of this cover and their minimum thicknesses are shown in Figure 2.3. The combined minimum thickness of the cover is 1.7 m. The thickness of individual components of the cover could be increased if needed to meet regulatory requirements. A description of each component in the cover is given below, taken primarily from DOE-RL (1993). The ILAW facility cover is similar in design to the Hanford Prototype Barrier (DOE-RL, 1999; DOE-RL, 1993) and is expected to perform in a similar manner.

2.2.1.1 Layer 1: Silt Loam Soil with Gravel

This layer consists of 50 cm of sandy silt to silt loam soil from the McGee Ranch area on the Hanford Site with 15% pea gravel by weight. The design bulk density of this layer is about 1.46 g/cm^3. The

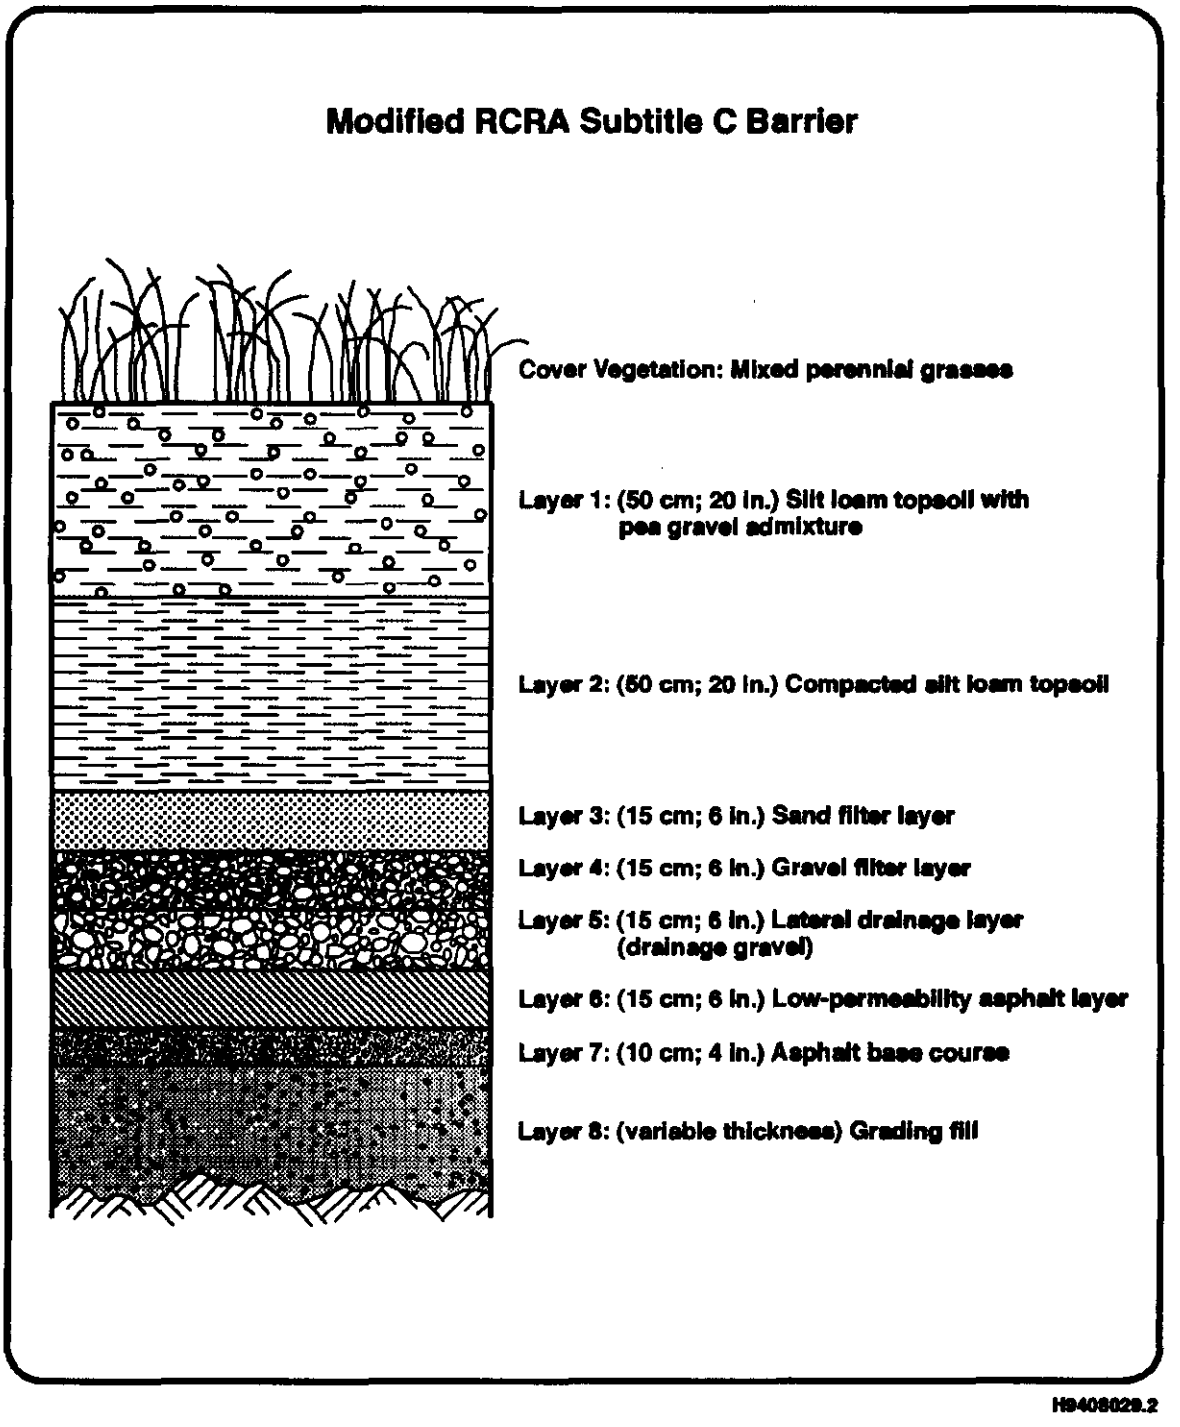

Figure 2.3. Schematic Profile of the Modified RCRA Subtitle C Barrier Currently Intended for Use on the ILAW Disposal Facilities. Note, minimum total barrier thickness is 1.7 m.

surface slope is limited to a maximum of 2% (after allowances for settlement and subsidence). The purpose of Layer 1 is to support vegetation and provide maximum storage capacity for precipitation and snowmelt. A large storage capacity in conjunction with evapotranspiration from vegetation will tend to minimize percolation from the cover (recharge). The pea gravel provides resistance to erosion of the silt loam.

2.2.1.2 Layer 2: Compacted Silt Loam Soil

This layer consists of an additional 50 cm of soil from the McGee Ranch area, but without the addition of pea gravel. This layer will be compacted during construction to a design bulk density of about 1.76 g/cm^3. The purpose of Layer 2 is to provide water storage capacity for precipitation and snowmelt and support for vegetation. The purpose of the compaction is to reduce the hydraulic conductivity of the layer.

2.2.1.3 Layer 3: Sand Filter

This layer consists of 15 cm of graded sand that is intended to serve, in conjunction with Layer 4, as a filter, preventing the fine particles of Layer 2 from moving into the lateral drainage layer (Layer 6). Particle size requirements for the sand filter were taken from Cedergren (1989) [also cited in Ecology (1987) and EPA (1989)] and are as follows.

Retention Criteria:	D_{15} (Filter)/ D_{85} (Filtrate) < 4 to 5
	D_{50} (Filter)/ D_{50} (Filtrate) < 25
Permeability Criterion:	D_{15} (Filter)/ D_{15} (Filtrate) > 4 to 5

The D values refer to the particle diameters on a particle size distribution curve (e.g., D_{15} is the particle diameter at which 15% of the particles are smaller). The filter material in this case is the sand; the filtrate material is the compacted silt loam. These filtration criteria were developed for applications in earth dams under saturated conditions. They are expected to be conservative for the unsaturated conditions of the ILAW surface cover.

The presence of the relatively coarse textured sand layer immediately beneath the fine textured silt loam will produce a capillary barrier effect at the interface. This effect arises because the unsaturated hydraulic conductivity of the sand will be significantly less than that of the silt loam for a large range of matric potential. Significant flow into the sand layer will not occur until the matric potential at the silt loam-sand interface becomes sufficiently large (close to zero) that water can move into the relatively large pores of the sand (Hillel, 1980). The capillary barrier will, in effect, increase the water storage capacity of the silt loam layers. Its ability to do so will depend on the hydraulic properties of the silt loam and sand materials.

2.2.1.4 Layer 4: Gravel Filter

This layer consists of 15 cm of a graded gravel that functions, with Layer 3, as a filter, preventing the fine particles of Layer 2 from moving into the lateral drainage layer (Layer 6). Particle size requirements for this layer are identical to those of the sand filter (Layer 3), with the exception that the filter material in this case is the gravel and the filtrate material is the sand. No slope is specified for the sand and gravel filter layers. It is assumed that they will be constructed at a 2% slope (as drawn in Figure 2.2) to minimize required thickness of the surface cover.

2.2.1.5 Layer 5: Gravel Lateral Drainage Layer

This layer consists of 15 cm of screened gravel with a required saturated hydraulic conductivity of no less than 1.0 cm/s. This layer will be constructed at a 2% slope. Its purpose is to divert (to the edge of the cover) water that passes through the filter layers and reaches the asphalt layer (Layer 6).

2.2.1.6 Layer 6: Asphaltic Concrete

This layer consists of 15 cm of a durable asphaltic concrete mixture consisting of double-tar asphalt with added sand as binder material, conforming to WSDOT M41-10, Section 9-02.1(4), Grade AR-4000W (WDOT, 1991). The asphaltic concrete will potentially be coated with a spray-applied asphaltic material. This layer will be constructed at a 2% slope. The asphalt layer is intended to function as a low permeability layer and as an inadvertent intruder barrier. As a low permeability layer, analogous to the compacted soil component of a standard RCRA Subtitle C barrier, the asphalt layer should be expected to have a maximum saturated hydraulic conductivity of 10^{-7} cm/s.

2.2.1.7 Layer 7: Asphalt Base Course

This layer serves as a stable base for placement of the asphalt and consists of 10 cm of screened, crushed surfacing material, with 100% passing the 32 mm sieve. The material must conform to WSDOT M 41-10, Section 9-03.9(3) (WDOT, 1991).

2.2.1.8 Layer 8: Grading Fill

This material consists of a well-graded, granular soil mixture, which may include as much as 20% by volume of cobbles measuring no more than 75 mm in the greatest dimension. This material will be used as needed to establish the base for construction of the other cover layers. Backfill material from excavation of the sites may serve as the grading fill.

2.2.2 Vault Materials

These materials include the vault itself as well as the materials of the waste packages and the filler material.

2.2.2.1 Concrete

The vaults will be constructed of steel-reinforced concrete approximately 1.0 m thick on the bottom and sides. After placing the waste packages and the filler material in the vault, 0.45 m of controlled density fill will be used to fill the vault to the level of the side walls. (Controlled density fill is a mixture of Portland cement, fly ash, aggregate, water, and admixtures proportioned to provide a non-segregating, self-consolidating, free-flowing, and excavatable material that will result in a hardened, dense, non-settling fill.) A steel-reinforced concrete layer 5 to 21 cm thick will be constructed on top of the controlled density fill to create a 2% sloped vault roof. No specifications have currently been given for the concrete or the controlled density fill.

2.2.2.2 Glass Waste and Container

The current design calls for molten glass waste to be poured into stainless steel containers. Although significant fracturing of the glass is anticipated, there have been no studies to determine the extent of the fracturing and the effect this will have on hydraulic properties of the glass.

2.2.2.3 Filler Material

Filler material may be used to fill the void space in the steel waste containers and will be used to fill the space in the vault between the waste containers. The inter-container filler is specified to be an inert material, such as graded sand. Crushed glass is also a possible filler material. Since the inter-container filler material will be poured into the vault from an overhead hopper, it must have a consistency that allows it to flow into the void spaces in the vault with little potential for bridging.

2.2.2.4 Leachate Collection System

A steel-reinforced concrete catch basin will be located beneath the vault to catch leachate. The catch basin will be sloped at 2% toward a trench in the center. The trench will be sloped toward each end of the basin. The interior of the catch basin walls must be no less than 25 cm outside of the exterior of the vault walls. Two 60-mil, high-density polyethylene liners will be used within the catch basin, with a polypropylene geonet placed between the liners and a 60 mil geotextile above the upper liner. Gravel will be placed above the liners and beneath the vault to facilitate movement of water to the leachate detection riser pipes.

2.2.3 Backfill

It is anticipated that backfill around the vault will consist of excavation spoils, potentially screened to remove large cobbles (for use as grading fill immediately beneath the surface cover, for instance). As a result of the excavation, re-emplacement, and compaction, the backfill hydraulic properties are expected to differ from the properties of the naturally occurring sediments. The backfill is likely to be more homogeneous and isotropic.

2.2.4 Water Conditioning Layer

A water conditioning layer consisting of quartz sand or crushed glass is being considered as a component of the facility. The intent of this layer is to increase the silica content of water that contacts the waste, thus reducing the dissolution of silica in the glass waste and decreasing the contaminant flux from the facility. The water conditioning layer would likely be located immediately above the concrete vault, or may even be used as the filler material within the vault. No specifications have been given for the material itself.

2.2.5 Diversion Layer

A diversion layer consisting of a sand and gravel capillary barrier may potentially be used in the final design of the facility covers. This diversion layer would be used as an alternative to, or in addition to, the asphalt low permeability layer. This layer would consist of a well-graded sand overlying a well-graded gravel. The diversion layer would likely be constructed at a 2% slope, corresponding to the other surface cover components.

The required hydraulic properties of the sand and gravel components of the diversion layer depend on the length of the layer and on the expected water flux reaching the layer. Appropriate hydraulic parameters could be determined using numerical modeling and matched to available materials.

3.0 Required Properties and Parameters of Near-Field Materials

This section provides a brief description of the properties and parameters required to model unsaturated flow and nonreactive contaminant transport in the near-field environment of the ILAW disposal facilities. Additional parameters required to model reactive transport are discussed in Kaplan and Serne (1999) and McGrail et al. (1999).

3.1 Particle Size Distribution

The particle size distribution (PSD) is typically presented as the cumulative fraction by weight of particles whose mean diameter is less than a specific value. This physical property is useful for classifying soils (e.g., sand, silt loam), but is not typically used directly in modeling. Those particles greater than 2 mm in diameter are often removed from the sample before measuring the particle size distribution using standard methods (ASTM D422-63; Gee and Bauder, 1986). For ILAW PA purposes, however, the fraction greater than 2 mm should be included in the particle size distribution or recorded as a gravel percentage.

In the absence of a direct measurement of water retention (see Section 3.5), the particle size distribution can be used to estimate water retention by assuming the particle size distribution reflects the pore size distribution (Arya and Paris, 1981).

3.2 Particle Density

Particle density (ρ_p) is the mass of solids in a sample divided by the volume of the solids. It is typically used to calculate porosity. The fraction less than 2 mm may be used in the measurement of particle density (Blake and Hartge, 1986b).

3.3 Bulk Density

The dry bulk density (ρ_b) is the mass of solids in a sample divided by the total (bulk) volume of the sample. The total volume includes the volume occupied by the solids, water (or other liquid), and air. Due to the potential for compaction during sampling, bulk density measured in the laboratory may vary from that measured *in situ* (Blake and Hartge, 1986a). Bulk density is used to calculate porosity and retardation coefficients. Some techniques for estimating water retention and hydraulic conductivity may also use the bulk density.

3.4 Porosity

Porosity (ϕ) is the volume of voids in a sample (the air- and liquid-filled volume) divided by the total volume of the sample. It is typically calculated using measured values of particle and dry bulk densities.

$$\phi = 1 - \rho_b/\rho_p \quad (3.1)$$

The porosity can also be measured directly (Danielson and Sutherland, 1986).

3.5 Water Retention

Water retention [$\theta = f(\psi)$]in a porous medium refers to the relationship between water content and matric potential. Volumetric water content (θ) is the volume of water in a sample divided by the total volume of the sample. The matric potential represents the capillary and adsorptive forces that attract and bind water to the soil matrix. (Matric potential is also referred to as soil water pressure or negative soil water tension.) A variety of methods are available to obtain water retention data (Klute, 1986; Rawlins and Campbell, 1986; Wierenga, et al., 1993). In some cases, laboratory measurements of water retention have been conducted on samples for which the gravel fraction (particle diameter > 2 mm) has been removed. The water contents obtained on such samples should be corrected for the gravel content (Bouwer and Rice, 1983; Gardner, 1986) before estimating the parameters of a water retention model.

Water retention is typically represented in simulation codes using one of a number of water retention models that have been presented in the literature. In this report, the model proposed by van Genuchten (1980) is used:

$$S_e(\psi) = [1 + (\alpha\psi)^n]^{-m} \quad (3.2)$$

where

ψ = matric potential

S_e = effective saturation = $\frac{\theta - \theta_r}{\theta_s - \theta_r}$, $0 \le S_e \le 1$

α = curve fitting parameter related to air entry pressure

n, m = curve fitting parameters related to pore size distribution; the relationship, m=1-1/n, is often assumed

θ_r = residual (or irreducible) water content

θ_s = saturated water content.

The saturated water content is often assumed to be equal to porosity. It has been observed in laboratory and field measurements, however, that soils often cannot be saturated to the full porosity. This effect is more pronounced in the field, presumably because of the greater variation in soil structure and the inability to carefully control wetting. For this reason, θ_s is sometimes a fitted parameter, in which case it represents a field-saturated water content. Klute (1986) states that field-saturated water content is typically 80 to 90% of the porosity.

The residual water content is interpreted here as an empirical parameter and thus is generally a fitted parameter. This interpretation is a subject of debate (Nimmo, 1991; Luckner et al., 1991). At very low matric potentials (large negative values), the van Genuchten model may provide a poor representation of water

retention. Alternative models have been proposed that improve the fit at low water contents (Rossi and Nimmo, 1994; Fayer and Simmons, 1995). Because water contents in the ILAW disposal facilities and the surrounding soils are expected to be low, accurate representation by the water retention model may be important. This is especially true if diffusion dominates the transport of contaminants and a water-content-dependent diffusion coefficient is used.

The remainder of the parameters in the van Genuchten water retention model are fitting parameters, estimated using measured or inferred water retention data.

There are many water retention models that could be used. Although the parameters in the van Genuchten model are related to the parameters used in other models, the transformation from one to the other is not always straightforward. Caution should be exercised in using the results presented in this report with water retention models other than the van Genuchten model.

Water retention in soils and sediment exhibits hysteresis: the observed water content at a given matric potential depends on whether the soil is being wetted or is drying. Models have been developed for describing this hysteresis, but the data on which the parameters of hysteresis can be estimated are often not available. Hysteresis is likely to be most important near the ground surface where water content changes with time will be the largest. In the deeper materials (below the cover), water content changes will be less significant and hysteresis effects are not anticipated to be significant.

3.6 Saturated Hydraulic Conductivity

Darcy's Law is used in models of subsurface flow to relate water flux to the potential gradient. Under saturated conditions, the proportionality constant in this relationship is the saturated hydraulic conductivity (K_s). Measurements can be made using a variety of methods (Klute and Dirksen, 1986). Saturated hydraulic conductivity may exhibit anisotropy: a value that depends on the direction in which it is measured. Data on anisotropy are typically not available. Hydraulic conductivity anisotropy is not anticipated to be significant in any single near-field material. At a scale that encompasses multiple near-field materials that have contrasting properties, anisotropy should be considered.

Saturated hydraulic conductivity measurements are often made on small-scale laboratory samples. Because of the variability in natural materials, these small-scale measurements should not be interpreted as field-measured hydraulic conductivity values, which are typically larger. Values used in numerical models should represent the scale of the numerical grid size. The appropriate scaling methods for deriving model values of saturated hydraulic conductivity from laboratory measurements is currently a matter of scientific debate. Because the near-field materials will be relatively homogeneous, this scale issue is anticipated to be less important than for the naturally occurring sediments.

3.7 Unsaturated Hydraulic Conductivity

Under unsaturated conditions, the water flux occurring through a porous material in response to a specified potential gradient is strongly dependent on the water content of the material. The unsaturated hydraulic conductivity [$K = f(\theta, \psi)$] describes this dependence. Direct measurement of the unsaturated hydraulic conductivity as a function of water content is possible using a steady-state method (Klute and Dirksen, 1986) and centrifugal methods (Nimmo et al., 1987; Nimmo, 1990; Conca and Wright, 1992; Wright et al., 1994), but such data is often not available. More typically, the unsaturated hydraulic conductivity relationship is estimated using water retention and saturated hydraulic conductivity measurements and adopting a particular model (Mualem, 1986). Eching and Hopmans (1993) and Eching et al. (1994) present an alternative method of estimating unsaturated hydraulic conductivity using outflow measurements, but this method also requires adopting a specific model.

The unsaturated hydraulic conductivity model used in this report is the model derived by van Genuchten (1980) using the relationship of Mualem (1976). This model can be written either in terms of the water content or the matric potential.

$$K(S_e) = K_s\sqrt{S_e}\left[1-\left(1-S_e^{1/m}\right)^m\right]^2 \tag{3.3}$$

$$K(\psi) = K_s\frac{\left\{1-(\alpha\psi)^{n-1}\left[1+(\alpha\psi)^n\right]^{-m}\right\}^2}{\left[1+(\alpha\psi)^n\right]^{0.5m}} \tag{3.4}$$

Parameters in these equations are as defined for the water retention model and can be estimated using both water retention and unsaturated hydraulic conductivity data when available. The factor of 0.5 in the exponent of the denominator of Equation 3.4 represents the pore interaction term. A value of 0.5 is typical.

Khaleel et al. (1995) found that the van Genuchten-Mualem model did not provide accurate estimates of unsaturated hydraulic conductivity for Hanford sediments at low water contents when these estimates were based solely on water retention data and a saturated hydraulic conductivity measurement. This condition may be explained by observing that the saturated hydraulic conductivity for these relatively coarse materials is dominated by large pores, whereas the unsaturated hydraulic conductivity appears to be dominated by small pores. Khaleel et al. (1995) recommended the use of at least one direct measurement of hydraulic conductivity at a low water content as a match point.

3.8 Dispersivity

Dispersivity (λ), when multiplied by the pore water velocity, yields the mechanical dispersion coefficient, which relates the dispersive solute flux to the solute concentration gradient. Dispersivity is generally larger in the direction of flow than in transverse directions and it is also scale dependent. Khaleel

(1999) provides a discussion of the issues related to scale-dependent dispersion. Because of the smaller scale and the relative homogeneity, this issue is likely to be less important for the near-field materials.

Field measurements of dispersivity are extremely rare and small-scale laboratory measurements have only marginal utility in estimating field values. In the absence of data, dispersivity values are often based on simple guidelines related to the size of the computation elements in numerical simulation codes.

3.9 Diffusion Coefficient

The diffusion coefficient is the proportionality factor in Fick's law that relates the diffusive transport flux to the gradient in solute concentration. Diffusion results in mass transport from regions of high solute concentration to regions of lower concentration and occurs as a result of the random thermal motion (Brownian motion) of molecules and atoms. Diffusive transport in a dilute water solution is quantified by the free-water diffusion coefficient, D_f. Several models have been proposed for calculating the diffusion coefficient of a dilute solute in water (Grathwohl, 1998). The viscosity of the solution, which depends strongly on temperature, affects D_f most directly. For most simple aqueous species D_f is about 10^{-5} cm^2/s (10^{-9} m^2/s). Kemper (1986) provides a table of diffusion coefficients of common ions in water; values range from approximately 4.8×10^{-6} to 1.6×10^{-5} cm^2/s at 15 °C.

In the constrained geometry of a porous medium, the diffusion coefficient is reduced compared to the diffusion coefficient in free aqueous solution. The intrinsic diffusion coefficient for a species within a saturated porous medium, D_i, can be expressed as

$$D_i = D_f \phi \delta/\tau \tag{3.5}$$

where δ = a constrictivity factor

$1/\tau$ = a tortuosity factor.

The intrinsic diffusion coefficient has also been referred to as the effective diffusion coefficient.

The constrictivity factor in Equation 3.5 represents a reduction in diffusion due to the constricted flow path caused by small pores and pore throats in the porous medium. The effect of constrictions on diffusion has been attributed to an increased viscocity in the vicinity of the pore walls (Grathwohl, 1998) and electrical interactions (Kemper, 1986). The tortuosity factor represents a reduction in diffusion due to the increased path length taken by solute molecules in traveling through the porous medium. The tortuosity factor is given by $1/\tau = (L/L_e)^2$, where L_e is the length of the tortuous path and L is the straight-line path length (Porter et al. 1960).

In a saturated porous medium, the cross-sectional area available for diffusion in the aqueous phase is reduced by the volume fraction of the void space. This fraction will be the total porosity, ϕ, if all porosity in the porous medium is interconnected and can thus contribute to contaminant diffusion. If there are pores that do not contribute to diffusion (such as dead end pores), the porosity appearing in Equation 3.5 will be less than the total porosity.

In practice, it is difficult to directly measure or reliably estimate the constrictivity and tortuosity factors. As a result, the intrinsic diffusion coefficient is frequently modeled as a function of the porosity alone.

$$D_i = D_f \phi^{\beta} \tag{3.6}$$

In this equation, β is an empirical parameter incorporating the tortuosity and constrictivity effects. The empirical form of this equation is attributed to Buckingham (1904) (although it was then proposed to describe the equivalent concept of effective diffusion of a vapor-phase species through the air-filled pore space of a porous medium). Millington (1959) derived a value of $\beta = 4/3$. Grathwohl (1998) states that the expected range of β for most natural porous media is 1.5 to 2.5.

In unsaturated porous media, Equation 3.5 or 3.6 must be modified to account for the additional reduction in cross-sectional area available for diffusion as a result of the reduced volumetric water content. Millington (1959) derived a model for gas-phase diffusion in unsaturated porous media that has also been applied to aqueous-phase diffusion. [See also Millington and Quirk (1959; 1961).] The Millington expression for the intrinsic diffusion coefficient in unsaturated porous media is

$$D_i = D_f \theta^{10/3}/\phi^2 \tag{3.7}$$

This model assumes $\delta = 1$ in Equation 3.5, replaces the porosity with the volumetric water content, and results in a tortuosity factor defined by $1/\tau = \theta^{7/3}/\phi^2$. In the saturated case with $\theta = \phi$, Equation 3.7 reduces to Equation 3.6 with $\beta = 4/3$.

Papendick and Campbell (1980), citing Brooks and Corey (1966), assumed a tortuosity factor in Equation 3.5 of $1/\tau = c\theta^2$. With $\delta = 1$ and the volumetric water content replacing the porosity, Equation 3.5 becomes

$$D_i = cD_f \theta^3 \tag{3.8}$$

Campbell (1985) suggested that the empirical parameter 'c' in this relationship could be taken as a constant with a value of $c = 2.8$.

Kemper and Van Schaik (1966), Olsen et al. (1965), Olsen and Kemper (1968) and Porter et al. (1960) developed a model for diffusive transport in agricultural systems.

$$D_i = a\, D_f \exp(b\theta) \tag{3.9}$$

where a = an empirical constant based on particle size (0.003 is a representative value for sand)

b = an empirical constant based on particle size (10 is a representative value for sand).

The value of the diffusion coefficient can vary significantly depending on which of the empirical relationships (Equations 3.7 to 3.9) is used, particularly at low water contents. For example, $\log(D_i)$ is linear in θ using Equation 3.9, but is nonlinear for the other two models. Furthermore, Equations 3.7 and 3.8 are similar for porosities of 0.4 to 0.6, but can be significantly different for porosities outside this range, particularly porosities that are smaller than 0.3. Fayer and Kincaid (1998)[1] demonstrate the potential impact of using different diffusion relationships for a waste-form-alone simulation (no vault) of the new

ILAW disposal facility. Predictions of dose were reduced by more than 80% when using Equation 3.7 as compared with using Equation 3.9. A discussion in Section 5.3 of available diffusion data suggests that the model of Kemper and Van Schaik (Equation 3.9) is inappropriate for use in the ILAW PA.

The chemical contributions to diffusion can potentially be quite varied (ion-exchange, specific adsorption, precipitation, and lattice substitution) as well as quite significant. If we assume a very simple chemical process, i.e., reversible surface adsorption having fast kinetics and a linear isotherm (adsorption is proportional to the concentration in solution via a fixed constant, K_d), then diffusion of a reactive contaminant can be characterized by an apparent diffusion coefficient, D_a:

$$D_a = D_i/\alpha' = D_f \delta \phi/(\tau \alpha') \tag{3.10}$$

using Equation 3.5 for the intrinsic diffusion coefficient. In this equation, α' is the capacity factor or ratio of the moles of contaminant per unit volume of water-saturated solid, C_s, to the moles of contaminant per unit volume of liquid, C_l. The capacity factor is related to the distribution coefficient, K_d, by the equation

$$\alpha' = \phi + \rho_b K_d \tag{3.11}$$

where ρ_b is the dry bulk density of the porous media and K_d is the amount of contaminant adsorbed per unit mass of porous solid divided by the amount of contaminant per unit volume of liquid. Also note that α'/ϕ is the familiar retardation factor used in transport modeling in water-saturated porous media:

$$\alpha'/\phi = R = 1 + \rho_b K_d/\phi. \tag{3.12}$$

For unsaturated porous media, it is appropriate to replace the porosity in Equations 3.10 to 3.12 with the volumetric water content.

Remember that these simple relationships are strictly valid only for reversible, linear adsorption reactions with fast kinetics. These conditions may not be met for many actual porous media-contaminant-solution interactions. Nevertheless such simplifying assumptions allow for some useful analysis such as performed in the ILAW PAs. In Equation 3.10 one can see that the term D_i contains all the physical aspects of diffusional transport and the term α' contains all the chemical aspects of diffusional transport. Because the distribution coefficient for different contaminants in various porous media can be substantially greater than 1 cm^3/g, the apparent diffusion coefficient may be significantly less than the value of the intrinsic diffusion coefficient.

4.0 Best-Estimate Values for Hydraulic Parameters of Near-Field Materials

This section contains best-estimate values for the hydraulic parameters of the near-field materials to be used in performance assessment analyses of the ILAW disposal facilities. A description of the source of these values is included. In determining the best-estimate parameter values it has been assumed in most cases that the saturated volumetric water content is equal to the porosity. This assumption was made to avoid the application of an arbitrary factor to account for field saturation in such disparate materials as gravel and concrete. In those cases where a model was fit to water retention data the saturated water content was a fitted parameter and may be less than the porosity. Best-estimate values for transport parameters are discussed in Chapter 5. Information on parameter uncertainty and changes in parameter values over time is discussed in Chapter 6.

4.1 Cover Materials

4.1.1 Silt Loam-Gravel Admix

The silt loam component of this material is specified to come from the McGee Ranch area on the Hanford Site. Gee et al. (1989) obtained sixteen samples of this soil from the top meter of a site in the McGee Ranch area. Particle size analysis of the samples yield textures from loam to silt loam with the percentage of sand ranging from 32 to 44%, silt from 42 to 59%, and clay from 7 to 16%. The average particle density of the samples was 2.72 g/cm^3. Samples were packed to a bulk density of 1.37 g/cm^3 and the saturated hydraulic conductivity and water retention (drying curve) were measured.

Gee et al. (1989) estimated hydraulic parameters of the van Genuchten-Mualem model for each McGee Ranch soil sample. In addition, they determined average parameters by simultaneously fitting data from all sixteen samples. Gee et al. (1989) reported that complete saturation was not achieved in the samples during the hydraulic conductivity measurements. Thus the saturated hydraulic conductivity was a fitted parameter in their study with the measured values used as match points. The average parameter values reported by Gee et al. (1989) for the McGee Ranch soil samples were as follows:

$\theta_s = 0.496$, $\theta_r = 0.0049$, $\alpha = 0.0163$ cm^{-1}, $n = 1.372$, and $K_s = 9.9 \times 10^{-4}$ cm/s.

To adjust the silt loam parameters for a 15% by weight addition of pea gravel, the relationships of Bouwer and Rice (1983) were used. These relationships have been used previously for Hanford soils (e.g., Khaleel and Freeman, 1995). The water content was updated using the relationship

$$\theta^{Mix} = (1 - F_g)\,\theta^{SiL} \tag{4.1}$$

where θ^{Mix} is the volumetric water content of the silt loam-gravel admix, θ^{SiL} is the volumetric water content of the silt loam, and F_g is the volume fraction of gravel (the volume of gravel divided by the total volume of the silt loam-gravel admix).

F_g can be calculated by assuming that the addition of gravel to the silt loam soil does not increase the volume of voids in the sample (i.e., there is no porosity associated with the gravel). With a 1000 g sample of silt loam-gravel admix, for example, the volume of silt loam is the ratio of silt loam mass (850 g) to silt loam bulk density (1.37 g/cm^3), or 620.4 cm^3. The volume of gravel is the ratio of gravel mass (150 g) to gravel particle density (2.72 g/cm^3), or 55.1 cm^3. The gravel particle density used is the average density reported by Rockhold et al. (1993) for samples from a borehole adjacent to the existing disposal facility, and is comparable to the values measured for cores taken from a borehole adjacent to the new ILAW disposal site.[1] Using the values above, the volume fraction of gravel in the silt loam-gravel admixture is $F_g = 55.1/(55.1 + 620.4) = 0.0816$. The bulk density of the admixture is 1.48 g/cm^3.

The saturated hydraulic conductivity of the silt loam-gravel admixture is estimated using a relationship from Bouwer and Rice (1983).

$$K_s^{Mix} = (e^{Mix}/e^{SiL})\, K_s^{SiL} \tag{4.2}$$

where K_s^{Mix} is the saturated hydraulic conductivity of the silt loam-gravel admixture, K_s^{SiL} is the saturated hydraulic conductivity of the silt loam, and e^{Mix} and e^{SiL} are the void ratios of the admixture and silt loam soils, respectively. The void ratio is a function of the porosity, with $e = \phi/(1 - \phi)$. Using the bulk and particle densities listed above and Equation 3.1 to calculate the porosities, the scaling factor for the saturated hydraulic conductivity is $e^{Mix}/e^{SiL} = 0.850$.

Applying the scaling factors for the water content and hydraulic conductivity to the silt loam parameters listed above results in the best-estimate physical and hydraulic parameters for the silt loam-gravel admixture given in Table 4.1.

Table 4.1. Best-Estimate Parameter Values for Silt Loam-Gravel Admixture

ρ_p (g/cm^3)	ρ_b (g/cm^3)	θ_s	θ_r	α (cm^{-1})	n	K_s (cm/s)
2.72	1.48	0.456	0.0045	0.0163	1.37	8.4×10^{-4}

4.1.2 Compacted Silt Loam

This material is also specified to come from the McGee Ranch area on the Hanford Site. The silt loam parameters obtained by Gee et al. (1989) were adjusted to account for an increase in bulk density from 1.37 g/cm^3 used by Gee et al. (1989) in their measurements to a value of 1.76 g/cm^3 as specified in DOE-RL (1993). The effect of the compaction was estimated using the relationships of Arya and Paris (1981). Since the compaction will not affect the particle size distribution, the equations presented in Arya

[1] Fayer, M.J., A.L. Ward, J.S. Ritter, and R.E. Clayton. 1998. "Physical and Hydraulic Measurements of FY 1998 Borehole Cores." Letter Report to Fluor Daniel Northwest, Inc., September 10, 1998, Pacific Northwest National Laboratory, Richland, Washington.

and Paris (1981) can be used with the compacted bulk density to estimate the expected change in water content and soil matric potential as a result of the compaction. Water contents are expected to be reduced by a factor of $(\rho_p - \rho_{bc})/(\rho_p - \rho_{bu})$ where the c and u subscripts indicate the compacted and uncompacted bulk densities. Soil matric potentials will be increased by a factor of $\sqrt{e_u/e_c}$ where e indicates the void ratio of the uncompacted and compacted soils and is calculated as $e = (\rho_p - \rho_b)/\rho_b$.

Preliminary water content-matric potential pairs were generated using the silt loam parameters determined by Gee et al. (1989). The generated values were then adjusted for the effect of compaction using the factors given above, and the van Genuchten water retention function was fit to the adjusted water content-matric potential pairs. The resulting parameters for the compacted silt loam soil are given in Table 4.2. The saturated hydraulic conductivity in this table is the geometric mean of two measurements made by Wing (1993) on compacted silt loam soil from the McGee Ranch area. These samples were compacted to 1.70 and 1.75 g/cm^3. This hydraulic conductivity value is similar to the value of 1.4×10^{-6} cm/s reported by Skelly (1994) for measurements on compacted silt loam samples from the McGee Ranch area.

Table 4.2. Best-Estimate Parameter Values for Compacted Silt Loam

ρ_p (g/cm^3)	ρ_b (g/cm^3)	θ_s	θ_r	α (cm^{-1})	n	K_s (cm/s)
2.72	1.76	0.353	0.0035	0.0121	1.37	1.8×10^{-6}

4.1.3 Sand Filter

Wing (1993) measured the physical properties and saturated hydraulic conductivity of a variety of materials used in the construction of a prototype Hanford Barrier on the Hanford Site. The design of this barrier is similar to the barrier design to be used in the ILAW disposal facilities. Wing (1993) report on the properties of two sand samples prepared from sediments gathered from the excavation spoil pile of the existing disposal facility. The sediments were sieved to provide two samples that bracketed a specified range in particle size distribution. Measurements were made on both the fine and coarse samples at two bulk densities, representing uncompacted and compacted conditions.

It is assumed here that the sand filter will be compacted during construction. The best-estimate parameter values for the sand filter are listed in Table 4.3. The particle density and bulk density are the average values of the compacted samples from Wing (1993). The porosity (and saturated water content) calculated from these two values is 0.318. The best-estimate saturated hydraulic conductivity is the geometric average of the compacted sand values reported by Wing (1993). Water retention parameters were estimated from the particle size distribution using the midpoint of the ranges specified in Wing (1993). The particle size distribution range specified in Wing (1993) and the distribution assumed here are shown in Table 4.4. The method of Arya and Paris (1981) was used to calculate water retention points from the particle size distribution. An average soil temperature of 20°C (PNL, 1973) and a contact angle of zero were

assumed in these calculations. The van Genuchten water retention function was fit to the calculated points to provide the parameter values for θ_r, α, and n shown in Table 4.3.

Table 4.3. Best-Estimate Parameter Values for Sand Filter

ρ_p (g/cm^3)	ρ_b (g/cm^3)	θ_s	θ_r	α (cm^{-1})	n	K_s (cm/s)

No. 200	0.075	1 - 25	12

4.1.4 Gravel Filter

Best-estimate parameter values for the gravel filter material were calculated in a manner similar to the sand filter. Wing (1993) obtained 5/8 in. crushed basalt road top course and prepared two samples corresponding to the fine and coarse extremes of a specified particle size distribution. This material was also used in the prototype Hanford Barrier (Buckmaster, 1993). The average particle and bulk densities of compacted samples of the crushed basalt are given in Table 4.5. Porosity (and saturated water content) was calculated from these two values. The best-estimate saturated hydraulic conductivity is the geometric mean of the two sample values measured by Wing (1993). Water retention parameters were calculated using the method of Arya and Paris (1981) with the particle size distribution assumed to be the midpoint of the values specified in Wing (1993). Particle size distributions are shown in Table 4.6.

Table 4.5. Best-Estimate Parameter Values for Gravel Filter

No. 200	0.075	0 - 10	5

4.1.5 Gravel Lateral Drainage Layer

No measurements are available for the gravel drainage layer material. It was assumed that this layer would be composed of crushed basalt and could be compacted to the same bulk density as the gravel filter layer. The particle density, bulk density, and porosity (saturated water content) were thus assumed to be the same as those of the gravel filter. Water retention parameter values for the gravel drainage layer were based on particle size distribution requirements for the gravel drainage component of the prototype Hanford Barrier as given in Buckmaster (1993). As with the sand and gravel filters, the midpoint particle size distribution was assumed and the Arya and Paris (1981) method was used to calculate the parameters, which are given in Table 4.7. The particle size distribution range and midpoint are given in Table 4.8. Saturated hydraulic conductivity is an estimated value based on the minimum required conductivity (1.0 cm/s) and the measurement (via the constant head method) of a gravel sample in Rockhold et al. (1993). This sample had a saturated hydraulic conductivity of 1.85 cm/s.

4.1.6 Asphaltic Concrete

No water retention measurements on asphaltic concrete have been found in the literature. In estimating parameters for use in the Grouted Tank Waste Disposal PA (Kincaid et al., 1995), Rockhold et al. (1993) assumed that the asphalt layer was impermeable to liquid water and assigned a low conductivity (10^{-20} cm/s) to achieve this. Clemmer et al. (1992) analyzed several asphalt samples and estimated a porosity of 3% to 4% and a hydraulic conductivity of 2×10^{-13} cm/s based on measured N_2 permeability. Hydraulic conductivity values reported in DOE-RL (1993) for asphaltic concrete are 10^{-10} cm/s based on falling head measurements in the laboratory and 10^{-7} to 10^{-9} cm/s for in-field values measured with a falling head permeameter (DOE-RL, 1994). These tests were carried out on materials used in the prototype Hanford Barrier. The spray-applied asphalt coating is expected to reduce the permeability of the asphaltic concrete layer. A polymer-modified asphalt coating from the Hanford Barrier prototype had measured hydraulic conductivity values of approximately 10^{-11} cm/s (Freeman et al., 1994).

Best estimate parameter values for the asphaltic concrete are given in Table 4.9. The average particle density was assumed to be the same as that of the concrete (see Section 4.2.1). The bulk density was calculated from this assumed particle density and the saturated water content. Water retention parameters θ_r, α and n are those assumed by Rockhold et al. (1993) and are not based on data. The saturated hydraulic conductivity assumes that a low permeability coating is applied to the asphaltic concrete.

Table 4.9. Best-Estimate Parameter Values for Asphaltic Concrete

ρ_p (g/cm^3)	ρ_b (g/cm^3)	θ_s	θ_r	α (cm^{-1})	n	K_s (cm/s)
2.63	2.52	0.04	0.000	1.0×10^{-7}	2.0	1.0×10^{-11}

4.1.7 Asphalt Base Course and Grading Fill

The asphalt base course and grading fill components fulfill structural requirements of the disposal facility, but are unlikely to have a significant impact on water flow or contaminant transport. For this rea-

son, they are assigned the hydraulic parameters of materials discussed in other sections. The best-estimate parameter values for the asphalt base course are the same as those of the gravel lateral drainage layer material (Section 4.1.5), which meets the maximum particle size requirement of the base course. These parameter values are repeated here in Table 4.10. The backfill material (Section 4.4.1) is likely to be suitable for use as grading fill. The parameter values of the backfill are thus assigned to the grading fill and given here in Table 4.11.

Table 4.10. Best-Estimate Parameter Values for Asphalt Base Course

ρ_p (g/cm^3)	ρ_b (g/cm^3)	θ_s	θ_r	α (cm^{-1})	n	K_s (cm/s)
2.725	1.935	0.290	0.006	17.8	4.84	2.0

1.89	2.76	0.316	0.049	0.035	1.72	1.91×10^{-3}

4.2 Vault Materials

4.2.1 Concrete

The concrete for the new ILAW disposal facility has not yet been specified and the hydraulic properties of the concrete in existing disposal vaults have not been measured. To provide representative parameter values for the concrete components of the disposal facilities (i.e., the vault itself and the leachate collection system), a number of cores were obtained from the wall of a concrete munitions bunker near Gable Butte on the Hanford Site. This bunker, designated 213J, was built in the late 1940s. This vault was chosen for coring because of the available access to the interior of the vault and because the outer wall has been buried in Hanford sediments for 50 years under natural conditions similar to those expected in the ILAW disposal vaults. Seven cores were drilled from the interior of the vault, five of which were cored all the way to the soil interface on the exterior side of the vault wall (approximately 30.5 cm, or 12 inches). Two of the cores were intact, one had a single clean fracture, and the others fractured when steel reinforcing bars were contacted. The cores were about 4.5 cm in diameter, a dimension chosen to allow collection of intact cores that could be used with minimal modification as samples in a centrifuge machine.

Two of the cores were selected for hydraulic property measurements. After removing a thin layer on the interior and exterior ends of the cores, three sections about 5.5 cm long were cut for samples. Two sections were from each end of the cores, and one section was from the middle. The samples were initially saturated with CO_2 and then vacuum saturated for at least 72 hours with a synthetic Hanford vadose zone

water. Bulk density was calculated from the dry weight and known bulk volume of each sample. Saturated water content was calculated from the difference between the dry and saturated sample weights and the known bulk volume of each sample. Particle density was calculated from the saturated water content and the bulk density.

Water retention and hydraulic conductivity were measured using centrifuge techniques.[1, 2] The parameters of the van Genuchten function, α and n, were fit to the water retention data. Residual water content was assumed to be zero in the fitting procedure, which resulted in superior fits to the data. Hydraulic conductivity was sufficiently low that no unsaturated values could be obtained. Average values for the six concrete samples are given in Table 4.12 and should be used as the best-estimate values until further information about the concrete specifications of the ILAW vaults is known. Arithmetic averages are given except for α and K_s, which are the geometric averages.[3]

Table 4.12. Best-Estimate Parameter Values for Concrete

ρ_p (g/cm^3)	ρ_b (g/cm^3)	θ_s	θ_r	α (cm^{-1})	n	K_s (cm/s)
2.63	2.46	0.067	0.00	3.87×10^{-5}	1.29	1.33×10^{-9}

4.2.2 Filler Material

The filler material to be used in the vault has not been specified. It is assumed here that a quartz sand will be used. This material provides the desired texture to fill the voids and will provide the additional benefit of serving as a water conditioning medium. The parameters given in this section should be used for both the filler material within the steel waste containers and for the filler material between the waste containers until additional specifications for these materials are available.

Kaplan et al. (1998) report measurements made on a coarse quartz sand sample that may be suitable as the filler material. [Kaplan et al. (1998) identify this sand as #2095 Industrial Quartz, Unimin Corp., Emmett, Idaho. It has also been referred to as No. 8 sand.] In this material, particle size was greater than 2 mm for 3.4%, between 1 and 2 mm for 87.5%, and between 0.5 and 1 mm for 8.2%. The particle density of this material was about 2.56 g/cm^3. It was packed to a bulk density of 1.56 g/cm^3 resulting in a porosity of

0.39. Saturated hydraulic conductivity and water retention measurements were made. The van Genuchten function was fit to the water retention data reported by Kaplan et al. (1998). The resulting parameters for the quartz sand are:

$\theta_s = 0.39$, $\theta_r = 0.005$, $\alpha = 0.014$ cm^{-1}, n = 2.82, and $K_s = 0.0712$ cm/s.

Because the matric potential values used by Kaplan et al. (1998) in their water retention measurements do not adequately delineate the water retention curve, the resulting parameters are not reliable.

The same quartz sand material analyzed by Kaplan et al. (1998) was also evaluated more recently using the multistep outflow method of Eching et al. (1994). A sample of the sand was packed to a bulk density of 1.586 g/cm^3; average particle density was measured at 2.63 g/cm^3. This resulted in a porosity of 0.397. Estimated water retention and hydraulic conductivity parameter values from the multistep outflow experiment are given in Table 4.13. These values are the best-estimate parameter values for the filler material.

Table 4.13. Best-Estimate Parameter Values for Filler Material

ρ_p (g/cm^3)	ρ_b (g/cm^3)	θ_s	θ_r	α (cm^{-1})	n	K_s (cm/s)
2.63	1.59	0.397	0.005	0.106	4.26	3.79×10^{-2}

4.2.3 Glass Waste

According to current plans, the glass waste will be poured into steel packages and allowed to cool. Significant fracturing is anticipated. It is assumed here that the fracturing will be sufficient to allow the glass waste to be treated as an effective porous medium, instead of a fractured medium, and thus the parameters are the same as for the other materials. All porosity in the glass will reside in the fractures (i.e., the glass matrix has no porosity). Total porosity is anticipated to be small – on the order of a few percent[1]. A porosity of 2% was assumed for the best estimate, given in Table 4.14. Bulk density was calculated from the porosity and the measured particle density of ILAW glass (BP1 glass)[1].

McGrail et al. (1998) report hydraulic measurements on crushed and sieved glass waste samples. Glass samples were crushed by hand and sieved to obtain particles between 0.15 and 0.212 mm (the size of fine sand). The sieved material was washed to remove fines smaller than 0.15 mm. Although the process of crushing the glass will result in a porosity much higher than expected to occur in the disposal containers, these are the only known measurements of the hydraulic properties of the glass waste.

The glass samples prepared by McGrail et al. (1998) were packed to a porosity of approximately 0.55. Water retention and unsaturated hydraulic conductivity were measured using centrifuge methods.

1. B.P. McGrail, July 1999, personal communication.

Although the results reported in McGrail et al. (1998) were limited, they indicate that the material behaved similarly to a fairly well-graded loam or sandy loam soil with an air-entry matric potential less than 50 cm. It is difficult, however, to draw conclusions about the best-estimate hydraulic parameters from these experimental results because of the dissimilarity between the expected glass waste form and these sample materials. Measurements on more representative materials are planned for FY 2000.

Assuming that the glass block will be sufficiently fractured to behave as an equivalent porous medium and with the additional assumption that the fracture apertures in the glass waste will have a relatively narrow distribution, it can be expected that the glass waste will behave like a well-sorted material. This suggests a value of n greater than 2 or 3. The value of α and K_s will depend on the actual fracture apertures, which are unknown. If significant fracturing occurs, and yet the porosity remains small, this suggests that the fracture aperture will be small. For the best-estimate hydraulic parameters of the fractured glass waste it has been assumed that the glass waste will behave similarly to a coarse sand. Parameter values, given in Table 4.14, are based on these assumed characteristics of the glass and on representative parameters for a coarse sand.

Note that Fayer et al. (1997) and Fayer and Kincaid (1998)[1] used properties of a clean gravel to represent the glass fractures in a dual porosity model of the new ILAW disposal facility. These properties were measured by Rockhold et al. (1993), with saturated and residual water contents reduced to reflect the low porosity of the fractured glass waste. Particle size in the sample measured by Rockhold et al. (1993) varied from 3.7 to 8 mm. The parameters given in Table 4.14 reflect a small anticipated fracture aperture and thus smaller α and K_s values. The best-estimate α and n values are comparable to the estimates obtained by Reitsma and Kueper (1994) from measurements made on a single fracture in a limestone rock sample.

Table 4.14. Best-Estimate Parameter Values for Glass Waste

2.68	2.63	0.02	0.00	0.2	3	0.01

4.3 Diversion Layer Materials

A diversion layer consisting of a sand drainage layer over a gravel capillary barrier is not a component of the current conceptual design of the new ILAW disposal facility as described in PHMC (1998). It is under active consideration, however, and may be included in the final design as a replacement for, or in addition to, the asphaltic concrete layer. Specifications for the hydraulic properties of the sand and gravel

[1] Fayer, M.J. and C.T. Kincaid. 1998. *Simulations to Guide Measurements of Near-Field Hydraulic Parameters.* Letter Report to Fluor Daniel Hanford, Inc., September 30, 1998, Pacific Northwest National Laboratory, Richland, Washington.

materials will depend on the required performance of the diversion layer and on the particular design of the layer in terms of its dimensions and slope. The materials will need to be chosen to achieve satisfactory hydraulic performance and long-term stability. Nichols and Meyer (1996) performed detailed, two- and three-dimensional simulations of capillary barrier performance for three sand/gravel combinations and three values of slope. Until further analysis is carried out to define the diversion layer materials for the ILAW facilities, hydraulic properties for the materials of the diversion layer are assumed equal to those of materials used in the simulations of Nichols and Meyer (1996) that resulted in the best performance.

4.3.1 Sand Drainage Layer

The best-estimate parameters of the sand drainage layer are those estimated by Rockhold et al. (1993) for a backfill sample. This sample was obtained from the excavation spoil pile of the existing disposal facility. The material was sieved to remove particles greater than 2 mm. The resulting material was 91% sand, 3% silt, and 6% clay. These parameter values were also used by Nichols and Meyer (1996) for the sand component of the best-performing capillary barrier they simulated. The parameter values are given in Table 4.15.

Table 4.15. Best-Estimate Parameter Values for Sand Drainage Layer

ρ_p (g/cm^3)	ρ_b (g/cm^3)	θ_s	θ_r	α (cm^{-1})	n	K_s (cm/s)
2.8	1.65	0.371	0.045	0.0683	2.08	3.00×10^{-2}

4.3.2 Gravel Capillary Barrier Layer

The best-estimate parameter values of the gravel capillary barrier layer are those estimated by Rockhold et al. (1993) for a gravel sample. This sample had particle sizes in the range of 4 to 8 mm. These parameters were also used by Nichols and Meyer (1996) for the gravel component of the best-performing capillary barrier they simulated. The parameter values are given in Table 4.16.

Table 4.16. Best-Estimate Parameter Values for Gravel Capillary Barrier Layer

ρ_p (g/cm^3)	ρ_b (g/cm^3)	θ_s	θ_r	α (cm^{-1})	n	K_s (cm/s)
2.8	1.38	0.518	0.014	3.54	2.66	1.85

4.4 Other Materials

4.4.1 Backfill Material

Kaplan et al. (1998) report measurements made on a backfill sample composited from archived samples collected from 200 East Area boreholes (85 individual samples obtained at depths of 3 to 17 m were composited). This material was 92.5% sand, 2.5% silt, and 5% clay. The sand component had particle size fractions of 11.8% between 1 and 2 mm, 33.8% between 0.5 and 1 mm, 30% between 0.25 and 0.5 mm, 13.5% between 0.1 and 0.25 mm, and 3.3% between 0.075 and 0.1 mm. Reported bulk density and porosity were 1.79 g/cm^3 and 0.29, respectively. Saturated hydraulic conductivity and water retention measurements were made. The van Genuchten function was fit to the water retention data reported by Kaplan et al. (1998) resulting in the following parameters for the composite backfill material:

$\theta_s = 0.34$, $\theta_r = 0.025$, $\alpha = 0.04$ cm^{-1}, $n = 1.49$, and $K_s = 0.0022$ cm/s.

Note that the fitted saturated water content is greater than the reported porosity. As with the quartz sand measurements discussed in Section 4.2.2, the matric potentials used by Kaplan et al. (1998) in their water retention measurements do not adequately delineate the water retention curve. As a result, the fitted parameters are not reliable.

The same composite backfill material was also evaluated more recently using the multistep outflow method of Eching et al. (1994). A sample of the material was packed to a bulk density of 1.889 g/cm^3; average particle density was measured at 2.762 g/cm^3. This resulted in a porosity of 0.316. Estimated water retention and hydraulic conductivity parameter values from the multistep outflow experiment are given in Table 4.17. These values are the best-estimate parameter values for the backfill material.

Table 4.17. Best-Estimate Parameter Values for Backfill

ρ_p (g/cm^3)	ρ_b (g/cm^3)	θ_s	θ_r	α (cm^{-1})	n	K_s (cm/s)
2.76	1.89	0.316	0.049	0.035	1.72	1.91×10^{-3}

4.4.2 Water Conditioning Layer

Quartz sand and crushed glass are being considered for the material of the water conditioning layer. The best-estimate values for the water conditioning layer are the parameter values obtained for the quartz sand sample discussed in Section 4.2.2. These parameter values are repeated here in Table 4.18.

Table 4.18. Best-Estimate Parameter Values for Water Conditioning Layer

ρ_p (g/cm^3)	ρ_b (g/cm^3)	θ_s	θ_r	α (cm^{-1})	n	K_s (cm/s)
2.63	1.59	0.397	0.005	0.106	4.26	3.79×10^{-2}

4.5 Summary

The best-estimate water retention and hydraulic conductivity functions for the near-field materials of the ILAW disposal facilities are displayed in Figure 4.1. These functions use the best-estimate parameters given in this chapter. The best-estimate parameter values are also collected together in Table 4.19.

Table 4.19. Summary of Best-Estimate Parameter Values for Near-Field Materials

Material	ρ_p (g/cm^3)	ρ_b (g/cm^3)	θ_s	θ_r	α (cm^{-1})	n	K_s (cm/s)
Silt Loam-Gravel Admix	2.72	1.48	0.456	0.0045	0.0163	1.37	8.4×10^{-5}

5.0 Best-Estimate Values for Transport Parameters of Near-Field Materials

This chapter presents the best-estimate values for the transport parameters of the near-field materials. Transport parameter values for the materials of the surface cover are not discussed, however, because contaminants are expected to travel primarily out and down from the concrete vaults. Although diffusion has been shown to be the primary means of transport in simulations of the ILAW disposal facilities, the small flux of water through the surface cover has been sufficient to prevent upward transport from the vaults.[1] If the simulations carried out for the 2001 ILAW PA behave differently, the effect of transport parameters in the surface cover materials may become more important.

Consideration of transport parameters here is also limited to dispersivity and diffusion coefficients. Parameters governing the chemistry of the near-field materials (e.g., adsorption distribution coefficients and solid phase solubility controls) can be found in other data packages (McGrail et al., 1999; Kaplan and Serne, 1999).

5.1 Dispersivity

Transport in the near-field is expected to take place within the materials of the vault and within the backfill. Thus, the discussion will be limited to those materials. Khaleel (1999) provides a discussion of dispersion in the naturally occurring sediments beneath the excavated areas of the ILAW facilities.

Mechanical dispersion is not expected to be a significant factor in transport at the ILAW disposal facilities. Fayer et al. (1997) performed a cursory sensitivity analysis of dispersivity using a waste-form-alone simulation of the ILAW disposal (i.e., no vault) and found that the value of the dispersivity had little effect on the contaminant transport results. Although these results applied to transport from the waste-form to the groundwater, they are expected to hold for near-field simulations as well. The transport flux in the near-field materials due to mechanical dispersion is expected to be small for a number of reasons.

- The scale of transport is limited to the extent of the near field. This limited scale tends to result in small values of dispersivity (Gelhar et al., 1992).
- The near-field materials are relatively homogeneous – the vault materials because they are constructed to be homogeneous and the backfill material because of mixing by construction equipment. This homogeneity will tend to reduce dispersivity (Gelhar, 1986).
- Pore water velocities in the near field are expected to be small due to the low water flux through the surface barrier. Such low pore water velocities decrease the magnitude of the dispersive flux relative to the diffusive flux.

---

[1] Fayer, M.J. and C.T. Kincaid. 1998. *Simulations to Guide Measurements of Near-Field Hydraulic Parameters.* Letter Report to Fluor Daniel Hanford, September 30, 1998, Pacific Northwest National Laboratory, Richland, Washington.

Measurements of dispersion in unsaturated field soils are rare. Indirect evidence suggests that the dispersivities in the backfill soil at the ILAW facilities will be on the order of a few centimeters. Rockhold et al. (1996) modeled a detailed tracer-infiltration experiment in heterogeneous sandy soils in New Mexico. The scale of the model was 7 m deep, comparable to the scale of the near-field depth at the ILAW disposal facilities. Excellent predictive results were obtained by Rockhold et al. (1996) using a dispersivity value of 3 cm.

Recently, Ward et al. (1998)[1] conducted a pair of tracer-infiltration tests in the 200 East Area of the Hanford Site, on the new ILAW disposal site. The first test measured field-scale flow and transport properties in the naturally occurring surface soils. After excavating to a depth of 1.5 m, the experiment was repeated. The scale of each experiment was approximately 1 m by 6 m in plan and 1.5 m deep (thus the second experiment sampled sediments 3 m below the surface). Dispersivities estimated from the experimental results of the second test increased with scale, but appeared to approach an asymptotic value of about 7 cm at a scale of about 1 m.

Many numerical methods for simulating contaminant transport in the subsurface have difficulty when dispersivity is significantly less than the dimension of the numerical grid. As a result, dispersivity values have often been selected to satisfy numerical restrictions. In the simulation of Rockhold et al. (1996) this problem was avoided by using a numerical grid size of 10 cm, sufficiently small to avoid numerical difficulties with the dispersivity of 3 cm they used. (This dispersivity value was based on tracer measurements.) The observations of Ward et al. (1998) and the expected conditions at the site suggest that, for the ILAW PA, longitudinal dispersivity in the near-field materials should be small. A value of 10 cm is recommended. If numerical requirements dictate that a larger dispersivity be used in the near-field, the effect of this choice should be investigated and estimated.

5.2 Apparent Diffusion Coefficients through Concrete

5.2.1 Conceptual Model of Diffusion through Cement

Atkinson (1983), Atkinson et al. (1986), and Atkinson and Nickerson (1988) present a useful conceptual model for describing the transport of contaminants through cement. The authors consider that the transport is a combination of both physical processes such as diffusion and chemical processes such as precipitation/dissolution and adsorption/desorption. The first two articles discuss diffusion-controlled release (leaching) of a contaminant out of cement while the latter article discusses how to evaluate the diffusion of

---

[1] Ward, A.L., R.E. Clayton and J.S. Ritter. 1998. *Hanford Low-Activity Tank Waste Performance Assessment Activity: Determination of In Situ Hydraulic Parameters of the Upper Hanford Formation.* Letter Report to Fluor Daniel Hanford, Inc., December 31, 1998, Pacific Northwest National Laboratory, Richland, Washington.

a contaminant through a slab of cement or into a thick slab of cement. All three articles are limited to water-saturated cement.

The model used by Atkinson and colleagues for the apparent diffusion coefficient was presented previously as Equation 3.5.

$$D_a = D_i/\alpha' = D_f \delta \phi/(\tau \alpha') \quad (5.1)$$

Recall that in this equation the term D_i contains all the physical aspects of diffusional transport and the term α' contains all the chemical aspects. Several experimental approaches can be used to measure these two parameters and, by observation, Atkinson et al. (1986) and Atkinson and Nickerson (1988) have determined which experimental techniques give the best results for various contaminants under various geochemical conditions.

5.2.2 Measurement of Diffusion Coefficients

Atkinson et al. (1986) suggest that classical leach tests of spiked cement solids (saturated with aqueous solution) that use the intermittent solution exchange method such as the ISO and ANSI/ANS-16.1 tests (see ISO, 1979; Mendel, 1982; and ANS, 1986), and the purely static leach test, can be used in concert to calculate D_a and α', respectively. Using the combination of two leach test methods, one can get fairly accurate values for the physical and chemical parameters of interest.

At long time periods, the static leach test provides a good estimate of the ultimate amount of contaminant that can leave the solid waste and go into solution for scenarios with limited water flux, such as is expected in the ILAW disposal facilities. From knowledge of the starting inventory in the waste, $A_s(t = 0)$, one can determine the final inventory left in the solid, $A_s(t = \infty)$, which represents equilibrium between the solid and solution phases. From knowledge of the volumes of solution and the volume of the solid present in the static test, one can calculate α' from Equation 5.2:

$$\alpha' = A_s(\infty)\, V_L/(A_L(\infty)\, V_s) \quad (5.2)$$

where A_s = amount of contaminant in solid, per volume, at end of test

A_L = amount of contaminant in solution, per volume, at end of test

V_L = volume of liquid used in static test

V_s = volume of solid used in static test.

After α' has been calculated, Equation 3.11 and known solid characteristics of porosity and dry bulk density can be used to estimate the K_d value. The intermittent solution exchange leach tests previously mentioned give a direct measurement of D_a. (Note that D_a is also referred to as the effective diffusion coefficient, D_{eff}, in the leaching literature.) Given that the apparent diffusion coefficient is related to the intrinsic diffusion coefficient of the porous media, D_i, by Equation 5.1, one can calculate D_i for each contaminant from its value of D_a (obtained from the intermittent leach test) and its value of α' (obtained from the static leach test).

Alternatively, one can make some other contaminant measurements and estimate D_i and α' for a given cement type and particular contaminant solely from the intermittent leach tests as follows. If one believes that there is a constituent that does not interact with the cement chemically, then it can be used to measure the intrinsic diffusion coefficient directly because α' will be equal to the porosity (because the K_d for a non-reacting constituent is zero, see Equation 3.11). Some researchers have assumed that nitrate, tritium, chloride, sodium, or potassium are non-reactive constituents in concrete or cement leach tests. If so, then the measured D_e can be used to estimate the intrinsic diffusion coefficient for the particular cement by multiplying it by the cement porosity (see Equations 3.10 and 3.11). In this instance, D_i is assumed to be a property solely of the cement and not the contaminants within the cement. Once D_i is established, then the other leach data for reactive constituents within the cement give a measure of their unique D_e, from which the individual values of α' can be calculated. In addition, from knowledge of the porosity and dry bulk density, the value of K_d for an individual contaminant can be estimated. Atkinson et al. (1986) suggest that such an approach should provide an estimate of α' that is within one order of magnitude for a contaminant with a large K_d and should provide a much better estimate for a contaminant with a small K_d. Measurements used as the basis for the best-estimate diffusion coefficients reported in later in this chapter have used nitrate as the noninteracting chemical.

5.2.2.1 Through-Diffusion Test

There are numerous through-diffusion and diffusion penetration profile experiments that have been performed by the nuclear waste community to evaluate contaminant fate. These data can also be used to estimate the two basic parameters in Atkinson and Nickerson's conceptual model, D_i and α', from which the K_d value can be obtained. We have found by analysis of many experiments that D_i is most accurately measured using the through-diffusion type of test where a thin slab of porous media is mounted between two reservoirs of liquid. In one reservoir the solution is devoid of the contaminant of interest, and in the other, the solution chemical composition is the same except that the contaminant is present. The "hot" reservoir is connected to a large recirculating reservoir such that there is no drop in the contaminant concentration throughout the test. The build-up of the contaminant in the initially "cold" reservoir is monitored until it reaches a steady state. Steady state is reached when a plot of C/C_0 on the Y-axis and time on the X-axis (the breakthrough curve) culminates in a straight line. D_i is related to the slope of such a plot by the constant factor ($\phi VL/A$)

where V = volume of solution in the initially "cold" reservoir (no contaminant present)

L = thickness of the porous slab or disk

A = geometric surface area of the porous slab or disk

C = concentration of the contaminant in the "cold" reservoir at time t

C_0 = concentration in the "hot" reservoir at all times (must be kept constant).

If the experiment is performed correctly the chemical term α' can also be estimated from the equation

$$\alpha' = 6\, D_i\, t_0 / L^2 \tag{5.3}$$

where t_0 = the intercept of the slope of the above mentioned plot with zero breakthrough (the amount of time delay before contaminant starts to appear in the cold reservoir under steady state conditions).

Atkinson and Nickerson (1988) suggested that through-diffusion tests give an accurate measure of D_i but they felt that the estimate of α' was not as accurate because there appear to be two types of porosity in cement. Dual porosity causes the estimates of α' to be smaller than they really are.

One type of porosity makes up a small percentage of the total porosity and is conceptualized as well-connected pores allowing fast transport and relatively lower chemical capacity (adsorption). The second type of porosity makes up the bulk of the total porosity and allows slow transport because of constrictions/tortuosity in the pore "connectiveness." Because this second type of porosity makes up most of the total porosity it also can adsorb (chemically react) more than the first type of porosity and thus it exhibits a higher chemical capacity factor, α'.

One drawback to the through-diffusion testing is that highly adsorbing contaminants take long time periods to show up in the cold reservoir. Also, for concretes with large aggregate, one must make the slabs or disks thicker to prevent short circuits around the individual grain boundaries of the large aggregates.

5.2.2.2 Penetration Profile Test

A second experimental approach generally referred to as the penetration profile test utilizes a slab of porous medium that has all but one side blocked off to solution penetration (e.g., by being cast in an epoxy mold or embedded in hydrophobic plastic or wax). If the slab is assumed to be semi-infinitely thick, then at any given time the penetration profile of a contaminant that is in contact with the surface ($x = 0$) of the slab is related to the physical aspects of diffusion, D_i, and the chemical capacity factor, α', through the complementary error function.

$$\frac{C_s(x)}{C_L} = \alpha' \mathrm{erfc}\left\{\sqrt{\frac{\alpha' x^2}{4 D_i t}}\right\} \tag{5.4}$$

where C_s = concentration of contaminant on solid at depth x and time t

C_L = concentration in liquid at time t

Brown et al. (1964; 1969), Phillips and Brown (1964), and Relyea et al. (1986) describe a convenient data reduction scheme that transforms the contaminant penetration profile into the cement or other porous medium as a probit probability distribution. One takes the breakthrough profile, determined as the concentration of the contaminant in cement at depth x and time t divided by the concentration of the contaminant in the face of the cement at $x = 0$ and $t = 0$, and after calculating this ratio (as a percentage) one looks up the equivalent probit value for all the data points between 5% and 95% using the probit table in Finney (1971) or equivalent tables of mathematical functions. The probit data are then plotted on the Y-

axis and the depth of penetration is plotted on the X-axis. Such plots should generate a straight line as opposed to the sigmoidal curve that is the outcome of Equation 5.4. Thus the probit transformation curve is easier to interpret. The apparent diffusion coefficient, D_a, is related to the slope, Δ, of the line formed by the data through the following equation.

$$D_a = (2\,\Delta^2\,t)^{-1} \tag{5.5}$$

Again by using several tracers or contaminants and having one that is considered a non-reactive constituent (perhaps nitrate, tritium or chloride), one can estimate K_d values for the other reactive constituents using Equations 3.10 and 3.11. This goes back to the original conceptual model that breaks transport into a purely physical term, D_i, and a purely chemical term α'. Because D_i is a property of the porous medium, it is the same for all the tracers or contaminants moving through a given cement. When one knows that a particular contaminant is non-reactive then its measured apparent diffusion coefficient, D_a, is equivalent to D_i/ϕ because the K_d of the non-reactive contaminant is zero. Once D_i is known, α' for each reactive contaminant can be calculated from its measured apparent diffusion coefficient, D_a, and the measured value of the cement's intrinsic diffusion coefficient, D_i, can be determined from the non-reactive contaminant. When α' has been determined for each reactive contaminant, then K_d can be estimated from Equation 3.10 and the known porosity and dry bulk density of the cement.

Application of these conceptual models and mathematical techniques to diffusion and leach data in the literature could increase the available estimates of K_d values for important contaminants, given that there are many more waste-form leach tests and diffusion tests for cement in the literature than there are well implemented adsorption tests. We have not pursued this approach for this data package, however. Instead, we have tabulated the apparent diffusion coefficients, D_a, directly without trying to separate the physical and chemical reaction components. For the next data package we will try to see if the leach and diffusion data in the literature are, in fact, readily converted and whether the calculated α' values seem plausible in comparison to direct K_d measurements on concrete/cement.

5.2.3 Best-Estimate Diffusion Coefficients

Tests using both the through-diffusion concrete slab test and the penetration profile test are currently underway as part of the ILAW PA project. In both cases we are studying the diffusion of I^- and TcO_4^- through concrete. The first results should be available in January 2000, but the through-diffusion test will likely require another year to reach steady state.

In the through-diffusion test, a 2-cm-thick slab of concrete with the composition shown in Table 5.1 is mounted between two reservoirs of liquid. In one reservoir the solution is devoid of the contaminant of interest and in the other (much larger reservoir) the chemical composition is the same except the contaminants are present. It was hoped that the reservoir was large enough that there would be no significant drop in the contaminant concentration throughout the test. Preliminary results suggest that the concentration of contaminants in the "hot" reservoir is decreasing with time. A more sophisticated mathematical algorithm

to analyze diffusion data has recently been published (Moridis, 1999). This algorithm can analyze data for which the concentration of contaminant in the hot reservoir decreases over time.

Table 5.1. The Composition of ILAW Concrete Used in Diffusion Testing

Material	Design Mix	Material Details
Cement	0.27	Portland Type I & II
Fly Ash	0.04	Class F fly ash; 20% of cement volume
Coarse Aggregate	0.04	Particle size 2.83 mm to 2 mm (ASTM sieve -7 to +10)
Fine Aggregate	0.48	Sand particle size < 2 mm (ASTM sieve -10)
Water	0.13	Water-to-cement ratio: 0.5
Steel Fiber	0.04	Deformed, nominal length 8 mm (0.32 in.)
Polyheed 997	3.75e-3	
Air Content	4.5%	

In the penetration profile test, two cells, one containing Hanford sediment and one consisting of a plug of concrete, are butted up to each other in a cylindrical half-cell arrangement. The soil cell is a typical Hanford sand soil (4 cm diameter and 25 cm long) while the concrete monolith (4 cm in diameter and 4 cm long) is spiked with 0.5 mCi/l of ^{125}I, 0.05 mCi/l of ^{99}Tc and 20 mg/l of U. Preliminary results of the penetration of the isotopes into the Hanford soil are expected in January 2000. Identical half-cells with spiked and unspiked Hanford sediment are used to differentiate the diffusion of contaminants out of the concrete and into the sediment.

Apparent diffusion coefficients for constituents migrating through cement are shown in Table 5.2. Sources for the diffusion coefficient data presented in Table 5.2 are Serne (1990), Serne et al. (1987), Serne et al. (1989a), Serne et al. (1989b), Serne et al. (1992), Serne et al. (1995), and Krupka and Serne (1996) and are predominantly from grouts and solidified cementitious waste forms without any aggregate present. We have found one recent article on the diffusion of Cl^-, considered a non-reactive species, through various concretes. The median value obtained was 8×10^{-8} cm^2/s (Bretton et al., 1992). This value can be compared to the apparent diffusion coefficients of several nonreactive constituents in grouts and cement (no aggregate present) from Table 5.2. The grout/cement diffusion values for nonreactive tracers are consistently ~5×10^{-8} cm^2/s. The slightly higher apparent diffusion coefficient in concrete may be attributable to the presence of aggregate and the relatively higher porosity around the aggregate/cement paste interfaces.

For the ILAW PA simulations, the values in Table 5.2 should be used directly if possible. In the event that the simulation codes cannot directly use the apparent diffusion coefficients, the free-water diffusion coefficients and capacity factors for the potential ILAW contaminants are given in Table 5.3. The free-water diffusion values were taken from Robinson and Stokes (1959). The values presented are for 25° C and should be adjusted for other temperatures by multiplying by the ratio of the viscosity of water at 25° C to the viscosity at the desired temperature. For example, at 15° C the D_f values in Table 5.3 should be multiplied by 0.782 to correct for the lower temperature. The capacity factors in Table 5.3 were calculated by taking the measured (or estimated) values of the apparent diffusion coefficients from Table 5.2 and assuming that nitrate has no interaction with the cements/grouts and thus has a capacity factor of one. The intrinsic diffusion coefficient, which represents the physical aspects of the grout/cement/concrete, therefore becomes 5×10^{-8} cm^2/s for all constituents. The estimated capacity factors are thus the intrinsic diffusion coefficient (5×10^{-8}) divided by each reactive constituent's apparent diffusion coefficient (see Equation 5.1).

5.3 Apparent Diffusion Coefficients in Backfill and Glass Waste

For nonreactive solutes diffusing through unsaturated sediments, one of the empirical relationships discussed in Section 3.9 can be used. Measurements of intrinsic diffusion coefficients were reported in Conca and Wright (1990 and 1991) for a variety of materials, including sediments from the Hanford Site. The results obtained by Conca and Wright suggest that the model of Kemper and Van Schaik (1966) (Equation 3.9) is inappropriate and may significantly overestimate the intrinsic diffusion coefficients at low water contents. The models of Millington (1959) and Campbell (1985) (Equations 3.7 and 3.8) are more representative of the relationship between the intrinsic diffusion coefficient and volumetric water content observed by Conca and Wright. It was also observed that the $D_i(\theta)$ relationship (for a chemically nonreactive solute) was remarkably similar for the variety of materials reported in Conca and Wright (1991), which included porous and nonporous tuff gravels, bentonite clays, Hanford sandy soils and gravels, and whole rock cores of non-welded tuff. This result suggests that the aqueous intrinsic diffusion coefficient may not depend strongly on the porosity of the material and that the model of Millington (Equation 3.7) may not be the most appropriate model for the ILAW PA. An informal comparison of the results presented in Conca and Wright (1991) and the diffusion models represented by Equations 3.7 and 3.8 suggest that a slightly modified version of the model of Campbell (1985) appears to fit the data of Conca and Wright (1991) reasonably well. This model has the form

$$D_i = 2.8 D_f \theta^{2.3} \quad (5.6)$$

which is Equation 3.8, with a slightly smaller exponent. Equation 5.6 can be used in the ILAW PA simulations to model diffusion of nonreactive constituents in the non-cementitious materials of the near field. The free-water diffusion coefficients, D_f, for individual contaminants can be selected from Table 5.3 or calculated using one of the available equations (see Grathwohl, 1998).

To estimate the effect of chemical interactions on the diffusion coefficients, the retardation factor can be used. Combining Equations 3.10 and 3.12, the apparent diffusion coefficient (which includes the chemical effects) can be obtained from the intrinsic diffusion coefficient (which includes only physical effects of the porous medium).

$$D_a = D_i / R\theta \quad (5.7)$$

The porosity in Equation 3.12 is replaced by the water content for unsaturated media. Estimated values for the K_d of a given constituent and sediment (required to calculate the retardation coefficient) can be obtained from the geochemistry data package (Kaplan and Serne, 1999).

6.0 Uncertainty and Other Issues Affecting Parameter Values

The best-estimate parameter values discussed in Chapters 4 and 5 are not the only values required for the 2001 ILAW PA. The PA must consider uncertainty in its predictions of facility performance and this uncertainty is due, in part, to uncertainty in the hydraulic and transport parameters of the near-field materials. In addition, the long time-frame of the PA analysis requires that potential changes over time in the near-field materials and their properties be considered. This chapter discusses the currently available information regarding near-field hydraulic and transport parameter uncertainty and changes in near-field material parameter values over time.

The issue of effective parameter values is also briefly discussed here. Effective parameter values are required when the scale of material heterogeneity represented in simulations is larger than the scale of that heterogeneity in the actual system being modeled. This issue is particularly important for the naturally occurring sediments beneath the excavated areas of the ILAW disposal facilities (and is discussed in Khaleel [1999]), but it is also relevant in the near-field simulations where the materials of the vault (concrete, glass waste, filler material, and steel corrosion products) are not likely to be represented in detail.

The materials of the surface barrier, except for the asphaltic concrete, are not discussed here. Fayer (1999) discusses the uncertainty in the recharge rate allowed through the surface barrier and the manner in which the recharge rate is expected to change over time as a result of changes in the surface barrier.

6.1 Uncertainty in Parameter Values

The best-estimate parameter values discussed in Chapter 4 are uncertain because they are based on limited data, they use indirect methods to estimate parameters (such as the Arya and Paris [1981] method), or they use data from existing materials that are not expected to be identical to the materials used in the ILAW facilities (such as the concrete). In addition, material properties are expected to vary spatially and the small-scale measurements obtained in the laboratory may not represent the large-scale behavior in the field. Improving the available data on critical materials and planning for construction of a test pad to make field-scale measurements are anticipated to be subjects of further investigation by the ILAW PA project in FY 2000. Available information concerning the uncertainty of the near-field material properties is discussed in this section.

This discussion of uncertainty is framed in terms of reasonable bounding cases that should be considered in the 2001 ILAW PA. As a result, the bounding parameter values provided in this section represent reasonable bounds on the average properties of each material. It is not unreasonable to expect that spatial heterogeneity in material properties may result in point measurements that are outside these bounding values.

In an uncertainty analysis, it is generally not necessary to consider all the parameters used in the simulation models. The input parameters that are most important to the uncertainty in the output of the

models (e.g., predictions of dose or contaminant concentrations) are those parameters that simultaneously possess two characteristics.

1. The uncertainty (or variability) of the parameter is significant. The parameter uncertainty can be represented by its coefficient of variation, which is the standard deviation of the parameter divided by its mean value. This can be estimated from measured data and/or from expert judgement and experience.
2. The sensitivity of the simulation model results to the value of the parameter is significant. The relative sensitivity of a model to its parameter values is measured by systematically or randomly varying parameter values and calculating the resulting changes in model output. It should be noted that the typical procedure of varying parameters individually ignores parameter correlation and the potential dependence of sensitivity on the values of other parameters.

It is worthwhile to note that significant parameter variability does not always mean large parameter variability. If simulation model results are very sensitive to a particular parameter, the variability of that parameter value may not need to be very large in order to be significant.

In evaluating parameters with respect to the two characteristics above for application to the ILAW PA, the authors have relied primarily on expert judgement and experience because there is currently no comprehensive sensitivity analysis of the ILAW disposal facilities and there is insufficient data to calculate parameter uncertainty in most cases.

6.1.1 Asphaltic Concrete

Although the water retention parameters of the asphaltic concrete layer are highly uncertain (because there are no known measurements of water retention on this material), these parameters are not anticipated to greatly affect the performance of this low permeability layer. This is because the asphaltic concrete is expected to remain saturated over a very wide range of matric potentials (see Figure 4.1). The hydraulic parameter expected to most significantly impact the performance of the asphaltic concrete is the saturated hydraulic conductivity. In addition, the porosity may be of secondary importance.

Several studies of the hydraulic conductivity of asphalt or asphaltic concrete conducted as part of the development of the Hanford Barrier were discussed in Section 4.1.6. Lacking other information, these studies form the basis of the reasonable bounds on the saturated hydraulic conductivity of the asphaltic concrete layer of the ILAW disposal facilities. The asphalt measurements of Clemmer et al. (1992) represent the lower bound on hydraulic conductivity (10^{-13} cm/s) and porosity (0.03). The in-field measurements of asphaltic concrete hydraulic conductivity reported in DOE-RL (1993) represent the upper bound (10^{-7} cm/s). This upper bound represents the potential for the in-field value to be significantly larger than the small-scale laboratory measurements and assumes that the asphalt coating fails to perform as designed or is not used. The upper bound porosity is taken from the largest porosities measured in the concrete cores obtained from the 213J bunker on the Hanford Site (0.08). Reasonable bounding values are given in Table 6.1.

Table 6.1. Reasonable Bounding Values for Critical Asphaltic Concrete Parameters. Best-Estimate Values Shown for Comparison

Parameter	Lower Bound	Best Estimate	Upper Bound
K_s (cm/s)	1.0×10^{-13}	1.0×10^{-11}	1.0×10^{-7}
ϕ (= θ_s)	0.03	0.04	0.08

6.1.2 Concrete

Because the concrete functions hydraulically as a low permeability layer, like the asphaltic concrete, the hydraulic parameter expected to most significantly impact concrete behavior is the saturated hydraulic conductivity. Water retention measurements on concrete are rare. However, the measurements on the cores obtained from the 213J vault on the Hanford Site are available to estimate potential variability in these parameters. These measurements and literature values are available to estimate potential variability in concrete saturated hydraulic conductivity.

The saturated hydraulic conductivity of concrete is known to vary significantly with the water/cement ratio, additives such as slag or fly ash, and the curing conditions (Whiting and Walitt, 1988). In addition, the hydraulic conductivity of concrete is typically greater than the hydraulic conductivity of the cement paste alone. Because of the difficulty in directly measuring hydraulic conductivity, gas permeability and electrical conductivity measurements are often used as indirect methods to estimate concrete hydraulic conductivity. Gas permeability measurements have been an unreliable estimator of water permeability and the electrical conductivity measurements appear to result in hydraulic conductivity estimates that are two orders of magnitude smaller than obtained with direct measurement (Tumidajski and Lin, 1998).

The concrete to be used in the new ILAW disposal facility has currently not been specified, but it is assumed here that it will be a standard concrete with no additives. The best-estimate value of saturated hydraulic conductivity is representative of the direct measurements on concrete that have appeared in the literature. This best estimate was based on measurements of a 50-year-old concrete with large aggregate. (The observed diameter of the aggregate was typically 2 cm, but exceeding 4.5 cm in one of the cores.) For the six concrete samples from the 213J vault, the measured hydraulic conductivity varied from 4.4×10^{-10} to 5.9×10^{-9} cm/s. Based on a survey of literature values, a reasonable lower bound for the saturated hydraulic conductivity of concrete is 5×10^{-11} cm/s. Currently available data are based on measurements made on small samples. It is possible that large-scale field measurements of concrete hydraulic conductivity will be significantly larger, as reported in DOE-RL (1993) for the asphaltic concrete of the Hanford Barrier. Assuming this is the case, a reasonable upper bound on the saturated hydraulic conductivity of concrete is 1×10^{-7} cm/s.

Reasonable bounds on the variability of the water retention parameters for concrete were based on the measurements from the six core samples obtained from the 213J vault on the Hanford Site. The lower and upper bounds were taken as the approximate 0.01 and 0.99 quantiles of the parameter distributions. A normal distribution was assumed for the saturated water content (porosity) and for the van Genuchten parameter, n. A lognormal distribution was assumed for the van Genuchten parameter, α. The mean and variance of each distribution was assumed to be the sample mean and variance obtained from the six concrete samples. The resulting lower and upper bounds are given in Table 6.2 for the water retention parameters and the saturated hydraulic conductivity.

Table 6.2. Reasonable Bounding Values for Concrete Parameters. Best-Estimate Values Shown for Comparison

Parameter	Lower Bound	Best Estimate	Upper Bound
K_s (cm/s)	5.0×10^{-11}	1.33×10^{-9}	1.0×10^{-7}
ϕ (= θ_s)	0.039	0.067	0.095
θ_r	0	0.00	0
α (cm^{-1})	8.67×10^{-6}	3.87×10^{-5}	1.73×10^{-4}
n	1.17	1.29	1.41

6.1.3 Glass Waste

The best-estimate parameter values for the glass waste were based on qualitative information about the expected final form of the glass waste. Because there were no direct measurements on this expected material and there are no measurements in the literature on analogous materials, the best-estimate parameter values are very uncertain. Because of the lack of data, the reasonable lower and upper bounds for the glass waste are based on a judgement about what the nature of the fractures might be. The lower bound parameter values represent a case in which there are fewer fractures and the fracture apertures are very small. The glass waste behaves more like a fine sand in this case, albeit one with a very low porosity. The upper bound parameters represent a case in which the fracture apertures are much larger. The glass waste behaves more like a gravel in this case. The values given in Table 6.3 reflect these assumptions.

The bounding values for the glass waste assume that the waste is sufficiently fractured that it can be represented as a porous medium. If the actual glass waste violates this assumption, the hydraulic behavior of the glass waste may be quite different than the best-estimate and bounding values presented. The resultant uncertainty in contaminant fate and transport is a key issue, anticipated to be a subject of further investigation by the ILAW PA project in FY 2000.

Table 6.3. Reasonable Bounding Values for Glass Waste Parameters. Best-Estimate Values Shown for Comparison

Parameter	Lower Bound	Best Estimate	Upper Bound
K_s (cm/s)	1.0×10^{-4}	0.01	1.0
ϕ (= θ_s)	0.01	0.02	0.05
θ_r	0	0.00	0
α (cm^{-1})	0.01	0.2	4
n	1.5	3	5

6.1.4 Filler Material

The best-estimate filler material parameters are based on a single measurement of a quartz sand. The actual material to be used, however, has not yet been specified, although it is likely to be a sediment with a sandy texture. Using regression techniques, Carsel and Parrish (1988) derived probability distributions for soil hydraulic parameters, classified by soil texture. Schaap and Leij (1998) calculated means and variances for hydraulic parameters obtained from fitting the van Genuchten water retention function to three large databases of water retention measurements. These results were also classified according to soil texture. These references, combined with the authors' judgement, form the basis of the reasonable upper and lower bounds for the hydraulic parameters of the filler material.

The lower and upper bounds for the saturated water content are the 0.10 and 0.90 quantiles of an assumed normal distribution for this parameter, with the mean and variance of the distribution taken from the sample statistics for sand soils presented by Schaap and Leij (1998) using all their data. The upper bound of the residual water content is calculated in the same manner. The lower bound for the residual water content is the best-estimate value, because this value is very low for a sand [lower than the 0.10 quantile from the statistics of Schaap and Leij (1998)]. The reasonable bounds for the van Genuchten parameters, α and n, and for the saturated hydraulic conductivity were calculated in a similar manner, with the assumption that these parameters were lognormally distributed. Schaap and Leij (1998) presented statistics for log(α), log(n), and log(K_s), implying that their data exhibited skewed distributions. The upper bound for α is the mean sand value from Carsel and Parrish (1988). The best-estimate value was greater than the 0.90 quantile using the statistics of Schaap and Leij (1998).

The reasonable bounding values for the filler material parameters are given in Table 6.4. These values were based on an assumption that the material would have a sand texture. If the ultimate material used as the filler violates this assumption, these bounding values (and the best estimate) should be reevaluated.

Table 6.4. Reasonable Bounding Values for Filler Material Parameters. Best-Estimate Values Shown for Comparison

Parameter	Lower Bound	Best Estimate	Upper Bound
K_s (cm/s)	1.3×10^{-3}	3.79×10^{-2}	4.3×10^{-2}
ϕ (= θ_s)	0.30	0.397	0.45
θ_r	0.005	0.005	0.09
α (cm^{-1})	0.017	0.106	0.15
n	1.9	4.26	5.4

6.1.5 Backfill

Reasonable bounding values for the backfill were based on the statistics presented in Khaleel and Freeman (1995) for the sediment samples they classified as gravelly sand. The sediment samples analyzed by Khaleel and Freeman (1995) were all obtained from boreholes located in the 200 Areas of the Hanford Site. Ten of the 183 samples included in the analysis were classified as gravelly sand. The gravelly sand classification was used for the backfill bounding values because the boreholes drilled at the new ILAW disposal facility indicated the presence of gravel in the near-surface sediments (see Figure 2.1) and the best-estimate parameter values for the backfill appeared to most closely match the mean parameters values for the gravelly sand class of Khaleel and Freeman (1995), with the exception of the saturated water content.

The reasonable bounding values for the backfill material were taken as the minimum and maximum values reported by Khaleel and Freeman (1995) for their 10 gravelly sand samples. These values bound the best-estimate values and are given in Table 6.5.

Table 6.5. Reasonable Bounding Values for Backfill Parameters. Best-Estimate Values Shown for Comparison

Parameter	Lower Bound	Best Estimate	Upper Bound
K_s (cm/s)	5.4×10^{-5}	1.91×10^{-3}	8.0×10^{-3}
ϕ (= θ_s)	0.20	0.316	0.33
θ_r	0.01	0.049	0.07
α (cm^{-1})	0.004	0.035	0.074
n	1.5	1.72	2.5

6.1.6 Diversion Layer Materials

As discussed in Section 4.3, the performance of the diversion layer will depend critically on the hydraulic parameters of the sand drainage and gravel capillary barrier layer. Because the required performance of the diversion layer and the specification of the materials are unknown, it is difficult to set reasonable bounds on the hydraulic properties. In addition, it is the combination of the two materials and their hydraulic interaction under the particular conditions of the ILAW facilities that can result in poor performance. It is suggested here that the approach of Nichols and Meyer (1996) be used in the 2001 ILAW PA to examine uncertainty in the diversion layer performance. They identified three combinations of sand and gravel hydraulic properties that resulted in progressively better performance under the conditions they simulated. The best performing properties were assigned as the best-estimate parameter values for the diversion layer materials (see Tables 4.15 and 4.16). The poorest performing materials used by Nichols and Meyer (1996) and those that performed moderately well are listed in Table 6.6. These parameter values could serve as a starting point for the ILAW PA sensitivity simulations of the diversion layer.

Table 6.6. Diversion Layer Parameters Used by Nichols and Meyer (1996) for their Poorest and Moderate Performing Cases. Best-Estimate Values Shown for Comparison

	Poorest Performance		Moderate Performance		Best Estimate	
Parameter	**Sand**	**Gravel**	**Sand**	**Gravel**	**Sand**	**Gravel**
K_s (cm/s)	1.0×10^{-4}	1.0×10^{-2}	3.0×10^{-2}	1.0	3.00×10^{-2}	1.85
θ_s	0.35	0.34	0.35	0.34	0.371	0.518
θ_r	0.01	0.02	0.01	0.02	0.045	0.014
α (cm^{-1})	0.044	0.101	0.044	0.4	0.0683	3.54
n	1.52	2.92	1.52	2.92	2.08	2.66

6.1.7 Diffusion Coefficient Uncertainty

Regarding the uncertainty in apparent diffusion coefficients for solute transport through concrete we suggest that the values given in Table 5.2 be considered realistic estimates or best-estimate values. Based solely on expert judgement, we recommend that reasonable bounding values for the apparent diffusion coefficients in concrete be taken as as a factor of ten larger and smaller than the values from Table 5.2. For the diffusion coefficients in other materials calculated using Equation 5.7, the contribution to uncertainty should be considered to come primarily from the retardation coefficient and from any uncertainty in the water content.

6.2 Changes in Parameter Values over Time

A number of the materials discussed in Section 2.2 may undergo significant changes over time, potentially affecting the performance of the disposal facilities. These changes will be caused by natural processes and in response to chemical changes in the near-field environment resulting from degradation of the glass waste. The materials for which hydraulic property changes over time are expected to most significantly impact the transport of contaminants are the asphaltic concrete of the surface barrier, the concrete vault, and the glass waste; corrosion of the steel waste containers is also expected to have a significant effect on contaminant transport. In addition, changes in backfill material, the filler material within the vaults, and the gravel capillary barrier material (if used as a component of the surface barrier) are potentially important. Potential changes in the hydraulic parameters of each of these materials as a function of time (material aging) is discussed below.

Changes in recharge through the surface cover either as a result of subsidence or in response to expansion of the waste containers due to steel corrosion are not discussed here. While these processes will not produce changes in the small-scale hydraulic properties of the surface cover materials (with the exception of the low-permeability asphaltic concrete layer), they may significantly affect the overall performance of the cover. Potential variations in the recharge rate over time as a result of changes in the volume of the waste are discussed in the recharge data package (Fayer et al., 1999).

6.2.1 Asphaltic Concrete

Changes to the hydraulic properties of the asphaltic concrete component of the surface barrier may increase the recharge rate reaching the concrete vaults. Because the upper layers of the surface barrier will protect the asphalt component from ultraviolet radiation and from extremes in temperature, the asphaltic concrete is expected to change little over the initial 500-year period from the time of construction. U.S. Nuclear Regulatory Commission (U.S. NRC) guidance for low-level waste disposal performance assessments recommends that the man-made components of the facility should be credited with a maximum of 500 years of as-built performance (NRC, 1997). Studies of naturally occurring asphalts, undertaken as part of the Hanford Barrier development (Waugh et al., 1994; Freeman and Romine, 1994), indicate that asphalt lifetimes under conditions expected in the ILAW disposal facilities are in excess of 500 years. One issue that has not been addressed, however, is the effect on asphalt of changes in pore water chemistry due to glass dissolution. Preliminary simulation studies of the near-field chemistry indicate that a high pH front may travel up towards the surface from the glass waste[1]. This issue will be given additional consideration before the disposal facility designs are finalized.

Given the current information, it is recommended that the best-estimate asphaltic concrete parameter values be assumed constant for a period of 500 years. The hydraulic properties of this barrier layer can

[1] B.P. McGrail. June, 1999. Personal communication.

be given the properties of the aggregate material of the concrete after the 500-year period of performance. This is consistent with the assumptions of the recharge rate discussed in the recharge data package (Fayer et al., 1999) and with the approach used in the initial ILAW PA (Mann et al., 1998).

6.2.2 Concrete

The concrete vaults provide a low-permeability barrier to water intrusion and also influence the chemistry of the water reaching the glass waste. For the purpose of low-level waste disposal, NRC guidance recommends assuming a 500-year service life for man-made components unless justification for a longer service life can be made. The degradation of concrete in response to the chemical conditions to which it is exposed has been studied extensively (Clifton, 1993). Service life predictions can be based on a comparison of performance to existing concretes; accelerated testing using elevated temperature, pressure, and chemical conditions; and mathematical modeling.

Simulations by Fayer and Kincaid (1998)[1] indicate that the presence of intact concrete may have either a relatively small effect on the peak dose from the ILAW facility or a fairly large effect, depending on the parameters assumed for the glass waste. In these simulations, various concrete hydraulic properties were assumed for intact, fractured, and degraded concrete. The peak dose over a 100,000-year period from a single vault was compared to the case where no concrete was used. Peak dose increased by 14% to 259% when no concrete was used as compared to the use of intact concrete. The wide range in the effect of the concrete was due to the particular model assumed for the glass waste. It must be pointed out that the hydraulic properties for the intact concrete and the glass waste were not the best-estimate values presented in Sections 4.2.1 and 4.2.3.

Sensitivity simulations for the 2001 ILAW PA should be carried out using (1) the intact properties of concrete given in Section 4.2.1 and (2) the backfill properties given in Section 4.4.1 in place of the concrete. This latter case represents an assumption that no concrete is used in the ILAW disposal facility. The two cases together serve to bound the importance of the concrete properties to the facility performance and consequently provide some guidance on the importance of modeling the degradation of concrete over time. If concrete degradation is to be modeled, the specific chemical conditions of the ILAW facilities should be included in the analysis. Available models such as described in Snyder and Clifton (1995), Berner (1992), Walton (1990), and Clifton and Knab (1989) may be useful in the estimation of concrete service life. An empirical approach, used in the Grouted Waste Disposal PA (Winkel, 1994), may also prove practical.

The volume occupied by the corrosion products of the steel waste containers is expected to be greater than the volume of the intact steel. Corrosion of the steel will thus result in additional stress on the

---

1. Fayer, M.J. and C.T. Kincaid. 1998. *Simulations to Guide Measurements of Near-Field Hydraulic Parameters.* Letter report to Fluor Daniel Hanford, Inc., Sept. 30, 1998, Pacific Northwest National Laboratory, Richland, Washington.

concrete vault, potentially producing cracks in the concrete[1]. Stress fractures will increase the effective hydraulic conductivity of the concrete. Wang et al. (1997) provide laboratory measurements of the relationship between hydraulic conductivity and crack width for concrete that has undergone stress fracturing. Depending on final design decisions for the disposal facilities, the interaction between corrosion of the steel waste containers, geotechnical stability of the disposal facility, and the near-field hydrology may be a subject of further investigation by the ILAW PA project in the future.

If the degradation of the concrete vault is not modeled explicitly, there is no technical basis for assuming a transition in concrete properties between the best-estimate values and the fully degraded properties. In addition, the simulations conducted by Fayer and Kincaid (1998)[2] resulted in minor differences between the peak dose when using fractured concrete properties and that obtained when using their fully degraded concrete properties. We recommend that the best-estimate parameter values for concrete be used for the first 500 years of facility operation and that the fully degraded concrete parameter values be used for the remainder of the time. The fully degraded concrete parameter values should be assigned based on the expected composition of the concrete aggregate, which has not been specified for the new ILAW disposal facility. It is assumed here that the fully degraded concrete can be represented as a mixture of 60% of the backfill material (see Section 4.4.1) and 40% of a gravel with particle diameters distributed relatively uniformly between 2 and 10 mm. The assumed particle size distribution for this material is given in Table 6.7.

Table 6.7. Assumed Particle Size Distribution for Fully Degraded Concrete

Particle Size (mm)	10	7	5	3	2	1	0.5	0.25	0.1	0.05	0.002
Percent Finer	100	95	88	75	60	52.9	32.6	14.6	6.5	4.5	3

The particle size distribution of Table 6.7 was used in the method of Arya and Paris (1981) to generate a set of sample water retention points for the fully degraded concrete. The bulk and particle densities were assumed to be the same as the best-estimate backfill values. Using the sample water retention points and the RETC code (van Genuchten et al., 1991), water retention parameters were estimated for the fully degraded concrete. Saturated hydraulic conductivity was estimated using the Kozeny-Carmen equation (Bear, 1972).

2. Fayer, M.J. and C.T. Kincaid. 1998. *Simulations to Guide Measurements of Near-Field Hydraulic Parameters.* Letter report to Fluor Daniel Hanford, Inc., Sept. 30, 1998, Pacific Northwest National Laboratory, Richland, Washington.

$$K_s = \frac{\rho g}{\mu} \cdot \frac{\phi^3}{(1-\phi)^2} \cdot \frac{d_m^2}{180} \quad (6.1)$$

where ρ and μ are the density and viscosity of water, respectively, g is the acceleration due to gravity, and d_m is a mean particle diameter. Density and viscosity were specified at 15° C. Porosity was assumed to be equal to the saturated water content. The mean particle diameter of 2.1 mm was calculated as the average of the particle size fractions defined in Table 6.7 weighted by the percent in each fraction. Parameter values for the fully degraded concrete are given in Table 6.8.

Table 6.8. Parameter Values for Fully Degraded Concrete

ρ_p (g/cm^3)	ρ_b (g/cm^3)	θ_s	θ_r	α (cm^{-1})	n	K_s (cm/s)
2.76	1.89	0.313	0.0	2.43	1.41	1.34×10^{-3}

6.2.3 Glass Waste

The hydraulic properties of the fractured glass waste are expected to undergo changes over time in response to chemical reactions between the glass waste and the water moving through the waste. Corrosion testing of potential low-activity waste glasses is discussed in McGrail et al. (1998). As discussed in Section 4.2.3, this testing was performed on crushed glass samples, whereas the actual glass waste form is expected to be a highly fractured material. As discussed in McGrail et al. (1998), corrosion of their crushed glass sample resulted in pronounced changes in the sample's water retention characteristic. The changes appeared to be related to the onset of precipitation of zeolitic alteration phases. Scanning electron microscope pictures revealed that the originally pristine fracture surfaces of the grains had a relatively thick coating of alteration phases.

The effect of the alteration phases coating the glass particle surfaces was to increase the water content of the sample at a given matric potential. Although a water retention model was not fit to the data observed by McGrail et al. (1998), the alteration phase coating apparently resulted in a sizeable decrease in the values of the α and n parameters in the van Genuchten water retention function. That is, the crushed glass sample behaved less like a coarse sand and more like a loamy-textured soil. Little change in the porosity or the saturated hydraulic conductivity was observed during the test conducted by McGrail et al. (1998), although this was attributed to the relatively short duration of the test.

The changes in the surfaces of the glass grains observed by McGrail et al. (1998) are expected to occur on the fracture surfaces of the ILAW glass waste and should produce similar changes in the hydraulic parameters of the glass waste, that is, a decrease in the α and n parameters in the van Genuchten water retention function. The magnitude of these changes are currently unknown and are anticipated to be a subject of further investigation by the ILAW PA project in FY 2000.

6.2.4 Steel Container Corrosion

The steel containers holding the glass waste are expected to be impermeable to water when initially put into the concrete vaults, but they are expected to corrode over time. The nature of the corrosion process and the consequent changes in the permeability of the steel and the ability of contaminants to be transported out of the steel containers has not been a subject of investigation. It is assumed here that the steel will eventually be converted completely to products of its corrosion. The hydraulic properties of these corrosion products is the subject of this section.

The specific products of steel or stainless steel corrosion depend on the unique environmental conditions within which corrosion takes place. Studies of steel exposed to the atmosphere, in non-polluted sea water, and in concrete have shown the iron oxides goethite (α-FeOOH) and lepidocrocite (γ-FeOOH) to be the dominant corrosion products. Schwertmann and Cornell (1991) describe the formation and transformation pathways of iron corrosion products. Under oxidizing conditions and with pH in the range of 5-7, the transformations lead from Fe^{2+} to goethite and lepidocrocite. Transformation of these phases to hematite depends on the environmental conditions (Cornell and Schwertmann, 1996). With pH > 8, Fe^{2+} will oxidize directly to magnetite, maghemite, and hematite (Schwertmann and Cornell, 1991).

Based on studies for disposal of high-level radioactive waste at Yucca Mountain and on modeling studies for the ILAW PA project[1], the dominant steel corrosion products in the ILAW disposal facilities are expected to be goethite and hematite. Although goethite is expected to transform to hematite, the reaction rate is expected to be slow enough that significant goethite will be present for a long period. (Actual corrosion transformation rates are unknown.)

Naturally occurring rock samples of hematite, goethite, and lepidocrocite were obtained to serve as surrogate materials for the steel corrosion products. The rocks were crushed in the laboratory to prepare samples for hydraulic property measurements. The crushed samples were hand-sieved using 2-mm (No. 10), 0.125-mm (No. 120), and 0.075-mm (No. 200) sieves to provide a general separation of particle sizes, but not a complete separation. Coarse-textured and fine-textured samples of crushed hematite and goethite were analyzed for physical and hydraulic properties (four samples total). A centrifuge method was used to measure water retention and unsaturated hydraulic conductivity[2].

Average particle densities of the goethite and hematite samples were 3.82 and 4.50 g/cm^3, respectively. Average bulk densities were 2.05 and 2.78 g/cm^3, respectively, for the goethite and hematite samples. Hydraulic parameters were fit to each sample using RETC (van Genuchten et al., 1991). A simultaneous fit to the water retention and hydraulic conductivity data was performed with all parameters

2. Meyer, P.D. 1999. *Hydraulic Parameters of Aged Near-Field Materials of the Immobilized Low-Activity Waste Disposal Facility*, Letter Report to Fluor Daniel Northwest, Inc., August 30, 1999, Pacific Northwest National Laboratory, Richland, Washington.

being fit[1]. Note that compaction of the fine-textured hematite sample during the centrifuge measurements and the relative difficulty of fitting unsaturated hydraulic conductivity data resulted in a variable quality of fit for each sample. Other than the particle and bulk densities, the texture of the samples (coarse or fine) seemed to have a greater influence on the parameter values than the mineral type. The average parameters of the fine goethite and hematite samples are given in Table 6.9. Arithmetic averages were used except for α and K_s, for which geometric averages are given. These parameters may be representative of the fully corroded steel containers. Average grain size measurements for the fine samples were 96% finer than 0.125 mm, 50% finer than 0.063 mm, and 36% finer than 0.045 mm.

Table 6.9. Representative Parameter Values for the Fully Corroded Steel Containers

ρ_p (g/cm^3)	ρ_b (g/cm^3)	θ_s	θ_r	α (cm^{-1})	n	K_s (cm/s)
4.16	2.30	0.39	0.04	0.0008	1.77	2.2×10^{-6}

6.2.5 Backfill and Filler Material between Waste Packages

The backfill and filler material within the vault may undergo changes in their hydraulic properties due to the high pH conditions expected within and around the vault. Kaplan et al. (1998) report on a series of experiments in which the quartz sand and backfill materials discussed in Sections 4.2.2 and 4.4.1 were exposed to NaOH solutions. NaOH was chosen as the experimental solution because its ions in solution are expected to be prevalent in the near-field pore water resulting from dissolution of the glass waste. Kaplan et al. (1998) performed batch and column experiments using 0.5, 1.0, 2.0, and 3.0 M solutions of NaOH with contact time of up to 10 months. No systematic changes in hydraulic properties were observed for either material. Results remained inconclusive, however, because biological growth was observed to occur in all samples. These experiments are currently being repeated on sediments that have been irradiated to sterilize them and minimize biological growth. Results will be available in FY 2000.

6.2.6 Gravel Capillary Barrier Layer

One of the changes suggested to occur from the degradation of the glass waste is the migration of a high pH front upward from the vault. If the diversion layer is used as a component of the surface barrier, the migration of a high pH front into the gravel capillary layer may produce mineral precipitation that could change the gravel hydraulic properties and potentially affect the performance of the diversion layer. Precipitation on the gravel grains would cause the hydraulic behavior of the gravel to become more like a sand; that is, the α and n parameters of the van Genuchten water retention function, and potentially the sat-

[1] Meyer, P.D. 1999. *Hydraulic Parameters of Aged Near-Field Materials of the Immobilized Low-Activity Waste Disposal Facility.* Letter Report to Fluor Daniel Northwest, Inc., August 30, 1999, Pacific Northwest National Laboratory, Richland, Washington.

urated hydraulic conductivity as well, would be reduced. Potential rates of mineral precipitation and resulting changes in hydraulic properties have not been quantified, but are anticipated to be a subject of further investigation by the ILAW PA project in FY 2000-2001.

6.3 Comments on Effective Parameter Values

Physical heterogeneity is widespread in natural porous media, and can be manifest on a hierarchy of scales from the sub-pore (microns) to the field (meters or more) (e.g., Cushman 1997; Whitaker 1999). A number of approaches have been proposed for deriving effective parameters when the scale of the heterogeneity is not explicitly represented in simulation models (Renard and de Marsily, 1997; Dagan, 1997). Although the near-field materials are not naturally occurring, there is nonetheless potentially significant physical heterogeneity due to the use of different materials over a fairly small scale, particularly within the vaults where concrete, glass waste, filler material, and steel corrosion products are all present. Nonuniform changes in material properties over time may also result in increasing heterogeneity of near-field materials. The methods developed for deriving the effective properties of naturally heterogeneous materials should also apply in simulations of the near-field materials.

Volume averaging is one approach that has been successfully used to formally account for the effects of subsurface heterogeneity on flow and transport. In volume averaging approaches, one seeks to describe the behavior of a system averaged over a volume of a porous medium. The approach can be applied in two distinct modes.

In the first mode, volume averaging is used to upscale random heterogeneous structures. Often, the problem that heterogeneity poses is that there exist structures in the porous medium that cannot be fully characterized deterministically because such a characterization is either impractical or impossible. For such cases, methods have been developed that use statistical information for developing the upscaled conservation equations and for determination of the effective parameters that appear in the conservation equation.

In the second mode, the method is used to upscale deterministic structure. Such upscaling may be necessary, for example, when one has available a high-resolution model (such as a geologic process model) of the heterogeneous porous media (Ahmadi and Quintard 1996). Under these circumstances, although the deterministic structure is available, it may be impractical to solve flow and transport equations in such a system because of computational limitations. This may be the case in near-field simulations, particularly because of the complex chemical reactions being modeled. In some instances, however, the domain can be re-discretized at a coarser scale by developing upscaled flow and transport equations (via volume averaging), and then calculating the associated effective parameters for each coarse grid block. Such a re-sampled system could then be solved with much less computational effort. Such approaches have been successfully employed to upscale deterministic structure in saturated systems (e.g., Ahmadi et

al., 1998), but have not yet been applied to the problems of identification of effective parameters for unsaturated systems.

Using an effective parameter value to represent a large volume of heterogeneous material assumes that the nature of the heterogeneity (whether random or deterministic) can be determined. If the degree of heterogeneity is underestimated, the derived effective parameter values may provide a poor representation of the actual flow and transport. Such difficulties can arise, for example, under conditions that produce preferential flow. Because the ILAW near-field materials are engineered, they are likely to be less heterogeneous than the far-field materials. In addition, a properly functioning surface cover will not only lower the water content in those materials beneath the cover, but it will also reduce temporal variations in flow. These conditions reduce the potential for significant preferential flow. With the larger water flux from a degraded cover and increasing heterogeneity from material degradation, preferential flow may become more important. This possibility can be examined in future work.

7.0 Conclusions

This report has discussed issues related to the appropriate hydraulic and transport parameters to use in simulations of the ILAW disposal facilities for the 2001 ILAW PA. This report is limited to those materials, both natural and man-made, that will be used within the excavated zone of the ILAW disposal facilities. Values for physical, hydraulic, and transport parameters are provided, although the transport parameters are limited to dispersivity and apparent diffusion coefficients. The apparent diffusion coefficients lump physical and chemical effects together. The current best-estimate parameter values are given along with a justification for their selection. In addition, the uncertainty of these parameters is discussed and reasonable upper and lower bounds are given for many of the parameters. These bounding values and the uncertainty information provided may prove useful in sensitivity or uncertainty analyses carried out as part of the 2001 ILAW PA. The report also includes a discussion of changes in material properties over time and how these changes are expected to affect the parameter values.

The parameter values provided in this report provide a starting point for the PA simulations. Changes in facility design, additional information and data that may become available, and unanticipated considerations may require that these parameter values be altered in the PA simulations. If this occurs, the new parameter values should be justified and the issues related to uncertainty and changes over time should be addressed for the new parameter values. Related parameters may also be used in other data packages being assembled for the 2001 ILAW PA. These data packages have not all been reviewed for consistency with this report.

Studies are ongoing as part of the ILAW PA project to better define the parameters of the near-field materials and to improve the analyses needed for completion of the PA. The PA will use the most current information available, which may supersede the contents of this report. This data package will be updated to collect all new information in a single source for use in future PAs.

APPENDIX M

FAR-FIELD HYDROLOGY DATA PACKAGE

FOR

IMMOBILIZED LOW-ACTIVITY TANK WASTE PERFORMANCE ASSESSMENT

Raz Khaleel

P.O. Box 1050
Richland, WA 99352

December, 1999

EXECUTIVE SUMMARY

A number of data packages are being assembled as part of 2001 Immobilized Low-Activity Tank Waste (ILAW) Performance Assessment (PA). This data package deals with the far-field hydrology data needed to perform vadose zone flow and transport modeling for the ILAW PA.

The ILAW PA shall be conducted for two sites; the new ILAW disposal site and the existing disposal site east of the new ILAW site in 200 East Area. Site characterization data are available for both sites. This report presents the laboratory measurements on physical and hydraulic properties for soil samples at the disposal sites, and results on application of stochastic theory to small-scale measurements. The effective (upscaled) parameter estimates are derived for saturated hydraulic conductivity, soil moisture retention and unsaturated hydraulic conductivity, bulk density, unretarded macrodispersivity and sorption-enhanced macrodispersivity. These parameters will serve as input to VAM3DF, a variably saturated vadose zone flow and transport code; VAM3DF will generate 'mean' solutions for the pressure head and contaminant concentration.

The stratigraphy at both disposal sites is dominated by two distinctly different sediment sequences. The upper part of the vadose zone is characterized by a sandy sequence, whereas the lower part is characterized primarily by a gravel sequence. At saturation, compared to the gravel-dominated sequence, the sand-dominated sequence is described by a smaller log-conductivity variance. However, compared to the gravel-dominated sequence, the log-unsaturated conductivity variance for the sand-dominated sequence is higher. Consequently, the macroscopic anisotropy relations for the sandy and gravelly sediments are different. The differences in the characteristics of the two sediment sequences also result in different macrodispersivity estimates. Overall, compared to sandy soils, gravelly soils are characterized by a much smaller saturated water content, higher bulk density, higher log-conductivity variance, smaller log-unsaturated conductivity variance, a much smaller macroscopic anisotropy and smaller macrodispersivities.

A methodology is presented to estimate uncertainties in model predictions. For far-field hydrology, three sources contribute to uncertainty estimates: (a) variations in model configurations, (b) uncertainties in the calculated mean solution for concentration, and (c) uncertainties around the calculated mean solution for concentration. The following approach will be used to evaluate these uncertainties. First, uncertainty will be defined for the 'mean' solutions for concentration distribution at the water table (as a function of position and time). The combined contribution to uncertainty in the mean solution due to model configuration and effective parameter (i.e., unsaturated hydraulic conductivity and macrodispersivity) variations will be investigated. A methodology developed by Kapoor and Gelhar (1994a,b) will then be used to estimate the uncertainty around the mean solution.

Model configurations will include variations in stratigraphy and clastic dike networks. Base case and uncertainty in stratigraphy and clastic dike network models will be provided in the geology data package. Selected VAM3DF runs will be performed to estimate the impact of these uncertainties on the resultant contaminant distribution at the water table. The uncertainty attributed to isotropy and sloped layering on calculated mean solutions will also be estimated.

Bounding estimates for concentrations at the water table will be provided through a choice of parameters and model configurations judged to provide a worst case representation of the system.

1.0 INTRODUCTION

The *Hanford Immobilized Low-Activity Tank Waste Performance Assessment* examines the long-term environmental and human health effects associated with the planned disposal of the vitrified low-level fraction of the waste presently contained in Hanford Site High-Level Waste Tanks. The objectives of the performance assessment are to provide a reasonable expectation that the disposal of the waste will be protective of the general public, groundwater resources, air resources, inadvertent intruder and surface water resources. A number of data packages are being assembled as part of 2001 Immobilized Low-Activity Tank Waste (ILAW) Performance Assessment (PA). This data package deals only with the far-field (Figure 1) hydrology data needed to perform vadose zone flow and transport modeling for the ILAW PA.

Figure 1 illustrates also the overall computational strategy for the ILAW PA. The near-field environment is defined as the domain through the vault to some distance below the floor of the disposal vault (Figure 1). A coupled unsaturated flow, chemical reactions, and contaminant transport simulator (STORM) will be used within the near-field (Bacon and McGrail 1997). The plume exiting the region near the vault is expected to be of high ionic strength and pH, and will migrate down into the near-field vadose zone for some distance. However, at some distance from the disposal vaults, geochemical conditions will approach those more typical of the Hanford vadose zone and for which simplifying assumptions (such as linear sorption, negligible precipitation/dissolution, no changes in hydraulic properties, and no density effects) can be used. This region is defined as the far-field environment and can be simulated using standard, nonreactive flow and transport codes. For the ILAW PA, computations in the far-field domain will be done by VAM3DF (Huyakorn and Panday 1995), a variably saturated flow and transport code. The primary reason for switching from the near-field simulator to VAM3DF is to apply a less complicated code for the far-field, and therefore a faster turnaround for the numerical simulations. The radionuclide flux exiting the far-field domain to the unconfined aquifer will be provided by VAM3DF and will be used as a boundary condition for the unconfined aquifer flow and transport simulator. The final step in the methodology is to compute the impacts, if any, from ingestion, inhalation, and external radiation to humans who become exposed to the contaminants by withdrawing water from the aquifer.

1.1 Scope of This Data Package

The scope for the far-field hydrology data package for the new ILAW disposal site and the existing disposal site include the following information:

- Stratigraphic cross-sectional models (Section 2.0). [Note that stratigraphic cross-sectional models are presented for context only; the scope of this data package does *not* include stratigraphic cross-sectional models. Such geologic models shall be provided as part of a separate data package (i.e., Reidel and Horton 1999)]

- Data on laboratory measurements for moisture retention, particle-size distribution, saturated and unsaturated hydraulic conductivity, and bulk density (Section 2.0).

- Effective (upscaled) moisture retention, saturated and unsaturated hydraulic conductivity, bulk density, diffusivity, and macrodispersivity estimates for geologic formations (Section 3.0).

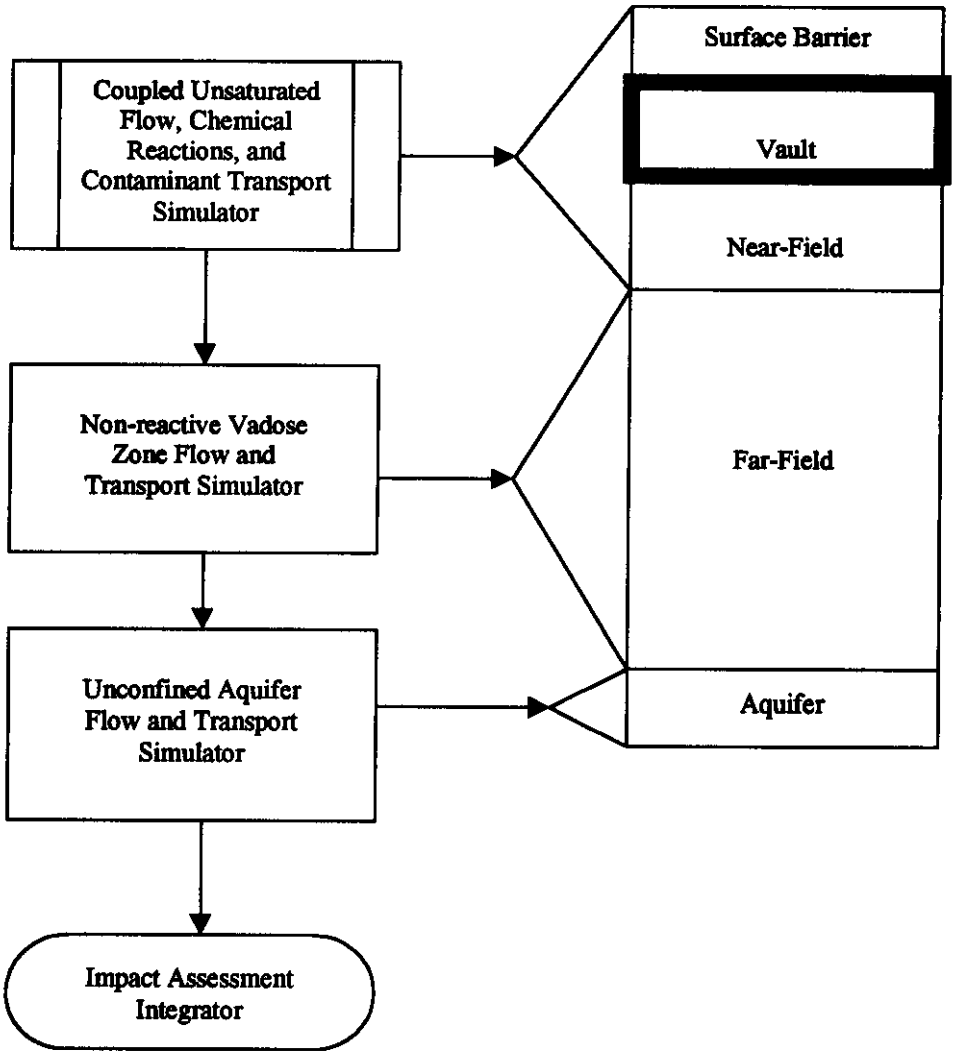

Figure 1. Modeling strategy for assessing ILAW disposal system impacts (after McGrail et al. 1998).

- Sorption-enhanced macrodispersivity estimates for selected radionuclide species (Section 3.0).

- Moisture retention, saturated and unsaturated hydraulic conductivity, bulk density, and macrodispersivity estimates for clastic dike infilling materials (Section 4.0).

- Bounding scenarios on model configurations and uncertainty estimates about the calculated mean concentration and around mean concentration (Section 4.0).

For the ILAW disposal facility with a capillary barrier and a surface barrier on top, the vadose zone water contents beneath the facility are expected to approach the natural moisture regime for arid soils. Field moisture contents are expected to be less than 10% (by volume); matric potentials of the order of -1000 cm and recharge rates of the order of 0.1 cm/yr. Under such arid conditions, the features and processes identified in the scope carry significant importance for the ILAW PA calculations. For example, the layered heterogeneous soils in 200 Areas are expected to show bulk anisotropic behavior, with the hydraulic conductivity parallel to the layers being larger than that normal to the layers. Furthermore, the degree of anisotropy increases rapidly with increasing tension or decreasing moisture content, becoming large in dry soils of the kind expected beneath the disposal facility. Also, the infiltrating water diverted around the vaults by the capillary barrier can potentially move beneath the vaults, creating moist conditions and enhancing contaminant movement to the water table. In addition, recent theoretical work and field experiments have shown that spreading of contaminants undergoing heterogeneous linear equilibrium sorption can be significantly larger than that of the non-sorbing tracer. Dispersivity enhancement can cause early arrival at the water table before they have had an opportunity to decay. Also, clastic dikes are of concern because they can potentially create preferred pathways.

2.0 LABORATORY MEASUREMENTS FOR SOIL PHYSICAL AND HYDRAULIC PROPERTIES

The purpose of this section is to summarize available data on laboratory measurements for moisture retention, particle-size distribution, saturated and unsaturated hydraulic conductivity, and bulk density for sediment samples from both new ILAW and existing disposal sites.

2.1 New ILAW Disposal Site

As part of site characterization activity for the new ILAW disposal site, sediment samples were obtained in fiscal year 1998 via a borehole drilling and sampling program (Reidel and Reynolds 1998). The borehole was drilled in the spring of 1998 (Reidel et al. 1998); Figure 2 shows the geologic cross section. The Hanford formation sandy sequence is about 200 ft thick and is the dominant facies at the site. The lower gravelly sequence is about 70 ft thick. For purposes of this data package, no distinction is made on gravel-dominated sequences of the lower Hanford formation and the upper Ringold Formation. The sediments from both of these formations have similar physical and hydraulic properties, and are characterized essentially as sandy gravel, with a significant gravel fraction (Khaleel and Freeman 1995a,b).

A work plan was prepared that provides details on the measurement and analysis of the hydraulic properties for the ILAW borehole sediment samples (Khaleel 1998)[1]. Details on sampling, laboratory procedures, and analysis of samples are provided in. Fayer et al. (1998)[2], and are included as Appendix A. The following summary is based on details provided in Appendix A.

A total of 45 cores were collected in liners, with core diameters ranging from 3.25- to 3.75- in. The total internal volume of the 3.25-in (8.26-cm) diameter cores was 803 cm^3; it was 1,069 cm^3 for the 3.75-in (9.53-cm) diameter core. It should be noted that, during drilling, sample recovery was less than 100% (Reidel et al. 1998), thereby biasing the recovered samples toward the finer fraction. Also, no vadose zone cores were collected below 242 ft because this zone was open framework gravel (i.e., gravel that supports itself with little to no finer grained material) and could not be sampled with the method used. Figure 2 shows the sampling locations relative to the geologic cross-section derived from the borehole data; twenty samples from these locations were used to obtain physical and hydraulic properties for the sandy sequence. As described later, for the gravel-dominated sequence, data on hydraulic properties from elsewhere on the Hanford Site were used as surrogates.

[2] Fayer, M.J., A.L. Ward, J.S. Ritter, and R.E. Clayton. 1998. Physical and hydraulic measurements of FY 1998 borehole cores. Letter Report to Fluor Daniel Northwest, Inc. September, 1998. Pacific Northwest National Laboratory. Richland, WA.

The procedures used to analyze the twenty samples are listed in Appendix A. Because several tests were performed on the same core, the following test sequence was established: saturated conductivity, multistep outflow, and steady state unsaturated conductivity. The multistep and steady state methods were used to obtain moisture retention and unsaturated conductivity data. Both methods were performed on the same core using the same sensor locations (see Appendix A for details). In addition to cumulative outflow, the multistep method, which is an improvement over the one-step method of Kool et al. (1985a, b), provides water content-matric potential (θ-ψ) pairs. These data were used in conjunction with the MULSTP program (Eching and Hopmans 1993), a numerical inversion procedure, to determine the optimal set of van Genuchten model (Appendix A) parameters. The steady-state method, described by Klute and Dirksen (1986), provides water content-matric potential-unsaturated conductivity (θ-ψ-K) triplets; the method was primarily used as a check on the multistep method.

Table 1 shows the van Genuchten model (van Genuchten 1980) parameters determined using the MULSTP program and data from the multistep test. The pore-size distribution parameter ℓ (Mualem 1976) was kept fixed at 0.5. Also listed in Table 1 are saturated conductivity and bulk density measurements for the 20 samples primarily from the sandy sequence. The particle-size distribution data are shown in Figure 3. The fitted moisture retention curves and unsaturated conductivity curves for the 20 samples from the sandy sequence are shown in Figure 4. Most of the borehole samples were fitted for α and n; eight of the samples were also fitted for θ_s.

2.1.1 100 Area Samples

As discussed earlier, no site-specific data on soil moisture characteristics are available at the disposal sites for sediments in the gravel-dominated sequence. However, as part of the Environmental Restoration Project, moisture retention and unsaturated conductivity data for sandy gravel sediments are available elsewhere (100 Area along the Columbia River) on the Hanford Site. Fifteen samples having a large gravel fraction were chosen. These samples ranged in gravel content from 43 to 75 percent and were used as surrogate to represent the hydraulic properties for the gravel-dominated sequence.

Standard laboratory and Westinghouse Hanford Company quality assurance procedures were used to analyze these gravelly samples. The moisture retention data for the fine fraction (< 2 mm) and for the drainage cycle of up to -1,000 cm of pressure head were measured using "Tempe" pressure cells; the rest of the drainage data up to -15,000 cm was measured using the pressure plate extraction method (Klute 1986). Saturated hydraulic conductivities for the bulk samples (including gravels) were measured in the laboratory using constant-head permeameter. A variation of the unit gradient method (Klute and Dirksen 1986; Khaleel et al. 1995) was used to measure unsaturated hydraulic conductivities for the bulk samples. The laboratory measured data on < 2mm size fraction were corrected for the gravel fraction (Gardner 1986; Khaleel and Relyea 1997).

No correction was needed for the saturated and unsaturated conductivities, since these were measured on the bulk sample.

The van Genuchten parameters were obtained via RETC (van Genuchten et al. 1991) and a simultaneous fit of both laboratory-measured moisture retention and unsaturated conductivity data; all five unknown parameters θ_r, θ_s, α, n, and K_s, with m=1-1/n (van Genuchten 1980), were fitted to the data. The pore size distribution factor, ℓ (Mualem 1976) was kept fixed at 0.5 during the simultaneous fitting. The laboratory data, following gravel-correction of the moisture retention data, are included in Appendix B for the 15 samples. Appendix B serves as the input data file for RETC. The fitted moisture retention curves and unsaturated conductivity curves for the 15 samples for the gravel sequence are shown in Figure 5. Note that, unlike the borehole samples, the 100 Area samples were fitted for θ_r, θ_s, α, n, and K_s.

2.2 Existing Disposal Site

The geologic cross-section in the vicinity of the existing disposal site is shown in Figure 6 (Kincaid et al. 1995). The cross-section appears to be very similar to that of the new ILAW disposal site. Again, for purposes of this data package, no distinction is made on gravel-dominated sequences of the lower Hanford formation and the Ringold Formation. Physical and hydraulic properties' information on sediments from borehole 299-E25-234 was obtained. Such information included particle-size distribution, bulk density, moisture retention, and saturated hydraulic conductivity. Unlike the new ILAW site, notably absent were any measurements of unsaturated hydraulic conductivity. It is, however, well recognized that estimated unsaturated conductivities, based on saturated conductivity and the van Genuchten retention model, can differ by up to several orders of magnitude with measured conductivities at the dry end (e.g., Khaleel et al. 1995). Therefore, it was decided to use, as much as possible, the new ILAW site sediment properties for the existing disposal site, since the geology for the two sites is not significantly different and measurements of both moisture retention and unsaturated conductivity are available for sediments at the new ILAW site. In fact, the average particle-size distribution for the sandy sequence sediments at the two sites is very similar: <1% gravel, 91% sand, 9% silt and clay for the existing disposal site and <2% gravel, 88% sand, 10% silt and clay for the new ILAW site. Similar to the new ILAW site, the gravel-dominated sequence at the existing disposal site is comprised primarily of sandy gravel. In summary, as indicated in Table 3, the soil physical and hydraulic properties at the new ILAW and existing disposal sites are similar.

Table 3. Comparison of mean parameter estimates for the sandy sequence at the new ILAW and existing disposal sites.

Parameter	New ILAW Disposal Site	Existing Disposal Site
θ_s	0.379	0.420
θ_r	0.033	0.023
K_s (geometric mean), cm/sec	0.0029	0.0016
Bulk Density, g/cm^3	1.71	1.58

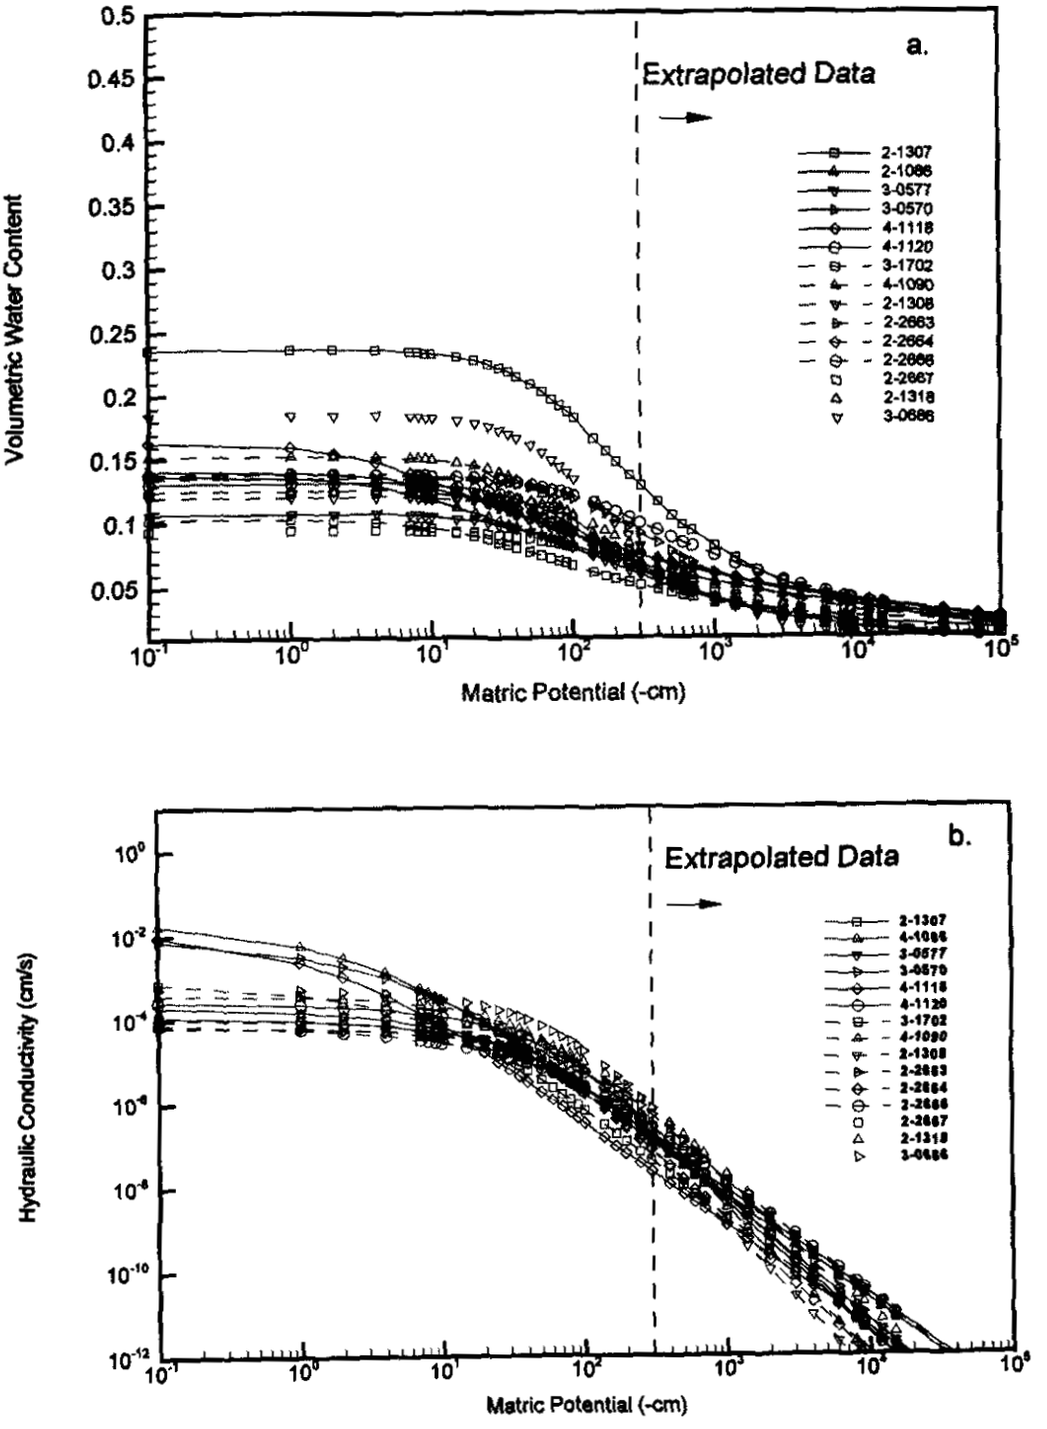

Figure 5. Fitted moisture retention and unsaturated conductivity curves for 15 samples for the gravel-dominated sequence (the symbols represent various samples, not experimental data).

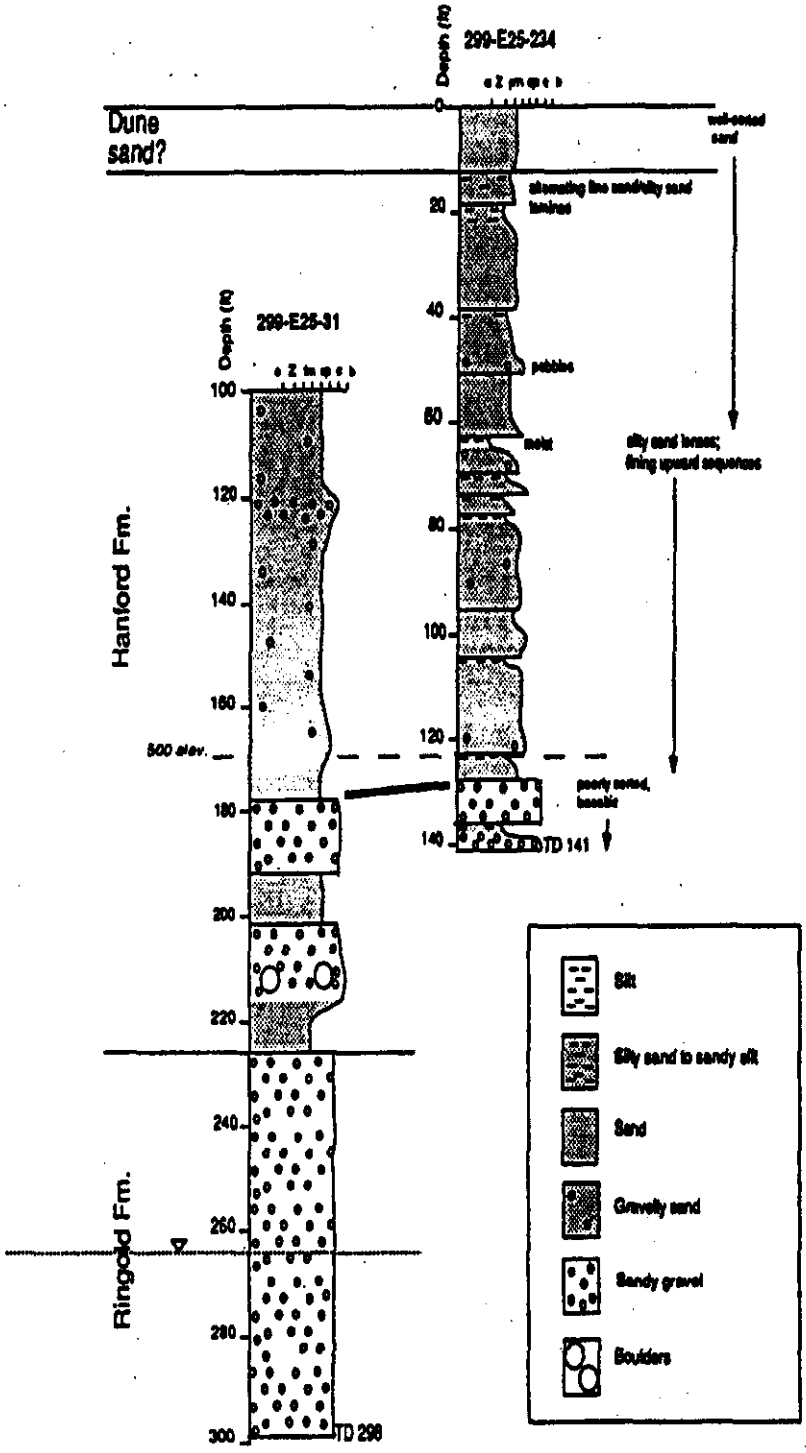

Figure 6. Geologic cross section of the existing disposal site (after Kincaid et al. 1995).

3.0 EFFECTIVE (UPSCALED) FLOW AND TRANSPORT PROPERTIES

Data on hydraulic properties, described in the preceding section, were obtained via laboratory tests on core samples (scales of the order of a few cm). However, numerical models of fluid flow and contaminant transport in the unsaturated zone require specifying hydraulic properties for each discretized grid block (scales of the order of meters). Therefore, the scale of the grid blocks is usually much larger than the scale at which the unsaturated properties were measured. The process of defining large-scale properties for the numerical grid blocks based on small, measurement-scale point measurements is called upscaling.

This section provides effective (upscaled) values of flow and transport parameters for the far-field vadose zone. Specific flow parameters include moisture retention, saturated and unsaturated hydraulic conductivity. Transport parameters include bulk density, diffusivity, and macrodispersivity. Sorption coefficients are included as part of another data package.

3.1 Effective (Upscaled) Flow Parameters

Any attempt at upscaling is confronted with the issue of spatial variability of hydraulic properties due to small-scale soil heterogeneities. The presence of spatial variability in hydraulic properties of Hanford soils has been well documented (e.g., Khaleel and Freeman 1995a). A fundamental issue is then how best to incorporate the effects of natural heterogeneity in modeling. A traditional approach is to use deterministic models and attempt to incorporate the overall heterogeneity of the system such as layering while neglecting the small-scale heterogeneity. The considerable spatial variability of Hanford soils makes complete characterization of the hydraulic properties at the field scale an almost impossible task, as an enormous amount of data is required for proper representation of the actual media heterogeneities.

An alternative approach is to define an equivalent homogeneous medium with average, effective (upscaled) hydraulic properties that are related to the local small-scale heterogeneities and thereby predict the mean flow and transport behavior of the field-scale, larger media. However, to represent a heterogeneous medium by its homogeneous equivalent, we need to estimate the effective hydraulic properties that represent this equivalent homogeneous medium. A straightforward approach would be to use statistical averages (arithmetic or geometric) of the local soil hydraulic properties, but such simple estimates may not always be able to properly describe the complicated nonlinear behavior in heterogeneous soils.

3.1.1 Stochastic Upscaling

For saturated media, an averaging of the heterogeneities in geologic media at a smaller scale leads to an effective hydraulic conductivity value, at the larger (macroscopic) scale, with the lateral hydraulic conductivity being much larger than the vertical conductivity (Freeze and Cherry 1979). For unsaturated media, theoretical (e.g., Mualem 1984, Yeh et al. 1985a, b; c, Bear et al. 1987; Mantoglou and Gelhar 1987; Green and Freyberg 1995) and experimental analyses (e.g., Stephens and Heerman 1988; Yeh and Harvey 1990; McCord et al. 1991) of field-scale unsaturated flow indicates that in stratified sediments, the effective hydraulic conductivity tensor is anisotropic with a tension-dependent (or moisture-dependent) degree of anisotropy. The anisotropy ratio of horizontal hydraulic conductivity to vertical hydraulic conductivity increases with decreasing moisture content. Variable, moisture-dependent anisotropy in unsaturated soils is therefore an effective, large-scale (macroscopic) flow property which results from media heterogeneities at a smaller scale, and provide a framework for upscaling laboratory-scale measurements to the effective (upscaled) properties for the large-scale vadose zone.

3.1.2 Field Observations

Field observations in the vicinity of the new ILAW and existing disposal sites do indeed provide evidence of saturation-dependent anisotropy and lateral migration. A test facility comprising an injection well at the center and a radial array of 32 monitoring wells was constructed in 1980 south of PUREX in 200 East Area. The facility was used in late 1980 and early 1981 to conduct an infiltration and multiple tracer (i.e., chloride, nitrate, barium, rubidium, Sr-85 and Cs-134) test, in which 45,000 L of liquid (in 11 increments) were injected at a depth of 4.7 m over a period of 133 days (Sisson and Lu 1984). Three-dimensional water content profiles in layered, coarse sediments were monitored to a depth of 18 m by down-hole neutron probe measurements. The initial water contents were measured at 30-cm increments over the 30- to 1800-cm depths in all 32 observation wells. In situ gamma energy analysis data were collected to determine the distribution of radioactive tracers. The unique three-dimensional nature of the experiment and the measured water content profiles provide evidence of tension-dependent anisotropy. The field data clearly show lateral spreading that occurred during injection. The horizontal wetting patterns dominated the experiment. In fact, numerical modeling results (Sisson and Lu 1984), based on the assumption of a uniform and isotropic model, showed a much deeper penetration of the moisture profile than occurring in the field (Sisson and Lu 1984). The degree of spreading was remarkable considering the apparent uniform lithology at the site.

3.1.3 Composite Macroscopic Relationships

Figures 4 and 5 show that moisture retention data show spatial variability, although the degree of variation at a given tension is more modest than that of hydraulic conductivity. Based on data in Tables 1 and 2, composite parameters for the moisture retention

relations were determined. For both sandy and gravelly soils, the composite van Genuchten parameters were obtained via RETC (van Genuchten et al. 1991) and a simultaneous fit of both moisture retention and unsaturated conductivity predictions; all four unknown parameters θ_r, θ_s, α, and n with m=1-1/n (van Genuchten 1980), were fitted to the data. The pore size distribution factor ℓ was kept constant at 0.5 during the simultaneous fitting. The saturated conductivity, K_s, was also kept constant as geometric mean of the sample estimates.

The fitted composite moisture retention and unsaturated conductivity curves are shown as Figures 7 and 8, respectively, for the sandy and gravelly sequences. Table 3 shows the fitted parameters. Equivalent horizontal and vertical hydraulic conductivities are derived using macroscopic anisotropy relations.

Table 4. Composite van Genuchten-Mualem parameters for the sand- and gravel-dominated sequences.

Formation	Number of samples	θs	θr	α (1/cm)	n	ℓ	K_s (cm/s)
Sandy	20	0.375	0.041	0.057	1.768	0.5	2.88E-03
Gravelly	15	0.138	0.010	0.021	1.374	0.5	5.60E-04

3.1.3.1 Stochastic Model for Macroscopic Anisotropy

As discussed earlier, variable, tension-dependent anisotropy provides a framework for upscaling small-scale measurements to the effective (upscaled) properties for the large-scale vadose zone. A stochastic model is used to evaluate tension-dependent anisotropy for sediments at the new ILAW site.

Yeh et al. (1985b) analyzed steady unsaturated flow through heterogeneous porous media using a stochastic model; parameters such as hydraulic conductivity are treated as random variables rather than as deterministic quantities. The Gardner (1958) relationship was used by Yeh et al. to describe unsaturated hydraulic conductivity (K) as a function of saturated hydraulic conductivity (K_s) and tension (ψ), i.e.,

$$K(\psi) = K_s \exp(-\beta\psi) \quad (1)$$

where β is a fitting parameter. Equation (1) can be written as

$$\ln K(\psi) = \ln K_s - \beta\psi \quad (2)$$

Equation (2) is referred to as the log-linear model, since lnK is linearly related to ψ through the constant slope β. However, such a constant slope is often inadequate in describing $\ln K(\psi)$ over ranges of tension of practical interest for field applications. As an alternative, the slope β can be approximated locally by straight lines over a fixed range of tension. The "$\ln K_s$" term in equation (2) can then be derived by extrapolating the local slopes back to zero tension.

Using a linear correlation model between the log-conductivity zero-tension intercept and β, Polmann (1990) presents a generalized model that accounts for the cross-correlation of the local soil property (i.e., $\ln K_s$ and β) residual fluctuations. Compared to uncorrelated $\ln K_s$ and β model, partial correlation of the properties is shown to have a significant impact on the magnitude of the effective parameters derived from the stochastic theory. The Polmann (1990) equations for deriving the effective parameters are as follows.

$$
\begin{aligned}
&< LnK >=< LnK_s > -A < \psi > -\sigma^2_{LnKs}\lambda[p - p^2 < \psi > -\zeta^2 < \psi >]/(1 + A\lambda) \\
&\sigma^2_{LnK} = \sigma^2_{LnKs}[(1 - p < \psi >)^2 + \zeta^2 < \psi >^2]/(1 + A\lambda) \\
&K_h^{eq} = \exp[< LnK > +(\sigma^2_{LnK}/2)] \\
&K_v^{eq} = \exp[< LnK > -(\sigma^2_{LnK}/2)]
\end{aligned}
\qquad (3)
$$

where σ^2_{LnK} = variance of log unsaturated conductivity (which depends on mean tension),

$<\psi>$ = mean tension,

σ^2_{LnKs} = variance of $\ln K_s$

$<\ln K_s>$=mean of $\ln K_s$,

p = slope of the β versus $\ln K_s$ regression line,

$\zeta = \sigma_\delta/\sigma_{\ln Ks}$,

σ_δ = standard deviation of the residuals in the β versus $\ln K_s$ regression,

A = mean slope, β, for $\ln K_s$ vs. ψ,

λ = vertical correlation lengths for $\ln K_s$ (assumed to be same as that of β),

K_h^{eq} = equivalent unsaturated horizontal conductivity, and

K_v^{eq} = equivalent unsaturated vertical conductivity.

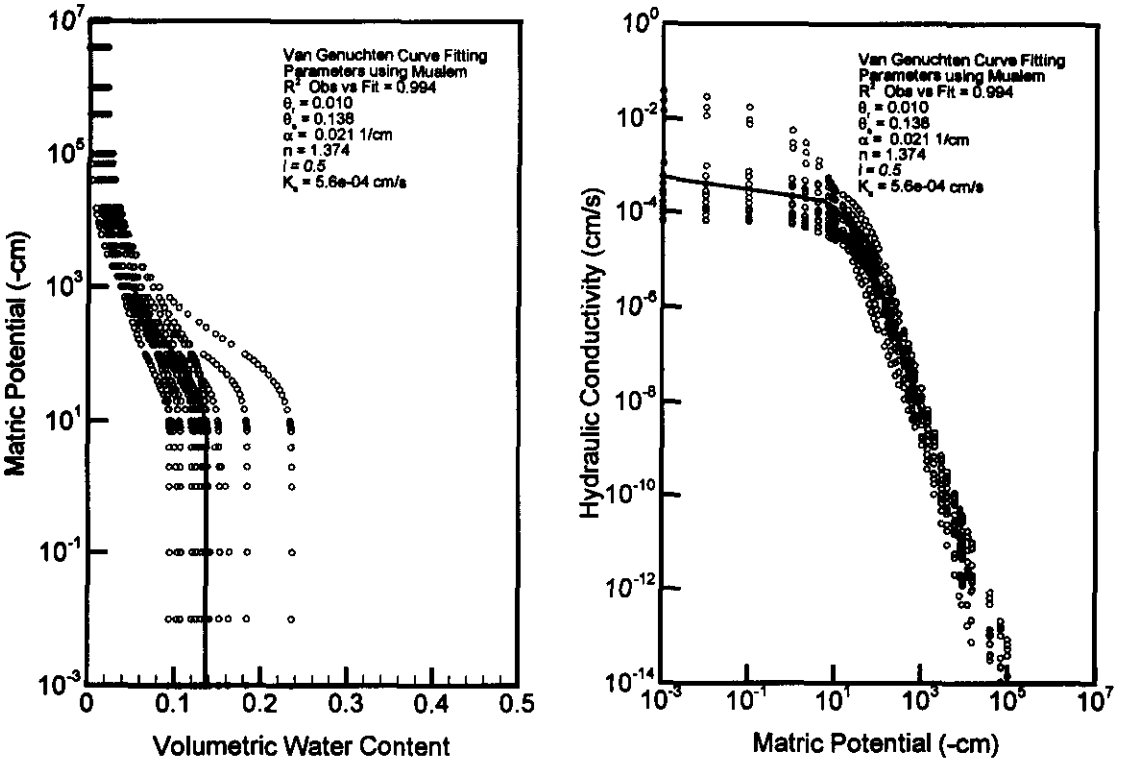

Figure 8. Composite moisture retention and unsaturated conductivity curves for the gravel-dominated sequence.

3.1.3.2 Macroscopic Anisotropy Relations

Results of application of equation (3) for variable anisotropy are presented below. The same 20 samples (Table 1) of the sandy sequence were used to obtain parameters $\langle \ln K_s \rangle$, $\sigma^2_{\ln K_s}$, p, ζ, and A. The slope and pseduo $\ln K_s$ estimates, discussed in the preceding section, were evaluated for the moisture regime of interest (i.e., tension range of 500 cm to 700 cm for the sandy sequence and 700 cm to 1000 cm for the gravelly sequence). It should be noted, however, that no experimental data are available for unsaturated conductivities in the tension range of interest; β and $\ln K_s$ estimates were based on the fitted van Genuchten-Mualem curves (Figures 7 and 8). The tension ranges are consistent with a base case recharge estimate of about 0.1 cm/yr (Figures 7 and 8).

An estimate of the correlation length, λ, is needed for anisotropy calculations. Most of the measurements in the vicinity of the ILAW site have been obtained at sampling intervals that are too coarse to yield a reasonable estimate for the correlation length. However, one data set is available that provides saturated conductivity estimates at about 30 cm intervals for a depth of 18 m within the Hanford formation; the site is located about 1/2 mile east of the ILAW site. Figure 9 shows the experimental variogram and the

fitted spherical variogram model for saturated conductivities. The fitted spherical variogram suggests a correlation length, λ, of about 50 cm; i.e., the distance at which the variogram drops to [1-(1/e)] times the sill (Figure 9). The correlation length, λ, for both lnKs and β were assumed to be equal.

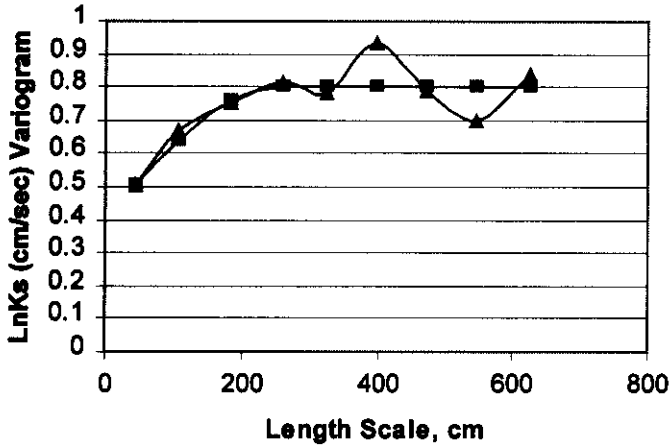

Figure 9. Experimental (triangles) and fitted theoretical (squares) variogram for LnKs.

The Polmann parameters for both sandy and gravel-dominated sequences are shown in Table 5. Note that, compared to the sandy soils, mean slope, A, <lnKs>, $\sigma^2_{LnK_s}$, and ζ values for the gravelly soils are significantly lower; σ_β^2 for the gravelly samples was also almost two orders of magnitude lower. Because of these different characteristics, the macroscopic anisotropy relations for the sandy and gravelly sediments are quite different. Figures 10 and 11 illustrate the macroscopic anisotropy relations for the two sediments. The anisotropy for the gravelly soils is much less compared to that for sandy soils. In fact, for the tension range of interest for ILAW PA modeling, anisotropy ratio is about two. Note that, for gravelly soils, no data were available for a variogram analysis. However, a smaller λ value (30 cm) is used (Table 5) because of a much higher variance of $\ln K_s$ for the gravelly soils than for the sandy soils.

Table 5. Macroscopic anisotropy parameters for the sand- and gravel-dominated sequences.

Formation	Number of samples	$<LnK_s>$	$\sigma^2_{LnK_s}$	p	ζ	λ (cm)	A
Sandy	20	-17.3	2.89	-1.4E-4	3.18E-4	50	0.00680
Gravelly	15	-15.6	1.03	1.9E-4	4.24E-4	30	0.00354

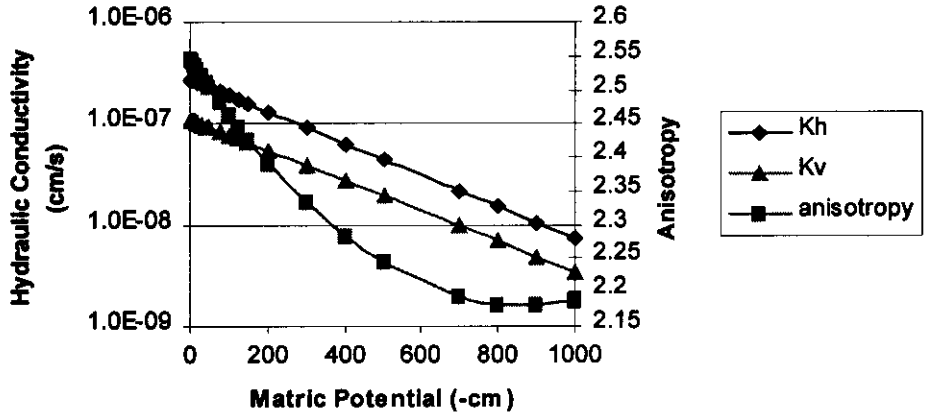

Figure 11. Calculated macroscopic anisotropy (equation 3) as a function of mean pressure head for the gravel-dominated sequence.

3.2 Effective Transport Parameters

Base case effective transport parameter (bulk density, diffusivity, and dispersivity) estimates are presented in this section. Because of natural variability, the transport parameters are all spatially variable. The purpose is again, similar to the flow parameters, to evaluate the effect of such variability on the large-scale transport process.

3.2.1 Bulk Density

Both bulk density (ρ_b) and K_d estimates are needed to calculate retardation factors for different species. The effective, large-scale estimate for the product [$\rho_b K_d$] is the average of the product of small-scale laboratory measurements for bulk density and K_d (Gelhar 1993). The laboratory measurements for ρ_b are shown in Tables 1 and 2, respectively, for the sandy and the gravel-dominated sequences, whereas the K_d measurements are available in Kaplan et al. (1998). Table 6 provides the effective, large-scale estimates.

Table 6. Effective parameter estimates, E[$\rho_b K_d$], for the product of bulk density (g/cm^3) and K_d (cm^3/g) at the new ILAW and existing disposal sites.

Species	E[$\rho_b K_d$]	
	Sandy	Gravelly
Cs	3473	1700
Sr	25.20	12.20
U	1.05	0.51
Se	11.32	5.56

3.2.2 Diffusivity

It is assumed that the effective, large-scale diffusion coefficients for both sandy and gravel-dominated sequences at both sites are a function of volumetric moisture content, θ. VAM3DF uses the Millington-Quirk (1961) empirical relation:

$$D_e(\theta) = D_0 \frac{\theta^{10/3}}{\theta_s^2} \qquad (4)$$

where $D_e(\theta)$ is the effective diffusion coefficient of an ionic species, and D_0 is the effective diffusion coefficient for the same species in free water. The molecular diffusion coefficient for all species in pore water is assumed to be 2.5 x 10^{-5} cm^2/sec (Kincaid et al.1995).

3.2.3 Dispersivity

An extended review is provided on the rationale of choice for vadose zone dispersivity estimates. Readers who are familiar with the state-of-the-art can proceed directly to Section 3.2.3.4.

A variety of factors such as the size of the flow domain, the flow regime (saturated versus unsaturated flow), field heterogeneities, and the contaminant species (retarded versus nonretarded) need to be recognized in estimating dispersivities. The objective of this section is to provide appropriate guidance on the choice of vadose zone dispersivity estimates for use in ILAW PA.

It should be noted that laboratory data would be of little use in estimating field-scale dispersivities. While well-designed, large-scale tracer experiments would provide useful information, limited field data are available at this time. Therefore, the dispersivity estimates needed for modeling are essentially based on literature values and the available stochastic equations.

Literature data suggest that much more information is available on dispersion in saturated media than in unsaturated media. Therefore, first the available data on dispersivities in saturated media are summarized (Gelhar et al. 1992). Second, available data on vadose zone dispersivities are presented, including results of small-scale tracer experiments in the vicinity of the new ILAW site in 200 East Area. Third, the stochastic framework used in obtaining dispersivity estimates is reviewed, and estimates are provided for use in ILAW PA.

3.2.3.1 Saturated Media Dispersivities For Field Sites

A critical review of dispersivity observations from 59 different field sites was performed by Gelhar et al. (1992). Extensive tabulations of information were included by Gelhar et al. on aquifer type, hydraulic properties, flow configuration, type of monitoring network, tracer, method of data interpretation, overall scale of observation and longitudinal, horizontal transverse and vertical transverse dispersivities from original sources. The information was then used to classify the dispersivity data into three reliability classes: low, intermediate, and high. Overall, the data indicate a trend of systematic increase of the longitudinal dispersivity with observation scale but the trend is much less apparent when the reliability of data (Figure 12) is considered. The longitudinal dispersivity ranged from 10^{-1} to 10^{5} m, but the largest scale for high reliability data was only 250 m. When the data are classified according to porous versus fractured media, no significant differences were apparent between these aquifer types. At a given scale, the longitudinal dispersivity values were found to range over 2 to 3 orders of magnitude and the higher reliability data approached the lower portion of this range. The high reliability dispersivity data ranged from a low of about 0.6 m at a scale of 15 m to about 1 m at a scale of 250 m; some data are on the order of 2 to 3.5 m at a scale of 30 m (Figure 12). It is not appropriate to represent the longitudinal dispersivity data by a single universal line.

The variations in dispersivity reflect the influence of differing degrees of aquifer heterogeneity at different sites. The data on transverse dispersivities are more limited but clearly indicate that vertical transverse dispersivities are typically an order of magnitude smaller than horizontal transverse dispersivities (Gelhar et al. 1992). Reanalysis of data from several of the field sites showed that improved interpretations most often lead to smaller dispersivities (Gelhar et al. 1992). Overall, Gelhar et al. concluded that longitudinal dispersivities in the lower part of the indicated range are more likely to be realistic for field situations. This suggests that, for conservative species, a longitudinal dispersivity of the order of a meter is a reasonable estimate for saturated media domains that are a couple of hundred meters in scale. Note that the estimates are for saturated media and conservative species. As discussed later, dispersivity estimates are enhanced due to heterogeneous sorption in both saturated and unsaturated media.

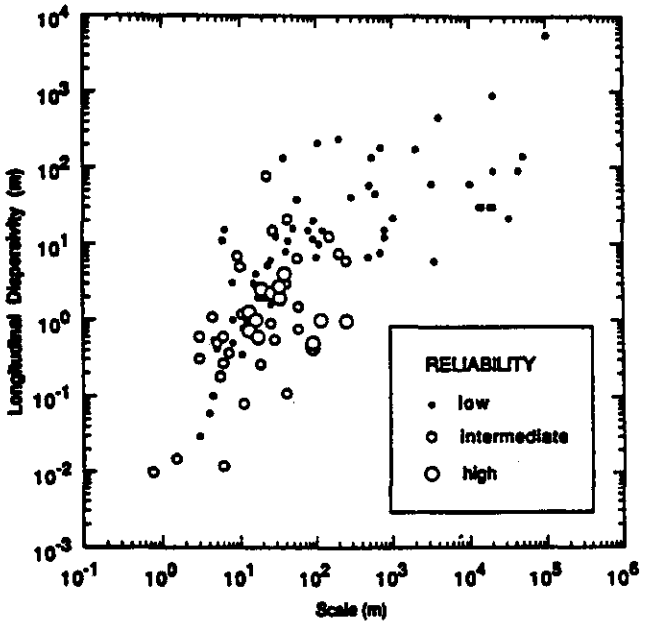

Figure 12. Longitudinal macrodispersivity in saturated media as a function of overall problem scale with data classified by reliability (after Gelhar et al. 1992).

3.2.3.2 Vadose Zone Dispersivities For Dry Desert Environment

As discussed earlier, for an engineered waste disposal facility with a capillary barrier and a surface barrier on top, the vadose zone water contents beneath the disposal facility are expected to approach the natural moisture regime for arid soils. Although exceptional precipitation events may cause transient high water contents near the soil surface, the source of the infiltration is not likely to be sustained at great depths within the vadose zone.

This inference is supported by the results of artificial tracer experiments on much shorter time scales. For example, two massively instrumented solute transport experiments were performed in desert soils near Las Cruces, New Mexico (Wierenga et al. 1991; Hills et al. 1991). Drip emitters were used to irrigate a plot adjoining a deep trench in a heterogeneous soil possessing well in excess of one order of magnitude standard deviation in saturated hydraulic conductivity. Monitoring of the trench face showed a spatially uniform progression of the wetting front and did not reveal indications of preferential flow (Wierenga et al. 1991). Hills et al. (1991) found that a dispersivity of 5 cm provided reasonably realistic simulations of ^{3}H and Br tracer distributions.

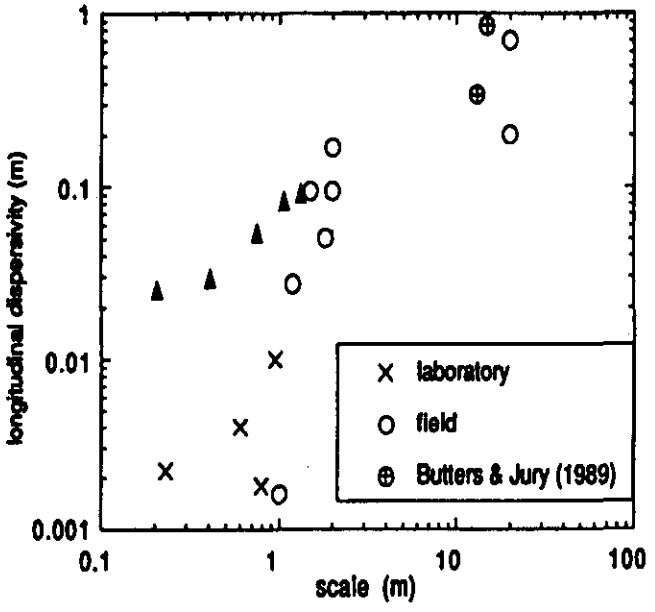

Figure 13. Longitudinal macrodispersivity in unsaturated media as a function of overall problem scale (after Gelhar 1993). [Note that the triangles are data from Ward et al. 1998]

For unsaturated flow, long-term environmental tracer studies at several arid southwestern sites indicate dispersivities of less than 10 cm. Phillips et al. (1988) assessed the degree of mixing in desert soils using the conventional advection-dispersion modeling, yielding

a dispersion coefficient of 50 cm^2/yr. This compares with the calculated effective diffusion coefficient of 25 cm^2/yr. A similar study by Scanlon (1992), at another southwestern arid site, obtained a dispersion coefficient of about 14 cm^2/yr. These, then, lead to effective dispersivities of about 7 and 4 cm, at the two arid sites, and Peclet numbers (displacement divided by dispersivity) of 23 and 17.

Ward et al. (1998)[3] obtained dispersivity estimates via field measurements at a location close to the ILAW site, using KCl as a tracer. Analysis of the data provided dispersivities that ranged from 1.3 to 7.8 cm for travel distances ranging from 25 to 125 cm (Appendix C). Dispersivity increased with depth to about 0.75 m, after which it essentially became constant. Although these estimates are for the Hanford formation similar to the ILAW site, the transport distance within the vadose zone is indeed of limited extent. Nevertheless, results based on the limited data are consistent with the concept of a scale-dependent dispersivity. Thus, although no data exist on large-scale dispersivities near the ILAW site, it is expected that they will be larger than those based on the small-scale tracer experiment of Ward et al. (1998).

Based on a survey of literature, Gelhar (1993) presented, as shown in Figure 13, the longitudinal vadose zone dispersivities as a function of the scale of the experiment. The figure shows a lack of data for scales larger than 2 m. Nevertheless, similar to saturated flow, Figure 13 show an increase of dispersivity with an increase in scale. Also, shown in Figure 13 are results from the Ward et al. experiment; their data are in close agreement with others.

3.2.3.3 Stochastic Models and Macrodispersivities for Large-Scale Media

Field-scale dispersivities are referred to as macrodispersivities. The heterogeneities that exist at various length scales result in a scale dependence of macrodispersivities. Stochastic models have been developed which relate the macrodispersive spreading to the spatial variability of saturated hydraulic conductivity field in a saturated porous media (e.g., Gelhar and Axness 1983; Dagan 1984). The Gelhar and Axness (1983) model provides the asymptotic estimates of macrodispersivity, while the Dagan (1984) model describes the preasymptotic estimates of macrodispersivities for the near-source, early-time period. The Dagan (1984) model predicts that under steady state flow with a uniform mean hydraulic gradient, the ensemble longitudinal macrodispersivity increases with time and displacement distance as the solute first enters the flow domain. A constant, asymptotic value (i.e., Fickian behavior) is eventually reached after the solute travels a few tens of correlation scales of the hydraulic conductivity field.

For prediction of contaminant transport during early time or for short travel distances, simulating effects of scale-dependence on macrodispersion is a consideration. The dispersivities increase with time (or equivalently with distance) until they tend to

[3] Ward, A.L., R.E. Clayton, and J.S. Ritter. 1998. Determination of in situ hydraulic parameters of the upper Hanford formation. Letter Report to Fluor Daniel Northwest, Inc. December, 1998. Pacific Northwest National Laboratory. Richland, WA.

converge on their unique asymptotic (large time) values. The second-moment evolution curve or the time-dependent, preasymptotic macrodispersivities are of particular interest, since it can take a long time (e.g., years or decades) for the asymptotic Fickian approximation to take hold. However, the early time scale dependence are of little consequence in simulations involving long times or large mean travel distances such as those for ILAW PA. For these predictions over large travel distances or large times, the use of a constant (asymptotic) dispersivity is considered to be adequate. An estimate of the maximum or asymptotic value of macrodispersivity for saturated media can be based on Gelhar and Axness' (1983) stochastic solution:

$$A_L = \sigma^2_{LnKs}\lambda \tag{5}$$

where λ is the vertical correlation scale (i.e., average distance over which conductivities are correlated) for log saturated hydraulic conductivity.

In addition to the size of flow domain and vadose zone soil heterogeneities, dispersivities are expected to be a function of soil moisture content (or matric potential). Macrodispersivities are expected to increase with a decrease in saturation (e.g., Polmann 1990; Gelhar et al. 1994). Russo (1993) suggests that vadose zone macrodispersivities can be defined in a manner similar to saturated media estimates. This is based on his finding that the product of the variance and the correlation scale of log conductivity for both saturated and unsaturated media are of similar magnitude. In other words, an increase in the variance of log conductivity (and, concurrently, in the velocity variance) as moisture content decreases is compensated in part by a decrease in the correlation scale of log conductivity (and, concurrently, in the correlation scale of the longitudinal component of the velocity). Such an approximation (a) assumes use of Gardner's (1958) equation to describe unsaturated conductivity as a function of matric potential, and (b) holds as long as the correlation scale of β in Gardner's equation is relatively small compared with that of log saturated conductivity.

3.2.3.4 Macrodispersivity Estimates For Non-Reactive Species

The Gelhar and Axness equation can be used to estimate asymptotic values of macrodispersivity. However, to account for effects of unsaturated flow, a modified version is used for both disposal sites:

$$A_L(<\psi>) = \sigma^2_{LnK}\lambda \tag{6}$$

where the longitudinal macrodispersivity depends on the mean tension $<\psi>$. To apply equation (6), an estimate of the vertical correlation scale for unsaturated conductivity is needed. As discussed earlier, a correlation length of the order of about 50 cm was obtained for the sandy formation. However, compared to the saturated K's, an increase in the variance of log conductivity is expected to be compensated in part by a decrease in the correlation scale of log unsaturated conductivity. A correlation length of 30 cm is assumed for both sandy and gravelly formations. Table 6 provides the log unsaturated

conductivity variances (at a recharge rate of about 0.1 cm/yr) and the estimated longitudinal (A_L) and transverse (A_T) macrodispersivities for the two formations. The transverse dispersivities are estimated as $1/10^{th}$ of the longitudinal values (Gelhar et al. 1992). Gelhar (1993) presented results of stochastic analysis of macrodispersion in unsaturated media by Mantoglou and Gelhar (1985). The large-scale macrodispersivity estimates in Table 7 are of similar magnitude to those reported in Gelhar (1993) for Panoche and Maddock soil types.

Table 7. Non-reactive macrodispersivity estimates for soils at the new ILAW and existing disposal sites.

Formation	σ^2_{LnK}	Correlation length, λ (cm)	A_L (cm)	A_T (cm)
Sandy	5.51	30	~200	20
Gravelly	0.96	30	~30	3

3.2.3.5 Heterogeneous Sorption Enhanced Macrodispersivities

As expected, the net effect of sorption is to retard the velocity of the contaminant in the soil. Because sorption for specific contaminants may be a function of soil properties, as the soil properties experience spatial variability, the sorption also varies (Gelhar 1993; Talbott and Gelhar 1994). The variation directly affects the velocity of the contaminant, which, in turn, enhances the spreading of the plume. The enhanced spreading is defined by a larger reactive longitudinal macrodispersivity, different from the non-reactive longitudinal macrodispersivity, as discussed in the preceding section. The increased plume spreading due to heterogeneous sorption (over and above the result for no sorption) is defined as the macrodispersivity enhancement. Stochastic theory and field data on contaminant plumes suggest that the effect of macrodispersivity enhancement only occurs in the longitudinal direction. The transverse macrodispersivity is unaffected by sorption variability (Garabedian et al. 1991). The results presented in this section will support the use of species-dependent enhanced longitudinal macrodispersivities in the ILAW PA modeling.

The radioisotopes considered are Cs-137, Sr-90, U, and Se. The objective is to evaluate differences in macrodispersivity enhancement due to a long-lived mobile radionuclide (e.g.,U) and a short-lived relatively immobile radionuclide (e.g., Sr-90). During the laboratory analysis, measurements of K_d for each species have been obtained on the same soil samples, as are measurements of unsaturated hydraulic conductivity.

Based on laboratory measurements of unsaturated conductivity, K (Fayer et al. 1998; see footnote on p. 4) and K_d (Kaplan et al. 1998) for the same 20 samples for the Hanford

sandy sequence, a direct correlation of K and K_d was derived for Cs-137, Sr-90, U, and Se. Stochastic theory developed by Gelhar (1993) was evaluated to determine the importance of varying longitudinal macrodispersivity by contaminant species on the basis of sorption heterogeneity and correlation with hydraulic conductivity. An enhancement of macrodispersivity can have significant effects on the expected contaminant predictions for numerical models.

In order to understand clearly the importance of heterogeneous, spatially variable sorption, a number of parameters were defined. The variable K_d may be prescribed by a mean (K_d) and a standard deviation (σ_{Kd}). Further, a retardation factor, R, was related to K_d by the following:

$$R = 1 + \frac{\rho_b K_d}{\theta} \tag{7}$$

where R may be described statistically by an effective retardation, $\overline{R}$ = E[R], and its standard deviation, σ_R.

By analyzing the mean and standard deviation of a sample data set of a measured soil property, and by showing a relationship between the soil property and R, $\overline{R}$ and σ_R were calculated as a function of the soil property data set.

The net result of the variation in the retardation and the relationship between the retardation and ℓnK is to increase the longitudinal macrodispersivity of the sorbed species according to the following equation given by Talbott and Gelhar (1994):

$$A_{11} = A_0 \left\{ \left[1 + \gamma \frac{\sigma_R}{\overline{R}\sigma_{LnK}} \sqrt{\zeta} \right]^2 + (1-\zeta) \frac{\sigma_R^2 \lambda_n}{\overline{R}^2 \sigma_{LnK}^2 \lambda_1} \gamma^2 \right\} \tag{8}$$

where A_0 is the non-reactive longitudinal macrodispersivity, λ_1 is the horizontal correlation scale, $\lambda_n \approx \lambda_1$, and γ is defined as the ratio of harmonic to geometric mean for unsaturated K.

Equation (8) is identical to that in Talbott and Gelhar (1994), except that the appropriate variables are evaluated for unsaturated conditions. Equation (8) assumes random K_d but constant bulk density and moisture content. However, using the more general case (p. 256, Gelhar 1993) when all three (i.e., K_d , bulk density and moisture content) vary, it was found that the contribution to equation (8) from variations of bulk density and moisture content were negligibly small, compared to variations of K_d.

The LnK versus R relation for the four species for the sandy sequence are shown in Figure 14. The result of stochastic analysis for macrodispersivity enhancement for the Hanford sandy sequence is shown in Table 8. Note that the unsaturated K's were

evaluated at -100 cm via the fitted van Genuchten-Mualem relation. As expected, the log conductivity variance, σ^2_{LnK} at a matric potential of -100 cm is much higher (~5.5) compared to the σ^2_{LnKs} (~1.0) for the same 20 samples at saturation. The macrodispersivity enhancement, A_{11}/A_o ranges from about 1.06 for Se to about 2.12 for U.

Table 8. Macrodispersivity enhancement for the sandy sequence at the new ILAW and existing disposal sites [ρ_b in g/cm^3 and K_d in cm^3/g].

Species	$\overline{K_d}$	$\sigma_{Kd}/\overline{K_d}$	$\overline{R}$	$\sigma_R/\overline{R}$	$\overline{\rho_b}$	$\overline{\theta}$	σ^2_{LnK}	γ	ζ	λ_n/λ_1	A_{11}/A_o
Cs-137	2055	0.29	31002	0.50	1.71	0.138	5.51	0.22	0.52	1	1.07
Sr-90	14.7	0.11	241	0.62	1.71	0.138	5.51	0.22	0.45	1	1.08
U	0.62	0.20	11.1	0.52	1.71	0.138	5.51	0.22	0.53	1	2.12
Se	6.73	0.28	98.5	0.28	1.71	0.138	5.51	0.22	0.68	1	1.06

The LnK versus R relation for the four species for the gravelly sequence are shown in Figure 15. The result of stochastic analysis for macrodispersivity enhancement for the Hanford gravelly sequence is shown in Table 9. Again, the unsaturated K's were evaluated at -100 cm via the fitted van Genuchten-Mualem relation for the 15 gravelly samples. No data are available on the measurements of sorption coefficients for the gravel-dominated sequence. Based on the information for the sandy samples, all gravelly samples were first assigned the same average sorption coefficient for their respective species. This resulted in the coefficient of variation (i.e., Col. 3 in Table 9) to be identically zero for all four species. The bulk (gravel and fine fraction) retardation coefficients are then based on a correction of the actual surface area available for sorption, based on the individual gravel fraction for the 15 samples. Unlike for the sandy sequence, the log conductivity variance, σ^2_{LnK} at a matric potential of -100 cm is much lower (~0.96) compared to the σ^2_{LnKs} (~5.31) for the same 15 samples at saturation. The macrodispersivity enhancement, A_{11}/A_o varies over a very narrow range -- from about 1.05 for U to about 1.07 for Cs-137.

Table 9. Macrodispersivity enhancement for the gravelly sequence at the new ILAW and existing disposal sites [ρ_b in g/cm^3 and K_d in cm^3/g].

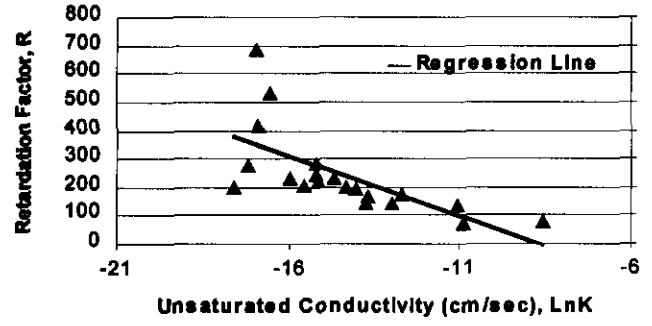
3.2.3.6 Numerical Considerations



A complicating factor in numerical modeling of contaminant transport in porous media is that both finite-difference and finite-element solutions are affected by "numerical dispersion," which refers to artificial dispersion caused by errors associated with discretization of the flow domain. To minimize such errors, the grid should be designed so that the Peclet number (P_e = discretized distance/dispersivity) is less than or equal to one, although acceptable solutions can be obtained with P_e as high as 10 (Huyakorn and Pinder 1983). With low dispersivities within the vadose zone, the Peclet number criterion results in grid spacings that are not very practical to implement. This is why numerical modelers often resort to higher values of dispersivity. An alternative is to consider use of "upwinding" option (Huyakorn and Pinder 1983) to control numerical dispersion.

Another consideration is discretization of simulation time so that the Courant number (C_r = pore velocity*time interval/grid spacing) is less than or equal to one. That is, the time step should be selected so that the chosen time interval is less than the value obtained by the ratio of grid spacing to pore velocity. Thus, the time step should be selected so that it is less than the time it takes for the solute to move one grid spacing. Note that, for a three-dimensional problem, the P_e and C_r criteria are applicable to transport in all three directions.

4.0 UNCERTAINTIES IN MODEL PREDICTIONS

As discussed in the preceding sections, the application of stochastic theory resulted in effective (upscaled) parameter estimates for saturated hydraulic conductivity, soil moisture retention and unsaturated hydraulic conductivity, bulk density, unretarded macrodispersivity and sorption-enhanced macrodispersivity. These parameters will serve as input to VAM3DF (Huyakorn and Panday 1995), a variably saturated flow and transport code; VAM3DF will generate 'mean' solutions for the pressure head and contaminant concentration.

The breakthrough curve due to contaminants released from the disposal facility is expected to appear as a "step" function at the water table, with the shape of the rise of the step function primarily governed by vadose zone heterogeneity, macrodispersivity, sorption, and radionuclide decay. Because of the long release time for the contaminants from the disposal facility, compared to the travel time through the vadose zone, it is reasonable to approximate the contaminant release as a step input function.

Three sources contribute to uncertainty calculations: (a) variations in model configurations, (b) uncertainties *in* the calculated mean concentration distribution at the water table, and (c) uncertainties *around* the calculated mean concentration distribution at the water table. Figure 16 illustrates the expected concentration distribution at the water table. The sigmoid-shaped mean concentration distribution (Figure 16) is calculated by VAM3DF, based on a particular conceptual model configuration and sensitivities to effective input parameters. However, the mean solution should be viewed as being an average of many 'realizations.' In other words, the expected peak concentration is not necessarily the calculated mean concentration (Figure 16). There is variation among different realizations, because of vadose zone heterogeneities. The variance (σ_C^2) about the mean characterizes such variation *around* a particular mean solution. While the uncertainties *in* the mean solution are calculated directly by VAM3DF, uncertainties *around* the calculated mean solution will be estimated based on available stochastic solutions, as described later.

4.1 Model Configurations

4.1.1 Variations in Stratigraphy

At this time, a basic layered geologic model is being postulated for VAM3DF base case calculations. Such a model is based on the most recent geologic information (Reidel et al.1998; Kincaid et al. 1995) available on the stratigraphy at the two sites. Dips and inclines (as identified in the geology data package) of the various strata will be considered as part of variations of base case model configurations for both disposal sites. Such variations of the basic stratigraphic cross-sections at the two sites are part of the geology data package.

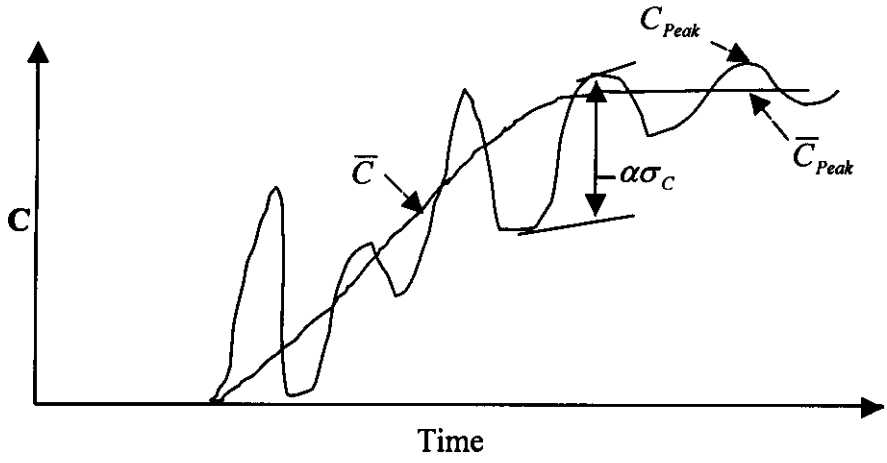

Figure 16. Schematic of concentration (C) distribution at the water table.

[$\overline{C}$ =calculated mean concentration, $\overline{C}_{Peak}$ =calculated mean peak concentration, C_{Peak} = peak concentration, σ_C =standard deviation of variation around the calculated mean solution, $\alpha\sigma_C$ =multiple of variation around the calculated mean solution for a particular model configuration and input effective parameters.]

4.1.2 Clastic dikes

Clastic dikes are ubiquitous sedimentary structures observed in outcrops and trenches that expose the Hanford formation in the 200 Areas. Their distribution, orientation, and other important characteristics are provided as part of the geology data package. The dikes are believed to represent dewatering structures that developed during compaction and settling of cataclysmic flood deposits during or soon after floodwaters drained from the Pasco Basin. The true nature and extent of clastic dikes are difficult to determine, because the dikes are rarely detected or observed in vertically oriented boreholes. Often they form a polygonal pattern where they intersect the ground surface.

An extensive atlas developed by Fecht et al. (1999)[4] addresses a subset of dikes (i.e., clastic injection dikes) that have been formed as a result of sediments in fissures. Clastic injection dikes are fissures which may total a meter or more in thickness. These dikes are typically filled with poor to well-sorted sand, but may also contain silt, clay, and gravel.

[4] Fecht, K.R., K.A. Lindsey, B.N. Bjornstad, D.G. Horton, G.V. Last, and S.P. Reidel. 1999. Clastic Injection Dikes of the Pasco Basin and Vicinity. BHI-01103 Rev. 0. July, 1999. Bechtel Hanford Inc. Richland, WA.

These dikes are of particular interest to the ILAW PA because they occur as near-vertical tabular bodies filled with multiple layers of unconsolidated sediments. Thin clay/silt linings separate the margins of most dikes and internal layers within dikes.

It is important to develop an understanding of the potential presence of these discrete structures in the vicinity of disposal sites such that uncertainties in flow and transport calculations can be adequately accounted for. Such an understanding on the presence of clastic dike networks in the vicinity of disposal sites will be provided as part of the geology data package. The potential for clastic injection dikes to provide preferential pathways will be examined as part of variations of model configurations at both disposal sites.

One particular scenario will be considered to provide a bounding estimate: presence of a near-vertical (or otherwise as characterized in geology data package) clastic dike directly below a vault and extending through the Hanford formation (or as identified in the geology data package). The width of the dike will be based on information in the geology data package.

Data on physical and hydraulic parameters are needed for clastic dike infilling materials to model their effects on flow and contaminant transport. Such physical and hydrologic properties (e.g., bulk density, particle-size distribution, moisture retention, saturated and unsaturated hydraulic conductivities) for clastic dike infilling materials are included in Fayer and Ritter (1999)[5]. A summary of the physical and hydraulic parameters is given in Table 10. As suggested in Table 10, the measured properties represent fine material. Other database (e.g., Fecht et al. 1998) will be consulted for possible presence of coarse infilling materials in a clastic dike.

Table 10. Van Genuchten parameters (based on the multistep method), saturated hydraulic conductivity, and bulk density for seven clastic dike samples (after Fayer and Ritter 1999).

Sample	θ_s (cm^3/cm^3)	θ_r (cm^3/cm^3)	α (1/cm)	n (-)	Saturated Hydraulic Conductivity (cm/s)	Bulk Density (g/cm^3)

4.1.3 Isotropy

The base case simulations will consider a layer-cake stratigraphy and tension-dependent anisotropy. This is expected to result in more of lateral than vertical migration of contaminants. A variation of the base case will consider an isotropic case. This is expected to result in enhanced vertical migration, compared to the base case.

4.1.4 Sloped Layering

Another case that will be considered has to do with the combined effects of variation in stratigraphy and anisotropy. For unsaturated flow, the degree of anisotropy depends not only on the variability of soil hydraulic properties, but also on the orientation of the soil layers relative to the mean hydraulic gradient. The tension-dependent anisotropy relationships will be reevaluated for dips and inclines identified (in geology data package) for variations in base case stratigraphy, and their effects examined via VAM3DF simulations.

4.2 Uncertainties in the Mean Solution due to Variations of Effective Parameter Estimates

As mentioned earlier, uncertainties in the mean solution are due to variations in conceptual model configuration and sensitivities to effective input parameters. Variations in conceptual model configuration have been discussed in the preceding section. Sensitivities to effective input parameter variations are discussed in this section.

The sensitivity of the model predictions to uncertainties in the effective parameters will be considered for two important parameters, i.e., unsaturated conductivity and macrodispersivity. Sensitivity of these two effective parameters and their estimated effects on the mean solution are discussed below. Note that variations in saturated conductivity will not be considered, since the moisture regime within the far-field vadose zone for the disposal sites is not expected to be at or near saturation. It should also be noted that recharge and variations in recharge estimates are another source of uncertainty. However, sensitivities to recharge estimates will be propagated via changes in effective parameter estimates for unsaturated conductivity and macrodispersivity.

The stratigraphy at both disposal sites is dominated by two distinctly different sediment sequences. The upper part of the vadose zone is characterized by a sandy sequence, whereas the lower part is characterized primarily by a gravel sequence. At saturation, compared to the gravel-dominated sequence, the sand-dominated sequence is described by a smaller log-conductivity variance. However, compared to the gravel-dominated sequence, the log-unsaturated conductivity variance for the sand-dominated sequence is higher. The variations in unsaturated conductivities for both sandy and gravelly sequences are discussed in detail earlier. Variabilities in unsaturated conductivities lead to macroscopic anisotropy relations for the sandy and gravelly

sediments that are quite different. Consequently, VAM3DF simulations incorporating variations in macroscopic anisotropy relations will produce different mean concentration distributions at the water table.

A much more important parameter that will affect mean concentration distribution, for a given model configuration, is macrodispersivity. Typically, in modeling transport, the same unretarded dispersivity value is assumed for all transported (retarded and unretarded) species. VAM3DF simulations will consider, for the transported species, comparisons of enhanced longitudinal macrodispersivity with that of a nonretarded macrodispersivity. The variability in these estimates, along with professional judgement (e.g., an increase or decrease of 25% of estimated macrodispersivities), will be used to quantify uncertainties in the mean solution.

Note that each VAM3DF-calculated mean solution incorporates effects due to model configuration variations and sensitivities to effective input parameter variations. The goal will be to limit the number of VAM3DF runs. Nevertheless, once the mean solutions are obtained for various VAM3DF runs, they can be used to obtain variance estimates for the mean solutions, and therefore characterize the uncertainty in the mean solutions.

4.3 Uncertainties Around the Mean Solution

As described earlier, since the effective concentration predictions represent a mean solution, fluctuations about this mean, due to heterogeneity, are another source of uncertainty. The variations in concentrations around the mean concentration can be characterized through a stochastic evaluation of the concentration variance. It will be assumed that the developed theory for the nonretarded species is applicable to the case with spatially variable sorption, provided that the enhanced macrodispersivity is used for the sorbing species. The concentration variance tends to be large in regions close to the source where concentration gradients are large. Using stochastic approaches described by Kapoor and Gelhar (1994a,b), the coefficient of variation of concentration will be estimated at the water table. Detailed equations are presented in Kapoor and Gelhar, but briefly the concentration variance is directly proportional to the mean concentration gradient for the VAM3DF-calculated mean concentration distribution at the water table and the longitudinal macrodispersivity, and inversely proportional to the local dispersivity values.

4.4 Bounding Estimates

Note that the cumulative effect of uncertainties is not additive. Rather, bounding scenarios will be based on combinations of various worst case conditions. For example, a bounding scenario may be postulated as the one having isotropic material properties for both sand- and gravel-dominated sequences, high recharge, clastic dike, and minimum values of macrodispersivity. In other words, bounding estimates will be dictated by

selected model configuration and effective parameter estimates that produce a higher mean concentration at the water table.

Physical and Hydraulic Measurements of FY1998 Borehole Cores

Physical and Hydraulic Measurements of FY 1998 Borehole Cores

MJ Fayer, AL Ward, JS Ritter, and RE Clayton
10 September 1998

Introduction

Pacific Northwest National Laboratory (PNNL) assists the Lockheed Martin Hanford Company (LMHC) in designing and assessing the performance of disposal facilities for radioactive wastes stored in single and double shell tanks at the Hanford Site. The preferred method of disposing of the portion that is classified as immobilized low-activity waste (ILAW) is to vitrify the waste and place the product in a near-surface, shallow-land burial facility. The current plans are that some of the ILAW will be placed in the existing vaults (built by the former Grout Project); the majority will be placed in the ILAW Disposal Site, to be located southwest of the PUREX Plant. The LMHC project to assess the performance of these two disposal facilities is known as the Hanford ILAW Performance Assessment (PA) Activity, hereafter called the ILAW PA.

Regulatory and public acceptance of ILAW disposal at Hanford depends on demonstrating that public health and the environment are adequately protected. This goal is achieved by predicting contaminant migration from the facility and using the predictions to calculate the impacts to public health and the environment. To predict contaminant migration requires estimates of the physical and hydraulic properties of sediments within the vadose zone beneath and around the disposal facility. These properties include water retention and hydraulic conductivity of the major sediment types as well as descriptions of their spatial variability. In addition to supporting the PA, these data and parameters can be used to support remediation and closure activities at sites such as tank farms and specific retention basins that have similar geology.

As part of site characterization activity for the ILAW disposal facility, sediment samples were obtained in fiscal year 1998 via a borehole drilling and sampling program (Reidel and Reynolds 1998). A work plan was also prepared that provides details on the measurement and analysis of the hydraulic properties for the ILAW borehole sediment samples (Khaleel 1998)[1].

As part of the work plan, a PNNL task was initiated, entitled "Hydraulic Property Lab Tests for ILAW Samples." The objective of this task is to provide the measured data for various geologic formations and soil types at the disposal sites (LMHC 1997; Reidel and Reynolds 1998). These data will provide the basis for upscaling of laboratory data to field estimates (Khaleel 1998), which will be used to predict the movement of contaminants from the disposal

[1] Khaleel R, January 1998. "Work plan for measurement and analysis of hydraulic properties for clastic dikes and the ILAW Borehole No. 1 sediment samples," Fluor Daniel Northwest, Inc., P.O. Box 1050, Richland, Washington.

facility to the groundwater. The objective of this letter report is to document the physical and hydraulic properties for the first characterization borehole.

Properties

Physical and hydraulic properties are required for each of the major geologic materials identified by Reidel and Reynolds (1998), namely, the Hanford sandy sequence, the Hanford lower gravel, and the Ringold Unit E. Multiple measurements of these properties are required to give some estimate of the degree of variability within each geologic material. The properties, which are required (directly or indirectly) by the models used for the ILAW PA, are:

Particle Size Distribution. Particle size distribution (PSD) refers to the fractions of the various particle-size classes (e.g., the fraction of particles with diameters between 1 and 2 mm).

Particle Density (ρ_p). Particle density is the mass of the sediment or construction material particles per unit volume of the same sediment or material. This property is used to relate the bulk density to the porosity.

Bulk Density (ρ_b). Bulk density is the mass of oven-dry material per unit bulk volume. The unit bulk volume is the combined volume of material, water, and air prior to oven drying.

Porosity (ϕ). Porosity is the volume of voids per unit bulk volume.

Water Retention. Water retention refers to the retention of water by the sediment at various matric potentials. Mathematical functions are fit to the retention data and the resulting parameters are used directly in computer models for predicting water and contaminant movement. Numerous functions are available, but the van Genuchten function is most commonly used:

$$\theta = \theta_r + (\theta_s - \theta_r)\left[(1 + (\alpha h)^n\right]^{-m}$$

where θ_s = saturated water content (cm^3/cm^3)
θ_r = residual water content (cm^3/cm^3)
h = matric potential (-cm)
α, n, m = empirical fitting parameters (α units are 1/cm; n and m are dimensionless)

Typically, m is approximated as $m = 1 - 1/n$

Saturated Hydraulic Conductivity (K_s). Saturated hydraulic conductivity is the proportionality constant in the Darcy equation that relates the flux density to a unit potential gradient.

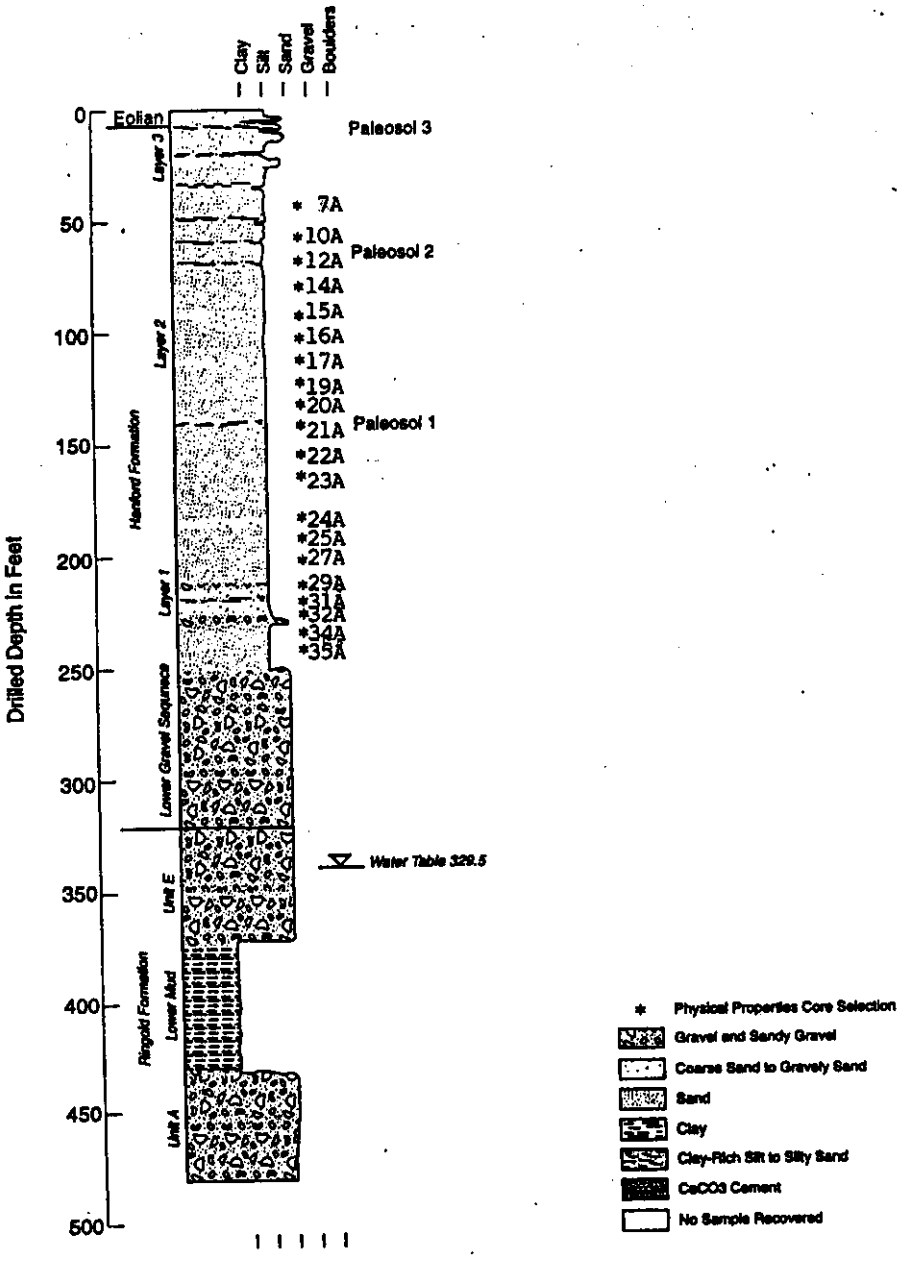
Unsaturated Hydraulic Conductivity [$K = f(\theta, \psi)$]. Unsaturated hydraulic conductivity is the proportionality factor in the Richards equation that relates the flux density to a unit potential gradient at a specific water content. Because the water content varies in the unsaturated zone, the unsaturated conductivity varies also.

Mathematical functions are used to represent the unsaturated conductivity data; these functions are typically estimated using the water retention functions and saturated conductivity. When measured unsaturated conductivity values are available, the conductivity and retention data can be fit to optimize both the retention and conductivity functions. Several functions are available, but the Mualem conductivity function is most commonly used (in conjunction with the van Genuchten retention function, assuming $m = 1 - 1/n$):

$$K = K_s \frac{\left\{1-(\alpha h)^{n-1}\left[1+(\alpha h)^n\right]^{-m}\right\}^2}{\left[1+(\alpha h)^n\right]^{\ell m}}$$

The K_s value and the pore interaction term (ℓ) are the only requirements for this model. The parameter ℓ is typically assigned a value of 0.5.

Borehole Cores



The FY 1998 borehole was drilled in the spring of 1998 (Reidel et al. 1998). A total of 45 cores were collected in liners. Thirty of the 45 liners had a 8.26-cm (3.25-inch) internal diameter and came from depths between 45 and 175 ft. The remaining fifteen liners had a 9.53-cm (3.75-inch) internal diameter and came from depths between 175 and 242 ft. All of the sediment from the depth interval from 0 to 45 ft went to the tracer task for tracer-specific analyses. The decision was made that undisturbed cores from this interval were not necessary for hydraulic property measurements because these sediments will not exist in their current state once the disposal facility is built. No vadose zone cores were collected below 242 ft. because this zone was open framework gravel (i.e., gravel that supports itself with little to no finer grained material) and could not be sampled with the method used.

PNNL was requested to analyze twenty of the FY 98 borehole cores for hydraulic and physical properties. Each of the 45 liners was inspected to verify whether a 15-cm (6-inch) long undisturbed section could be obtained. Thirteen liners did not meet this requirement because they were either incompletely filled, the sediments were disturbed, or the liner material was damaged. These liners will be stored for possible future testing. Of the remaining 32 acceptable liners, twenty liners were chosen for testing by the FDNW principal investigator for the ILAW PA far-field hydrology task, in consultation with the PNNL principal investigator. These twenty liners were chosen on the basis of providing somewhat evenly spaced coverage of the sampled vadose zone. Table 1 lists the sample numbers, depths, and diameters. Figure 1 shows the location of the liners relative to the geologic cross-section derived from the borehole data.

Table 1. Liner samples analyzed for the first characterization borehole

Sample ID	Total Depth Interval ft	Internal Diameter in.	Depth Interval of Intact Core ft
B8500-07A	45.9 to 47.9	3.25	46.3 to 46.8
B8500-10A	57.8 to 59.8	3.25	58.0 to 58.5
B8500-12A	69.4 to 70.95	3.25	69.8 to 70.3
B8500-14A	80.3 to 82.8	3.25	80.8 to 81.3
B8500-15A	90.5 to 93.0	3.25	90.8 to 91.3
B8500-16A	100.5 to 103.0	3.25	102.0 to 102.5
B8500-17A	109.8 to 112.2	3.25	111.3 to 111.8
B8500-19A	121.0 to 123.5	3.25	122.6 to 123.1
B8500-20A	129.7 to 132.0	3.25	131.1 to 131.6
B8500-21A	141.5 to 144.0	3.25	141.8 to 142.3
B8500-22A	151.9 to 154.4	3.25	153.7 to 154.2
B8500-23A	160.4 to 162.9	3.25	162.1 to 162.6
B8500-24A	180.7 to 182.7	3.75	181.9 to 182.4
B8500-25A	189.7 to 191.7	3.75	190.9 to 191.4
B8500-27A	199.3 to 201.3	3.75	200.5 to 200.9
B8500-29A	209.4 to 211.4	3.75	210.6 to 211.1
B8500-31A	219.6 to 221.6	3.75	220.9 to 221.3
B8500-32A	226.1 to 228.1	3.75	227.4 to 227.9
B8500-34A	236.1 to 238.1	3.75	237.2 to 237.7
B8500-35A	239.5 to 241.5	3.75	240.7 to 241.2

Figure 1. Geologic cross section of the disposal site based on the borehole samples (after Reidel et al. 1998).

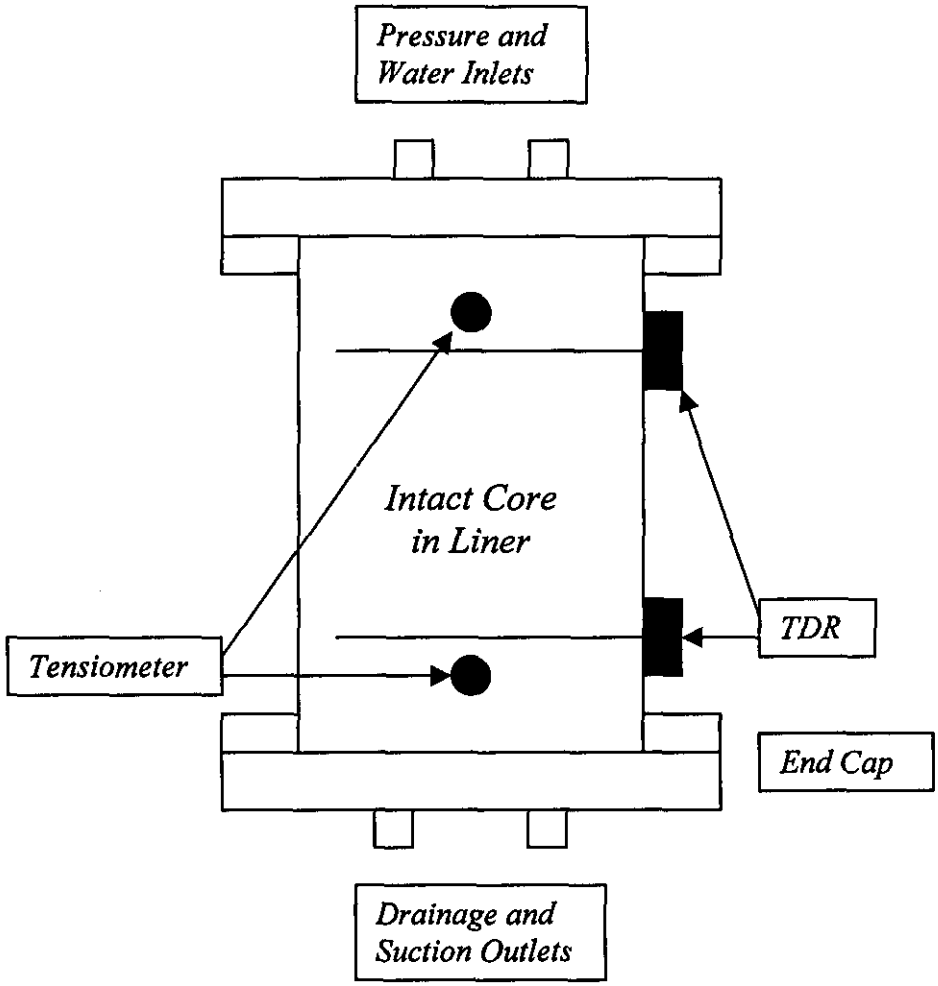
Methods

Two types of subsamples were removed from each liner. One subsample was an intact portion of the liner that retained its undisturbed nature. This intact core was used for the unsaturated conductivity tests and for determining bulk density and porosity. The depth intervals of these intact cores are listed in Table 1. A second subsample was taken from a 4 to 5 inch portion of the liner next to the intact core. This loose material, which ranged from 850 to 1200 g, was placed in a sealed bag and mixed thoroughly. It was used for the tests of particle size distribution, particle density, initial water content, and water retention using pressure plates and vapor adsorption, as well as the sorption tests that were conducted by another task under this project.

Intact Core Preparation

Each 0.6-m-long liner was inspected to identify portions that displayed no visible disturbance such as cracking or mixing. Within the undisturbed portion, a 15-cm length was chosen for the unsaturated conductivity test. The liner was marked where the base plate would go. A band saw was used to cut most of the way through the liner, then a thin metal plate was advanced into the cut as the blade proceeded around the liner for the final cut. This technique kept sediment loss to a minimum. When completely cut, the sample was placed vertically upside down and the bottom end cap was attached[2]. The sample was then placed horizontally, marked, and cut in the same manner as before. The sample was then placed vertically upright and the upper end cap was attached. The entire assembly was weighed. The total internal volume of the 3.25-in diameter cores was 803 cm^3; it was 1,069 cm^3 for the 3.75-in diameter core.

Two holes were drilled horizontally into the liner and tapped to yield threads for the tensiometer assemblies. The holes were positioned 1.5 cm from each end plate. Each tensiometer was 0.62 cm in diameter and 6.4 cm long, which allowed the tensiometers to penetrate about 75% of the core diameter. The sediment was fairly soft so each tensiometer was pushed directly into the sample without removing any material.



Two additional holes were drilled horizontally into the liners to accommodate the time-domain reflectometry (TDR) probes. The holes were offset 90 degrees laterally from the tensiometers and about 1 cm from the plane of the tensiometers and towards the core center. Because of the thinness of the liner, plexiglass blocks were glued to the outside of the liner in the TDR location to provide enough material to tap and provide threads for the TDR assemblies. The TDR rods were 0.23 cm in diameter and 8 cm long, which allowed the TDR rods to penetrate about 95% of the core diameter. Like the tensiometers, the TDR rods were pushed directly into the samples without removing material.

Figure 2 shows the final assembly with tensiometers, TDR rods, end plates, and two ports on either end plates to facility liquid and gas addition or removal from the core. Each assembly was tested at 0.5 bar positive pressure to identify leaks prior to conducting the conductivity tests.

---

[2] End caps were purchased from Soil Measurements Systems of Tucson, Arizona. Each end cap contained a rubber gasket and rubber O-ring to ensure a tight seal with the core liner.

Figure 2. Conductivity testing cell

Leaks were eliminated using Teflon™ tape, vacuum grease, and Silly Putty™. After leak testing, a vacuum was applied to one of the upper ports of each assembly. The entire assembly was then wetted from below using a solution comprising tap water and 5 g thymol per 20 L of water for control of bacterial growth. Wetting in this manner placed the samples on the primary drainage path.

Procedures

Table 2 lists the procedures used to analyze the samples. Additional details for each procedure are discussed below.

Particle Density. Two replicates of the particle density test were performed using 30 g of the loose subsample for each test using the pycnometer method (Blake and Hartge 1986a).

Initial Water Content. Two replicate measurements of the initial water content were made using the loose subsample for each test using the method of Gardner (1986).

Particle Size Distribution. The PSD test was performed using 40 g of the loose subsample for each test using the methods ASTM 1985 and Gee and Bauder (1986).

Bulk Density. A single measurement of bulk density was made using the intact core. Following the conductivity test, the sediment in the core was oven dried and weighed. Dividing this weight by the volume of the core yielded the bulk density, as per the method of Blake and Hartge (1986b).

Porosity. A single estimate of porosity was made using the bulk density of intact core and the average particle density. The formula used was $\phi = 1 - \rho_b / \rho_s$ (Freeze and Cherry 1979).

Water Retention. Water retention data were obtained using the pressure-plate extraction and vapor equilibrium methods described by Klute (1986). Additional measurements were obtained during the unsaturated conductivity tests.

Saturated Hydraulic Conductivity. Saturated hydraulic conductivity was measured on the intact core prior to the unsaturated conductivity tests using the method of Klute and Dirksen (1986). The measurement of saturated conductivity was conducted several times to verify that a steady value of conductivity was achieved.

Unsaturated Hydraulic Conductivity. The multistep and steady state methods were used to measure unsaturated conductivity. Both methods were performed on the same core using the same sensor locations. The multistep method, which is an improvement of the one-step method of Kool et al. (1985 a,b), provides θ-ψ pairs and cumulative outflow. These data were used in conjunction with the MULSTP program (Eching and Hopmans 1993) to determine the optimal set of hydraulic parameters. MULSTP employs a numerical inversion procedure to find the set

Klute (1986)	Water Retention: Laboratory Methods	Pressure plate and vapor adsorption methods
Klute and Dirksen (1986)	Hydraulic Conductivity and Diffusivity: Laboratory Methods	Steady-state flux control method for unsaturated conductivity
Eching and Hopmans (1993)	Unsaturated Hydraulic Properties	Multistep outflow method for unsaturated conductivity and water retention estimation

of parameters that minimizes the differences between simulated variables and those test variables contained in the objective function. For these tests, the objective function contained the cumulative outflow data and the matric potential data. Eching and Hopmans (1993) found that this objective function yielded excellent results when compared to independently measured data. Although this method relies on specific retention and conductivity functions and it does not yield specific values of conductivity, it promises to be quicker than the steady-state method and could represent a cost savings for future sample analyses.

The steady-state method, described by Klute and Dirksen (1986), provides θ-ψ-K triplets, which can be fitted with retention and conductivity functions. The value of this method is that it provides simultaneous triplets that are independent of retention and conductivity models. If the resulting parameter set for these functions is equivalent to the set derived by the multistep method, then the multistep method could be employed more frequently to achieve the same result.

Because several tests must be performed on the same core, the following test sequence was established: saturated conductivity, multistep unsaturated conductivity, and steady state unsaturated conductivity. Following the saturated conductivity test, the cores were re-wetted to saturation and analyzed using the multistep method. Two pressure changes were used: 0.06 and 0.3 bars. Changes in water content and matric potential were monitored with a datalogger every 0.1-h following each pressure change. Outflow was monitored manually at time intervals ranging from 3 minutes to 24 hours. The next change in pressure was initiated only after the most recent change outflow was less than 1% of the cumulative outflow since the last pressure change.

Following the multistep test, the cores were re-wetted to saturation and analyzed using the steady-state method. A Mariotte-type reservoir was used to provide a source of water at a pre-defined matric potential at the upper surface of the samples. Fluxes into each sample were unique and dependent on the unsaturated conductivity of the sample at the imposed matric potential. Concurrent with establishing the matric potential at the top of the sample, the matric potential at the bottom of the sample was set to the same value by lowering the outflow tube. Water content and matric potential were measured continuously. Once the matric potential values within the sample ceased changing, indicating steady flow conditions had been achieved, the matric potential at the top of the sample was lowered to the next value and the outflow tube was lowered a similar amount. After equilibrating with the final and lowest potential, the cores were opened and the bulk density values were determined.

Results

Table 3 shows that particle density varies between 2.71 and 2.82 g/cm^3 for this section of the Hanford formation. The average and median values are both 2.74 g/cm^3, which would indicate a normal distribution. However, the two deepest values are the highest. These two samples, as shown below, have a higher gravel content. Subsequent tests could be used to determine whether the gravel has a particle density that is higher than the finer sediment.

Table 3 also shows that the initial water contents of the loose subsample material ranged from 0.0119 to 0.0382 g/g. The average and median values were similar: 0.020 and 0.0196 g/g, respectively. These water content values are low but not atypical of the Hanford formation. They were measured two to three months after drilling and, during that interval, the liners were stored in a refrigerated container where they could have experienced some evaporative losses. However, the water content values in Table 3 are very similar to values measured by Ellyn Murphy, another ILAW project researcher. Dr. Murphy measured water contents on a small sample from the end of each core immediately after the cores were drilled. Her average water contents were about 10% less than what is shown in Table 3.

Table 4 shows the results for both the sieve and hydrometer methods. In all but two samples, the gravel content was less than 2%. In contrast, samples 34A and 35A had 13 and 25% gravel, respectively. These were the deepest samples that were analyzed (between 236 and 242 ft). As shown in Figure 1, this depth range corresponds to the lower gravel sequence of the Hanford formation. Figure 3 shows all of the data combined to highlight the degree of variability in particle size distribution.

Table 5 shows that the bulk density ranged from 1.52 to 1.98 g/cm^3. The mean and median were identical: 1.70 g/cm^3. The highest densities were associated with the two samples (34A and 35A) that had significant gravel contents. Khaleel and Relyea (1997) found a similar effect from high gravel contents. Table 5 also shows the porosity data, which ranged from 0.299 to 0.444 and had nearly identical mean and median values of 0.377 and 0.374, respectively.

When opened for the bulk density measurements, most of the cores appeared homogenous. However, several cores had noticeable layering. The most dramatic layering

occurred in sample 7A, which had about 7 cm of sand in the upper part of the core and 8 cm of finer-textured sand in the lower part of the sample. It appeared that the upper set of sensors penetrated the coarser material and the lower set penetrated the finer material. Sample 19A had a 1-mm thick, silty-looking layer located about 1 cm from the top of the sample. Layers in two other samples were less distinct and not recorded.

Another feature that we observed when the cores were opened was the presence of a layer of finer and denser material along the walls of roughly half of the liners. We had observed this effect when we were preparing the cores, but it was more obvious when the cores were wet. One possible explanation is that the drilling technique caused migration of fines to the wall, where the heat from drilling caused water to more towards the interior of the sample, thus allowing the fines to consolidate more densely. We estimated the thickness of this zone as no more than 2 mm, which accounts for less than 5% of the sample area. Because of the small area, we expect that this phenomenon did not have a major impact on the measurements reported here, but it should be looked at more closely if another borehole is drilled for samples.

Table 6 shows the pressure plate data for four pressures. As expected, samples that were finer-textured (e.g., 31A) had higher water contents at any given pressure. The mean values at each pressure are all greater than the mean value of the initial water contents reported in Table 3. This result suggests that the *in situ* matric potential values were less than -4,080 cm (4 bar), the lowest pressure tested.

Table 7 shows that the vapor adsorption data covered a significant range of matric potential, from -4,170 cm to as dry as -1,110,000 cm. The associated water contents ranged from 0.056 to 0.0 g/g. This range of water content encompasses the initial water contents reported in Table 4.

Table 8 shows the saturated hydraulic conductivity values for the intact cores. The values range from 2.65E-4 to 1.32E-2 cm/s, with average and median values of 4.30E-3 and 2.94E-3 cm/s, respectively. The two highest values were for the two deepest cores (34A and 35A), which contained the highest gravel content.

Table 9 shows the parameter estimates determined using the MULSTP program and data from the multistep test. Parameters α and n were fitted to matric potential data, drainage data, and a single retention point using a weighting scheme to adjust the importance of each; typical weightings were 1, 1, and 1, respectively. Some samples had weightings of 0.5 and 0 for tension data; these are identified in Table 9. During parameter estimation, θ_s and saturated K were fixed at measured values; θ_r was estimated for tension value of 15,300 cm using linear interpolation between pressure plate reading of 4,080 cm and wettest vapor adsorption value that was still drier than 15,300 cm.

Figure 3 shows how the predictive model, based on MULSTP-derived parameters, simulates the experimental data for matric potential and drainage for the 20 samples. In general, the comparison is good.

Table 10 shows the θ-ψ-K triplets that were generated using the steady state method. The measurements are all at matric potentials above -40 cm. Even so, unsaturated conductivity values were 1 to 2 orders of magnitude less than the saturated values. Because the potentials were so high, the water contents were also relatively high. Water contents were much lower at the end of the multistep test.

Summary

Twenty intact cores from the FY 98 ILAW PA borehole were analyzed for physical and hydraulic properties. These data and parameters will be used to predict the movement of contaminants from the disposal facility to the groundwater. Health and environmental impacts from the contamination will be calculated and the results used to ascertain the suitability of the disposal facility to protect the public and the environment. In addition to supporting the ILAW PA, these data and parameters can be used to support remediation and closure activities at sites such as tank farms and specific retention basins that have similar geology.

The twenty cores reported here were from the geologic unit known as the Hanford formation sandy sequence. The cores showed a fairly uniform set of properties deriving from the high percentage of medium to fine sand in nearly all of the cores. The variability among the twenty cores is within the range reported by Khaleel and Freeman (1995) for the 200 Areas. What is significant and valuable is that the data reported here give a true indication of the parameters and their variability *beneath the ILAW disposal site*. These data are also significant to the ILAW analysis for other reasons. First, a complete set of physical and hydraulic properties was measured on undisturbed cores. The tests included measurements of unsaturated conductivity and water retention in dry sediments. Secondly, a set of geochemical measurements was performed on the core material. Having a complete set of physical, chemical, and hydraulic data on site-specific cores is rare and should facilitate the PA calculations and enhance their credibility.

Two zones in the borehole were finer in texture and had lower saturated conductivity values than the other zones. These zones, or layers, could impact flow and transport calculations and increase lateral spreading. The results in this report will be considered in forming the conceptual model of the site. Additional boreholes planned for FY 1999 and FY 2000 will help to verify whether these and other particular layers are continuous across the disposal site.

A unexpected feature of the ILAW borehole site was the presence of a relatively thick open-framework gravel sequence below 250 ft. No data are available at present on the physical and hydraulic properties of this sequence. However, plans are in place to collect the necessary data for the gravelly sequence as part of the ILAW site characterization via boreholes No. 2 and 3.

Regarding parameter estimation of vadose zone hydraulic properties, several issues were raised by the 1997 external peer-review panel for the ILAW PA (Mann et al. 1998). These include a) use of the standard van Genuchten-Mualem approach with the saturated conductivity as a match point, b) correction for the presence of gravel in sediments, and c) upscaling of laboratory-measured data to block scale values in numerical models. Issues (a) and (b) are being

addressed as part of the analysis and parameter estimation of hydraulic properties for the borehole samples. The upscaling issue is being addressed as part of other FY98 tasks.

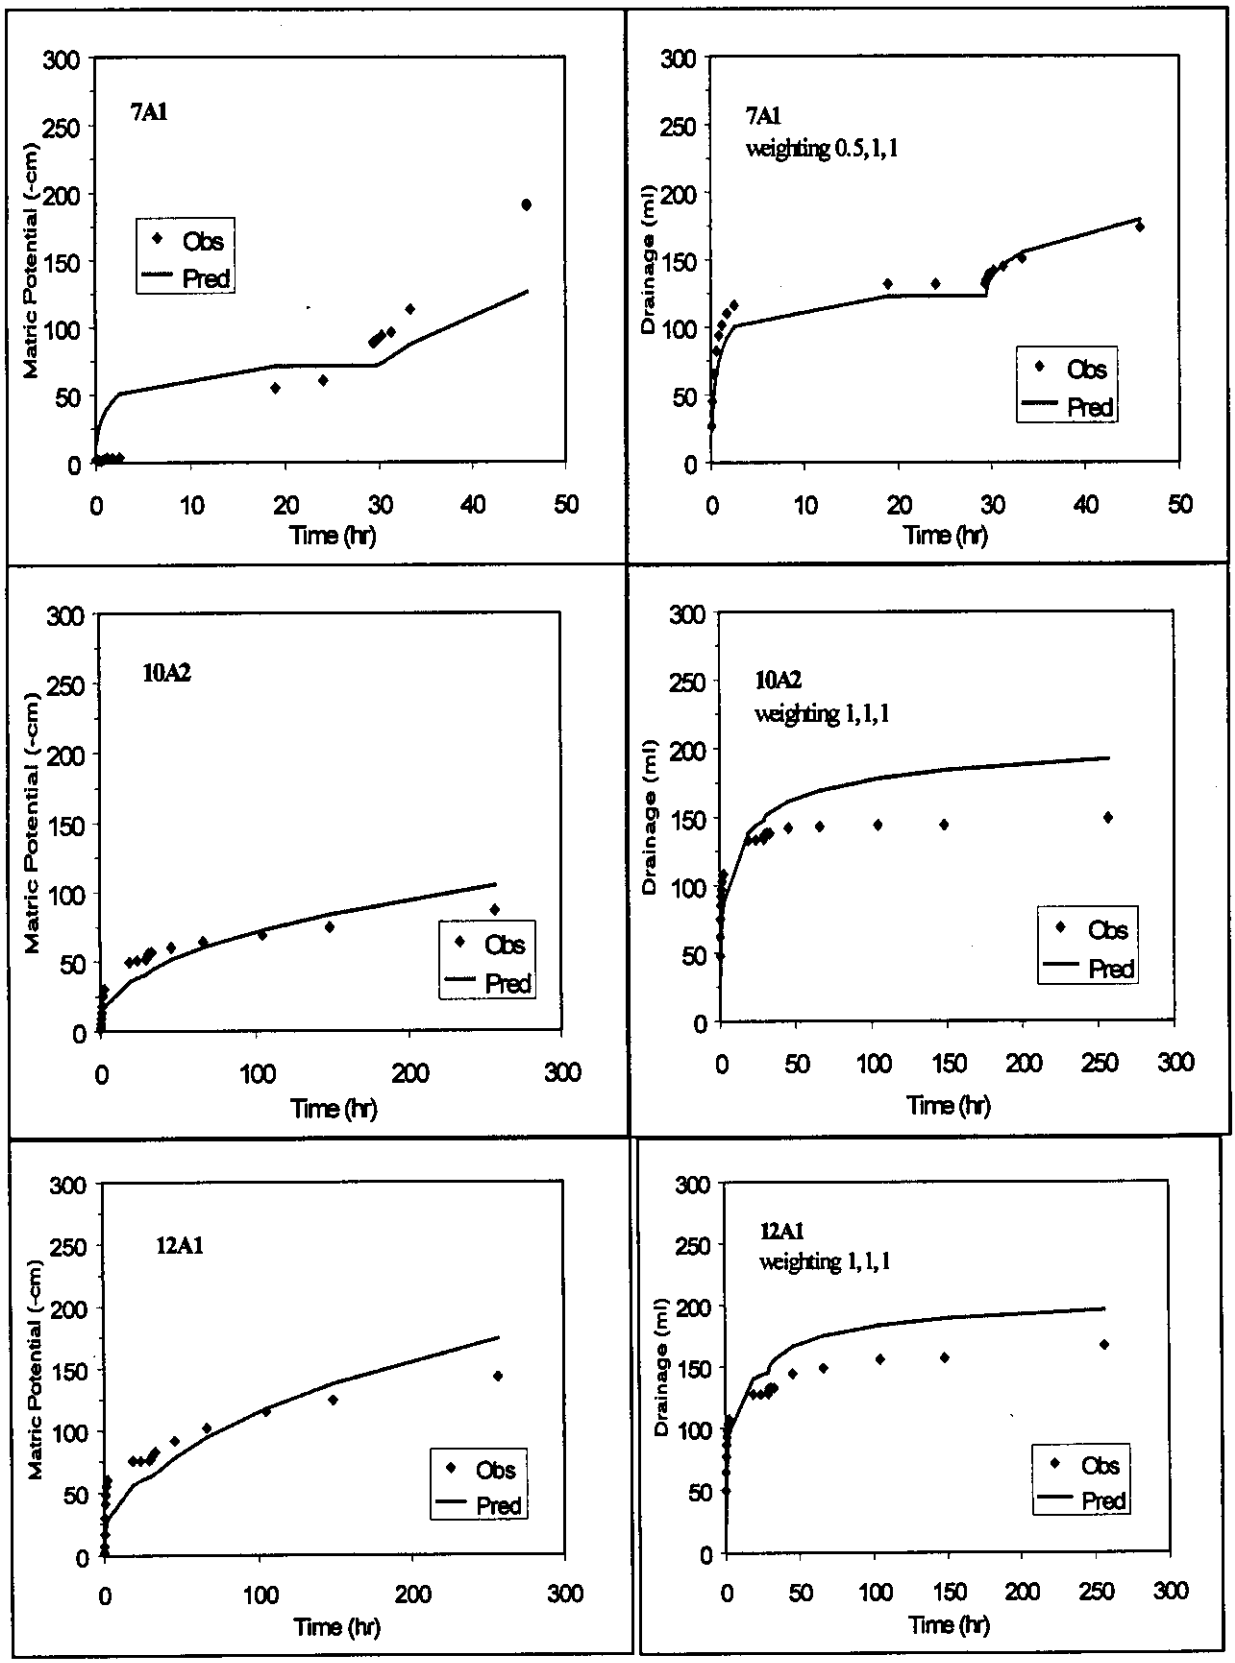
Table 9. Van Genuchten parameters (based on the multistep method) for 20 ILAW borehole samples from the sandy sequence. Parameters α and n were fitted to matric potential data, drainage data, and a single retention point using a weighting scheme to adjust the importance of each. The typical weightings were 1, 1, and 1, respectively. The superscript a indicates the weightings were 0.5, 1, and 1. The superscript b indicates the weightings were 0, 1, and 1. In these special cases, the matric potential weighting was reduced until the R^2 exceeded 0.6.



Sample	θ_s (cm^3/cm^3)	θ_r (cm^3/cm^3)	Fitted α (1/cm)	Fitted n (-)	R^2

APPENDIX C

Hydraulic Parameters of the Upper Hanford Formation

This page intentionally left blank.

Hanford Low-Activity Tank Waste Performance Assessment Activity:

Determination of In Situ Hydraulic Parameters of the Upper Hanford Formation

AL Ward, RE Clayton and JS Ritter
31 December 1998

Introduction

Under the Hanford Low-Activity Tank Waste Project, the Lockheed Martin Hanford Company (LMHC) is designing and assessing the performance of a disposal facility for radioactive wastes currently stored in single and double shell tanks at the Hanford Site. Part of the performance assessment of such a facility involves the use of numerical models to predict the potential migration and fate of contaminants in through the vadose zone.

A general feature of soils is their spatial heterogeneity, i.e., variation of their hydraulic properties in space. The relation between the matric potential, ψ, and the volumetric water content, θ [the soil water characteristic, $\psi(\theta)$], the hydraulic conductivity tensor, $\mathbf{K}(\theta)$, and the diffusivity, $D(\theta)$] are all spatially variable and have been shown to exhibit scale dependence. Thus, vadose flow and transport is a complex, three-dimensional phenomenon, even in soils that appear to be uniform. In addition to the inherent variability, typical field soils may exhibit a number of other structural elements, e.g. lenses, and clastic dikes, that often cause the redirection and concentration of water and solute flux at the local scale. Consequently, a major hindrance to the interpretation and prediction of vadose zone transport is the difficulty in measuring the constitutive properties and the uncertainty over the range of spatial scales required by numerical models. The associated uncertainty in hydraulic properties and its effect of performance of disposal facility is requirement is recognized in the DOE revised interim policy for waste disposal facilities.

The DOE revised interim policy requirement of a reasonable expectation that a disposal facility will comply with the LAW performance objectives implies consideration for uncertainty in model predictions of facility performance. Thus, any model of transport in the vadose zone requires, in the least, knowledge of the average properties of the medium, as well as the magnitude and characteristic length scale of the variations of those properties. Since a major source of uncertainty in model predictions of facility performance will be due to the uncertainty

in hydraulic and transport parameters, there is a need for information on the unsaturated hydrologic properties of the porous media.

The Pacific Northwest National Laboratory (PNNL) is providing geotechnical support to LMHC to assist in the design and performance assessment of the disposal facility. Two related components of the geotechnical support to be provided by PNNL are the determination of *in situ* unsaturated hydraulic parameters for Hanford surface sediments (Task 4b) and the upper Hanford sand sequence (Task 4c) at the proposed location of the disposal facility. In FY 1998, laboratory and field activities for the two tasks were completed and a letter report for Task 4b prepared (Ward et al., 1998). Data analysis and report preparation for Task 4c were deferred until FY-1999. This report represents the completion of Task 4c.

Methods

The experimental site is located approximately 325 m southwest of PUREX plant and about 220 m west of the injection site in the 200E Area used by Sisson and Lu (1984). On completion of the measurements in the surface sediments, a 1.5-m deep trench was excavated and the bottom of the trench instrumented in a manner identical to the surface. Detailed descriptions of the site, experimental design, and instrumentation have presented in the test plan of Ward (1997) and reiterated in the Task 4b letter report (Ward et al., 1998). Briefly, probes were installed along the centerline of the test plot in 25 short rows spaced 0.2 m apart (Figure 1). Each row consisted of 5 TDR probes installed vertically to depths of 0.25, 0.50, 0.75, 1.0, and 1.50 m (Figure 2).

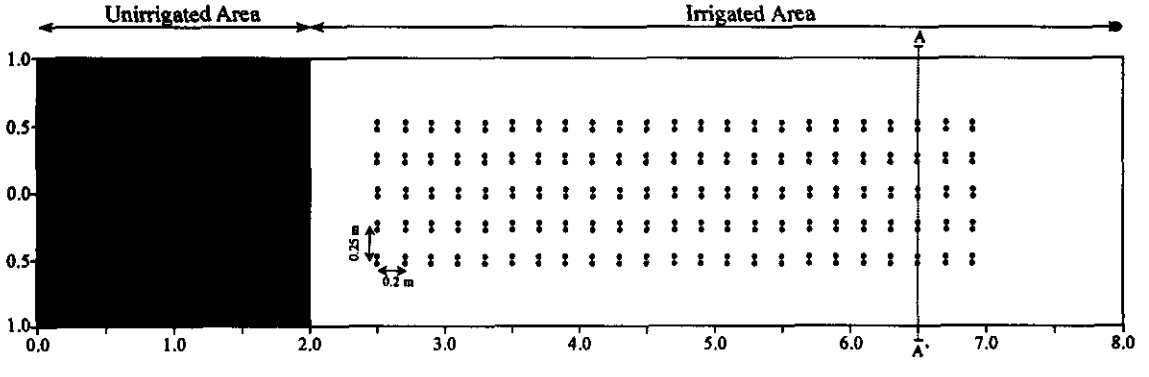

Figure 1. Plan View of Test Plot Showing Instrument Layout. The shaded 2-m section is the unirrigated control.

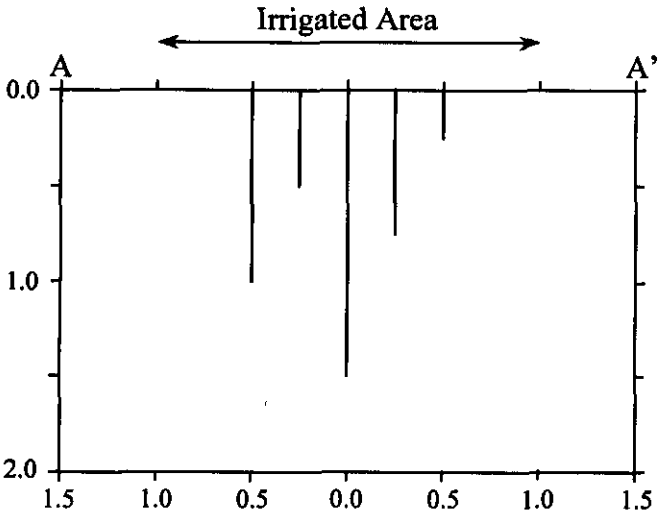

Figure 2. Cross-Sectional View of Test Plot Showing Installation Depths of the Instruments

Six infiltration experiments were conducted over the course of the study. Each experiment was conducted at a different flux density, J_w, to allow determination of $K(\theta_e)$. The values J_w used in the experiment were the same as in the first experiment, i.e., $4.7x10^{-3}$ cm s^{-1}; $2.5x10^{-3}$ cm s^{-1}, $1.292x10^{-3}$ cm s^{-1}, $3.093x10^{-4}$ cm s^{-1}, $3.54x10^{-5}$ cm s^{-1}, and $1.35x10^{-5}$ cm s^{-1}. The maximum application rate during the course of the experiments was determined by the nozzles used on the irrigation system. The lower rates were obtained by increasing the amount of time between each pass by the irrigation system.

Data reduction methods identical to those reported for Task 4b were employed. Briefly, hydraulic parameters for each depth interval were obtained by fitting the van Genuchten (1980) functions to the measured $\psi(\theta)$, and $K(\theta)$ data with the RETC computer program. The RETC program uses non-linear least squares techniques to fit the observed $\theta(\psi)$ and $K(\theta)$ data to closed-form analytical functions (van Genuchten et al., 1991). Unlike in the first experiment, saturated hydraulic conductivity, K_s was measured at fixed intervals along the transect using a tension infiltrometer according to the method of Zhang (1997). The measured K_s provided an additional constraint for the RETC analysis.

Solute breakthrough curves were derived from time domain reflectometry (TDR) measurements of the changes in bulk resistivity, R_L, in response to the application of KCl as a tracer (Ward et al. 1994; Kachanoski and Ward, 1994). The specific mass of tracer applied to the

surface, M_T, was 80 g Cl^- per m^2 of soil surface. At each level of J_w and associated equilibrium water content, θ_e, the specific mass of the tracer present from the surface to depth z=L (L being the length of the TDR probes), as a function of time, $M_L(t)$ [g cm^{-2}], was calculated from R_L at each probe location. The probability density function (pdf) of relative solute mass flux, $f_L(t)$, was calculated from the first derivative of $M_L(t)$ with respect to time. This is equivalent to the measured amount of solute, relative to the amount applied, that fluxes past the end of the TDR probe and represents the solute travel-time pdf.

Three methods were compared for determining transport parameters from measured $f_L(t)$. The first and most common approach fitted the solution to the convection-dispersion equation (CDE) to observed $f_L(t)$ to obtain estimates of the mean transport velocity ($\bar{v}$) and the dispersion coefficient (D). This solution assumes a Dirac delta-function input of solute at the surface and vertical one-dimensional flow. For a semi-infinite soil system, $f_L(t)$ is given by Jury and Roth (1990)

$$f_L(z,t)=\frac{z}{2\sqrt{\pi D t^3}}\exp\left[\frac{-(z-\bar{v}t)^2}{4Dt}\right] \quad (1)$$

where D [L^2 T^{-1}] is the dispersion coefficient, $\bar{v}$ [L T^{-1}] is the mean pore water velocity, z [L] is distance positive downward, and t [T] is time. The dispersion can also be expressed as $\lambda\bar{v}$, where λ [L] is the dispersivity of the soil, controlled by the geometry of the transport volume. It is assumed that the TDR probes measure the total amount of solute in the range $0 \le z \le L$, regardless of the distribution of the solute along the probes. Then $M_L(t)$ represents the mass of solute, relative to the amount applied, that remains in the region $0 \le z \le L$ and is given by

$$M_L(t)=1-\int_0^t f_L(L,\tau)\,d\tau=1-C_F \quad (2)$$

where C_F is the flux-averaged, reduced concentration for a step function input of solute, given by (Parker, 1984)

$$C_F=\frac{1}{2}erfc\left[\frac{L-\bar{v}t}{2\sqrt{Dt}}\right]+\frac{1}{2}\exp\left[\frac{\bar{v}L}{D}\right]erfc\left[\frac{L+\bar{v}t}{2\sqrt{Dt}}\right] \quad (3)$$

A similar development for the convective lognormal transfer function (CLT) model gives the following relationship (Jury, 1983)

$$M_L(t)=\frac{1}{2}erfc\left[\frac{\ln(t)-\mu}{\sqrt{2}}\right] \tag{4}$$

in which μ [ ] is the mean of log transform of the travel time, ln(t), σ is the standard deviation of ln(t). Fitting of Eq. [4] to observed data to obtain μ and σ constitutes the second approach. The third and final approach makes use of time moment analysis to obtain the transport parameters from $M_L(t)$. The mean or expected travel time, E_{LT}, is given by (Kachanoski et al, 1992)

$$E_{LT}=\frac{\int_0^T[-dM_L(t)/dt]t\,dt}{A_{LT}} \tag{5}$$

while the variance of the solute travel time, $Var_{LT}(t)$, is given and by

$$Var_{LT}(t)=\frac{\int_0^T[-dM_L(t)/dt](t-E_{LT})^2\,dt}{A_{LT}} \tag{6}$$

where

$$A_{LT}=\int_0^T[-dM_L(t)/dt]dt \tag{7}$$

and represents the area under the breakthrough curve.

Differences between the three approaches lie in the assumptions made about the transport process. The CDE is essentially the far-field limit for solute transport. It assumes that v is the same at every location and differences in arrival time at an observation plane are due to random diffusion/dispersion processes. Thus, travel time of a solute particle to a depth z = L is assumed to be uncorrelated to its travel time in the next depth increment. In contrast, the CLT does not require any particular assumption about the underlying transport process, except that it is linear and stationary. Information on the transport process is implicit in the measured transfer function. At any particular location, *v* is constant with depth, but it varies in the horizontal plane. Thus, solute spreading at the field scale is attributed to the horizontal spatial variability in vertical transport velocity. Since the vertical solute velocity at any given location is constant with depth,

the horizontal spatial pattern of travel times to an observation plane at z = L is correlated with the spatial pattern of travel time in the next depth increment. The CLT can be used for all transport regimes and is not restricted to near- or far-field limits. However, because of the assumption of linearity and stationarity, this form of the CLT is not applicable to contaminants that exhibit nonlinear interactions with soil components, or to situations of transient water flow. In addition, it provides an integral description of transport from the surface to depth L and there are no provisions for either predicting transport to depths shallower or deeper than the measurement depth. The method of moment is a direct method and makes no assumption about the transport process. Moments can be used to determine parameters of any stable, linear process that can be represented by a transfer function. The n^{th} moment of $f_L(t)$ is given by

$$M_n = \int_0^\infty f_L(t) t^n \, dt \tag{8}$$

The mean travel time of the system is equal to the first moment, M_1; the second moment M_2 is a measure of the dispersion; while the third moment, M_3, is related to the skewness. The main problem with ordinary moments is that higher moments are unreliable due to magnification of small errors in the tail. Nevertheless, for a particular flow model, specific relations exist between the moments and the model parameters.

In each approach, the dispersivity was calculated from the fitted parameters. The dispersivity for the CDE, λ_{CDE}, was calculated as

$$\lambda_{CDE} = \frac{D}{\bar{v}} \tag{9}$$

An equivalent dispersivity for the CLT, λ_{CLT} was calculated as

$$\lambda_{CLT} = \frac{L}{2}[\exp(\sigma^2) - 1] \tag{10}$$

while from moment analysis method, λ_{MOM} was calculated as

$$\lambda_{MOM} = \frac{L}{2} \frac{Var_{LT}}{E_{LT}^{\ 2}} \tag{11}$$

Results

Saturated Hydraulic Conductivity

Figure 3 shows the mean K_s measured at 40-cm intervals along the surface and 1.5-m deep transects. The three high values at the proximal end of the two transects were likely due to poor surface contact and treatment as outliers can be statistically justified (Acton, 1966). Overall, the results show an unexpected similarity in K_s at the two depths. At the surface, measured K_s (minus the outlier at x = 1.6 m) was 0.0013 ± 0.0006 cm s^{-1}, while at z = 1.5 m, K_s was 0.0008 ± 0.0003 cm s^{-1}. An analysis of variance was performed to test the null hypothesis of no difference between K_s measured in the two transects (Snedecor and Cochran, 1980). The value of F was significant at the 1% level (F^{**} = 7.82 < F[0.99;1,24]=8.25). Thus, measured K_s are from two different populations or soil types.

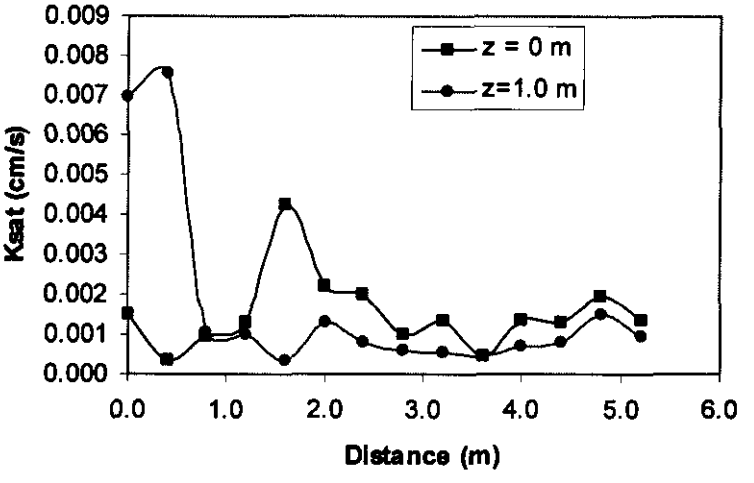

Figure 3. Mean saturated hydraulic conductivity measured along the surface and 1.5-m deep transects. Measurements were made using a tension infiltrometer at a head of -2 cm. Values at x =0 and 0.4 m (z = 0 m) and x=1.6 m(z=1.5 m) were treated as outliers in calculating the mean and variance of K_s.

Spatial Variation in Water Flux Density

An added advantage of using the TDR system for infiltration measurements is its ability to measure soil water storage, *W*, as a function of time, *t*. For a given probe length, *W(t)* is given

simply by $\theta(t) \cong L$, where $\theta(t)$ is the water content averaged over the length of the probe. During the time before the wetting front first reaches a depth L, the derivative of cumulative W with respect to time should be equal to the water flux at the soil surface, assuming no plant water uptake or evaporation (Parkin et al., 1992). Thus, spatial variation in water flux density, from which the variation in infiltration rates can be inferred, can be determined from early time measurements of $W(t)$.

Figure 4 shows the W(t) (L =0 .25 m; x=0 m) and the linear relationship fitted at early time. The rate of application at the soil surface was 2.5×10^{-6} cm s^{-1}. The calculated flux is 3.95×10^{-5} cm s^{-1}, an indication of the variability in the hydraulic conductivity.

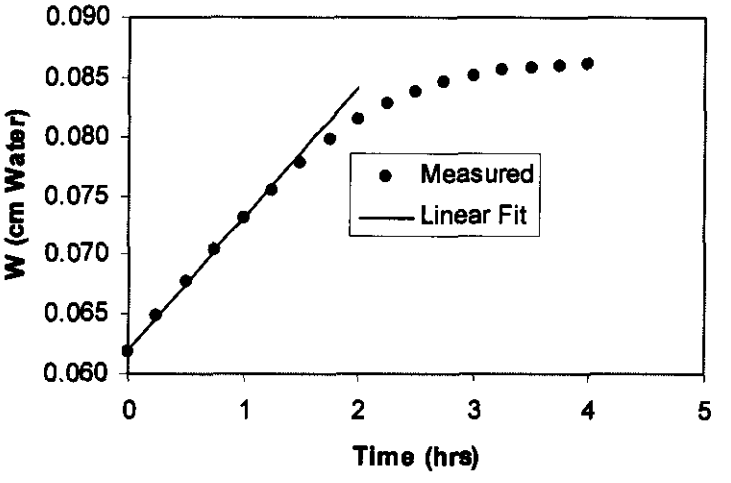

Figure 4. Cumulative storage versus time with a 25-cm probe at x = 0 m. The solid line shows a linear fit used to determine water flux density.

Figure 5 shows the distribution of flux along the transect based on measurements at the 25-cm depth. This result show that even under a constant flux of water at the surface, the actual infiltration rate can be quite variable. The local-scale average (an average of the 24 measurements) is 2.38×10^{-6} cm s^{-1}, while the field-scale average (valued fitted to the average $W(t)$ curve) is 2.61×10^{-6} cm s^{-1}. Similar increases in flow and transport properties from the local scale to the field scale have been made by other researchers (e.g. Kachanoski et al., 1990). The increase from the local scale to field scale is related to the scale dependence of the lateral

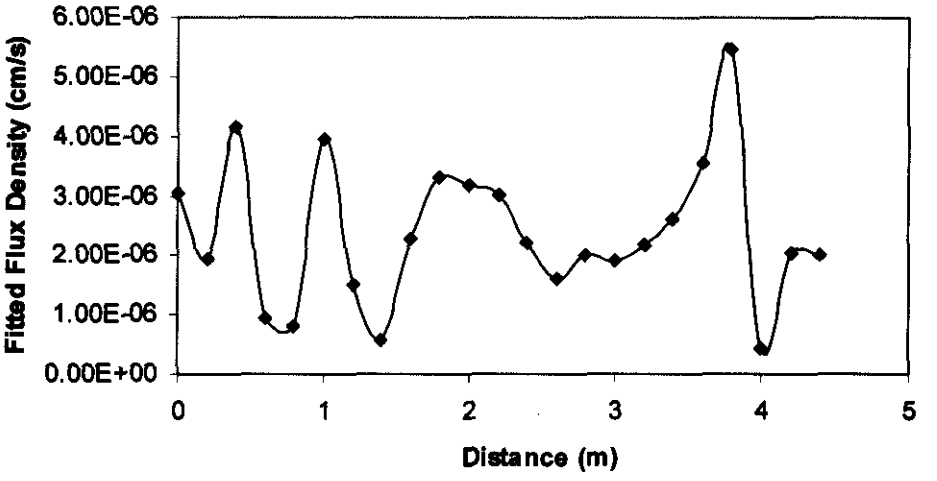

Figure 5. Spatial variation in measured surface flux density. Measurements were made with a 25-cm probe.

variations in water flux density. In this case, most of the variation can probably be explained by the distribution of sagebrush root channels (many of which were present) and micro-topography.

Water Retention Properties

Figure 6 shows the field-averaged moisture characteristic and the fitted van Genuchten relationship for the plot. Figures 7 through 11 show the plots of the individual depths. These data represent mostly imbibition data, collected as the profile was wetted to steady state at each flux of interest. There are some desorption data, mostly obtained between wetting cycles as maintenance was performed on the system. There was generally very little drainage during these periods and the data are not obvious from the plots.

As seen from the data presented, there are not many measurements at matric suctions greater than around 500 cm. The profile remained relatively wet following the first experiment, except very near the surface. In addition, most of the joints between the transducer and tensiometer failed at suctions greater than 400 to 500 cm.

Figure 6 shows that the data can be treated as essentially one population, suggesting some degree of homogeneity. To determine whether there was any advantage to be gained from treating the data otherwise, the measurements were separated out by depth interval and the

parameters fitted for each depth. The van Genuchten parameters θ_r, α, n, and θ_s were all fitted and are summarized in Table 1. Table 1 also compares these results with those from the surface sediments and from a set of independent measurements conducted on cores.

The results from this study (Task 4c) compare reasonably well with the previous results, falling within the range of values observed on samples 1 and 2 from the former Grout Site (Khaleel and Freeman, 1995). However, the fitted parameters suggest soil of a somewhat finer texture than expected for this site. As further verification of the field-measured properties, soil samples were taken from the pit on completion of the infiltration experiments and an analysis of particle sizes performed in the laboratory. Results of the analysis show a mean distribution 70.6% sand, 17.7% silt and 11.6% clay. The high silt and clay content may explain the low values of n and α observed in this study.

Solute Transport Parameters

Figure 12 shows the TDR-measured relative mass flux, M(t), at L=0.25 m. The variability in transport, even at such a shallow depth is clear. This behavior is consistent with the variability in water flux density and K_s observed at the surface.

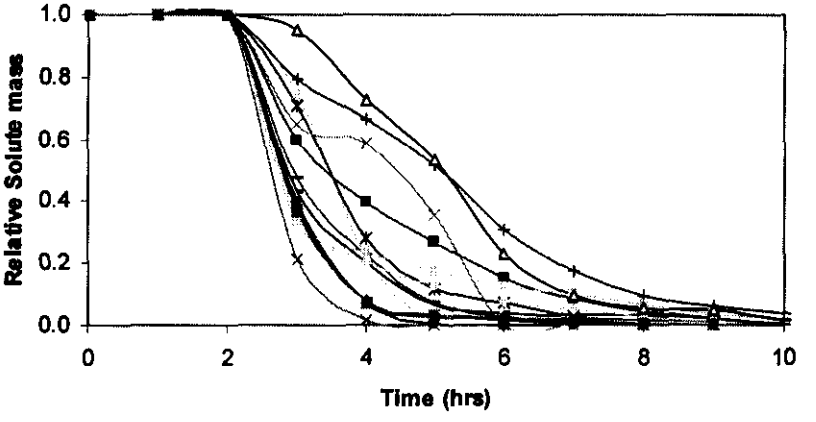

Figure 12. Spatial variability in TDR-measured relative solute mass flux at a depth of 0.25 m. Twenty four measurements were obtained along a 5 m transect at 0.20 m intervals.

Figure 13 shows an example of the observed data, and the fitted results obtained with the CDE and CLT transport models. In both cases, the models diverge from the observed data at late time ($t \geq 5$ hrs), leading to a higher predicted dispersion coefficient and travel-time variance. Although the discrepancy is not large, it suggests that these models may not be the most appropriate for predicting field-scale solute transport.

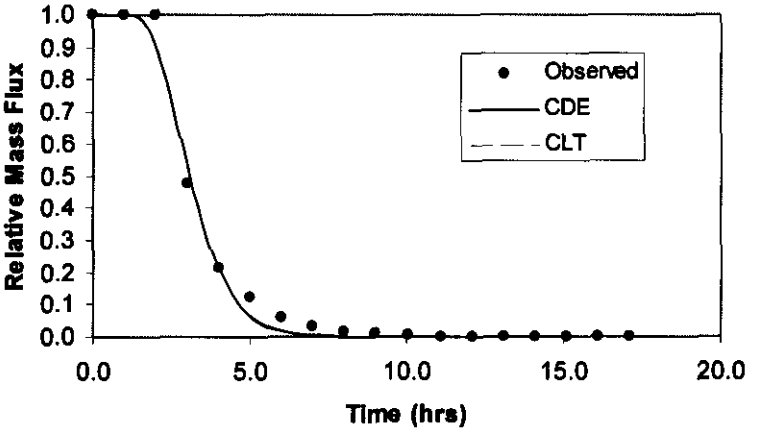

Figure 13. Example of $M_L(t)$ and the least squares fit of the convective dispersion equation (CDE) and convective lognormal transfer function (CLT) models.

Figure 14 shows an example of the solute travel time probability density function obtained by taking the first derivative of an M(t) curve. Theoretically, the area under $f_L(t)$ should equal exactly 1.0, provided all of the solute mass applied can be accounted for. In most cases, the value was less than 1.0, suggesting that either some of the solute may have moved beyond the measurement depth without being detected (preferential flow); moved laterally; or experienced some other delay in vertical transport. The long tails observed in Figure 12 support the hypothesis of delayed vertical movement. The results of the transport analysis are summarized in Table 2.

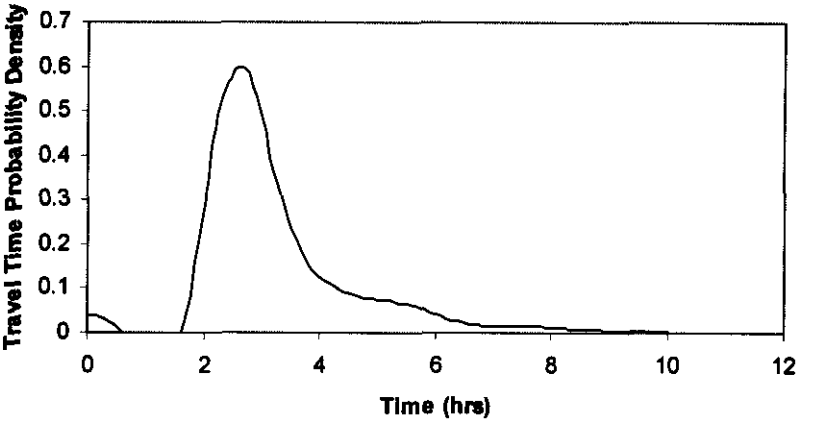

Figure 14. Solute travel time probability density function obtained by taking the first time derivative of the relative mass flux shown on Figure 13.

Table 2. Parameter estimates for the upper Hanford Formation from field transport experiments. D and v are the dispersion coefficient and pore water velocity of the convective dispersion equation (CDE); μ_p and σ_p are the population mean and variance of the convective lognormal transfer function (CLT); M_1 and M_2 are the expected travel time and travel time variance obtained by moment analysis; and λ_{CDE}, λ_{CLT} and λ_{MOM} are the dispersivities obtained by the three techniques.

Generally the CDE and CLT models predict the same average transport velocity, but differ in their predicted dispersion or degree of solute spread. A useful comparison of the CDE and CLT

has been given in terms of the existence or absence of correlated travel times with depth (Jury, 1982). For uncorrelated flow, the CDE predicts a linear increase in travel time variance with depth. For correlated flow, the CLT predicts an increase in travel time variance as the square of the distance. By comparing the results of the analysis, conclusions can be made on the appropriateness of different transport models.

The CDE, CLT and moment analysis shows reasonably good agreement in the transport parameters. All three methods predict essentially the same mean travel times to the depths of interest. Travel time was linear with depth, except for a small decrease (increase in v) that corresponded to a decrease in θ_e. This is probably due to increasing coarseness of the soil with depth.

The change in travel time variance with depth show that M_2 at the 0.50-m depth was 2 times that at the 25-cm depth, while M_2 at 100 cm was 4 times that at 50 cm. The 2x increase from 25 cm to 50 cm does not meet the criterion for correlated flow required by the CLT model but satisfies the 2x increase required for uncorrelated flow described by the CDE (Jury, 1982). In general, a 4x increase in variance requires constant velocity with depth, which does not exist initially, but becomes more so at greater depth. A CDE approach would be appropriate for modeling transport in this soil.

Table 2 also shows generally good agreement in the dispersivities obtained with the two models. However, λ_{MOM} was almost double the α_{CDE} and α_{CLT}, particularly at the smaller depths. The higher λ_{MOM} values reflect the larger travel time variance used in their derivation. Nevertheless, the range $1.32 \geq \lambda \geq 2.67$ cm observed in the shallow depths is comparable to the $0.01 \geq \lambda \geq 2.0$ cm reported for unconsolidated cores by Freeze and Cherry (1979). Another point worth noting is the increase in λ with depth down to 0.75 m, after which it essentially becomes constant. This result is consistent with the concept of a scale-dependent dispersivity and suggests for vertical transport in this soil, the scale over which λ becomes constant may be smaller than predicted from literature values obtained from horizontal transport in the saturated zone. With respect to upscaling and the extrapolation of data from one site to the next, these observations suggest a need for site-specific transport measurements at a range of scales and concomitant measurements of $\psi(\theta)$ in the same transport volume.

Summary and Conclusions

Field-measured hydraulic properties have been shown to be more representative of natural flow and transport processes but are generally difficult to measure. In this study, it was shown that vertically-installed time domain reflectometry (TDR) probes, when combined with a sprinkler-imposed constant flux system, can be used to measure the spatially variable hydraulic properties. The infiltration rate, when combined with the measured equilibrium water content and matric potential, provide direct measurements of the moisture characteristic function, $\psi(\theta)$, and the unsaturated hydraulic conductivity function, $K(\theta)$ at the field scale.

A series of infiltration tests were conducted at the site of the proposed LLTWDS during the summer of 1998. Measurements of K_s were made using a tension infiltrometer. The spatial distribution of K_s and water flux density determined from water storage measurements appear to be related to micro-topogrpahy and root channels.

Saturated water content and the other van Genuchten parameters, α, n, and θ_r were fitted with the program RETC. The goodness of fit was generally good with coefficients of determination (r^2) all exceeding 0.95.

The fitted mean saturated water content ranged from 0.3172 $m^3\ m^{-3}$ to 0.440 $m^3\ m^{-3}$, increasing slightly with depth. Neither the fitted α nor n showed any dependence on depth. Both parameters were less variable than those observed for the surface sediments.

Solute transport parameters were also obtained field measurements using KCl as a tracer. Analysis of the data using the traditional CDE and the less common CLT models, as well as with moment analysis, showed reasonably good agreement in the transport parameters. The three methods predicted the same mean travel times. Fitted dispersivities also showed good agreement between methods and are within the range observed on unconsolidated cores. Dispersivity also increased with depth down to 0.75 m, after which it essentially became constant. This result suggests a scale-dependent dispersivity, which in this soil appears to be somewhat smaller than predicted from measurements in the saturated zone.

This test has resulted in a data set that can be used the development of a catalogue of hydraulic and transport properties, one that will be amenable to geostatistical analysis and will facilitate the testing of upscaling theories. Comparisons of the data from this study with those from previous studies show remarkable similarity.

APPENDIX D

Physical and Hydraulic Measurements of FY1998 Clastic Dike Samples

Physical and Hydraulic Measurements of FY 1998 Clastic Dike Samples

MJ Fayer and JS Ritter
19 March 1999

Introduction

Pacific Northwest National Laboratory (PNNL) assists the Lockheed Martin Hanford Company (LMHC) in designing and assessing the performance of disposal facilities for radioactive wastes stored in single and double shell tanks at the Hanford Site. To predict contaminant migration from these facilities requires estimates of the physical and hydraulic properties of sediments within the vadose zone beneath and around the disposal facility. An unusual feature of the Hanford Site is the presence of vertical sediment structures known as clastic dikes in all of the major lithologies of the unsaturated zone. Fecht et al. (1998)[1] discussed dike structure and etiology and summarized some of the measurements that have been made.

Because clastic dikes could impact the performance of the ILAW disposal site, a work plan was prepared that provides details on the measurement and analysis of clastic dikes (Khaleel 1998)[2]. As part of the work plan, a PNNL task was initiated, entitled "Hydraulic Property Lab Tests for ILAW Samples." One objective of this task is to provide the measured data for clastic dike samples. Samples were obtained in fiscal year 1998 for characterization. The objective of this letter report is to document the physical and hydraulic properties of the clastic dike samples.

Properties

Physical and hydraulic properties are required for the clastic dike samples and the samples of the surrounding matrix. Multiple measurements of these properties are required to give some estimate of the degree of variability within each geologic material. The properties are:

Particle Size Distribution. Particle size distribution (PSD) refers to the fractions of the various particle-size classes (e.g., the fraction of particles with diameters between 1 and 2 mm).

Particle Density (ρ_p). Particle density is the mass of the sediment or construction material particles per unit volume of the same sediment or material. This property is used to relate the bulk density to the porosity.

Bulk Density (ρ_b). Bulk density is the mass of oven-dry material per unit bulk volume. The unit bulk volume is the combined volume of material, water, and air prior to oven drying.

Porosity (ϕ). Porosity is the volume of voids per unit bulk volume.

Water Retention. Water retention refers to the retention of water by the sediment at various matric potentials. Mathematical functions are fit to the retention data and the resulting parameters are used directly in computer models for predicting water and contaminant movement. Numerous functions are available, but the van Genuchten function is most commonly used:

$$\theta = \theta_r + (\theta_s - \theta_r)\left[(1 + (\alpha h)^n\right]^{-m}$$

where θ_s = saturated water content (cm^3/cm^3)
θ_r = residual water content (cm^3/cm^3)
h = matric potential (-cm)
α, n, m = empirical fitting parameters (α units are 1/cm; n and m are dimensionless)

Typically, m is approximated as $m = 1 - 1/n$

Saturated Hydraulic Conductivity (K_s). Saturated hydraulic conductivity is the proportionality constant in the Darcy equation that relates the flux density to a unit potential gradient.

Unsaturated Hydraulic Conductivity [$K = f(\theta, \psi)$]. Unsaturated hydraulic conductivity is the proportionality factor in the Richards equation that relates the flux density to a unit potential gradient at a specific water content. Because the water content varies in the unsaturated zone, the unsaturated conductivity varies also.

Mathematical functions are used to represent the unsaturated conductivity data; these functions are typically estimated using the water retention functions and saturated conductivity. When measured unsaturated conductivity values are available, the conductivity and retention data can be fit to optimize both the retention and conductivity functions. Several functions are available, but the Mualem conductivity function is most commonly used (in conjunction with the van Genuchten retention function, assuming $m = 1 - 1/n$):

$$K = K_s \frac{\left\{1 - (\alpha h)^{n-1}\left[1 + (\alpha h)^n\right]^{-m}\right\}^2}{\left[1 + (\alpha h)^n\right]^{\ell m}}$$

The K_s value and the pore interaction term (ℓ) are the only requirements for this model. The parameter ℓ is typically assigned a value of 0.5.

Clastic Dike Samples

In March 1998, grab samples were collected from clastic dikes near the towns of Touchet and Lowden, WA (sites identified by Fecht et al. as No. 64 Touchet Road and No. 76 West Lowden). These samples were processed only for particle density and size distribution because of their small size and disturbed nature.

In September 1998, core samples were collected from a clastic dike and surrounding matrix at the Goose Egg site described by Fecht et al. (1998); this site is 6.3 km south-southwest of the ILAW Disposal Site. Two-foot long core liners were constructed from 3.0 in. ID PVC. One end of each liner was sharpened and placed on selected spots, either on a dike or the matrix. A sledge hammer was used to sink the liner into the sediment. The liners did not penetrate very easily and we could see broken, loose material on the top of the sample. The liners were brought back into the laboratory and sectioned into 6-in. lengths, starting with the sharpened end, which was deepest and least affected by the disturbance at the top of the liner. A total of seven undisturbed sections of these lined cores were identified as suitable for testing. All cores were taken from near surface (< 1 m) deposits within 10 m of Army Loop Road. Table 1 lists the sample numbers, depths, and diameters.

Methods

The core samples were tested with the multistep and steady-state methods, then sectioned for the tests of particle size distribution, particle density, and water retention using pressure plates and vapor adsorption. The cores were prepared for the multistep and steady-state tests according to the procedures described by Fayer et al. (1998)[3].

Procedures

Table 2 lists the procedures used to analyze the samples. Additional details for each procedure are discussed below. These additional details are almost exactly the same as those used by Fayer et al.

Particle Density. Two replicates of the particle density test were performed using the pycnometer method (Blake and Hartge 1986a). The Touchet and Lowden sample size was 10 g. For the Goose Egg samples, the entire core was homogenized following the bulk density test. Of this loose material, 8 to 28 g was used for the particle density test. The only deviation was for sample 4A. Because it was so heterogeneous, sample 4A was sub-sampled in three distinctly different regions. Each subsample was tested for particle density.

Eching and Hopmans (1993)	Unsaturated Hydraulic Properties	Multistep outflow method for unsaturated conductivity and water retention estimation

Particle Size Distribution. The PSD test was performed using the methods ASTM 1985 and Gee and Bauder (1986). The Touchet and Lowden sample size was 40 g. For the Goose Egg samples, the entire core was homogenized following the bulk density test. Of this loose material, 80 g was used for the particle size distribution test. The only deviation was for sample 4A. Because it was so heterogeneous, sample 4A was sub-sampled in three distinctly different regions (as mentioned previously). Each subsample was tested for particle density.

Bulk Density. A single measurement of bulk density was made for each intact Goose Egg core. Following the conductivity test, the sediment in the core was oven dried and weighed. Dividing this weight by the volume of the core yielded the bulk density, as per the method of Blake and Hartge (1986b).

Porosity. A single estimate of porosity was made using the bulk density of intact Goose Egg cores and the average particle density. The formula used was $\phi = 1 - \rho_b / \rho_s$ (Freeze and Cherry 1979).

Water Retention. Water retention data for the Goose Egg samples were measured using the pressure-plate extraction and vapor equilibrium methods described by Klute (1986). The tests were conducted on the subsample created after the bulk density core was homogenized. For sample 4A, separate tests were conducted for the three subsamples mentioned previously. Additional retention measurements were obtained during the unsaturated conductivity tests.

Saturated Hydraulic Conductivity. Saturated hydraulic conductivity for the Goose Egg cores was measured on the intact cores prior to the unsaturated conductivity tests using the method of Klute and Dirkson (1986). The measurement of saturated conductivity was conducted several times to verify that a steady value of conductivity was achieved.

Unsaturated Hydraulic Conductivity. The multistep and steady state methods were used to measure unsaturated conductivity of the Goose Egg cores. Both methods were performed on the same core using the same sensor locations. The multistep method, which is an improvement of the one-step method of Kool et al. (1985 a,b), provides θ-ψ pairs and cumulative outflow. These data were used in conjunction with the SFOPT program (a modified version of the MULSTP program of Eching and Hopmans 1993) to determine the optimal set of hydraulic parameters.

Because several tests must be performed on the same core, the following test sequence was established: saturated conductivity, multistep unsaturated conductivity, and steady state unsaturated conductivity. Following the saturated conductivity test, the cores were re-wetted to saturation and analyzed using the multistep method. After equilibrating the cores with zero pressure at the lower plate, three pressure increments were used that were equivalent to head values of 10.9, 71, and 315 cm. Following the multistep test, the cores were rewetted and tested using the steady-state method.

Results

When opened for the bulk density measurements, several cores had noticeable layering. The most dramatic layering occurred in sample 4A, in which it appeared that most of the sample was fine-textured dike material. Three sections of this core were sub-sampled for individual tests of particle density and size distribution, and water retention. These samples are referred to as 4A1, 4A2, and 4A3 in Tables 3, 4, 6, and 7.

Table 3 shows that particle density varies between 2.65 and 2.73 g/cm^3 for the various infill, clay skin, and matrix materials. There appears to be no distinction between infill, skin and matrix in the two locations studied. The particle densities of the three subsamples of 4A are identical.

Table 4 shows the results for both the sieve and hydrometer methods. In all samples, the gravel content was less than 1%. Figure 1 shows all of the data combined to highlight the degree of variability in particle size distribution. Included in Figure 1 are the distributions for dune sand from the southern edge of the ILAW site and sandy gravel from the Grout spoils pile. The clay skins and dike material have the finest particle size distribution. The infill material has a predominance of sand particles between 100 and 200 μm diameter, as does dune sand. Almost all of the infill material particles sizes are less than 500 μm, whereas about 20% of the dune sand particles are greater than 500 μm. The particle size distributions of the subsamples within 4A showed sand contents varying from 42 to 90%. These differences help to explain the water retention differences discussed below.

Table 5 shows that the bulk density ranged from 1.46 to 1.57 g/cm^3. Table 5 also shows the porosity data, which ranged from 0.424 to 0.464. These ranges are smaller than the variations observed by Fayer et al. for the FY 1998 ILAW borehole samples.

Table 6 shows the pressure plate data for four pressures. As expected, samples that had dike material had higher water contents at any given pressure. Within 4A, water content varied between 0.04 and 0.155 cm^3/cm^3 at a matric potential of -530 cm, and 0.024 and 0.089 cm^3/cm^3 at a matric potential of -4080 cm. These differences are large and will make it challenging to represent the properties of the entire core with the properties measured at discrete locations.

Table 7 shows that the vapor adsorption data covered a range of matric potential from -11,600 cm to as dry as -1,460,000 cm. The associated water contents ranged from 0.08 to 0.004 g/g. Most of the measurements are in the very low potential range. There are very few measurements in the range from -10,000 to -100,000 cm.

Table 8 shows the saturated hydraulic conductivity values for the Goose Egg Hill cores range from 1.8×10^{-4} to 5.4×10^{-3} cm/s. The matrix samples generally had the highest values. The results in Table 8 are consistent with other measurements. For the matrix at their dike sites, Fecht et al. measured K_s values that mostly ranged from 1 to 4×10^{-3} cm/s. The one sample that was different had a K_s value of 2×10^{-5} cm/s. This particular sample was measured with a different technique (i.e., the unsaturated flow apparatus, or UFA). For samples with various amounts of dike material and clays skins, Fecht et al. measured K_s values ranging from 5×10^{-5}

to 9 x 10^{-4} cm/s. The values in Table 8 fall within this range. Most of the values also fall within the lower portion of the range of values reported by Fayer et al. for the FY 1998 ILAW borehole samples. The lowest value in Table 8 (1.8 x 10^{-4}) is only slightly lower than the lowest ILAW borehole value (2.6 x 10^{-4}).

Table 9 shows the parameter estimates and fitting statistics determined using the SFOPT program with data from the multistep test. The parameter α varied from 0.0092 to 0.0839, a factor of about 10, and the parameter n ranged from 1.33 to 2.49. These ranges seemed small given the presence of fine-grained zones in some samples, but the statistics indicated reasonable fits to the data.

Some additional fitting tests were performed. To demonstrate the impact of the location of the tensiometer, sample 2A was refitted using the upper rather than lower tensiometer data. Of all the samples, sample 2A had the greatest differences in tension (about 40 cm) between the two tensiometer locations. The refitting reduced α by half (to 0.0342 cm^{-1}) and increased n by 33% (to 2.63). The R^2 was actually improved (from 0.747 to 0.894) and the mass error was reduced (from 1.51 to 0.59%). Outflow data represent the response of the entire sample, whereas the matric potential data are derived from a sample volume that could almost be considered a point. An assumption of the fitting process is that the material is homogeneous. With clastic dikes, the samples are not homogeneous, so point measurements are more likely to deviate from the expected values. The results from refitting sample 2A using the upper tensiometer data illustrate the parameter differences that could be encountered by using tension measurements elsewhere in the column. The matric potential sets from the other samples were much closer in value, so the differences in fitting results (between using the upper versus lower tensiometer data) should not be so large.

An additional fitting exercise was performed to demonstrate the impact of weighting the data. In this exercise, the matric potential and water retention weights were progressively reduced from 1.0 to 0.0 for sample 2A using the upper and lower tensiometer data. Figure 2 shows the sensitivity of the parameter estimates to the weighting used. Because tension is a point measurement, we may want to consider reducing the weight given to such data. One solution may be to weight the tension data according to the fraction of the sample volume that it measures.

The same fitting exercise using variable weighting was also performed for sample 3A using just the lower tensiometer data. The results were similar for most weights. The only exception was a weight of 0.0, which caused the program to terminate without a solution. In this case, the outflow data were not sufficient to allow the program to find an optimal solution.

Table 10 shows the θ-ψ-K triplets that were generated using the steady state method. All of the measurements are at matric potentials above -54 cm. Even so, unsaturated conductivity values were 1 to 2 orders of magnitude less than the saturated values. Because the potentials were so high, the water contents were also relatively high.

Summary

Samples were collected from clastic dike sites in the Columbia Basin in September 1998 and analyzed for physical and hydraulic properties. Eight disturbed samples were obtained from two sites in the towns of Touchet and Lowden, Washington. Seven undisturbed cores were obtained from a site near Goose Egg Hill, which is located 6.3 km SW of the ILAW site. Testing included particle density, particle size distribution, bulk density, water retention, and saturated and unsaturated conductivity. Saturated conductivity values were similar to values reported by Fecht et al. for other clastic dike samples. The samples exhibited some variability but not as much as reported by Fayer et al. for the ILAW borehole samples. The impacts of tensiometer location and data weighting were demonstrated.

Figure 2. Effect of data weighting on prediction of parameters α and n.

Quality Assurance/Quality Control (QA/QC) Considerations

Quality Assurance/Quality Control (QA/QC) Considerations

This data package is based on data reported in appendices A through D or taken from peer-reviewed, open literature. Data reported in appendices A, C, and D were collected by Pacific Northwest National Laboratories (PNNL), following applicable PNNL QA/QC procedures. Data reported in appendix B were collected by Westinghouse Hanford Company Geotechnical Engineering Laboratory (GEL), following applicable GEL QA/QC procedures.

For analysis of data collected in the laboratory and field and those based on literature, a peer review procedure was established and followed. The peer review members were selected based on their experience and knowledge of specific subject areas. The internal peer review was provided per Fluor Daniel Northwest (FDNW) internal procedures. PNNL provided the Hanford technical review for the data package. A review of the data package was also provided by the Hanford Site Vadose Zone/Groundwater Integration Project. Finally, an external peer reviewer (i.e., Professor L. W. Gelhar, Massachusetts Institute of Technology, Cambridge, MA) has reviewed the data package.

This document was too large to scan as a single document. It has been divided into smaller sections.

Abstract

Lockheed Martin Hanford Company (LMHC) is designing and assessing the performance of disposal facilities to receive radioactive wastes that are currently stored in single- and double-shell tanks at the Hanford Site. The preferred method of disposing of the portion that is classified as low-activity waste (ILAW) is to vitrify the liquid/slurry and place the solid product in near-surface, shallow-land burial facilities. The LMHC project to assess the performance of these disposal facilities is the Hanford ILAW Performance Assessment (PA) Activity. The goal of this project is to provide a reasonable expectation that the disposal of the waste is protective of the general public, groundwater resources, air resources, surface water resources, and inadvertent intruders. Achieving this goal will require prediction of contaminant migration from the facilities. This migration is expected to occur primarily via the movement of water through the facilities and the consequent transport of dissolved contaminants in the pore water of the vadose zone.

Pacific Northwest National Laboratory (PNNL) assists LMHC in their performance assessment activities. One of the PNNL tasks is to provide estimates of the geochemical properties of the materials comprising the disposal facility, the disturbed region around the facility and the physically undisturbed sediments below the facility (including the vadose zone sediments and the aquifer sediments in the upper unconfined aquifer). The geochemical properties are expressed as parameters that quantify the adsorption of contaminants and the solubility constraints that might apply for those contaminants that may exceed solubility constraints. The common parameters used to quantify adsorption and solubility are the distribution coefficient (K_d) and the thermodynamic solubility product (K_{sp}), respectively. In this data package we approximate the solubility of contaminants using a more simplified construct called the solution concentration limit, a constant value. In future Geochemical Data Packages we will determine whether a more rigorous measure of solubility is necessary or warranted based on the dose predictions emanating from the ILAW 2001 PA and reviewers' comments.

The K_d's and solution concentration limits for each contaminant are direct inputs to subsurface flow and transport codes used to predict the performance of the ILAW system. In addition to the best-estimate K_d's, a reasonable conservative value and a range are provided. We assume that K_d values are log normally distributed over the cited ranges. Presently we do not give estimates for the range in solubility limits or their uncertainty. However we supply different values for both the K_d's and solution concentration limits for different spatial zones in the ILAW system and supply time-varying K_d's for the concrete zone, should the final repository design include concrete vaults or cement amendments to buffer the system pH.

If warranted, more technically rigorous information on uncertainty in the geochemical parameter values and estimates of the changes in parameter values over time will be supplied in future data packages.

Acknowledgements

We wish to thank the following Hanford and external reviewers for their insightful reviews of this data package from many perspectives. The reviewers considered geochemical technical comments, systems performance assessment comments and readability comments for both lay persons and waste management/regulators who must make policy decisions based on the long-term predictions that emanate from PA activities.

1.0 Introduction

The Hanford Immobilized Low-Activity Tank Waste Performance Assessment (ILAW-PA) examines the long-term environmental and human health effects associated with the planned disposal of the vitrified low-activity fraction of waste presently contained in Hanford Site tanks. Greater than 200,000 m^3 of tank waste has been created as the result of separating nuclear materials from irradiated nuclear fuels. This waste has been stored in 18 underground tank farms. The tank waste is to be retrieved, separated into low-activity and high-level fractions, and then immobilized by private vendors. The high-level fraction, which will be of low volume but contain most of the radionuclides, will be stored at Hanford until a national repository is approved. The low-activity fraction will be disposed as vitrified waste in the Hanford Site 200 East Area.

The design of the ILAW disposal facilities is evolving. Although there are four existing concrete vaults with a total useable volume of about 15,000 m^3 that could be used current design staff are contemplating trench disposal in the 200-E Area of the Hanford Reservation.

The first ILAW performance assessment of the 200 East Area was completed in 1998 and it showed that groundwater transport presents the greatest potential for long-term dose uptake by humans (Mann et al. 1998). Of the numerous radionuclides evaluated in this PA,(included Ac, Am, C, Ce, Cm, Co, Cs, Eu, I, Nb, Ni, Np, Pa, Pb, Pu, Ra, Ru, Se, Sn, Sr, Tc, Th, U, and Zr), the following isotopes were identified as posing the greatest potential health hazard: ^{129}I, ^{237}Np, ^{79}Se, ^{99}Tc, and $^{234/235/238}U$. Kaplan et al. (1995) described the geochemical factors affecting the transport of these radionuclides in the Hanford Site subsurface environment. It was also determined that the outcome of these simulations was very sensitive to the parameter describing the extent to which radionuclides sorbed to the subsurface sediment, the distribution coefficient, K_d. The distribution coefficient is the ratio of the radionuclide concentration associated with the solid phase to that in the liquid phase (described in more detail below). Near the buried vitrified waste, solubility constraints may also control the solution concentrations of contaminants. Thus, this data package contains empirically chosen "solubility limits" for selected contaminants in the regions close to the vitrified waste (see discussions below).

The purpose of this data package is to document the basis for selecting geochemical parameters and input values that will be used in the 2001 version of the ILAW-PA. In addition to the database, the philosophy, approach, and review process are presented.

2.0 Philosophy

2.1. Relation Between Distribution Coefficients and Retardation Factors

The distribution coefficient, or Kd value, is the simplest construct describing contaminant sorption to sediments. It is the ratio of the contaminant concentration sorbed to the solid phase divided by the contaminant concentration in the liquid surrounding the solid phase (Equation 1):

$$Kd = \frac{C_{solid}}{C_{liquid}} \quad (1)$$

where C_{solid} (M kg^{-1}) and C_{liquid} (M L^{-1}) are the concentration in the solid and liquid phases, respectively. It is important to note that sorption, as expressed by Kd values, is normalized by weight. Contaminant transport modelers commonly use Kd values to account for chemical interactions between the contaminant and the sediment. The Kd value is used to define the retardation factor, which is the ratio of the average linear velocity of water (m s^{-1}) divided by the average linear velocity of the contaminant (m s^{-1}). For water saturated systems, the Kd value is related to the retardation factor (Rf, unitless) by the bulk density (ρ_b, kg m^{-1}) and the porosity (η, m^3 m^{-3}) as follows (Valocchi 1984, Bouwer 1991):

$$Rf = \left(1 + \frac{Kd\rho_b}{\eta}\right). \quad (2)$$

The bulk density and porosity terms in Equation 2 convert the weight-normalized Kd value into a volume-normalized value. Note that for partially saturated sediments, the porosity term is replaced by the volumetric water content of the vadose zone sediments.

2.2. "Empirical" Kd Construct

The geochemical behavior of radionuclides in the subsurface will be described for the ILAW-PA using two parameters, the distribution coefficient (Kd value) and the solubility product (K_{sp}) of a specified solid. The distribution coefficient is a thermodynamic construct. It is the ratio of the concentration of a species reversibly adsorbed/exchanged to a geomedia's surface sites divided by the concentration of the species in the surrounding solution. Using uranyl as an example, the definition of a specie-specific Kd as a thermodynamic construct is:

$$K_{d-thermo} = \frac{X{\equiv}UO_2^{2+}}{UO_2^{2+}} \quad (3)$$

where $X{\equiv}UO_2^{2+}$ is the activity of the uranyl species reversibly adsorbed to a specific surface site X, and UO_2^{2+} is the activity of dissolved "free" uranyl species at equilibrium with the surface site

X. Among the many assumptions underpinning $K_{d\text{-}thermo}$ is that adsorption is fully reversible and the presence of adsorbed uranyl species does not influence subsequent adsorption of other dissolved uranyl or other contaminant species. Thus, a single distribution coefficient is used to represent both sorption and desorption of each contaminant species.

However, in order to apply the Kd construct to contaminant transport and performance assessment calculations, the definition of the construct is relaxed. The definition needs to be relaxed for several reasons. In natural systems, a multitude of different types of sorption sites exists. Also, it is very difficult to measure the thermodynamic activity of individual chemical species on the adsorbents' surfaces. Furthermore, the measurement of thermodynamic activities of dissolved species is rarely performed and, as just mentioned for adsorbates on solids, no techniques exist for the measurement of their thermodynamic activity. The parameters that can be readily measured are the total contaminant concentration or radionuclide activity (not to be confused with thermodynamic activity) as opposed to the concentration/radioactivity of each individual species. Thus, the Kd construct, as defined in Equation 3, requires differentiating and quantifying each type of surface site and each solution species. Additionally, spatial variability of the surface sites and groundwater chemistry in natural systems can not practicably be characterized to the degree necessary for the full implementation of species' specific sorption models, such as the triple layer surface complexation model (see Kent et al. 1988 for a good overview and Jenne 1998 for a recent compilation of related articles).

The empirical definition of the Kd value becomes the ratio of the concentration of the complete suite of species [the sum of the total concentration of all species that include the contaminant of interest] sorbed by an assemblage of surface sites, divided by the summed concentration of the suite of species (total concentration) in solution. Again, using uranyl as an example, the definition of the thermodynamic Kd construct would be for a simple system that contained three U(VI) species [UO_2^{2+}, $UO_2(OH)^+$, and $UO_2(OH)_2^0$]:

$$K_{d-therm} = \frac{\sum Adsorbed\ U\ Spieces}{\sum Dissolved\ U\ Spieces} = \frac{X{\equiv}UO_2^{2+} + X{\equiv}UO_2(OH)^+ + X{\equiv}UO_2(OH)_2^0}{UO_2^{2+} + UO_2(OH)^+ + UO_2(OH)_2^0} \quad (4a)$$

where X≡ is an average sorbent site (more than one sorbent site-type is expected in nature). The numerator and denominator in Equation 4a are summed over contaminant species sorbed as well as sorbent sites. The empirical Kd equation would be

$$K_d = \frac{total\ U(VI)\ \ on\ solid}{total\ U(VI)\ in\ solution}. \quad (4b)$$

Among the reasons for selecting the "empirical" Kd construct for the 2001 ILAW-PA, as exemplified by Equation 4b, is

1) the bulk of the existing sorption literature on radionuclide sorption, especially at Hanford can be classified as "empirical" K_d values,

2) under the expected low concentrations of the contaminants in the far field, sorption can be considered to be independent of contaminant concentration and, therefore, K_d is a constant for a given contaminant/geological material combination under identical (geo)chemical conditions,
3) Kd can be used directly in codes used for performance assessments such as the code PORFLO used in past ILAW predictions and the code VAM3DF to be used in future far-field vadose zone transport calculations (see Khaleel 1999), and
4) perhaps most importantly, there is presently no thermodynamically-based conceptual model or numerical code that is robust enough to accurately predict the degree of radionuclide adsorption by natural sediments (see below).

By using site-specific materials in ILAW-funded experiments, it is possible to gather relevant data directly and not to rely on extrapolation from other sediment and aqueous systems. The problem with the rigorous thermodynamic species approach is that, there is presently no numerical or conceptual model developed that is sufficiently robust to predict accurately the degree of radionuclide adsorption by natural sediment (Sposito 1984, Westall 1994, Westall 1986, Wang et al. 1997, Davis et al. 1998). However, mechanistic models provide the necessary paradigms upon which technically defensible "empirical" Kd values must be based. For most of the data used in the ILAW PA geochemical data package, sorption experiments have been conducted with site-specific sediment and site-specific groundwater, which resembles natural vadose-zone porewaters.

Mechanistic models, although impractical for PA purposes, provide the necessary paradigms upon which "empirical" Kd values must be based.

Another aspect of the Kd construct that is typically relaxed when used in contaminant transport calculations is the chemical process that it describes. As pointed out earlier, Equation 3, implies an adsorption or exchange reaction that is reversible. The laboratory Kd measured with complex natural sediments and perhaps complex natural groundwater solutes, often reflect not only adsorption and exchange reactions, but also absorption, specific or somewhat irreversible adsorption, surface complexation, and varying degrees of (co)precipitation reactions. Identifying the processes that govern radionuclide chemical behavior is the single most important task necessary for estimating Kd values for the ILAW PA. Once the dominant geochemical process is identified for a specific geological and chemical environment, the range of "empirical" Kd values can be narrowed. Radionuclide geochemical processes have been ascertained primarily through experiments in which a key parameter is systematically varied, e.g., suspension pH or ionic strength. The trends displayed during these experiments provide key information regarding radionuclide behavior and also shed light on which processes may be controlling the radionuclide interaction between the solid and liquid.

Identifying the processes that govern radionuclide chemical behavior is the single most important task necessary for estimating Kd values. Once the dominant geochemical process is identified for a specific set of environmental conditions, the range of reasonable values for the "empirical" Kd parameter can be narrowed.

The importance of first identifying the dominant geochemical process affecting radionuclide concentrations in the mobile aqueous phase can be illustrated through an

experiment conducted for this project (Kaplan et al. 1998a). In this experiment, as the pH of Hanford sediment-groundwater slurries was increased from pH 8 to 10, U(VI)-K_d values gradually increased from 1.3 to 3.5 mL/g. Above pH 10.5 the amount of U(VI) removed from the aqueous phase increased by >500 fold. The initial increase in K_d between pH 8 and 10 was attributed to increased cation exchange capacity of the sediment. That is, the number of pH-dependent adsorption sites in the natural sediment, which attract cations, increased as the pH increased. The latter more dramatic increase was attributed to (co)precipitation of U(VI) with carbonate phases. These conclusions were supported by independent solubility calculations. What we learn from this particular study is much more than simply the magnitude of the K_d value that should be used as an input parameter to the ILAW PA; we gain a plausible explanation of the processes governing U(VI) removal from solution. As this example illustrates, changes in the dominating chemical processes may account for an appreciable amount of variability in derived K_d values under different geochemical conditions.

2.3. Solubility Constraints

In addition to the K_d construct, solubility products, (both thermodynamically and empirically based), are being used to describe radionuclide geochemical behavior in the ILAW disposal site. The solubility constraints used for conditions where the calculated concentrations of the radionuclides are believed to exceed the solubility of an assumed controlling phase. The selection of controlling solid phases will be based on laboratory experiments and when experimental data are not available, on literature results. If the thermodynamic data for the solid phase is not available from laboratory experiments or the literature, then it will be calculated using chemical speciation and solubility algorithms. Once the solid phase is selected, the upper limit of radionuclide concentration will be calculated with the appropriate background electrolyte composition. If the background electrolyte composition remains essentially constant then the solubility product can be assumed to also be nearly constant. This has lead some PA practitioners to refer to solubility constraints as constants but in reality the solubility constant, K_{sp}, varies with solution chemistry. When radionuclide concentrations exceed the K_{sp}, precipitation can be expected and subsequent radionuclide aqueous concentrations and behavior is controlled by solubility. At concentrations below this limit, the radionuclide concentration will be controlled by the "empirical" K_d construct. When the controlling solid can not be identified but empirical solubility tests clearly indicate that some unidentified phase is controlling solution concentration, then an empirical solubility relationship will be used. This empirical solubility product will include the key solution parameters as independent variables and the empirical solubility product as the dependent variable. In some cases the empirical K_{sp} data may be simplified as a constant concentration limit. This is especially true for the 2001 ILAW PA because little site/waste form/engineered barrier solubility work has been performed that identifies the controlling solids. Recent thermodynamic tabulations by the Nuclear Energy Agency in France may prove to be valuable references. Three books are currently available with data on U, Am, and Tc [see Grenthe et al. 1992, Silva et al.

When the controlling solid could not be identified but empirical solubility tests clearly indicate that some phase is controlling solution concentration, then an empirical solubility relationship will be constructed.

1995, and Amaia Sandino and Osthols 1999, respectively]. Other solubility data for other radionuclides can be found at the NEA web page http://www.nea.fr/html/dbtdb.

2.4. Parametric-K_d Model

When using the constant-K_d model, the retardation factor is a constant for each layer of geologic media (each layer is assumed to have a constant bulk density and water content or saturated effective porosity). The transport equation based on a constant-K_d model does not require knowledge of any other geochemical parameters such as pH or mineralogy, and it is easily solved to determine the solution concentration as a function of time and space. It is the use of the constant-K_d model in retardation factor (Equation 2) that has caused most of the criticism; few natural groundwater pathways are spatially or geochemically homogeneous to the extent that the retardation factor for a species remains constant.

Clearly, the greatest limitation to the constant-K_d approach is that it describes solute partitioning between the aqueous and solid phases for only one set of environmental conditions. Such homogeneity does not exist in nature and therefore greatly compromises the usefulness of the constant. For instance, when the aqueous phase chemistry was varied, Am-K_d values in a Hanford sediment ranged from 0.2 to 53 mL/g, roughly a 200-fold range (Delegard and Barney 1983). Additional variability in the Am-K_d values, albeit less, was observed when slightly different Hanford sediments were used: 4.0 to 28.6 mL/g (Delegard and Barney 1983, Solution 1). Using similar aqueous phases but sediments from around the country, Sheppard et al. (1976) measured Am-K_d values ranging from 125 to 43,500 mL/g. (Interestingly, the lowest K_d in this survey of 12 soils/sediments from DOE-national laboratories was in a Hanford sediment.)

The K_d value in the parametric model varies according to empirically derived relationships with aqueous and solid phase independent parameters. Thus, it has the distinct advantage of being more robust and removes the burden of determining new K_d values for each environmental condition. Because the K_d is a function of a large number of variables, it is common to vary systematically several parameters simultaneously in one experimental study. Factorial design strategies are most often invoked to determine the systematic change resulting from varying the independent variables on the dependent variables, typically the distribution coefficient (Cochran and Cox 1957, Davies 1954, Plackett and Burman 1946, Box and Behnken 1960). Statistical methods commonly used to derive quantitative predictor equations include standard linear or nonlinear regression (Snedecor and Cochran 1967), stepwise regression (Hollander and Wolfe 1973), and adaptive-learning networks (Mucciard et al. 1979, 1980). All these techniques have been used to develop empirical relationships describing K_d values in terms of other variables (Routson and Serne 1972, Serne et al. 1973, Routson et al. 1981, Delegard and Barney 1983).

The empirical predictor equations commonly take the form of a nonlinear multinomial expression. For example, after evaluating solutions consisting of several sodium salts, organic chelates, and acids, Delegard and Barney (1983) came up with the following expression for a americium's K_d value on one particular Hanford sediment:

$$\text{Log } [K_d(Am)] = 2.0 + 0.1[NaOH] - 26.8[HEDTA] + 153.4[HEDTA]^2 \quad (5)$$

The independent parameters and their ranges used to develop Equation 5 were selected to simulate the plume of a HLW emanating from a steel-lined concrete tank into a sediment in the Hanford Site 200 Area Plateau. Numerous salts were found to have no significant effect on americium K_d values and therefore were not included in the expression. Delegard and Barney (1983) also evaluated higher exponential and logarithmic terms and determined that these terms did not improve the predictive capabilities of the expression (i.e., the regression coefficients were not significant at $P<0.05$).

Although the empirical relationships generated from these types of statistical analyses are more powerful than knowledge of individual K_d values, they cannot be used to predict K_d values for conditions beyond the range studied. For example, the parametric-K_d values generated by Delegard and Barney (1983) for the 200 Area Plateau are likely inappropriate for the vitrified LLW plume because the chemistry of the aqueous phase will be appreciably different.

These types of statistical relationships are devoid of causality and therefore provide no certain information on the mechanism by which the radionuclide partitioned to the solid phase, whether it be by adsorption, absorption, precipitation, or coprecipitation. That is, the statistical analyses may suggest a very strong relationship between one variable, for instance pH, and the distribution coefficient, when the actual sorption process may be controlled by iron oxide adsorption. Because pH and iron oxide surface charge are covariant, a statistical relationship could be calculated, suggesting that sorption is solely caused by pH.

The parametric-K_d model can be used in the retardation factor term (Equation 2). When used in a transport equation, the transport code must also keep track of the current value of the independent variables (such as [NaOH] and [HEDTA] for the examples described above; Equation 5) at each point in space and time. Keeping track of other variables is necessary to continually update the concentration of these independent variables that change the K_d value. Thus, the code must track many more parameters, and some numerical solving techniques (such as closed-form analytical solutions) can no longer be used to perform the integration necessary to solve for the contaminant's concentration. Generally, computer codes that can accommodate the parametric-K_d model use a chemical subroutine to update the K_d value used to determine the R_F, when called by the main transport code. The added complexity in solving the transport equation with parametric-K_d sorption models and its empirical nature may be the reasons this technique has been used sparingly for waste disposal safety assessment exercises.

2.5. Overview of Mechanistic Adsorption Models

Mechanistic models explicitly accommodate the dependency of K_d values on contaminant concentration, competing ion concentrations, variable surface charge on the adsorbent, and solute species distribution. Incorporating mechanistic, or semi-mechanistic, concepts into models is attempted because the models become more robust and, perhaps more importantly, for the standpoint of the ILAW PA, scientifically defensible. There are several mechanistic models describing solute adsorption; some are accurate only under limited environmental conditions (Sposito 1984). For

instance, the Stern model is a better model for describing adsorption of inner-sphere complexes, whereas the Gouy-Chapman model is a better model for describing outer-sphere or diffuse swarm adsorption (Sposito 1984, Westall 1986). The complexity of installing these models into existing transport codes that are favored for complete disposal system performance assessment and the diversity of Hanford waste leachate/sediment/contaminant combinations of interest would require a data collection effort more intense and costly than is likely to be available. A brief description of the state of the science is present below. References to excellent review articles have been included in the discussion to provide the interested reader with additional information.

Several mechanistic models have been proposed; however, their application to complex natural sediments is not resolved (Westall and Hohl 1980, Sposito 1984, Westall 1986, Schindler and Sposito 1991). Any complete mechanistic description of chemical reactions at the mineral-electrolyte interface must include a description of the electrical double layer. While this fact has been recognized for years, a satisfactory description of the double layer at the mineral-electrolyte interface still does not exist.

Part of the difficulty of characterizing this interface stems from the fact that natural mineral surfaces are very irregular. They consist of many different micro-crystalline structures that exhibit quite different chemical properties when exposed to solutions. Thus, examination of the surface by virtually any experimental method yields only averaged characteristics of the surface and the interface. Parson (1982) discussed the surface chemistry of single crystals of pure metals and showed that the potential of zero charge of different crystal faces of the same pure metal can differ by over 400 mV. For an oxide surface, this difference was calculated by Westall (1986) to be energetically equivalent to a variation in the zero-point-of-charge of more than six pH units. This example indicated that an observable microscopic property of a polycrystalline surface might be the result of a combination of widely different microscopic properties and that characterizations of these surfaces will remain somewhat operational in nature.

Another fundamental problem encountered in characterizing reactions at the mineral-electrolyte interface is the coupling between electrostatic and chemical interactions, which make it difficult to distinguish their effects between each other. Westall and Hohl (1980) have shown that many models for reactions at the mineral-electrolyte interface are indeterminate in this regard.

Many of the studies from which our current understanding of reactions at the mineral-electrolyte interface have developed were based on titration of colloidal suspensions of minerals. Resolving questions left open by such research requires that the mineral surfaces be better defined (by many different spectroscopic and experimental methods), and that mathematical methods be developed for interpreting the data.

Experimental data on interactions at the mineral-electrolyte interface can be represented mathematically through two different approaches: 1) empirical models and 2) mechanistic models. An empirical model can be defined as a mathematical description of the experimental data without any particular theoretical basis. For example, the K_d, Freundlich isotherm, Langmuir isotherm, Langmuir Two-Surface Isotherm, and Competitive Langmuir are considered empirical models by this definition (Sposito 1984). Mechanistic models refer to models based on thermodynamic concepts such as reactions described by mass action laws and material balance equations. Four of

the most commonly used mechanistic models include the Helmholtz, Gouy-Chapman, Stern, and Triple Layer models (Sposito 1984). The empirical models are often mathematically simpler than mechanistic models and are suitable for characterizing sets of experimental data with a few adjustable parameters, or for interpolating between data points. On the other hand, mechanistic models contribute to an understand of the chemistry at the interface and are often used for describing data from complex multi-component systems for which the mathematical formulation (i.e., functional relations) for an empirical model might not be obvious. Mechanistic models can also be used for interpolation and characterization of data sets in terms of a few adjustable parameters. However, mechanistic models are often mathematically more complicated than empirical relationships. Adjustable parameters are required for both mechanistic and empirical models, but not for the K_d model.

2.6. Gravel-K_d Issue

Essentially all K_d values in the literature and that have been measured at the Hanford site were generated from sediments that do not contain any gravel, particles >2-mm. However, there are regions in the subsurface of the ILAW site that are composed primarily of gravel-sized particles. At issue is that K_d values will likely be lower in sediments containing gravel because of the reduced surface area in the field as compared to the lab tested solids for the radionuclides to interact with. This is referred to as the gravel-K_d issue. Experiments were conducted with Hanford sediments to evaluate a number of methods to address the gravel-K_d issue (Kaplan et al. 1999 and see Appendix A). Three gravel-corrected K_d conceptual models, Kd_{gc}, were evaluated in this study: a correction based on surface area ($Kd_{gc,surf}$), a correction based on the assumption that the gravel simply diluted the $Kd_{<2mm}$ and had no sorption capacity ($Kd_{gc,g=0}$), and a correction based on the assumption that the K_d of the entire sediment (Kd_{tot}) was a composite of the $Kd_{<2mm}$ and the $Kd_{>2mm}$ values ($Kd_{gc,g=x}$). Based on data for the adsorption of trace concentrations of Sr, on average, $Kd_{<2mm}$ tended to overestimate Kd_{tot} by 28%; $Kd_{gc,g=x}$ overestimated Kd_{tot} by only 5%; $Kd_{gc,g=0}$ and $Kd_{gc,surf}$ underestimated Kd_{tot} by 10 and 13%, respectively. Although, $Kd_{gc,g=x}$ provided the best estimate of actual values (Kd_{tot}), the input values for $Kd_{gc,g=0}$ are appreciably easier to acquire. Additional data regarding the gravel-correction can be found in Appendix A.

To account for the presence of gravel in the study area, K_d values will be lowered in a conservative method, whereby the gravel will be assumed to have no sorptive capacity for the radionuclides.

The $Kd_{gc,g=0}$ will be used to correct for the conservative case "empirical" Kd values in the gravel-dominated sequence (described in more detail below) and is defined as:

$$Kd_{gc,g=0} = (1-g)Kd_{<2mm}, \quad (6)$$

where g is the gravel weight fraction of sediment in the field and $Kd_{<2mm}$ is the traditional K_d value measured using the <2-mm fraction. Equation 6 greatly improves the accuracy of the "empirical" K_d construct for Hanford sediments and perhaps more importantly from the stand

point of the ILAW PA, it provides in all cases a more conservative K_d value than the traditional $Kd_{<2mm}$ commonly used in such calculations.

2.7. Moisture Dependency of K_d Values

The moisture dependency of K_d values has been and continues to be evaluated by our group (Lindenmeier et al. 1995, Kaplan et al. 1996, and Gamerdinger et al. 1998). Based on our findings to date, as well as the literature, our present belief on this subject is that there is a slight decrease in U(VI)-K_d values as the moisture content in a system decreases. In support of this contention is that four of the five sediments tested to date showed this trend. The sediment that did not show this trend had only two K_d data points, one from a saturated system and the other from an unsaturated system (Kaplan et al. 1996). This decrease in K_d for U[VI]) as percent saturation decreased may be attributed to the fact that as the degree of saturation decreases, solutes come into contact with fewer exchange sites. But with more contact time between the vadose zone sediments and the porewater, diffusion processes may allow the contaminants to interact with sediment adsorption sites that are "hidden" in dead-end pore spaces. The dead-end pore spaces may be created during the laboratory flow-through column experiments performed at unsaturated moisture contents, although they also occur in nature as determined in some field studies. That is, the slight dependency (decrease in K_d for U[VI]) of K_d as percent saturation decreased may be caused by a physical process, which will become less important in the field, than a chemical process. An alternative explanation is that higher ionic strength fluid exists in the double layer of partially saturated sediments leading to weaker sorption. This latter explanation is less likely since the double-layer around particle surfaces reach only nanometers into the water, whereas the uniform film thickness of pore fluid around unsaturated Hanford sediments is estimated to be several micrometers (see Appendix C for a short discussion). For the 2001 ILAW PA we will ignore the K_d dependency on moisture content and use the K_d values measured in traditional saturated tests. If the flow models used in the future PA's (beyond the 2001 ILAW PA) are capable of modeling the mobile-immobile water concepts presented in van Genuchten (1981), then the effect of moisture content on the retardation factor can be accommodated without altering the K_d value. Consequently, all K_d estimates used in the future PA's for the vadose zone would be slightly lower than values derived from traditional tests conducted in saturated systems. We will also continue studies on the effects of partial saturation on the K_d of U(VI) for one more year in hopes of resolving the issue.

To account for a possible moisture dependency of K_d values, all K_d estimates assigned to the vadose zone will be slightly lower than values derived from traditional tests conducted in saturated systems.

2.8. Colloid-Facilitated Transport of Contaminants

Contaminant transport is traditionally modeled as a two-phase system: a mobile aqueous phase and an immobile solid phase. Over the last 15 years, there has been an increasing awareness of a third, mobile solid phase. This mobile solid phase, mobile colloids, consists of organic and/or inorganic submicron-particles that move with groundwater flow. When radionuclides are associated with colloids, the net effect is that radionuclides can move faster

through the system than would be predicted on the basis of reversible sorption. It is not known whether colloids in the subsurface environment of the Hanford Site enhance contaminant transport. Furthermore, it is not known if mobile colloids in a plume emanating from the ILAW waste site will have significant effects on contaminant transport rates.

Mobile colloid formation is commonly described as a three-step process: genesis, stabilization, and transport. Colloid genesis describes how the submicron particles are formed in groundwater. Stabilization describes how the colloids are brought into suspension, which is a function of the colloid and groundwater composition and water flow forces. Transport describes how the suspended colloids move through the porous media or are retained by physical forces (such as diffusion, straining, or gravitational settling) or physicochemical attraction to the matrix.

Regarding the first step, colloid genesis, there is little doubt that radionuclide-bearing colloids will be generated at the ILAW disposal site. Ramsay (1988) presented strong evidence for the existence of colloid particles in glass and cement leachate and provided an in-depth review of the various types of colloids that can/may exist (e.g., glass fragments, precipitation products, geological materials, secondary phases formed from glass leachate). However, based on experiments using Hanford groundwater and colloids, there is little likelihood that colloids would remain suspended in glass leachate, cement leachate, or Hanford groundwater (McGraw and Kaplan 1997). The ionic strength of these solutions greatly exceed the critical flocculation concentration (the minimum electrolyte concentration to induce colloid flocculation) of most particles. Even in uncontaminated Hanford groundwater, where the ionic strength would be at its lowest, the critical flocculation concentration is likely exceeded by 300 to 600%, depending on the type of colloid in suspension. This would minimize colloid-facilitated transport of radionuclides from the disposal site. Hence, colloid-facilitated transport of contaminants will not be considered as an important transport process in the ILAW PA until there is compelling evidence that our assessment is flawed.

There is little doubt that colloids with radionuclides associated with them will be generated at the disposal site. However, there is little likelihood that colloids would remain in suspension in glass leachate, cement leachate, or even uncontaminated Hanford groundwater because of the high ionic strength of these waters. This would minimize colloid-facilitated transport of radionuclides from the disposal site.

3.0 Geochemistry of Key Radionuclides

This section provides a brief description of the geochemistry of radionuclides identified by preliminary subsurface transport simulations as presenting the greatest health risks. Emphasis is placed on describing the chemical processes relevant to the Hanford unsaturated zone, which is a coarse-sand textured, alkaline, sediment with low natural organic matter concentrations. Geochemical information relevant to other environments, such as reducing environments, is also provided to address possible near-field systems and a possible localized stagnant silt/mud region in the upper unconfined aquifer.

3.1. Iodine

There are 24 known isotopes of I, 18 of these isotopes have half-lives of less than 1 day. The only stable isotope is ^{127}I. Its average natural abundance in geologic materials is 5 mg/kg (Gu and Schulz 1991) and its concentration in uncontaminated surface waters is typically <1 mg/L (Stumm and Morgan 1981). The isotope of concern for long-term disposal at the Hanford Site is ^{129}I, which has a half-life of 1.7×10^7 years.

3.1.1. Aqueous Speciation

Iodine usually exists in fresh water in the minus one oxidation state as iodide (I^-) (Whitehead 1984). In alkaline and marine environments, iodine usually exists in the VII oxidation state as iodate (IO_3^-) (Whitehead 1984). Iodide and IO_3^- were the most commonly detected species in rainwater collected after the Chernobyl accident (Muramatsu et al. 1990). The other oxidation states of iodine, III and V, are much less frequently found in nature. Iodide is likely to be the dominant iodine species in the Hanford upper unconfined aquifer because its domain of predominance extends throughout the pH scale, completely covering a large part of the stability domain of water (Figure 1; Ticknor and Cho 1990). Oxidation of I_2 to produce IO_3^-, the second most abundant form of iodine in aqueous systems, is easily accomplished in basic solution by the reaction:

$$3I_2 + 6OH^- = 5I^- + IO_3^- + 3H_2O \qquad (7)$$

(Cotton and Wilkinson 1972). Thus, the IO_3^- form of iodine is likely dominant in well-oxidized, high-pH systems as may exist in the near field of the ILAW disposal site. Iodide and IO_3^- tend to exist as free ions, but the complexes they do form are generally the most soluble of all halide complexes.

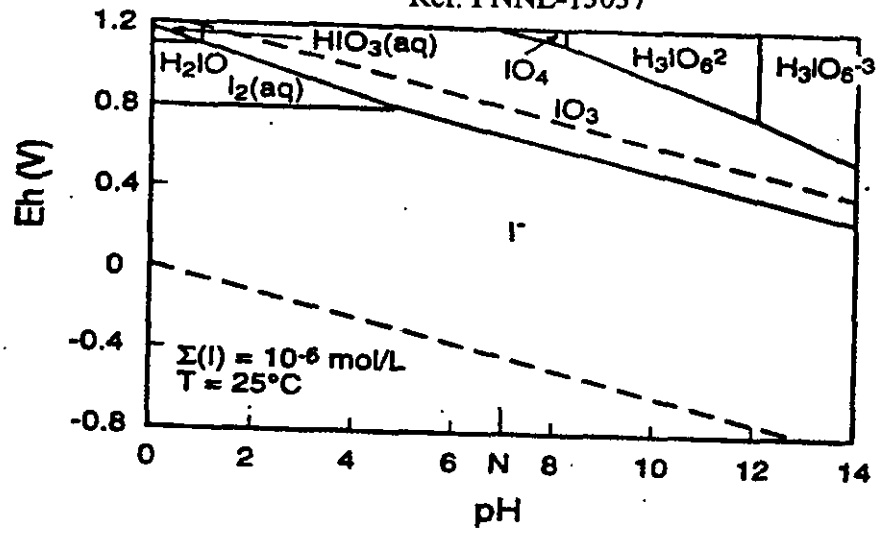

Figure 1. Eh and pH Diagram for Iodine/Water System (Ticknor and Cho 1990)

3.1.2. Precipitation and Coprecipitation

Precipitation of iodide compounds is not likely to be a dominant reaction path for iodide in the glass leachate. Iodide, in comparison with the other halides, forms especially weak complexes with metal ions as a result of its large size (0.22-nm ionic radius, Langmuir 1979). The metals with which I^- and IO^-_3 form sparingly soluble compounds, Ag, Ba, Hg, Pb, and Pd (Pourbaix 1966) exist in nature at very low concentrations. The low concentrations of iodine in the contaminant plume will likely exist as either free species or as highly soluble complex species. However we are finding that the weathering products of glass, zeolites and clays, do seem to incorporate several anionic contaminants, including pertechnetate, Se, and I (it is not clear whether the species is I^- or IO_3^- at this time). Results will be published in a PNNL progress report in early FY00 and past progress that describes preliminary tests are found in Mattigod et al. 1998. At the present time we will not include this apparent co-precipitation or specific adsorption (see below) of iodine leached from the glass into or onto the zeolites and clays that form in transport calculations or the geochemical data package for the 2001 ILAW PA. This will build in a degree of conservatism that will be dealt with (removed) when quantitative data on co-precipitation is available certainly by the time that the 2003 ILAW PA is scheduled.

3.1.3. Sorption

Two types of reactions between anions and inorganic solids are recognized: specific adsorption and nonspecific adsorption. Specific adsorption refers to incorporation of anions as a ligand in the coordination shell of an adsorbent, while nonspecific adsorption refers to adsorption of anions by simple coloumbic (electrostatic) interactions with positive charges. Iodine anions are believed to sorb primarily through nonspecific, anion-exchange reactions on mineral surfaces (Gu and Schulz 1991) and through specific adsorption on organic substances (Walters and Winchester 1971). Nonspecific sorption may occur at the localized positive charges that occur on 1) Fe- and Al- oxide surfaces, 2) edges of aluminosilicate clay surfaces where the oxygen

atoms are not fully coordinated by Al or Si atoms, and 3) on amine and amino groups of organic substances. These positive charges, which increase with decreasing pH, attract anions electrostatically. Whitehead (1973), for example, reported that sorption of I^- by soils was associated with both soil organic matter and Fe and Al oxides, with the oxides increasingly important under more acidic conditions. The maximum amounts sorbed by two surfaces occurred at pH 6.6. At this pH, the amounts of I^- sorbed were found to be closely related to the contents of organic matter but not to Fe- or Al- oxides or clay. At pH<5, the removal of Fe- and Al-oxides resulted in a marked reduction in I^- sorption. Whitehead (1974) further observed that freshly precipitated ferric- and Al-oxides sorbed substantial amounts of I^- from solutions of pH <5.5 but the amount decreased to zero as the pH approached 7. Presumably, this trend reflects the presence of an increasing amount of positive charge (anion-exchange capacity) on the amphoteric oxide surfaces at lower pH levels.

Ticknor and Cho (1990) studied the interaction of I^- and IO^-_3 over a pH range of 7.5 to 8.0 with a number of minerals including calcite, chlorite, epidote, goethite, gypsum, hematite, kaolinite, bentonite, muscovite, and quartz. No I^- sorption was detected from any of the solutions on any of the minerals. Iodate was removed from solution to a somewhat greater extent then I^-. Bentonite, calcite, gypsum, and muscovite adsorbed no IO_3^-. Muramatsu et al. (1990) reported that neither I^- nor IO_3^- sorbed to quartz sand. The authors concluded that the low I^- and IO^-_3 sorption was the result of the low anion-exchange capacities of the minerals at the high pH of the systems investigated. Recently, Kaplan et al. (1999) showed that some naturally occurring 2:1 phyllosilicate minerals have the ability to sorb large amounts of iodide. Kd values >60 mL/g were measured for illites. Illite generally accounts for about 20% of the clay fraction of Hanford sediments. Even at pH >9, iodide Kd values for these illites were >20 mL/g. Subsurface Hanford sediment with a pH of 8 had Kd values that average 3 mL/g and ranged from 0.1 to 10 mL/g.

3.2. Neptunium

There are 16 known isotopes of Np from ^{228}Np to ^{241}Np (Keller, 1971). Only ^{237}Np, a neutron reactor product of ^{238}Np (n, 2n), and ^{235}Np (n, γ), with a half-life of 2.14×10^6 years, are of interest to the ILAW PA.

3.2.1. Aqueous Speciation

Neptunium exists in aqueous solutions in five oxidation states, Np(III), Np(IV), Np(V), Np(VI), and Np(VII). In the absence of complexing agents, the first four oxidation states exist as hydrated ions Np^{+3}-H_2O, Np^{+4}-H_2O, NpO_2^+-H_2O, NpO_2^{+2}-H_2O (Ames and Rai 1978). Np(VII) is a strong oxidizing agent that is stable in strong alkaline solution as NpO_5^{-3}. Between pH 0 to 9, NpO_2^+ is the common Np species formed in aqueous environments (Ames and Rai 1978). Above pH 9 (and >100 mg/L carbonate) an uncharged bicarbonate complex is formed. According to Keller (1971), Np(V) does not form hydroxide complexes below pH of 7. Np(V) exists as the singly-charged neptunyl ion, NpO_2^+, with symmetrical linear bonding $(O\text{-}Np\text{-}O)^+$. It hydrolyses only at a pH of greater than 7, disproportionates only at high-acid concentrations, and

forms no poly-nuclear complexes (Keller 1971). NpO_2^+ ion complexes only weakly with inorganic ligands.

3.2.2. Precipitation and Coprecipitation

In an oxidizing environment, Np solids in an increasing order of stability are $Np(OH)_4$, NpO_2, $NpO_2(OH)_2$. Because NpO_2 can maintain a very high concentration of Np in solution, it is unlikely that NpO_2 would be found as a discrete solid in terrestrial environments. It may exist in very reducing conditions as a solid.

3.2.3. Sorption

A singly charged neptunyl ion, NpO_2^+, is likely the dominant species of Np in the oxidizing environment of the Hanford vadose zone (Ames and Rai 1978). NpO_2^+ does not compete favorably with Ca^{2+} and other common divalent ions for adsorption sites on sediments; consequently, Np-K_d values are usually relatively low (Routson et at. 1976, Sheppard et al. 1976). Benson (1961) examined Np sorption to 25 common sulfide, silicate, and carbonate minerals using trace amounts of Np in Columbia River water at 80°C. Neptunium was adsorbed poorly or not at all by the minerals tested. Robertson (1974) determined the speciation of Np in the cooling water effluent from the Hanford N Reactor. Through the use of ultrafiltration and cation and anion exchange resins, the following distribution was observed: 25% particulate, 70% cationic, <3% anionic, and <1% non-ionic. The fact that Np may become associated with a particulate phase may have significant ramifications regarding the potential role of subsurface mobile colloids in enhancing contaminant transport. A few studies have been conducted to evaluate the propensity of Np to adsorb to Hanford sediments (Rouston et al. 1976, Serne et al. 1993). Their results suggest low-to-moderate adsorption and are included in this data package.

A singly charged neptunyl ion, NpO_2^+, is likely the dominant species in the oxidizing environment of the Hanford vadose zone. Neptunyl sorbs poorly to most minerals.

3.3. Selenium

^{79}Se is a long-lived fission product whose half-life is not well established. One estimate is 6.5×10^4 years but the value may be as much as ten times larger. ILAW is monitoring current efforts to resolve the half-life issue. ^{79}Se is commonly found as a fission product in spent fuel elements. The stable, nonradioactive form of Se is ubiquitous, especially in the western U.S. sediments. After nonradioactive Se was found to be the cause of reduced fecundity of migrating birds in the mid-1980s, much research was directed at understanding the environmental fate of Se.

3.3.1. Aqueous Speciation

Selenium exists in natural aqueous environments in –2, +4, and +6 valence states. Most of the Se species in natural waters exist as anions: selenate [Se(VI)] or selenite [Se(IV)]. Under reducing conditions, H_2Se^0 would dominate below pH 3.8 and HSe^- would dominate above pH 3.8 (Rai and Zachara 1984). The selenite species would predominate under intermediate to slightly oxidizing conditions. Highly oxidizing conditions (pe + pH >15) are necessary for SeO_4^{2-} to form to a significant extent. Selenate and selenite may form ion-pair species with Ca^{2+}. Solid phases in order of increasing solubility are $FeSe_2$, FeSe, and CuSe (Rai and Zachara 1984). However, the solubility product K_{sp}, for $FeSe_2$ or the other compounds are not well-defined.

3.3.2. Precipitation and Coprecipitation

Although several solid phases (such as $FeSe_2$) are predicted to be stable under relatively reducing conditions, and some studies indicate precipitation may be occurring, no definitive information on solubility-controlling solids is available. $Fe(OH)_4SeO_3$ was proposed (Geering et al. 1968) to help explain the insolubility of Se in soils as well as the strong association of Se with Fe in precipitates. Benjamin and Bloom (1981) observed that metal ion adsorption onto amorphous iron oxyhydroxides was enhanced in the presence of an Fe-Se solid phase adsorbed on the oxyhydroxide surface. Benjamin and Bloom (1981) observed that selenite was irreversibly adsorbed on crystalline iron oxide surfaces (goethite, hematite). As mentioned in the Iodide section, recent laboratory tests where glass doped with anionic forms of Se, I, and Tc were weathered in water show that significant masses of these elements are incorporated into secondary minerals (clays and zeolites) that form. Thus ignoring co-precipitation and/or specific adsorption of these elements in the vault region may significantly over-estimate the transport and dose calculations in the 2001 ILAW PA. However, until we gain a better understanding of the glass weathering products, their long-term stability, and the incorporation process(es), we will not take credit for these retention processes until the 2003 ILAW PA.

3.3.3. Sorption

Laboratory studies indicate that, in spite of their anionic nature, selenite and selenate may be adsorbed significantly by some soils. The experimental evidence suggests that crypto-crystalline and amorphous forms of SiO_2, Al_2O_3, and Fe_2O_3 control Se adsorption (John et al. 1976, Singh et al. 1981). Studies with pure mineral phases demonstrate that hydrous oxides of Fe and Al and amorphous aluminosilicates have a high affinity for Se(IV, VI) (Leckie et al. 1980, Hingston et al. 1968), which significantly exceeds that of layer lattice silicates (Frost and Griffin 1977, Hamdy and Gissel-Nelson 1977). (Singh et al. 1981). Selenate may be adsorbed more strongly by clay minerals than selenite (Frost and Griffin 1977), while the inverse applies to hydrous oxides of Fe (Leckie et al. 1980, Benjamin and Bloom 1981).

Though selenite (pK_2:7.9) and selenate (pK_2:1.7) differ appreciably in their acidity, little difference is seen in their adsorption by soil.

The adsorption of Se(IV) and Se(VI) on goethite, amorphous iron oxyhydroxide, and gibbsite is strongly pH dependent (Hingston et al. 1968, Leckie et al. 1980, Hingston et al. 1972). The anions are strongly sorbed under acidic conditions, but sorption decreases with increasing pH. Limited experimental evidence suggests that, at a given pH, Se adsorbs to neutral and positively charged amphoteric oxide surfaces displacing water, hydroxyls, and other adsorbed ligands (e.g., sulfate, silicate) until the surface is neutral in charge (Rajan 1979).

The presence of competing anions may reduce Se(IV) and Se(VI) adsorption by using limited ligand exchange sites and reducing surface net positive charge. Phosphate reduces Se adsorption on goethite, though some sites are specific to Se (Hingston et al. 1971). Sulfate reduces SeO_4^{2-} adsorption on amorphous iron oxyhydroxides in a manner consistent with the competitive Langmuir equation (Leckie et al. 1980). The Se adsorption tests using Hanford-specific sediments and groundwater/alkaline leachates are described in this data package.

3.4. Technetium

All isotopes of Tc are radioactive. Several Tc isotopes are obtained by the fissioning of nuclear fuels of U in the reactor. The Tc isotopes and their yields resulting from U fission include: ^{99}Tc, 6.06%; ^{101}Tc, 5.6%; ^{102}Tc, 4.3%; ^{103}Tc, 3.0%; ^{104}Tc, 1.8%; ^{105}Tc, 0.9%; and ^{106}Tc, 0.19%. Of these fission products, only ^{99}Tc is a potential hazard from long-term burial of ILAW, because this isotope has a long half-life (2.12×10^5 years).

3.4.1. Aqueous Speciation

Technetium exists in valence states from (VII) to (-I). The most stable and characteristic oxidation state of Tc in slightly acid, neutral, or basic aqueous solutions in equilibrium with the atmosphere is pertechnetate ion (TcO_4^-) in which Tc is in the heptavalent state (Coughtrey et al. 1983, Hanke et al. 1986). Various Tc(V), Tc(IV), or Tc(III) species may be formed under reduced conditions (Pilkington 1990). However, the most stable of these reduced oxidation states is generally Tc(IV) (Bondietti and Francis 1979). The nature of the Tc(IV) species is uncertain: the most common species is TcO_2(s) (Bondietti and Francis 1979, Gu and Schulz 1991). The reduced Tc species are rapidly oxidized to Tc(VII) by atmospheric oxygen (Coughtrey et al. 1983), and therefore, regardless of the oxidation state of the Tc emanating from the near field, it is likely to be in the (VII) oxidation state once it reaches the far field.

Pertechnetate ion is highly soluble (Baes and Mesmer 1976, Pilkington 1990). In alkaline solutions and a low redox potential, the Tc(IV) species are more prevalent and its complexes are typically much less soluble, on the order of 10^{-7} to 10^{-8} mol L^{-1} over a range from pH 4 to 10 (Pilkington 1990). The solubility of Tc in contact with hydrated TcO_2 was investigated by Pilkington (1990). He found that pH had little effect on measured solubility of Tc over the pH range of 1 to 12.5. However, the presence of organic materials increased the measured solubility of Tc by a factor of 10, indicating that complexation between the dissolved organic materials and the Tc is important. Wildung et al. (1986) suggested that low molecular

weight organic ligands may increase the solubility of reduced forms of Tc, whereas complexation with the high molecular weight organic ligands, particularly insoluble organic ligands, may lead to precipitation. Schulte and Scoppa (1987) showed that Tc(IV) had a strong tendency to coordinate with ligands containing highly polar groups and negatively charged ligands.

3.4.2. Precipitation and Coprecipitation

Precipitation of TcO_4^- - containing solids is not likely to be an important geochemical process affecting ^{99}Tc transport through the Hanford vadose zone. Technetium(VII) forms very soluble oxides and halide complexes (Baes and Mesmer 1976). However, if Tc(VII) is reduced to Tc(IV) in the near field, it may form a number of sparingly insoluble complexes such as TcO_2 or Tc-sulfide solids. As mentioned above, the glass weathering products formed in the short-term lab tests sequester significant amounts of Tc present in the glass as the pertechnetate species. Thus ignoring this removal process in the 2001 ILAW PA would appear to be adding a level of conservatism to the final predictions.

3.4.3. Sorption

A number of studies have shown that retention of Tc by solid phases is related to the physicochemical properties of the solid phase (reviewed by Ames and Rai 1978, Gu and Schulz 1991). These studies indicate that systems containing low amounts of clay, organic carbon, and Al/Fe oxides show very little adsorption. Bowen (1966) reported that in oxic conditions, 90% of added TcO_4^- was readily extractable from soils and assumed to remain in solution either as the free ion or weakly adsorbed to ion-exchange sites. Similarly, Wildung et al. (1977) reported that under oxic conditions, 78 to 88% of the TcO_4^- added to the soil could be extracted easily 30 days after application. Under anaerobic conditions, Cataldo et al. (1978) reported that Tc removal from solution by soils could exceed 97% in 2 to 5 weeks.

In a study of 7 mineral soils and 27 organic soils, Sheppard et al. (1990) reported that in addition to the redox status, the organic matter content of soils plays an important role in Tc sorption. Evidence of the complexation between organic materials and Tc has also been presented by Van Loon et al. (1986). They indicated that such complexes can be readily synthesized by chemical reduction of pertechnetate in the presence of organic matter.

Reduced Tc precipitates or organic matter-Tc complexes are not resolubilized by the chelating agents, EDTA and DTPA, which are known to form stable Tc complexes (Stalmans et al. 1986). This would indicate that EDTA and DTPA complexes are not as strong as the Tc-organic matter complexes, suggesting that naturally occurring organic matter may play a significant role in Tc transport by forming relatively stable Tc complexes. Whether these complexes are soluble or insoluble, depends on the size of the organic ligand. It is not known whether the

Retention of Tc is largely determined by the oxidation states of the system, due to the vast difference in the solubility between Tc(VII) and Tc(IV) containing compounds; Tc(VII) is retained appreciably less than Tc(IV).

organic matter – Tc(IV) complexation reaction can favorably compete with Tc(IV) hydrolysis reactions.

Many Hanford-specific adsorption studies with Hanford sediments and waters under oxidizing conditions have been performed and they generally show no adsorption of the pertechnetate anion. Specifics are found in this data package mainly in the tables found in Section 5.

3.5. Uranium

The natural abundance of U in geologic matter is about 3 mg/kg (Ames and Rai 1978). Naturally occurring U typically contains 99.283% ^{238}U, 0.711% ^{235}U, and 0.0054% ^{234}U by weight. Geologically, U occurs as U(IV) in minerals such as pitchblende, uraninite, carnotite, autunite, and as U(VI) in uranophane. It is also found in phosphate rock, lignite, and monazite sands at levels that can be commercially recovered. In the presence of lignite and other sedimentary carbonaceous substances, U enrichment in nature is believed to be the result of U reduction to form insoluble precipitates, such as uraninite. The U isotopes of interest in waste disposal and their respective half-lives include: ^{233}U, 162,000 years; ^{234}U, 247,000 years; ^{235}U, 7.13×10^8 years; ^{236}U, 2.39×10^7 years; and ^{238}U, 4.51×10^9 years.

3.5.1. Aqueous Speciation

Uranium can exist in the (III), (IV), (V), and (VI) oxidation states. The aqueous U(VI) uranyl cation (UO_2^{2+}) is the most stable ion in oxidizing solutions. The U(III) species easily oxidizes to U(IV) under most reducing environmental conditions, while the U(V) aqueous species (UO_2^{+}) readily disproportionates to U(IV) and U(VI). In aqueous systems, U(IV) species will not be present to any great extent as a result of the low solubilities of U(IV) species, such as uraninite (UO_2) or some other solids with O/U ratios between 2.3 and 2.7 (Bruno et al. 1988, Bruno et al. 1991). Average U concentrations in natural waters under reducing conditions are between 3 and 30 ppb (Bruno et al. 1991); this is consistent with equilibrium concentrations controlled by UO_2(s) (Bruno et al. 1988). In the absence of complexing agents, U(IV) is expected to hydrolyze to form mononuclear hydroxo complexes, $U(OH)_n^{4-n}$ (Langmuir 1978). Complexation of (IV) actinides with natural organic humic and fulvic acids has been suggested as an important process (log K = 12 to 16; Birch and Bachofen 1990). Hence, U(IV) could form stable organic complexes, increasing the solubility of the U(IV). In general, (IV) actinides species form stronger organic complexes than do the (VI) actinides species (Birch and Bachofen 1990).

Aqueous U(VI) or uranyl, UO_2^{2+}, tends to form strong complexes with inorganic oxygen-containing ligands such as hydroxide, carbonate, and phosphate. Aqueous UO_2^{2+}, hydrolyses to form a number of aqueous hydroxo complexes including UO_2OH^{+}, $(UO_2)_2(OH)_2^{2+}$, $(UO_2)_3(OH)_5^{+}$, and $UO_2(OH)_3^{-}$. In aqueous systems equilibrated with air or higher pCO_2 waters at near neutral to high pH, the carbonate complexes [$UO_2CO_3^0$, $UO_2(CO_3)_2^{2-}$, $UO_2(CO_3)_3^{4-}$] will dominate, but at lower pH the hydrolysis species will dominate as CO_2 solubility decreases.

Phosphate-UO_2^{2+} complexes ($UO_2HPO_4^0$, $UO_2PO_4^-$) could be important in aqueous systems with a pH between 6 and 9 when the total concentration ratio $(PO_4^{3-}{}_{Total}/CO_3^{2-})_{Total}$ is greater than 10^{-1} (Sandino and Bruno 1991, Langmuir 1978). Complexes with SO_4^{2-}, F^-, and possibly Cl^- are potentially important U(VI) species where concentrations of these anions are high. However, their stability is considerably less than that of the carbonate and phosphate complexes (Grenthe 1991). Because of the high hydroxide, high carbonate, and low organic matter concentrations expected in both the near and the far field of the Hanford ILAW disposal sites, U(VI) is likely to exist as a complexed carbonate and/or to a lesser extent, as a hydroxide-complexed species.

3.5.2. Precipitation and Coprecipitation

Precipitation or coprecipitation of a solid phase will likely not control the mobility of U(VI) in the far field vadose zone. However, reduced conditions may be created in the near field that may maintain the waste U as a uraninite precipitate, $UO_2(s)$, (Rai et al. 1990). Uranium is also sequestered in the glass weathering products formed in short-term laboratory experiments such that coprecipitation reactions in the glass vault should be considered in the 2003 ILAW PA after more quantitative data are available. Besides determining the "loading" capacity of the weathering products for U and other contaminants, the long-term stability of the weathering products needs to be established. U(VI) insoluble compounds also appear to control solution concentrations of U in cementitious environments (see Brady and Kozak 1995, Krupka and Serne 1998, and Serne et al. 1996).

3.5.3. Sorption

Uranium is most mobile in oxidizing, carbonate-rich solutions. Therefore, under these conditions, one would anticipate that U would be most soluble. However, other secondary factors may affect the mobility as well. For example, in low ionic strength solutions, the uranyl ion concentrations will probably be regulated, in part, by cation-exchange adsorption process. The uranyl ion will adsorb onto clays, organics, and oxides, and this will limit its mobility. As the ionic strength of an oxidized solution increases, other ions, notably Ca^{2+}, Mg^{2+}, and K^+ will displace the uranyl ion, forcing it into solution. Not only will other cations out compete the uranyl ion for exchange sites, but carbonate ions will form strong soluble complexes with the uranyl ion, further lowering its affinity for positively charged solids while increasing the total amount of U in solution (Yeh and Tripathi 1991). The anionic uranyl-carbonate complexes do not adsorb to the naturally negatively-charged Hanford sediments at neutral to alkaline pH conditions.

The uranyl ion is particularly mobile in high-ionic-strength solutions such is expected to exist in the plume emanating from the Hanford LLW burial site.

Some of the sorption processes in which uranyl ion participates are not completely reversible. Sorption onto iron and manganese oxides can be a major process for extraction of U from solution. These oxide phases act as a short-term irreversible sink for U in soils. Uranium bound in these phases is not generally in isotopic equilibrium with dissolved U in the same

system, suggesting that the reaction mediating the transfer of the metal between the two phases is slow.

Solid phase organics are another possible sink for uranyl ions in soils, and to smaller extents, in sediments. The mechanisms for U sequestration onto organic-rich sediments are numerous and complex. One mechanism may involve sorption of the uranyl cation onto exchange sites such as carboxylic acid groups. These groups can coordinate with the uranyl ion, displacing water of hydration and form stable complexes. A process such as this probably accounts for a significant fraction of the organically bound U in soils, and perhaps, in sediments. Alternatively, sedimentary organics may reduce dissolved UO_2^{2+} species to U(IV) species. These reduced species are generally low in solubility and may remain associated with the organic phase after precipitation as a reduced oxide. Little seems to be known about the nature of organic-U associations in soils or sediments on a molecular level, although several different types of interactions may be taking place. The amount of naturally-occurring organic substances, such as fulvic and humic acids, is quite low in the subsurface of the Hanford Site. However, there is a possibility that the contaminant plume leaving the near-field may contain some organic substances (sulfur polymer cement contains 5% organic binder and asphalt also may be used in covers). Both of these engineered materials possess some of chemical properties of the naturally-occurring organic substances found in natural systems.

Uranium sorption to iron oxides and smectite clay has been shown to be extensive in the absence of CO_3^{2-} (Kent et al. 1988, Hsi and Langmuir 1985, Ames et al. 1982). In the presence of CO_3^{2-} and organic complexants, however, sorption was shown to be substantially reduced or severely inhibited (Hsi and Langmuir 1985, Kent al. 1988, Ames et al. 1982). The importance of U(VI) sorption to inorganic solid phases, such as clays and iron oxides, may be minor in many natural environments because of the limited quantity of these materials and because of the presence of particulate or dissolved organic matter and dissolved carbonate.

Rancon (1973) studied the adsorption of U using four soils and three pure phase minerals. Quartz was characterized as inert (K_d = 0 mL/g), calcite was a poor U adsorber (K_d = 7 mL/g), and illite and other 2:1 clays (K_d = 139 to 270 mL/g) were the best adsorbers of U from solution. Acid, organic-rich soils showed higher U sorption (K_d = 33 mL/g) than soils containing carbonate minerals (K_d = 16 mL/g).

Formation of complexes between U(VI) and organic ligands such as humic and fulvic particulates has been studied most frequently because of interest in ore-forming environments. At ambient temperatures (~25 ^{0}C), U is adsorbed to humic substances through rapid ion-exchange and complexation processes with carboxylic and other acidic functional groups (Idiz et al. 1986, Boggs et al. 1985, Shanbhag and Choppin 1981, Nash et al. 1981, Borovec et al. 1979, Szalay 1964). The adsorption is often followed by reduction to the U(IV) species followed by precipitation of UO_2 (Andreyev and Chumachenko 1964). In studies with lignite, however, the uranyl species formed a stable complex with the lignite without subsequent reduction; reduction only occurred at elevated temperatures (Nakashima et al. 1984). However, organic matter does have the capacity to act as a reductant, most notably because of the presence of quinone, sulfone, and reduced metal porphyrin (tetrapyroles) moieties (Macalady et al. 1986).

4.0 Approach

The geochemical data for both the far field and the near field were organized into five look-up tables, one for each environmental zone that was chosen to represent the ILAW pathway from the glass repository to the Columbia River. The concept and features of these five geochemical zones are presented in Table 1. A schematic representation of the five zones is presented in Figure 2. Each look-up table contains "empirical" K_d values and/or solubility data. For each contaminant in each environmental zone, a most-probable estimate, a reasonable lower-bounding estimate, and a likely range of estimates are provided. The distribution for all contaminant specific K_d and solubility parameters is assumed to be log normal for stochastic modeling. For each data entry, comments and references are provided to support the values.

Geochemical data will be organized into a number of look-up tables containing K_d values and/or solubility data for five environmental zones.

Whenever possible, the estimates provided in these tables were based on Hanford site-specific experiments. Generic literature or off-site data was used when site-specific data were not available. Careful selection of generic literature K_d values was required to ensure that the experimental conditions used to generate the K_d values were appropriate for the Hanford-specific zones. Consequently, expert opinion and geochemistry experience was utilized where non-site specific data was used; rationale and experimental evidence to support the expert opinion is provided. In some cases there was no generic data available and we were forced to use "expert judgement" to estimate values. The estimated values that have no actual measurements to defend the choices are marked.

Based on borehole 299-E17-21, the stratigraphy below the ILAW disposal site has two sequences, a sand-dominated sequence that exists from about 0- to 75-m depth and a gravel-dominated sequence that exists from about 75- to >475-m depth (Reidel et al. 1998). The sand-dominated sequence has essentially no gravel, except for a few gravel lenses (Reidel et al. 1998). The gravel-dominated sequence consists of about 90% gravel. Gravel-corrected K_d values (g in Equation 6 = 0.9) were used for radionuclides in the gravel-dominated layers (Zones 4 and 5 in Table 1). Little information is available about the properties and distribution of a mud layer that may exist within the gravel-dominated sequence at about 13- to 30-m below the water table (125- to 142-m below surface). Unique K_d values will not be assigned to this potential layer. This is a conservative simplification because reducing (sulfide odor is associated with core samples) clays in this zone, likely have a large sorption capacity as a result of a large cation-exchange-capacity (CEC) and surface area, and large potential for reductive precipitation. If this reducing mud layer was found to be present in a large area underneath the ILAW sites it would warrant more attention, especially for the fate of the high-dose redox-sensitive contaminants, such as Tc, U, Np, and Se discussed in Section 3.

Table 1. Conceptual features of the five geochemical zones

Zone (Data Table)	Solid Phases	Aqueous Phase	Geo-chemical Parameters Used in Zone
Zone 1 – Near Field (Table 2)	Glass, secondary phases formed from glass degradation, and backfill and engineered barrier materials	Glass leachate: high pH, high ionic strength, high radionuclide concentrations	Kd, solubility constraints
Zone 2 – Degraded Concrete Vault (Table 3) As of 12/01/99 this Zone may not be relevant in future repository design.	Three assemblages of minerals will exist, based on concrete age; fresh concrete with pH = 12.5, moderately aged concrete with pH ~10.5, and completely aged concrete with pH ~ 8.5.	Three types of concrete leachate chemistries controlled by different aged solid phases: young concrete leachate pH 12.5, then pH 10.5, final pH 8.5; generally high in ionic strength and high radionuclide concentration	Kd, solubility constraints
Zone 3 – Chemically Impacted Far Field in Sand Sequence (Table 4)	Sand-dominated sequence, slightly altered due to contact with moderately caustic aqueous phase	pH 8 (background) to 11, ionic strength 0.01 (background) to 0.1, low radionuclide concentration	Kd
Zone 4 – Chemically Impacted Far Field in Gravel Sequence (Table 5)	Same as Zone 3 except in gravel-dominated sequence	Same as Zone 3 except in gravel-dominated sequence	Kd_{gc}
Zone 5 – Far Field in Gravel Sequence (Table 6)	Unaltered Hanford gravel sequence (90% gravel, 10% <2-mm)	Unaltered Hanford groundwater except for trace levels of radionuclides	Kd_{gc}

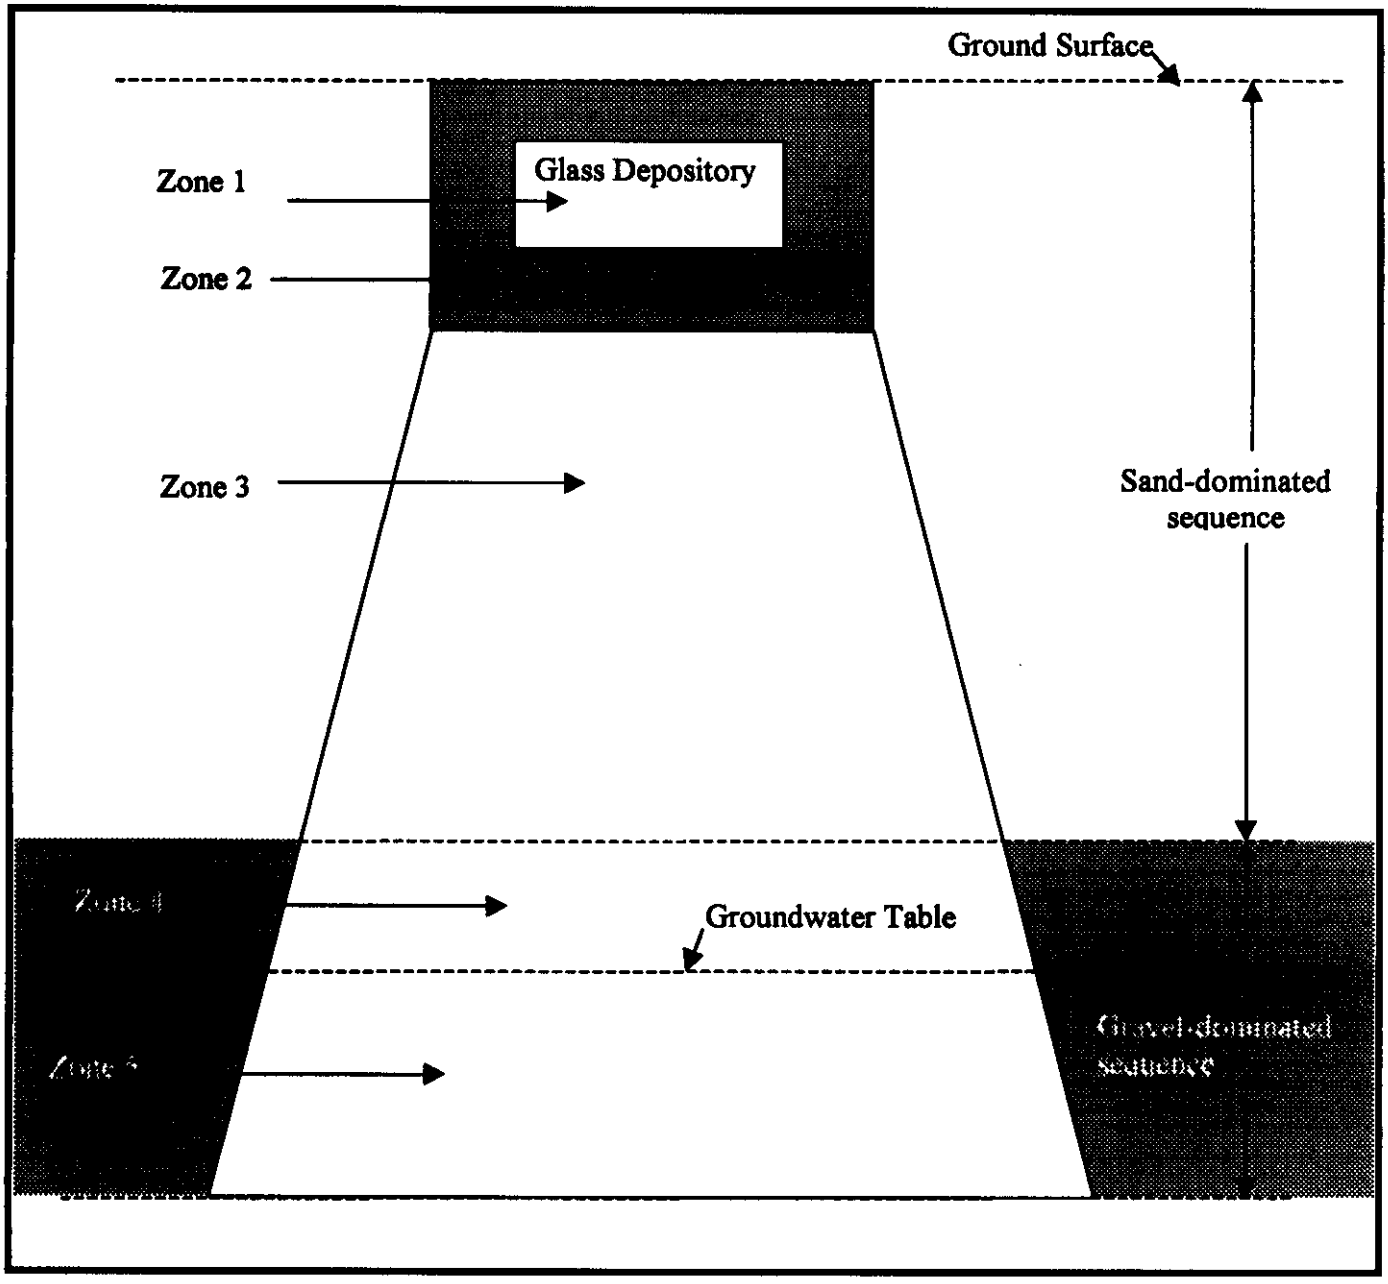

Figure 2. Schematic representation of the five geochemical zones.

The conceptual details of each of the five geochemical zones is described below.

1. Near Field: The chemistry in this zone is dominated by the presence of glass leachate until all the glass has dissolved. Glass leachate has high pH, ionic strength [especially soluble Na], and radionuclide activity. Radionuclide behavior in this zone is affected by unique solid phases dominated by glass, its weathering products, and backfill/engineered barrier materials. Initially, little or no contaminant adsorption will be considered on the glass. As reaction time

increases, radionuclides will be incorporated, coprecipitated, into secondary phases formed from glass-dissolution. Accounting for these processes will be closely linked with the glass waste-form leaching data package [see McGrail et al. 1999]. For the 2001 ILAW PA no credit will be taken for the coprecipitation of contaminants into the weathered glass secondary phases because we have not obtained adequate quantitative data for secondary minerals formed on the new BNFL glass formulations. We have also not determined the long-term stability of the weathering products found in the short-term hydrothermal [90 °C] tests. However, it seems clear from past [see Mattigod et al., 1998] and on-going studies on secondary phases formed from weathering other glass recipes that the coprecipitation process for trace contaminants into the zeolites and clays that form is significant. We have not presently finished determining how to take the empirical observations and generate mathematical algorithms for inclusion in the near-field transport code. Laboratory studies on determining the nature of the weathering products and trace contaminant sequestration amounts have been underway since early FY99 (Mattigod et al. 1998). Adequate data should be available for the 2003 ILAW PA.

2. Degraded Concrete Vault: Note that as of 12/01.99 the ILAW repository may not include concrete vaults; however crushed cement may still be used in the near field for pH control. The chemistry in this zone is dominated by the presence of cement leachate and weathered cement minerals/compounds, which have high pH, moderate ionic strength, and high to moderate radionuclide activity. The cement leachate chemistry will change with time as the concrete degrades and weathers. The assemblage of secondary minerals that form is different from that formed from glass degradation; thus, the radionuclide behavior is expected to differ from Zone 1. Zone 2 will also contain backfill materials. The cement weathering time evolution discussed in Krupka and Serne (1998) and Bradbury and Sarott (1995) were used to develop lookup tables for both K_d's (onto degraded concrete/aggregate) and solubilities (in concrete porewaters and porewaters from concrete) as a function of time. Three temporal environments are being considered at present; fresh concrete with pH 12.5, moderately aged concrete with pH ~10.5, and completely aged concrete with pH ~ 8.5. It is possible that the glass leachate will maintain a basic pH condition for tens of thousands of years such that only the first two time-dependent chemistries will be experienced in the ILAW PA system conceptual model. We will rely on the 2001 ILAW PA results to refine the conceptual model for this zone.

The convention of Bradbury and Sarott (1995) for the three types of physicochemical environments that all cements and concretes progress through was used for the development of a preferred database of K_d and solubility constraints. The following text describing the three temporal environments was taken from Krupka and Serne (1998).

Temporal Environment I: This environment occurs immediately after the cement hardens and is wetted by infiltrating water. The cement pore water is characterized as having a high pH [>12.5], high ionic strength, and high concentrations of potassium and sodium resulting from the dissolution of alkali impurities in the clinker phases. The high concentration of sodium is sometimes augmented by the dissolution of inorganic salts that have been solidified and buried in the disposal facility. Hydration is still continuing during Environment I with the formation of C-S-H gel [short hand for the $CaO\text{-}SiO_2\text{-}H_2O$ amorphous material that hardens

and constitutes "cement"] and portlandite [$Ca(OH)_2$]. The composition of the cement pore fluid is at equilibrium with portlandite during this time. The duration of Environment I is relatively short when compared to the later "environments." Based on the modeling estimates discussed in Berner (1992), this environment may last for the first 100 to 10,000 years.

Temporal Environment II: During this period, the soluble salts of the alkali metals are all dissolved. The pH of the cement pore water is controlled at a value of 12.5 by the solubility of portlandite. The C-S-H and portlandite are the major solid phases present. Environment II may last for a long time. Its duration depends on how much water percolates through the system and the mass of cement present in the concrete structure. The flux of water must dissolve all the slightly soluble portlandite before this environment changes. Using the estimates from Berner (1992), this environment may last from 100-10,000 years to 1,000-100,000 years.

Temporal Environment III: The concentration of portlandite has been reduced to such an extent by this period that the solubility of C-S-H now controls the pH of the cement pore fluid. The C-S-H starts to dissolve incongruently with a continual decrease in pH. At the end of this evolution, Environment III can be conceptualized as leaving only silica (SiO_2) as the solubility control for the pore fluid pH. The ionic strength of the cement pore fluid during this period is low, and its pH is ~10 or less. For the sake of simplicity, the final end point of Environment III can be considered somewhat analogous to the geochemical conditions of the "normal" ambient soil environment. Of the three "environment" types, the duration of Environment II is thus the longest in which the pore fluid composition is influenced by the hydration and dissolution reactions of the cement components.

3. Chemically Impacted Far Field in Sand Sequence: The chemistry in this zone has been impacted by the glass and concrete leachates, such that the porewater has a moderate pH between 8 (background) and 11, a moderate ionic strength between 0.01 (background) to 0.1, and low radionuclide activity (below solubility limits). This zone contains moderately altered Hanford formation sediment. This zone starts at the outside edge of the cement vault/engineered barriers and ends at the start of the gravel-dominated sequence (Figure 2). Contaminants will be controlled primarily by adsorption and not solubility constraints. However, we will consider [for the 2003 ILAW PA] the use of solubility controls in this zone should additional information become available that supports doing so. If the glass leachate and cement/engineered barrier leachates do evolve to less basic and lower ionic strength chemical solutions at long times, then the K_d values in Zone 3 will approach those in Appendix B, K_d values for the Far field in the Sand Sequence. Appendix B shows K_d values for <2 mm sized sediments for natural Hanford groundwater.

4. Chemically Impacted Far Field in Gravel Sequence: The chemistry in this zone has been impacted by the glass and concrete leachate, such that its pore water has a moderate pH between 8 (background) and 11, a moderate ionic strength between 0.01 (background) to 0.1, and low radionuclide activity (below solubility limits). This zone exists in the gravel-dominated sequence. The K_d values in this zone will be identical to those for Zone 3, except that the K_d values are gravel corrected. If the glass leachate and cement/engineered barrier leachates do evolve to less basic and lower ionic strength chemical solutions at long times,

then the K_d values in Zone 4 will approach those for Zone 5 at some time during the PA calculation.

5. Far Field in Gravel Sequence: This zone is located below the water table and is in the gravel-dominated sequence. The groundwater is assumed to dilute the major solutes down to natural background levels. The water in this zone is assumed to be "significantly tainted" only by contaminants and not by major common constituents of the glass and/or cement/backfill leachate. Hanford groundwater is dominated by calcium and bicarbonate, and has a pH of 8 and an ionic strength of 0.005 to 0.01 M. The K_d values in the look-up table for this zone will remain constant with time. This is equivalent to assuming that the salts emanating from Zones 1 and 2 have been completely removed by the geomedia or diluted to insignificant levels when compared to natural groundwater by the time the solution reaches Zone 5. This is equivalent to assuming that the groundwater flow is sufficiently large that it will dilute the leachate to the point that no competitive effects exist from the waste form and barrier's leachates. The K_d values in zone 5 can be considered to be time invariant in our conceptual model.

5.0 Summary Tables

Geochemical input values for the five zones identified in Table 1 and Figure 2 are presented in Tables 2 through 6. For Zones 1 and 2, solubility constraints are provided for some contaminants where appropriate. If the near-field solution concentration of a contaminant is above the "Solubility Limit," the solubility value will be used to control the solution concentration; if the solution concentration is below this value, then the K_d values will be used in the retardation factor equation to calculate solution concentrations. Four K_d values are provided in each table cell: a Reasonable Conservative K_d, a "Best" estimate (or most probable) K_d, and Upper and Lower K_d Limits. The Reasonable Conservative K_d is a reasonable lower-bounding value that takes into consideration potential conditions that may enhance radionuclide migration. This estimate was usually identical to the lower value of the range. For a few situations, the lower limit was not selected as the Reasonable Conservative K_d value because the lower limit value originated from a questionable experiment or the experimental conditions used to generate the value would yield a lower value than the conditions of the zone of interest merit. The "best" estimates are presented to provide guidance on what the most likely K_d value is for a given condition. This was based primarily on some central value of the literature or laboratory K_d values and on expert judgement. The concept of using a central value, the statistics, and the raw data involved in identifying this central value were presented by Kaplan and Serne (1995) for I, Np, Se, Tc, and U. The range is provided to help in uncertainty estimates and sensitivity analyses. The distribution of K_d values within this range is assumed to be log-normal.

For the empirical solubility estimates only Reasonable Conservative and "Best" estimate (or most probable) values are given. No ranges or solubility distributions are given at this time. If the 2001 ILAW PA shows that solubility constraints are important then some effort will be undertaken to improve the uncertainty/sensitivity calculations during the 2003 ILAW PA. Finally, supporting references for the selection of the various K_d and solubility values or estimates is provided.

Table 2a. K_d values for Zone 1 – Near Field[a]

Radio-nuclide	Reasonable Conservative K_d (mL/g)	"Best" K_d (mL/g)	K_d Range (mL/g)	Justification/References [b]
^3H, Cl, I, Se, Ru, C	0	0	0 to 1.1	C, Se, Cl, and I are anionic. ^3H will move with H_2O. Ru has often been suggested as being water coincident in tank leak scenarios based on gamma borehole logging. C as carbonate in high pH tank environments is insoluble and combines with alkaline earths. To account for insolubility a K_d value > 0 is appropriate but to keep C from getting stuck permanently in this source (high impact) zone the value was set at 0 (1, 2, 3).
Tc	0.1	1	0.1 to 1.2	Non-zero Tc K_d values exist for this condition, 1.04 ± 0.02 and 1.07 ± 0.03 mL/g, were measured in Hanford sediments in high pH, high ionic strength conditions (8).
Ac, Am, Ce, Cm, Eu	2	5	2 to 10	Estimated (2, 4)
Cs	1	1.5	1 to 25	Based on observations at T-106, cesium-137 seemed to peak at about 10 ft below the base (elevation) of the tank and nitrate at about 80ft. This implies an in situ Rf of about 8 or a K_d value of about 1 or 2 mL/g during the initial tank leak. The lack of cesium in groundwater beneath tanks suggests it has not broken through. Serne and Burke (7) measured a K_d of 26 ml/g for simulated REDOX tank liquor. But the results are not consistent with inferred Cs migration using gamma borehole logging at SX tank farm (6).
Co, Ni, Nb, Np, Pa, Sn	0.1	0.2	0.1 to 4	Estimated (4).
Sr, Ra	4	10	4 to 20	Sr is known to be rather insoluble in tank liquors and does not migrate through soils in tank liquor as rapidly as other cations (4).
Th, Zr, Pb, Pu	5	10	5 to 100	Estimated (2, 4).
U	5	20	10 to 800	Kaplan et al. (5) reported U- K_d values increased from ~2 to >500 mL/g when the pH of a Hanford sediment/groundwater slurry increased from 8.3 to > 10.5. The extremely high K_d was

Table 2a. K_d values for Zone 1 – Near Field[a]

				attributed to U (co)precipitation either as uranium phases or as calcite phases. Over a 1000-year period, it is anticipated that the solutions pH of any near field would eventually decrease. Thus, over time, the K_d values would be expected to decrease as the pH increased above ~10.5 and the uranium dissolved from the solid phase.

[a] The aqueous phase has a high pH, high radionuclide concentrations, and high ionic strength; the solid phase is dominated by backfill, glass, and glass secondary phases (Table 1 and Figure 1). No gravel correction to K_d values.

Table 2b. Solubility Values for Designated Solids in Zone 1 – Near Field[a]			
Radio-nuclide	Reasonable Conservative Solubility Limit (M)	"Best" Solubility Limit (M)	Justification/References [b]
^{3}H, Cl, Tc, I, Se, Ru, C	—	—	At present, none of these contaminants have solubility constraints in glass leachate. Tc, C, Se, Cl, and I are anionic. ^{3}H is considered to be present as water. Ru may be present as the RuO_4^-.
Ac, Am, Ce, Cm, Eu,	1×10^{-7}	1×10^{-9}	Assume that glass leachate has high pH and is similar to concrete leachates. Concrete leachate solubility values can be realistically applied for hydrous oxide/metal hydroxides being the controlling solid. Solubility of these types solids are dependent almost solely on pH and nothing else in the pore fluids (1, 2, 3)
Cs	—	—	No solubility constraint is expected. But Cs could be incorporated into the glass weathering products. Ignoring this should be conservative but not overly so, seeing as adsorption will prevent Cs from reaching the water table.
Co, Ni	5×10^{-4}	5×10^{-7}	Assume that metal hydroxide is controlling solid and thus pH is the only sensitive variable. There is data for alkaline cement conditions and we will assume they hold for alkaline glass leachates (1, 2, and 3).
Nb, Np, Pa, Sn	5×10^{-4}	5×10^{-6}	Assume that metal hydroxide is the controlling solid. There is empirical data in Ewart et. al.(3) that predicts much lower than thermodynamic predictions (1, 2, 3).
Ra	1×10^{-5}	3×10^{-6}	Ra sulfate is the controlling solid. Bayless et al. (4) found no precipitation for Ra at 10^{-7} M in concrete leachate.
Sr	2×10^{-5}	1×10^{-7}	Sr carbonate forms in cements (1, 2, and 3) but for glass leachates we are not sure. These values may need to be revised or not used in order to be conservative.
Th, Zr, Pb, Pu	5×10^{-7}	1×10^{-8}	Assume solubility controlling phase of hydroxide/hydrous oxides for Th, Zr, Pu and hydroxycarbonates for Pb. There is data for Th and Pu in cement leachates under oxidizing and reducing conditions. We chose the oxidizing conditions (Ewart et al. (3)). Other assessments of these values are presented in (1,2).

Table 2b. Solubility Values for Designated Solids in Zone 1 – Near Field[a]

U	1×10^{-6}	1×10^{-7}	Two reports (1,2) discuss solubility in cements using U(VI) hydrous oxide [schoepite] and uranophane [calcium U(VI) silicate] as solubility control. Ewart et. al. (3) shows some empirical data for solubility in cement waters. Kaplan et al. (5) reported U- K_d values increased from ~2 to >500 mL/g when the pH of a Hanford sediment/groundwater slurry increased from 8.3 to > 10.5. The extremely high K_d was attributed to U (co)precipitation either as uranium phases or as calcite phases.

[a] The aqueous phase has a high pH, high radionuclide concentrations, and high ionic strength; the solid phase is dominated by backfill, glass, and glass secondary phases (Table 1 and Figure 2). No gravel correction to Kd values.
[b] References; 1 = Krupka and Serne (1998); 2 = Brady and Kozak (1995); 3 = Ewart et al. (1992); 4 = Bayliss et al. (1989); 5 = Kaplan et al. 1998a.

Table 3a. K_d Values for Zone 2 – Degraded Concrete[a]

Rad	Young Concrete (pH~12.5)			Moderately Aged Concrete (pH~10.5)			Aged Concrete (pH~8.5)			Justification/References [b]
	Conservative K_d (mL/g)	"Best" K_d (mL/g)	K_d Range (mL/g)	Conservative K_d (mL/g)	"Best" K_d (mL/g)	K_d Range (mL/g)	Conservative K_d (mL/g)	"Best" K_d (mL/g)	K_d Range (mL/g)	
^3H, Tc	0	0	0 to 2	0	0	0 to 2	0	0	0 to 1	Tc may be slightly sorbed to concrete, albeit, very little (1, 2, 3, 4, 5, and 6).
Cl	0.8	8	0.8 to 25	1	2	1 to 5	0	0	0 to 1	Estimated. French sulfate-resistant cement had a Cl K_d of 25 mL/g (7). Cl diffused through cement disks slower than ^3H (8). Cl K_d to cement powder after 24-hr contact time = 0.8 mL/g (9)
I	10	20	10 to 150	5	8	5 to 15	1	2	1 to 5	Iodide K_d values of 7 types of concrete samples increased gradually over 3 months, than leveled off to between 25 and 130 mL/g (10, 11). After 300 days contact with various cements, 77 to 98% iodide sorbed; even more iodate sorbed. I^- sorption to cement is very concentration dependent: at 10^{-8} I^- K_d = 1000 mL/g at 10^{-2} M I^- K_d = 1.4 mL/g (12). I^- sorption to cement is highly reversible (12). Iodine K_d in 7 day contact = 2.5 mL/g; after 30 days 7.7 mL/g (13).
C	10	20	10 to 1000	5	10	5 to 1000	0	0	0	Carbon-14 chemistry is complicated in cement; C (co)precipitation more important process in concrete than adsorption. See solubility discussion in Table 3b and (18).
Ac, Am, Ce Cm, Eu	2000	5000	2000 to 40000	1000	5000	1000 to 30000	400	500	400 to 1000	Trivalent metal K_d values to concrete exceed those to sediments (1). Am K_d >10,000 mL/g (14). Am K_d ~12,000 mL/g based on diffusion

Table 3a. K_d Values for Zone 2 – Degraded Concrete[a]										
										tests of cement (15). Am K_d values ranged from 2,500 to 35,000 mL/g for 7 different fresh (unaged)-concrete blends (10, 11). Am K_d for 65-yr old concrete sample = 10,000 (10, 11). Fresh cement Am-K_d = 2000 for 24-hr contact time (9). Eu-K_d = 2,400 mL/g for 24 hr contact time (9).
Co, Ni, Ra, Sn	70	100	70 to 250	70	100	70 to 250	7	10	7 to 25	Co-K_d = 4,300 mL/g (9). Ni-K_d for 3 cement types: 500 to 3000 mL/g (16), 1500 mL/g (9), and 500 to 3000 mL/g (17.
Nb, U	700	1000	700 to 2500	700	1000	700 to 2500	70	100	70 to 250	U(VI)-K_d's for 7 types of cement = 350 to 13,000, average = ~1000 and median = 1400 mL/g (10, 11)
Cs	2	3	2 to 5	20	30	20 to 50	20	30	20 to 50	Cs K_d's in hardened HTS cement discs, pH ~13.3, were 3 mL/g (7). Cs Kd's of 0.2 mL/g were measured in hardened sulfate resisting cement (12). Many authors have reported increase sorption at pH ~12.5 (13, reviewed by 23).
Np, Pa	1400	2000	1400 to 10000	1400	2000	1400 to 10000	140	200	140 to 500	The dominant protactinium species is assumed to be Pa O_2^+. NpO_2^+ is assumed to be a reasonable analog (19). Np sorption test to 7 different 65-yr old cements using cement pore water reached steady state after 30 days, Kd's ranged 1500 to 9500 mL/g (10, 11).
Ru, Se	1	2	1 to 800	1	2	1 to 100	0	1	0 to 300	Estimated. Dominant species for Se and Ru were assumed to SeO_4^{2-} and RuO_4^{2-} respectively (19). Ru K_d's in Hanford sediment (not concrete) did not change systematically with pH; at pH 8.5 the K_d was 274 mL/g; at pH 10.4, 44 mL/g; and at pH 14, 752 mL/g (21). Using a

Table 3a. K_d Values for Zone 2 – Degraded Concrete[a]

										pH 12 simulated tank waste solutions and Hanford sediment, K_d values for Ru ranged from 2.14 to 0 mL/g, averaging about 0.8 mL/g (20). Sulfate may be used as an analog for selenate chemical behavior in concrete. Sulfate (or sulfite) is often included in concrete mixes and therefore it would be expected to be retained strongly by concrete, primarily by (co)precipitation constraints. Selenate adsorption, independent of precipitation processes would be expected to be rather large.
Pb, Pu, Th	1000	5000	1000 to 10000	1000	5000	1000 to 10000	100	500	100 to 1000	Estimated. Using 3, 65 yr-old, crushed concrete samples, and 7 different fresh concrete samples, Th-K_d were 2500 to 5500 mL/g (10, 11). Th-K_d values were: consistently less than Am-K_d's, greater than U-K_d's, and very similar to Np Pu K_d's (10, 11). Pu-K_d's ranged from 1000 to 12,000 mL/g (10, 11). Concrete containing reducing agents (BFS) did not have greater Pu K_d's than those that did not contain reducing agents. The high K_d values are attributed to high solubility of Pu in high pH solutions, not to adsorption/absorption processes (22)

[a] The aqueous and solid phases in this zone are greatly influenced by the presence of concrete. The concrete is assumed to age and form three distinct environment (Krupka and Serne 1998).

[b] References: 1 = Angus and Glasser 1985; 2 = Gilliam et al. 1989; 3 = Tallent et al. 1988; 4 = Brodda 1988; 5 = Serne 1990; 6 = Serne et al. 1992; 7 = Sarott et al. 1992; 8 = Johnston and Wilmot 1992; 9 = Kato and Yanase 1993; 10 = Allard et al 1984; 11 = Hoglund et al. 1985; 12 = Atkinson and Nickerson 1988; 13 = Hietanen et al. 1985; 14 = Ewart et al 1988; 15 = Bayliss et al. 1991; 16 = Hietanen et al. 1984; 17 = Pilkington and Stone 1990; 18 = Allard et al. 1981; 19 = Pourbaix 1966; 20 = Ames and Rai 1978; 21 = Rhodes 1957a,b; 22 = Krupka and Serne 1998; 23 = Bradbury and Sarott 1992.

Table 3b. Solubility Limits for Designated Solids for Zone 2 – Degraded Concrete[a]

Rad	Young Concrete (pH~12.5)		Moderately Aged Concrete (pH~10.5)		Aged Concrete (pH~8.5)		Justification/References [b]
	Conser-vative (M)	"Best" Solubility (M)	Conser-vative (M)	"Best" Solubility (M)	Conser-vative (M)	"Best" Solubility (M)	
^{3}H, ^{36}Cl, Tc, I, Ru, Se	—	—	—	—	—	—	We will assume no solubility constraint for these species although there could be some isotope exchange into cement and secondary minerals.
C	10^{-5}	10^{-6}	10^{-3}	10^{-4}	10^{-2}	10^{-3}	Estimated. Carbon-14 chemistry is complicated in cement; C (co)precipitation more important process in concrete than adsorption. Calcite will be a good controlling solid and the carbon-14 will be isotopically exchanged with stable C For young concrete assume that portlandite controls Ca to 6×10^{-3} M. For moderately aged cement and aged cement that the Ca is controlled at 10^{-2} M by some undefined reactions.
Ac, Am, Ce, Cm, Eu	1×10^{-7}	1×10^{-9}	3×10^{-7}	3×10^{-8}	1×10^{-5}	1×10^{-7}	Known cement values can be realistically applied for hydrous oxide/metal hydroxides being the controlling solid. These solids are dependent almost solely on pH, and nothing else in the pore fluids (1, 2, and 3).
Co, Ni	5×10^{-4}	5×10^{-7}	5×10^{-4}	1×10^{-6}	1×10^{-3}	2×10^{-5}	Assume that metal hydroxide is controlling solid and thus pH is the only sensitive variable. There is data for alkaline cement conditions and predictions for groundwater (aged cement end member) (1, 2, 3).

Table 3b. Solubility Limits for Designated Solids for Zone 2 – Degraded Concrete[a]

Rad	Young Concrete (pH~12.5)		Moderately Aged Concrete (pH~10.5)		Aged Concrete (pH~8.5)		Justification/References [b]
	Conser-vative (M)	"Best" Solubility (M)	Conser-vative (M)	"Best" Solubility (M)	Conser-vative (M)	"Best" Solubility (M)	
Nb, Np, Pa, Sn	5×10^{-4}	5×10^{-6}	1×10^{-3}	5×10^{-4}	1×10^{-3}	5×10^{-4}	Assume that metal hydroxide is the controlling solid. There is empirical data in Ewart et. al.[3] that predicts much lower than thermodynamic predictions (1, 2, 3).
Cs	—	—	—	—	—	—	No solubility constraint is expected.
Ra	1×10^{-5}	3×10^{-6}	1×10^{-5}	3×10^{-6}	1×10^{-5}	3×10^{-6}	Ra sulfate is the controlling solid. Bayless et al. (4) found no precipitation for Ra at 10^{-7} M in concrete leachate.
Sr	2×10^{-3}	1×10^{-7}	2×10^{-4}	1×10^{-6}	5×10^{-3}	1×10^{-3}	Sr carbonate forms in cements (1,2,3) and could be a plausible control in sediments also.
Pb, Pu, Th, Zr	5×10^{-7}	1×10^{-8}	5×10^{-7}	1×10^{-8}	5×10^{-6}	1×10^{-7}	Assume hydroxide/hydrous oxides for Th, Zr, Pu and hydroxycarbonates for Pb. There is data for Th and Pu in cement leachates under oxidizing and reducing conditions. We chose the oxidizing conditions (3). Other assessments of Pb, Pu, Th, and/or Zr solubility under these conditions have been conducted (1, 2).

Table 3b. Solubility Limits for Designated Solids for Zone 2 – Degraded Concrete[a]

	Conser-vative (M)	"Best" Solubility (M)	Conser-vative (M)	"Best" Solubility (M)	Conser-vative (M)	"Best" Solubility (M)	
U	1×10^{-6}	1×10^{-7}	1×10^{-6}	1×10^{-7}	1×10^{-6}	1×10^{-7}	Two reports (1,2) discuss solubility in cements using U(VI) hydrous oxide [schoepite] and uranophane [calcium U(VI) silicate] as solubility control. Ewart et. al. (3) shows some empirical data for solubility in cement waters. Kaplan et al. (5) reported U-Kd values increased from ~2 to >500 mL/g when the pH of a Hanford sediment/groundwater slurry increased from 8.3 to > 10.5. The extremely high Kd was attributed to U (co)precipitation either as uranium phases or as calcite phases. Serne et al. (6) discusses solubility of U in presence of groundwater.

[a] The aqueous and solid phases in this zone are greatly influenced by the presence of concrete. The concrete is assumed to age and form three distinct environment (Krupka and Serne 1998).

[b] References; 1 = Krupka and Serne (1998); 2 = Brady and Kozak (1995); 3 = Ewart et al. (1992); 4 = Bayliss et al. (1989); 5 = Kaplan et al. (1998a); 6 = Serne et al. (1999).

Table 4. Kd Values for Zone 3 – Chemically Impacted Far Field in Sand Sequence[a]

Radio-nuclide	Reasonable Conservative K_d (mL/g)	"Best" K_d (mL/g)	K_d Range (mL/g)	Justification/References[b]
^3H, Cl, Tc	0	0	0 to 0.1	Tc and Cl are anionic. ^3H will move with H_2O.
Ac, Am, Ce, Cm, Eu	100	350	100 to 1500	Am-K_d's: In low ionic strength Ca system, >1200 mL/g; In low ionic strength Na system, 280 mL/g (1)
C	5	20	5 to 50	Estimated. ^{14}C geochemistry complex and poorly described by K_d construct. ^{14}C is expected to enter liquid, solid and gas phase through volatilization (CO_2-gas), precipitation with calcite, isotopic exchange, and adsorption. Based on Martin (9), who measured ^{14}C-K_d values in Hanford sediments using uncontaminated Hanford groundwater (relatively low ionic strength). ^{14}C as $H^{14}CO_3K_d$ values increased during a 70 day contact time from 0 (1-hr contact time) to 400 mL/g in sediment and 20 (1-hr contact time) to 360 mL/g in calcrete. ^{14}C removed by solid phases never stabilized during 70 days, suggesting (co)precipitation reaction.
Co	150	300	150 to 2000	In 0.01 to 1 M Na system, K_d is 1060 to 4760 mL/g (2) In 0.01 to 1 M Ca system, K_d is 222 to 640 mL/g (2) Forms complexes, especially with organics.
Cs	40	80	40 to 2000	Estimated. In low ionic strength Na system, K_d is 64 to 1170 mL/g (2). No complexes. In low ionic strength Ca system, K_d is 790 to 1360 mL/g (2). Unpublished recent results from Zachara (PNNL, EMSP project) using Hanford sediments and simulated tank waste indicate that Cs sorption decreases markedly compared to when ionic strength is appreciably lower.
I	0	0	0 to 2	Anion. Estimated.
Ni, Sn, Nb	40	80	40 to 400	Ni is similar to Co but adsorbs slightly less possibly because of moderate complexing. Estimated (3, 4)
Np, Pa	0.2	0.8	0.2 to 5	Np K_d's in low ionic strength solutions = 0.4 to 4 mL/g (1). The dominant protactinium species is assumed to be PaO_2^+. NpO_2^+ is assumed to be a reasonable analog (10). Based on studies conducted at the Whiteshell Laboratories (personnel communications with Tjalle T

Table 4. Kd Values for Zone 3 – Chemically Impacted Far Field in Sand Sequence[a]

				(Chuck) Vandergraaf, Atomic Energy of Canada Limited, Pinawa, Manitoba, Canada), Pa sorbs appreciably more than Np. Thus, Pa-K_d estimates based on measured Np- K_d values will be conservative.
Pb	20	100	20-1000	Good absorber, insoluble. Estimated (4).
Pu	80	200	80 to 1000	K_d is >98 mL/g (5)
Ra, Sr	0.2	10	0.2 to 50	Na system, 1.7 to 42 mL/g for Sr-K_d (2). Ca system, 0.3 to 1.6 mL/g for Sr-K_d (2). In 4 M $NaNO_3$, Sr-K_d in Hanford sediment was 5 mL/g (pH 8), and 10 mL/g (pH 10) (12). Near identical K_d values using Savannah River Site Sediments and 30% $NaNO_3$ (13). Based on periodicity considerations, Ra would be expected to sorb more strongly to sediments than Sr. However, no Hanford Ra-K_d values are available. Thus, basing Ra-K_d estimates on measured Sr-K_d values will likely provide a conservative Ra-K_d estimate.
Ru	0	1	0 to 500	May form RuO_4^{2-} and/or anionic complexes with nitrates and nitrites. Estimate (3, 6, and 7).
Se	2	4	2 to 10	Anionic. Se K_d measured at the ILAW disposal site had K_d values of 6.7 ± 0.4 mL/g (14). Unpublished results of a Se sorption experiment to Hanford sediments in high ionic strength (NaOH and $NaOCl_4$) indicate Se Kd values of ~4 mL/g.
Th, Zr	40	300	40 to 500	Sandy soil data, K_d is 40 to 470 mL/g for Th (8).
U	2	10	2 to 500	Anionic and neutral carbonate and hydroxide species. Kaplan et al. (11) reported U-K_d values increased from ~2 to >500 mL/g when the pH of a Hanford sediment/groundwater slurry increased from 8.3 to > 10.5. The extremely high K_d was attributed to U (co)precipitation either as uranium phases or as calcite phases.

[a] The aqueous phase is moderately altered from the cement and glass leachate emanating from Zones 1 and 2; pH is between 8 (background) and 11, and the ionic strength is between 0.01 (background) and 0.1. The solid phase is in the sand-dominated sequence and is slightly altered due to contact with the moderately caustic aqueous phase (Table 1 and Figure 2).

Table 5. Gravel-corrected Kd Values (Kd_{gc}) for Zone 4 – Chemically Impacted Far Field in Gravel Sequence[a]

Radio-nuclide	Reasonable Conservative Kd_{gc} (mL/g)	"Best" Kd_{gc} (mL/g)	Kd_{gc} Range (mL/g)	Justification/References [b]
^3H, Cl, Tc	0	0	0 to 0.01	No gravel-corrected K_d data available. Tc and Cl are anionic. ^3H will move with H_2O.
Ac, Am, Ce, Cm, Eu	10	35	10 to 150	No gravel-corrected K_d data available. Am-K_d's: In low ionic strength Ca system, >1200 mL/g; In low ionic strength Na system, 280 mL/g (1)
C	0.5	2	0.5 to 5	Estimated. No gravel-corrected K_d data available. ^{14}C geochemistry complex and poorly described by K_d construct. ^{14}C is expect to enter liquid, solid and gas phase through volatilization (CO_2-gas), precipitation with calcite, isotopic exchange, and adsorption. Based on Martin (9), who measured ^{14}C-K_d values in Hanford sediments using uncontaminated Hanford groundwater (relatively low ionic strength). K_d values increased during a 70 day contact time from 0 (1-hr contact time) to 400 mL/g in sediment and 20 (1-hr contact time) to 360 mL/g in calcrete. ^{14}C removed by solid phases never stabilized during 70 days, suggesting (co)precipitation reaction.
Co	15	30	15 to 200	No gravel-corrected K_d data available. In low ionic strength Na system, 1060 to 4760 mL/g (2) In low ionic strength Ca system, 222 to 640 mL/g (2) Forms complexes, especially with organics.
Cs	4	8	4 to 200	No gravel-corrected K_d data available. No complexes. Estimated. In 0.01 to 0.1 M Na system, 64 to 1170 mL/g (2). In 0.01 to 0.1 M Ca system, 790 to 1360 mL/g (2). Unpublished recent results from Zachara (PNNL, EMSP project) using Hanford sediments and simulated tank waste indicate that Cs sorption decreases markedly compared to when ionic strength is appreciably lower.
I	0	0	0 to 0.2	No gravel-corrected K_d data available. Anion. Estimated.
Ni, Sn, Nb	4	8	4 to 40	Ni is similar to Co but adsorbs slightly less possibly because of moderate complexing. Estimated (3, 4)

Table 5. Gravel-corrected Kd Values (Kd_{gc}) for Zone 4 – Chemically Impacted Far Field in Gravel Sequence[a]

Np, Pa	0.02	0.08	0.04 to 0.5	No gravel-corrected K_d data available. Np K_d's in low ionic strength solutions = 0.4 to 4 mL/g (1). The dominant protactinium species is assumed to be PaO_2^+. NpO_2^+ is assumed to be a reasonable analog (10). Based on studies conducted at the Whiteshell Laboratories (personnel communications with Tjalle T (Chuck) Vandergraaf, Atomic Energy of Canada Limited, Pinawa, Manitoba, Canada), Pa sorbs appreciably more than Np. Thus, Pa-K_d estimates based on measured Np- K_d values will be conservative.
Pb	2	10	2 to 100	No gravel-corrected K_d data available. Good absorber, insoluble. Estimated (4).
Pu	8	20	8 to 100	No gravel-corrected K_d data available. >98 mL/g (5)
Ra, Sr	0.02	1	0.02 to 5	Na system, 1.7 to 42 mL/g for Sr-K_d (2). Ca system, 0.3 to 1.6 mL/g for Sr-K_d (2). In 4 M $NaNO_3$, Sr-K_d in Hanford sediment was 5 mL/g (pH 8), and 10 mL/g (pH 10) (12). Near identical K_d values using Savannah River Site Sediments and 30% $NaNO_3$ (13). Sr-K_d values measured in low ionic strength conditions and with Hanford sediments containing sediments are presented in Appendix A. Based on periodicity considerations, Ra would be expected to sorb more strongly to sediments than Sr. However, no Hanford Ra-K_d values are available. Thus, basing Ra-K_d estimates on measured Sr-K_d values will likely provide a conservative Ra-K_d estimate.
Ru	0	0.1	0 to 50	No gravel-corrected K_d data available. May form RuO_4^{2-} and/or anionic complexes with nitrates and nitrites. Estimate (3, 6, and 7).
Se	0.2	0.4	0.2 to 1	No gravel-corrected K_d data available. Anionic. Se Kd measured at the ILAW disposal site had K_d values of 6.7 ± 0.4 mL/g (14). Unpublished results of a Se sorption experiment to Hanford sediments in high ionic strength (NaOH and $NaOCl_4$) indicate Se K_d values of ~4 mL/g.
Th, Zr	4	30	4 to 50	No gravel-corrected K_d data available. Sandy soil data, 40 to 470 mL/g for Th (8).
U	0.2	1	0.2 to 50	No gravel-corrected K_d data available. Anionic and neutral carbonate and hydroxide species. Kaplan et al. (11) reported U-Kd values increased from ~2 to >500 mL/g when the pH of a Hanford sediment/groundwater slurry increased from 8.3 to > 10.5. The extremely high Kd was attributed to U (co)precipitation either as uranium phases or as calcite phases.

[a] The aqueous phase is moderately altered from the cement and glass leachate emanating from Zones 1 and 2; pH is between 8 (background)

Table 5. Gravel-corrected Kd Values (Kd_{gc}) for Zone 4 – Chemically Impacted Far Field in Gravel Sequence[a]

and 11, and the ionic strength is between 0.01 (background) and 0.1. The solid phase is in the sand-dominated sequence and is slightly altered due to contact with the moderately caustic aqueous phase (Table 1 and Figure 2).

[b] References: 1 = Routson et al. 1976; 2 = Routson et al. 1978; 3 = Ames and Serne 1991; 4 = Kaplan et al. 1995; 5 = Rhodes 1957a, b; 6 = Ames and Rai 1978; 7 = Barney 1978; 8 = Sheppard et al. 1976; 9 = Martin 1996; 10 = Pourbaix 1966; 11 = Kaplan et al. 1998a; 12 = Rhodes and Nelson 1957; 13 = Prout 1959; 14 = Kaplan et al. 1998c.

Table 6. Gravel-corrected Kd Values (Kd_{gc}) for Zone 5 – Far Field in Gravel Sequence[a]

Radio-nuclide	Reasonable Conservative Kd_{gc} (mL/g)	"Probable" Kd_{gc} (mL/g)	Kd_{gc} Range (mL/g)	Justification/References[b]
^3H, Cl, Tc	0	0	0 to 0.06	No laboratory results of gravel-K_d values available. Tc exists predominantly as TcO_4^-. A review of Hanford sediment Tc-K_d values showed a range of -2.8 to 0.6 mL/g for 15 observations; median was 0.1-mL/g (1). Later studies did not change this range but did decrease the median slightly to -0.1 mL/g (2). Negative K_d values are possible and may not be an experimental artifact (2). ^3H is expected to move along with water. Cl is expected to behave as a dissolved anionic species. Most recent results using ILAW specific borehole sediments [299-E17-21] yielded Tc-K_d of 0 mL/g (18). Gravel correction of negative K_d values in Estimated K_d Range was assumed to make Kd less negative by a factor of 0.9 because of reduced surface area that would create the anion exclusion.
Ac, Am, Ce, Cm, Eu	6	30	6 to 130	No laboratory results of gravel-K_d values available. Am-K_d: 67 to >1200 mL/g (3). Am-K_d: 125 to 833 mL/g (4)
C	0.05	0.5	0.05 to 100	No laboratory results of gravel-K_d values available. Assumed dominant species: HCO_3^-. Three processes will be acting on the ^{14}C to take it out of solution: adsorption onto the calcite surface, volatilization as CO_2 gas, and precipitation into the calcite structure. The latter process is largely irreversible, therefore it is not well represented by the K_d construct (K_d assumes that adsorption occurs as readily as desorption). Volatilization is entirely removed from the definition of the K_d construct. In systems that contain higher concentrations of carbonate minerals, such as the calcrete layer in the 200 West Area, an appreciably higher K_d should be used to account for the isotopic dilution/precipitation reaction that may occur, a K_d of 100 mL/g would be appropriate for such a system. Since most of the 100 and 200 plateau areas contain <1% carbonate, lower K_d values are warranted for these areas, such as 0.5 mL/g. K_d values of ^{14}C of >250 mL/g have been measured in calcite ([5]). At 100K Area, the C-14 is widely distributed down gradient from a major source (crib). Additional references: 6, 7, 8, 9, and 10. Estimated range.

Table 6. Gravel-corrected Kd Values (Kd_{gc}) for Zone 5 – Far Field in Gravel Sequence[a]				
Co	100	200	100 to 1250	No laboratory results of gravel-K_d values available. Na system, 1290 to 2120 mL/g (11); Ca system, 2000 to 3870 mL/g (11); Hanford sediment/groundwater system 11600 to 12500 mL/g (12)
Cs	50	200	50 to 400	No laboratory results of gravel-K_d values available. Na system, 1410 to 1590 mL/g (11) Hanford sediment/groundwater system, 540 to 3180 mL/g (12).). Most recent results using ILAW specific borehole sediments [299-E17-21] yielded K_d of 2,030 ± 597(18).
I	0	0.01	0 to 1.5	No laboratory results of gravel-K_d values available. A review of Hanford sediment I-K_d values showed a range of 0.7 to 15 mL/g for 9 observations; median was 0.7-mL/g (1). Later studies increased this range to 0.2 to 15 mL/g; the median was decreased to 0.3 mL/g (2). Most recent results using ILAW specific borehole sediments [299-E17-21] yielded K_d of 0 mL/g. See Kaplan et al. (18) for details.
Ni, Sn, Nb	5	30	5 to 250	No laboratory results of gravel-K_d values available. Ni: Hanford sediment/groundwater system, 440 to 2350 mL/g (12) Ni: A study of a broad range of sediments, including those from Hanford had Ni-Kd's of 50 to 340 mL/g (13).
Np, Pa	0.2	1.5	0.2 to 2.5	No laboratory results of gravel-K_d values available. A review of Hanford sediment Np-K_d values showed range of 2.4 to 21.7 mL/g for 4 observations; median was 17.8 mL/g (1). Later studies increased the K_d's to 2.2 to 21.7 mL/g; the median of these later studies was 15 mL/g (2). The dominant protactinium species is assumed to be PaO_2^+ and NpO_2^+ is assumed to be a reasonable analog (19). Based on studies conducted at the Whiteshell Laboratories (personnel communications with Tjalle T (Chuck) Vandergraaf, Atomic Energy of Canada Limited, Pinawa, Manitoba, Canada), Pa sorbs appreciably more than Np. Thus, Pa-K_d estimates based on measured Np- K_d values will be conservative.
Pb	800	1000	800 to 8000	No laboratory results of gravel-K_d values available. pH 6 and no competing ions: 13,000 to 79,000 mL/g (14)
Pu	5	15	5 to 200	No laboratory results of gravel-K_d values available. Pu(V, VI): pH 4 to 12: 80 to >1980 mL/g (17)
Ra, Sr	0.5	1.4	0.5 to 20	Sr K_d values: Na system, 173 mL/g, 49 to 50 mL/g (11), Ca system, 8 to 13 mL/g, 5 to 19 mL/g (11), 5 to 120 mL/g (15), 19.1 to 21.5 mL/g (12), Na system, pH 7 to 11, 14.9 to 25.1 mL/g (16). Recent data using ILAW borehole sediment [299-E17-21] yielded Sr-K_d values

Table 6. Gravel-corrected Kd Values (Kd_{gc}) for Zone 5 – Far Field in Gravel Sequence[a]

				of 14.3 ± 1.6 mL/g (18). See Appendix A for Sr K_d values measured with sediments containing gravel. Based on periodicity considerations, Ra would be expected to sorb more strongly to sediments than Sr. However, no Hanford Ra-K_d values are available. Thus, basing Ra-K_d estimates on measured Sr-K_d values will likely provide a conservative Ra-K_d estimate.
Ru	1	2	1 to 100	No laboratory results of gravel-K_d values available. Estimated (17 as cited in 11)
Se	0.3	0.7	0.3 to 1.5	No laboratory results of gravel-K_d values available. Hanford groundwater/sediment system: -3.44 to 0.78 mL/g (12). Most recent data using ILAW borehole sediment [299-E17-21], which did not contain measurable amounts of gravel, yielded K_d values ranging from 3.75 to 10.85 mL/g and had an average of 6.7 ± 1.9 mL/g (18).
Th, Zr	4	100	4 to 250	Estimated. No laboratory results of gravel-K_d values available. Zr: pH 6 to 12 : 90 to >2000 mL/g (15)
U	0.05	0.06	0.01 to 8	No laboratory results of gravel-K_d values available. A review of Hanford sediment U-K_d values showed range of 0.1 to 79.3 mL/g for 13 observations; median was 0.6-mL/g (1). Results from later studies support the range (2). In all reported data, some U was adsorbed by Hanford sediments and >90% of the values were between 0.6 and 4 mL/g. Most recent work with the ILAW Borehole sediment [299-E17-21] yielded K_d of 0.6 ± 0.1. See (18).

[a] The aqueous phase is untainted Hanford groundwater except for trace levels of radionuclides; the solid phase is composed of the unaltered gravel-dominated sequence material (Table 1 and Figure 2). Kd_{gc} is the gravel-corrected Kd value as defined in Equation 6. Kd values for the far field, without a gravel correction, are presented in Appendix B.

6.0 Review Process

6.1. Internal PNNL Review

Scientists from the Applied Geology and Geochemistry group that are not contributors to the ILAW project performed an internal peer review concurrent with the Hanford Review and to cover the required PNNL/DOE document clearance process. The Data Package was created in the format of a typical PNNL topical report.

6.2. Hanford Review

The Hanford Personnel who reviewed this data package are:

- Fred Mann, Fluor-Daniel Northwest
- Harry Babad, WHC retired (private consultant)
- Tom E. Jones, MacTec-Meier

We have received and addressed the comments of the Internal Hanford Review Team in the September 10, 1999 version of the document. The comments were not contentious enough to warrant a comment resolution meeting prior to submittal for review by the other Hanford organizations [DOE/BHI/LMHC].

The September 10, 1999 version of the Geochemical Data Package was then sent concurrently to DOE-RL/ORP [Richland Operations Office of River Protection], BHI, and LHMC project management for review. Their comments were minor. The Data Package was revised a second time on September 20, 1999. This revision was sent to the external review team.

6.3. External Review

We solicited review comments from external reviewers. The members of the External Review were:

- Patrick V. Brady, Sandia National Laboratory
- Steve Serkiz, Westinghouse Savannah River Company
- Tjalle T. (Chuck) Vandergraaf, Atomic Energy of Canada, Limited at Pinawa, Manitoba, Canada.

Resumes for these three reviewers are available from R. J. Serne at PNNL. The reviewers were given the Data Package and instructions on what is expected of them. After they reviewed the instructions and had all questions answered, the review process started in FY00. The three sets

of review comments were considered and our responses to the individual questions were shared among all external reviewers. This occurred in mid-December 1999. A final review was performed by Fred Mann prior to submittal to Lockheed and DOE-RL on December 20, 1999. Each reviewer prepared comments on the electronic September 20, 1999 draft and in emails. Our responses to the main comments were prepared and an electronic file [Respon~2.doc] was circulated. The final draft of the data package December 20, 1999 and the response file will be used by the reviewers to finalize any comments. These final comments, the Respon~2.doc electronic file and the data package will become part of the public record associated with this data package.

6.4. Scope of the Work Reviewed

The reviewers (both internal and external) were given the data tables of Kd and solubility controls for each of the six geochemical zones for each contaminant, the reference to the publicly available documents that were used , and the rationale for the choice of each value. The rationale, for those values that were chosen by relying on expert judgment and generic literature, were especially clearly documented. We also prepared a general description of our overarching philosophy on approaching the selection of geochemical parameters for the ILAW PA in chapter 2. In the final version of the data package public record we will include an assessment of how satisfied we are with the technical defensibility of each selected value and a priority listing on which parameters deserve the attention of future funding. The prioritization will also include a brief discussion of the types of test that would best be performed to improve technical defensibility and what key parameters should be controlled, varied or monitored in the experimental test program.

6.5. Review Criteria

The reviewers were given all the above material and were asked to review/comment on several levels including:

- understandability of the overall geochemical approach from a "layman's " and "systems PA" approach
- technical defensibility of the overall geochemical approach (peer to peer technical comments)
- technical opinion on the particular Kd and solubility constraints provided for each geochemical zone and contaminant
- request for missing/overlooked data that the reviewers think would improve selected values
- opinion on our assessment of satisfaction of the "defensibility" for each value or contaminant's overall geochemical data base
- assessment of our choice and prioritization for future work regarding contaminants that need more study and on the type of tests to perform and what are the key parameters to vary, monitor, or control.

6.6. Schedule

TABLE 7. SCHEDULE FOR GEOCHEMICAL DATA PACKAGE APPROVAL

	Item	Date
1	Send Data Package Plan to Technical Representative for Review	March 30, 1999
2	Final Plan, Incorporating Comments Issued By The Tech. Rep.	April 30, 1999
3	Inform technical representative by electronic message that Kd selection of Zones 3, 4, 5 and 6 have been completed	June 30, 1999
4	Send out Draft Data Package for Internal Hanford Review	July 1, 1999
5	Get comments back from Hanford Technical Review	July 12, 1999
6	Send out Draft Data Package to DOE/BHI/LHMC	September 30, 1999
7	Get comments back from other Hanford Organizations	October 15, 1999
8	Respond to Hanford Reviewers' comments	October 31, 1999
9	Send final Hanford Reviewed Draft to Outside Reviewers	October 8, 1999
10	Respond to Outside Reviewers First Round of Comments	November 15, 1999
11	Respond to Outside Reviewers 2nd Round of Comments	December 10, 1999
12	Get final/formal letter comments back from Reviewers and Complete Data Package	December 31, 1999

Appendix A - A Less Conservative Approach to Correcting Kd Values for the Presence of Gravel

An alternative approach to correcting Kd values that is less conservative than the approach used in the data package is provided. This approach was developed from a project conducted in conjunction with the ILAW PA. A manuscript of this research has been submitted for publication and is included in this appendix.

The equation used for gravel-corrected Kd values was:

$$Kd_{gc,g=0} = (1-f)Kd_{<2mm} \quad \text{(A-1)}$$

where f equaled 0.9. Thus, all the Kd values in the gravel-dominated sequence was reduced by an order of magnitude (1 – f = 1 – 0.9 = 0.1). An alternative correction would be:

$$Kd_{gc,g=x} = (1-f)Kd_{<2mm} + (f)Kd_{>2mm}. \quad \text{(A-2)}$$

Equation A-1 underestimated actual Kd_{total} by 28 to 47%, whereas Equation A-2 slightly overestimated Kd_{total} by 3 to 5%. Equation A-1 is conservative and Equation 2 is not, although the difference between Kd_{total} and $Kd_{gc,g=x}$ is not significant ($P < 0.05$). Equation A-1 becomes less and less accurate, i.e., the degree to which it underestimates Kd_{total} increases, as the percent of gravel (f) increases. At $f = 0.9$, $Kd_{gc,g=0}$ will greatly underestimate the actual Kd_{total}.

An attempt was made to apply Equation A-2 to the gravel corrections. We have laboratory data on Sr and Cs for $Kd_{>2mm}$, i.e., for 2 of the 26 radionuclides for which Kd data is needed for the data package. The ratio of $Kd_{>2mm}/Kd_{<2mm}$ for Sr and Cs were 0.23 and 0.42, respectively.

Assuming all radionuclides have a $Kd_{>2mm}/Kd_{<2mm}$ of 0.23, we can rewrite Equation A-2 as:

$$Kd_{gc,g=x} = (1-f)Kd_{<2mm} + (f)0.23Kd_{<2mm}. \quad \text{(A-3)}$$

and then by setting $f = 0.9$, this simplifies to:

$$Kd_{gc,g=x} = 0.31Kd_{<2mm}. \quad \text{(A-4)}$$

Thus, gravel corrected Kd values based on Equation A-4 will be 210% greater than those based on Equation A-1. Equation A-4 is likely to provide a more accurate estimate than Equation A-1, especially at the high gravel concentrations needed for the PA. However, and perhaps more importantly, more uncertainty is associated with the approach presented in A-4, due to the lack of $Kd_{<2mm}$ for each radionuclide.

Gravel-Corrected Kd Values

Abstract

Standard measurements of solute sorption to sediments are typically made on the <2-mm sediment fraction. This fraction is used by researchers to standardize the method, and to ease experimental protocol, whereby large labware is not required to accommodate the large gravel fraction (>2-mm particles). Since sorption is a phenomenon directly related to surface area, sorption measurements based on the <2-mm fraction would be expected to underestimate actual whole-sediment values for sediments containing gravel. This inaccuracy, referred to as the Gravel-Kd Issue, is a problem for ground water contaminant transport modelers who use laboratory-derived sorption values, typically expressed as a distribution coefficients (Kd), to calculate the retardation factor (Rf), a parameter that accounts for solute-sediment chemical interactions. The objectives of this laboratory study were to quantify the effect of gravel on Kd and Rf values and to develop an empirical method to calculate gravel-corrected Kd values. Three gravel corrections, Kd_{gc} values, were evaluated: 1) a correction based on the assumption that the gravel simply diluted the $Kd_{<2mm}$ and had no sorption capacity ($Kd_{gc,g=0}$), 2) a correction based on the assumption that the Kd of the intact sediment (Kd_{tot}) was a composite of the $Kd_{<2mm}$ and the $Kd_{>2mm}$ ($Kd_{gc-g=x}$), and 3) a correction based on surface area ($Kd_{gc,surf}$). On average, $Kd_{<2mm}$ tended to overestimate Kd_{tot} by 28 to 47%; $Kd_{gc,g=x}$ overestimated Kd_{tot} by only 3 to 5%; $Kd_{gc,g=0}$ and $Kd_{gc,surf}$ underestimated Kd_{tot} by 10 to 39%. Although, $Kd_{gc-g=x}$ provided the best estimate of actual values (Kd_{tot}), $Kd_{gc-g=0}$ was appreciably easier to acquire. These results have important implications regarding the traditional approach to modeling contaminant transport which uses $Kd_{<2mm}$ values. Such calculations may overestimate the ability of gravel-containing sediments to retard contaminant migration, thereby overestimating lower-bounding limits of contaminant migration. Use of gravel-corrected Kd values will improve such lower-bounding estimates.

Introduction

The extent that contaminants sorb to sediments is typically measured in the laboratory using a batch test in which the <2-mm particle size fraction of the sediment is placed into contact with an aqueous phase containing the contaminant of interest. The <2-mm fraction is used to standardize the method and to ease the experimental protocol, whereby large labware is not required to accommodate the gravel (>2-mm particles). The distribution coefficient, or Kd value, is the simplest construct describing contaminant sorption to sediments. It is the ratio of the contaminant concentration sorbed to the solid phase divided by the contaminant concentration in the liquid surrounding the solid phase (Equation 1):

$$Kd = \frac{C_{solid}}{C_{liquid}} \tag{1}$$

where C_{solid} (M kg^{-1}) and C_{liquid} (M L^{-1}) are the concentration in the solid and liquid phases, respectively. Since sorption is typically a surface reaction phenomenon (Sposito 1984), the extent of sorption based on the <2-mm fraction will overestimate the true extent of sorption for the entire sediment, especially in sediments dominated by gravel.

The discrepancy between the laboratory Kd value and the true field value due to excluding the gravel from the laboratory samples is referred to as the "gravel-Kd issue." Contaminant transport modelers commonly use Kd values to account for chemical interactions between the contaminant and the sediment. The Kd value is used to define the retardation factor, which is the ratio of the average linear velocity of water (m s^{-1}) divided by the average linear velocity of the contaminant (m s^{-1}). The Kd value is related to the retardation factor (Rf, unitless) by the bulk density (ρ_b, kg m^{-1}) and the porosity (η, m^3 m^{-3}) as follows (Valocchi 1984, Bouwer 1991):

$$Rf = \left(1 + \frac{Kd\rho_b}{\eta}\right). \tag{2}$$

As gravel concentrations in a sediment increase, the Kd value would be expected to decrease because the specific surface area of the sediment decreases; the bulk density would be expected to increase. These changes in sediment properties have opposite effects on the magnitude of the retardation factor (Equation 2). Bulk density values in the subsurface typically vary between 2650 kg m^{-3} (the density of a solid quartz crystal) to 1180 kg m^{-3} (the density of closely packed clay-size particles). Kd values of many metals and cationic radionuclides often vary by several orders of magnitude as a function of particle size (reviewed by Ames and Rai 1978 and Thibault et al. 1990). Thus, it is likely that the introduction of gravel to a system will cause the actual retardation factor to decrease because the Kd values will decrease to a greater extent than bulk density values will increase. An important implication of this conclusion is that transport modelers using traditional Kd values measured with the <2-mm sediment fraction will likely overestimate the ability of a gravel-containing sediment to retard contaminant movement, thereby overestimating lower-bounding limits of contaminant migration.

The objectives of this study were to: 1) quantify the effect of gravel on Kd and Rf values, and 2) develop a method to calculate gravel-corrected Kd values (Kd_{gc}). The intent of this research was to conduct batch-sorption experiments to develop a Kd_{gc} that would be beneficial to contaminant transport modelers. Thus, we wanted the corrections to be based on the traditional Kd value, $Kd_{<2mm}$, for which there is an extensive literature base. Also, any additional parameters needed for the correction had to be easily obtainable, which would rule out extensive solid phase characterization.

Materials and Methods

Two laboratory experiments were conducted using similar experimental protocols. In the Natural Sediment Experiments, Sr sorption to various size fractions of eight natural, gravel-containing sediments was measured. In the Gravel-Amended Experiment, Sr sorption to sediments amended with varying amounts of gravel was measured. Three gravel corrections were evaluated: 1) a correction based on the assumption that the gravel simply diluted the $Kd_{<2mm}$ and had no sorption capacity ($Kd_{gc,g=0}$), 2) a correction based on the assumption that the Kd of the intact sediment (Kd_{tot}) was a composite of the $Kd_{<2mm}$ and the $Kd_{>2mm}$ ($Kd_{gc-g=x}$), and 3) a correction based on surface area ($Kd_{gc,surf}$). Strontium was selected as a trace solute because its geochemistry is relatively simple. It exists almost exclusively as the Sr^{2+} species between pH 3 to 9.5 and it sorbs to sediments almost exclusively by cation exchange (Ames and Rai 1978, Kaplan et al. 1998). It was anticipated that the relative simplicity of Sr geochemistry would ease data interpretation.

General Sorption Procedure

The general procedure used in the two experiments was identical. The solid phases (natural sediment or gravel-amended sediment) was first pre-equilibrated with an uncontaminated ground water collected from the Hanford Site located in Richland, Washington (Well 600-S3-25, Table 1). This was accomplished by adding the ground water to the solid phases (typically in a 40:1 solution to solid ratio), shaking the suspensions overnight, centrifuging, decanting the supernatant, and then measuring the supernatant pH. This was repeated until the pH of the wash solution did not change by more than ± 0.05 units before and after contact with the solid phase. Equilibration by this method typically required three washings. The purpose of the pre-equilibration step was to isolate the Sr-adsorption reaction from other reactions that may occur while sediments and solutions came to chemical equilibrium.

A portion of the equilibrated ground water solution was amended with 25-μCi L^{-1} ^{85}Sr, as carrier-free Sr^{2+}, and then mixed overnight on a platform shaker. The ^{85}Sr-amended solution was then placed in contact with the solids. The solid-to-solution ratio was 1:30 (wt:wt). This relatively low solid-to-solution ratio provided optimal sensitivity for measuring K_d values in the range of 10 to 30 L kg^{-1}. The aqueous ^{85}Sr/sediment suspensions were placed on a slow-moving platform shaker to equilibrate for 14 days. After equilibration, the suspensions were centrifuged and then passed through 0.45-μm filters. The ^{85}Sr activity and pH of the filtrates were measured. The ^{85}Sr activity was measured with a germanium detector. All radiological counting was performed to a 3% total error.

Distribution coefficients (K_d, L kg^{-1}) were calculated using Equation 3. This equation accounts for the dilution of the initial ^{85}Sr-amended solution by the interstitial ground water remaining in the sediment after the final pre-equilibrating wash (i.e., the ^{85}Sr-free ground water left in the tube after pre-equilibration):

$$Kd = \frac{(C_{initial} \times V_{initial}) - C_{final}(V_{initial} + V_{interstitial})}{C_{final} \times M_{sediment}} \quad (3)$$

where $V_{interstitial}$ is the volume of the interstitial solution left after the final pre-equilibration wash (L), $M_{sediment}$ is the sediment mass (kg), $V_{initial}$ is the volume of the ^{85}Sr-amended solution added to the sediment (L), C_{final} is the ^{85}Sr concentration in the effluent solution after contact with the sediment (Ci L^{-1}), and $C_{initial}$ is the ^{85}Sr concentration in the ^{85}Sr-amended solution added to the solids (Ci L^{-1}).

Two types of control treatments were included in these experiments: a negative and a positive control. The positive control consisted of the ^{85}Sr-amended aqueous phase, $C_{initial}$, and no solid phase. This control monitored Sr sorption to labware and filters. The negative control consisted of the solid and aqueous phases without added ^{85}Sr. This control quantified the amount of ^{85}Sr in the uncontaminated aqueous and solid phases or introduced into the experiment through laboratory activities. Four replicates of controls and of each treatment were included in the experimental design.

The ground water used in this study was characterized by standard methods. Inductively coupled plasma-atomic emission spectroscopy (ICP-AES) was used to determine dissolved cation concentrations. It had an analytical precision of $\leq \pm 4\%$ at 5 mg L^{-1} cation concentrations. Ion chromatography (IC) was used to determine dissolved anion concentrations. It had an analytical precision of $\leq \pm 4\%$ at 5 mg L^{-1} anion concentrations. A carbon analyzer was used to determine total and inorganic carbon (Nelson 1987).

Sediment characterization was conducted using standard methods. Cation exchange capacity (CEC) was determined by the Na^+ - ion exchange method that is specifically designed for arid sediments (Rhodes 1987). Particle size distribution was determined by the sieve and pipette method (Gee and Bauder 1987). Bulk density and porosity were determined gravimetrically by repacking dry sediments in a column assembly (Klute and Dirksen 1986). pH was determined by the 1:1 solid:solution method (McLean 1987).

Three gravel corrections, Kd_{gc} values, were evaluated: a correction based on the assumption that the gravel simply diluted the $Kd_{<2mm}$ and had no sorption capacity ($Kd_{gc,g=0}$), a correction based on surface area ($Kd_{gc,surf}$), and a correction based on the assumption that the Kd of the entire sediment (Kd_{tot}) was a composite of the $Kd_{<2mm}$ and the $Kd_{>2mm}$ values ($Kd_{gc,g=x}$). $Kd_{gc,g=0}$ was defined as:

$$Kd_{gc,g=0} = (1-f)Kd_{<2mm} \quad (4)$$

where f if the weight fraction of gravel in the total sediment.

$Kd_{gc,g=x}$ was defined as:

$$Kd_{gc,g=x} = (1-f)Kd_{<2mm} + (f)Kd_{>2mm}. \quad (5)$$

One important disadvantage of $Kd_{gc,g=x}$ compared to $Kd_{gc,g=0}$ is that it requires $Kd_{>2mm}$, a parameter that may be difficult to measure. The additive approach would be expected to overestimate the extent of actual sorption because it does not account for masking of sorption sites by particles contacting each other.

The definition of $Kd_{gc,surf}$ is:

$$Kd_{gc,surf} = (1-f)\left(Kd_{<2mm}\right) + (f)\left[\left(Kd_{<2mm}\right)\left(\frac{SA_{>2mm}}{SA_{<2mm}}\right)\right] \quad (6)$$

where $SA_{>2mm}$ and $SA_{<2mm}$ is a specific surface-area estimate ($m^2\ kg^{-1}$) of the greater-than and less-than 2-mm fractions of the sediment, respectively (further defined below). The first term on the right side of Equation 6 is the weight-averaged Kd value of the <2-mm fraction. The second component on the right side of the equation accounts for the Sr sorption to the >2-mm fraction. Such a correction to the $Kd_{<2mm}$ assumes that the sorptive surfaces and sorption site density of the <2-mm and >2-mm fractions are similar. Furthermore, it assumes that the cause for differences between $Kd_{<2mm}$ and $Kd_{>2mm}$ values is due to the differences in the surface areas of the >2-mm and <2-mm fractions. These may be reasonable simplifying approximations in systems where the surfaces are coated with Fe-oxyhydroxides, organic matter, or carbonates.

In the absence of direct measurement, specific surface area can be approximated by assuming spherical particles, and from the particle surface area, volume, and particle density,

$$SA_i = (4\pi r_i^2)\left[\left(\frac{1}{4/(3\pi r_i^3)}\right)\left(\frac{1}{\rho_{p-i}}\right)\right], \quad (7)$$

where r is the average particle radius, ρ_p is the particle density, and the subscript i refers to either the <2-mm or >2-mm fraction. The term within the square brackets in Equation 7 converts the surface area of one particle (m^2 particle^{-1}) to the specific surface area of a particle ($m^2\ kg^{-1}$). By assuming that $\rho_{p-<2mm}$ is equal to the $\rho_{p->2mm}$, the ratio of $SA_{>2mm}/SA_{<2mm}$ in Equation 6, simplifies to $r_{<2mm}/r_{>2mm}$. For this study, $r_{<2mm}$ was estimated by multiplying the percent clay, silt, and sand in each sediment by 1.025, 0.026 and 0.001 mm, respectively, and then averaging these three numbers. $r_{>2mm}$ were assumed to be 3 mm.

Natural Sediment Experiment

Eight subsurface sediment samples were collected from the walls of a 20-m deep trench located in the 200 East Area of the Hanford Site, Richland, Washington. Samples were collected from sediment layers exposed by the trench to provide a wide range of gravel concentrations. At each sampling location, the surface 0.2-m of sediment was discarded prior to collecting approximate 1-kg sample. Samples were collected within 200 m of each other, in the same geologic formation and appeared to be composed of similar mineral assemblages. The samples were air-dried and then characterized for CEC, pH, bulk density, and porosity. Strontium-sorption tests were conducted on total, <2-mm, and >2-mm fractions following the General Sorption Procedure described above. There were four replicates for each gravel-amendment and both controls. Gravel-corrected Kd values were calculated using Equations 4 through 7.

Gravel-Amended Experiment

The solids used in these Sr-sorption experiment were composites created by combining varying amounts of gravel with the <2-mm sediment fraction from Sediment F of the Natural Sediment Experiment. The composite samples contained 0, 20, 40, 60, 80, and 100% (wt) gravel. The gravel used to make these samples was itself a composite of the gravel-fractions isolated from the sediments used in the Natural Sediment Experiment. The air-dried samples were characterized for CEC, pH, bulk density, and porosity. Strontium-sorption tests were conducted on the entire composite sample following the General Sorption Procedure described above. There were four replicates of each gravel-amendment and both controls. Gravel-corrected Kd values were calculated using Equations 4 through 7.

RESULTS AND DISCUSSION

Natural Sediment Experiment

Selected physical and chemical properties of the sediments used in the Natural Sediment Experiment are presented in Table 2. The gravel, sand, and silt-plus-clay (<50 μm fraction) fractions varied greatly between the sediments, ranging from 11.5 to 64.8 %(wt) gravel, 35.1 to 88% sand, and 0.1 to 25 %(wt) silt-plus-clay. Sediment pH, porosity, and bulk density did not vary greatly; pH ranged by <1 pH unit, porosity by <0.12-m^3 m^{-3}, and bulk density by 280 kg m^{-3}. There was no significant correlation ($P \leq 0.05$ at 7 degrees of freedom) between gravel concentrations and CEC, porosity or bulk density. One would expect that as the gravel concentrations increased that bulk density would increase, and CEC and porosity would decrease. There was also no significant correlation between pH and CEC. There were significant differences between the bulk density and porosity values of the <2-mm and >2-mm fractions. The bulk density for the <2-mm fraction was always less than the bulk density for the whole sediment (except Sediment H). The porosity for the <2-mm fraction was always greater than the porosity for the whole sediment (again, except for Sediment H).

The various measured Kd values and gravel-corrected Kd values are presented in Table 3. Means and standard deviations for four replicates of the measured Kd values, Kd_{tot}, $Kd_{<2mm}$, and $Kd_{>2mm}$, are presented. No estimate of the variance associated with the gravel-corrected values is

available because they had to be calculated from averaged $Kd_{<2mm}$ and gravel concentration (f) values. All the gravel corrected Kd values were significantly correlated to Kd_{tot}, with $Kd_{gc,g=x}$ and $Kd_{<2mm}$ having the largest correlation coefficients (Table 3). However, based on the percent difference with Kd_{tot} (Equation 8), the accuracy of the various gravel-corrected Kd values for estimating Kd_{tot} varied appreciably.

$$\%\Delta Kd_x = \left(\frac{Kd_x - Kd_{tot}}{Kd_{tot}} \right) \times 100 \qquad (8)$$

where Kd_{tot} is the Kd value measured using the entire sediment sample, Kd_x is a measured or gravel-corrected Kd value (Equations 4 – 7), and $\%\Delta Kd_x$ is the percent difference between Kd_x and Kd_{tot}. On average, $Kd_{<2mm}$ was 28% greater than Kd_{tot}, indicating that the $Kd_{<2mm}$ overestimated the Kd of the entire sediment sample by 28% (Table 3). Conversely, $Kd_{>2mm}$ was on average 45% smaller than Kd_{tot}. On average, $Kd_{gc,g=0}$ underestimated Kd_{tot} by 10%, indicating that the >2-mm fraction had some sorptive capacity. This is not surprising in light of the fact that Hanford subsurface sediments typically contain iron-oxyhydroxide and carbonate coatings. Kaplan and Serne (1998) reported that three subsurface Hanford Site sediments contained about 0.3% (wt) Fe_2O_3 and 1.8% $CaCO_3$. These coatings may enhance the sorptive capacity of the feldspar, and quartz particles that typically comprise the larger particles of Hanford Site sediments. On average, $Kd_{gc,g=x}$ overestimated Kd_{tot} by only 5%. On average, $Kd_{gc,surf}$ values underestimated Kd_{tot} by 13%.

The average ratio of $Kd_{>2mm}$ to $Kd_{<2mm}$ for these sediments was 0.42 ± 0.08 (Table 3). Stated differently, the Kd value of the gravel was 42% of the Kd value of the <2-mm fraction. By using Equation 9, which assigns the $Kd_{>2mm}$ a value 0.42 times $Kd_{<2mm}$, it was possible to calculate precisely the average Kd_{tot} (Table 3).

$$Kd_{gc,g=0.42} = (1 - f)Kd_{<2mm} + (f)0.42Kd_{<2mm}. \qquad (9)$$

Equation 9 provides the most accurate average gravel correction. Although Equation 8 requires only the knowledge of f and $Kd_{<2mm}$, it is limited insofar that the robustness of the 0.42 factor is not known. The 0.42 factor is likely not applicable to other contaminants or even to Sr in other sediment systems, since other sorption processes will often be involved.

Retardation factors were calculated (Equation 2) using the various measured and calculated Kd values (Table 3). For these calculations, the porosity and bulk density values of the total sediment (Table 2) were used because these parameters are essentially always measured on the entire sediment sample, as opposed to the <2-mm sieved fraction used for the Kd measurement. The Rf value for the sediments, Rf_{tot}, averaged 231 ± 64, meaning that Sr would be expected to move through these sediments at an average rate that was 231 times slower than water. The various Rf values varied proportionally to their respective Kd values, since the difference between the two constructs is a scalar (i.e., the ratio of ρ_b/η was constant for a given sediment). Thus, the % differences and correlation coefficients between the various Rf values and Rf_{tot} are identical to those listed in Table 3 for their respective Kd values.

The relation between sediment properties and the various Kd values were evaluated through linear regression analyses and correlation coefficients (Table 4). As expected, gravel fraction (*f*) and bulk density were generally inversely related to the various Kd and $\%\Delta\text{-}Kd_x$ values, whereas porosity and CEC were generally directly related to these parameters. Increases in gravel concentrations could decrease Sr Kd values by a number of processes, including reducing the sediment surface area. Increases in bulk density would be expected to result in decreased Sr Kd values because bulk density tends to increase in coarse sediments (Hillel 1980) and coarse sediments tend to have low specific surface areas (or low binding site concentrations) for Sr sorption. Conversely, increases in porosity would be expected to result in increased Sr Kd values because porosity tends to decrease in coarse sediments (Hillel 1980). The positive correlation coefficients with CEC may be attributed to the greater number of sorption sites available for Sr sorption.

Gravel-Amended Experiment

This experiment provided an estimate of the effect of gravel on sediment Sr-Kd values under more controlled conditions than in the Natural Sediment Experiment. In this experiment, the gravel fractions and the <2-mm fractions of each of the composite sediments had identical mineralogy, particle-size distributions, and surface chemistry. The only thing that changed between the samples was the proportion of the two size fractions.

The sediment properties used in the Gravel-Amended Experiment varied in an expected manner consistent with the amount of gravel added to the sediments (Table 4). As more gravel was added, the cation exchange capacity decreased ($r = -0.999$, $P \leq 0.001$), porosity decreased ($r = -0.990$, $P \leq 0.001$), and the bulk density increased ($r = 0.66$, $P \leq 0.05$). Unexplainably, pH also increased with increasing gravel additions ($r = -0.991$, $P \leq 0.001$).

$Kd_{gc,g=x}$ estimates most closely reflected the measured Kd_{tot} values; overestimating the Kd_{tot} values on average by $3 \pm 3\%$ (Equation 8 and Figure 1). $Kd_{gc\text{-}surf}$ underestimated Kd_{tot} values on average by $-33\% \pm 32\%$, the degree of underestimation increased as the amount of gravel added increased. Similarly, $Kd_{gc,g=0}$ underestimated Kd_{tot} values on average by $-39 \pm 37\%$, the degree of underestimation also increased as the amount of gravel added increased. A ranking of the Kd values by percent difference with Kd_{tot}, i.e., by their overall accuracy in estimate Kd_{tot}, is consistent with the ranking for the Natural Sediment Experiment (Figure 2): $Kd_{<2mm} > Kd_{gc,g=x} > Kd_{tot} > Kd_{gc,g=0} \geq Kd_{gc,surf} > Kd_{>2mm}$. For this experiment, $Kd_{>2mm}$ was 15.2 L kg^{-1} and $Kd_{<2mm}$ was 29.5 L kg^{-1} (Figure 1). The $Kd_{>2mm}/Kd_{<2mm}$ was 0.52, compared to the average ratio in the Natural Sediment Experiment of 0.42 (Table 3).

Strontium retardation factors calculated with Kd_{tot} values (Equation 2) varied from 235 for the <2-mm fraction treatment (0% gravel-added sediments in Figure 2) to 166 for the gravel amended (100% gravel-added sediments in Figure 2). $Rf(Kd_{gc,g=x})$ values estimated actual Rf values, $Rf(Kd_{tot})$, very closely. $Rf(Kd_{<2mm})$ overestimated and $Rf(Kd_{gc,surf})$ and $Rf(Kd_{gc,g=0})$ underestimated $Rf(Kd_{tot})$. All of these trends are consistent with those observed for the respective Kd values (Figure 1). Unlike the other Rf values, $Rf(Kd_{<2mm})$ values increased as the percent of added gravel increased. Since the value of $Kd_{<2mm}$ used to calculated $Rf(_{Kd<}2mm)$ remained constant for the various added-gravel treatments, the increase in Rf values reflects

changes in the ratio of bulk density to porosity (Equation 2). The bulk density to porosity ratio varied from 7.84 to 11.37 as the percent of added gravel increased from 0 to 100% (Table 5). This is an increase of 45% with respect to the ratio of the 0% added-gravel treatment. Since an increase in Rf is not expected as more gravel is added to a system, this illustrates an intrinsic error with keeping the Kd constant while varying the bulk density and porosity values. Since bulk density and porosity are more easily measured or estimated by empirical relations, it is not improbable that a modeled system would make this error.

Conclusions

Two experiments were conducted to quantify the gravel-Kd issue. Additionally, these experiments sought to evaluate methods an empirical method or formula to permit the conversion of the $Kd_{<2mm}$ value traditionally collected from laboratory experiments to gravel-corrected Kd values. The worse estimate of the actual Kd and Rf values for gravel-containing sediments was the traditional $Kd_{<2mm}$. On average, $Kd_{<2mm}$ over estimated actual Kd values by 28% in the Natural Sediment Experiment and 47% in the Gravel-Added Experiment. In one experiment, $Rf(Kd_{<2mm})$ values actually increased as the actual Rf values decreased. Of the various gravel-corrected Kd values, $Kd_{gc,g=x}$ provided the best estimate of the actual Kd value, Kd_{tot}, slightly overestimating Kd_{tot} values on average by between 3 and 5%. In both experiments, $Kd_{gc-x=0}$ and $Kd_{gc,surf}$ underestimated actual Kd values, the disparity systematically increased as the amount of gravel in the sample increased. This suggests that the gravel corrections for both constructs are less than perfect and therefore become systematically worse as the amount of gravel in the sample increases.

Although $Kd_{gc,g=x}$ clearly provided the best estimate of the actual Kd value, it has the important disadvantage in that it requires knowledge of the Kd value for the >2mm fraction. This is experimentally difficult to measure and requires additional resources to acquire. When this information can not be acquired, the $Kd_{gc,g=0}$ or $Kd_{gc,surf}$ constructs may be a reasonable alternative. $Kd_{gc,g=0}$ has the advantage over $Kd_{gc,surf}$ in that the former requires knowledge of the percent gravel, whereas the latter requires knowledge of percent gravel and mean particle sizes in the <2-mm and >2-mm fractions. Percent gravel in a sediment may be inexpensively acquired by sieve analysis or if need be, estimated from common stratigraphic descriptions of well boreholes.

The findings in this study have important implications regarding the traditional approach to modeling contaminant transport using $Kd_{<2mm}$ values because such modeling may overestimate the ability of gravel-containing sediments to retard contaminant migration. This is a problem insofar that lower-bounding estimates, that is, conservative estimates, of contaminant migration may not be in fact truly lower-bounding and therefore worse-case scenarios may be improperly estimated. Use of gravel-corrected Kd values will improve such lower-bounding estimates.

Acknowledgements

The work funded in this manuscript was funded by the Hanford Immobilized Low-Activity Waste Performance Assessment Project. The Westinghouse Savannah River Company

is operated for the U.S. Department of Energy under contract DE-AC09-89SR-18035. The Pacific Northwest National Laboratory is operated by Battelle Memorial Institute for the U.S. Department of Energy under Contract DE-AC06-76RLO-1830. The authors thank Dr. Gary Iversen (SCUREF, Columbia SC) and Dr. Steven M. Serkiz (WSRC, Aiken, SC) for reviewing an earlier version of this manuscript.

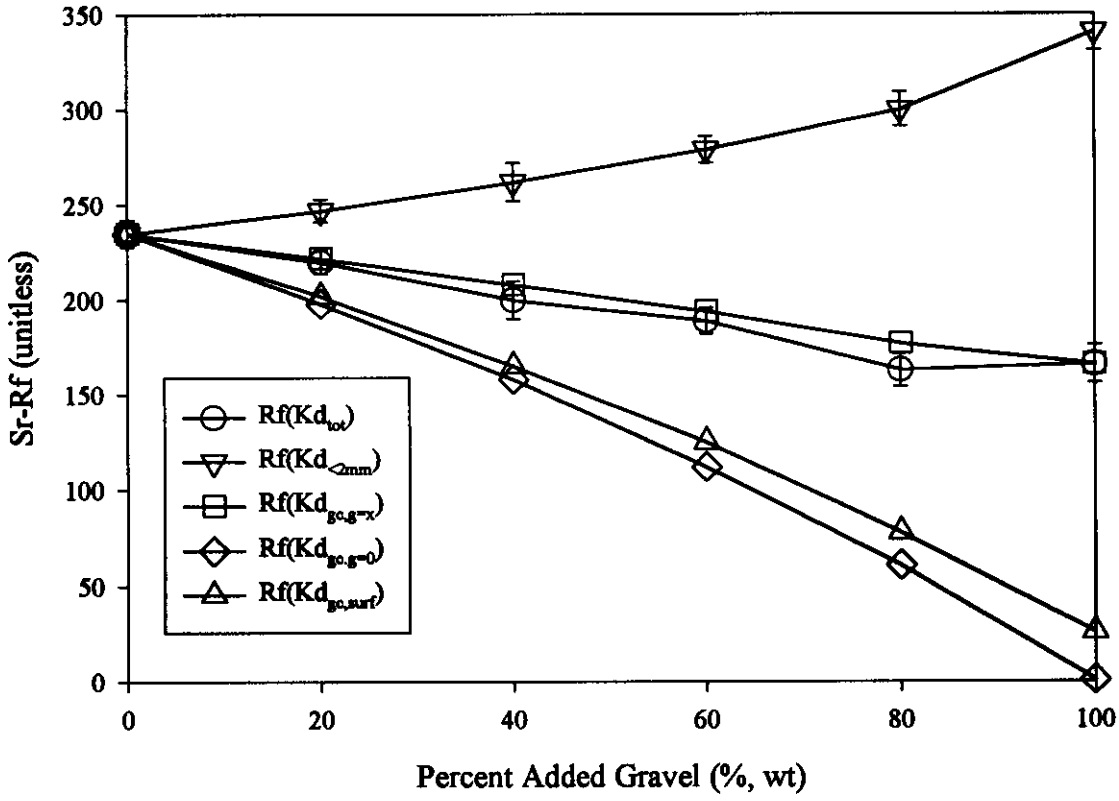

Fig. 2. Strontium retardation factors (Rf) as a function of added gravel. Rf values calculated with Kd_{tot}, $Kd_{<2mm}$, $Kd_{gc,g=0}$ (Equation 4), $Kd_{gc,g=x}$ (Equation 5), and $Kd_{gc,surf}$ (Equation 6), and measured bulk density and porosity values (Table 4). $Rf(Kd_{tot})$ is the mean and standard deviation of 4 replicates. Rf values from gravel-corrected Kd values were calculated using means, therefore no measure of variability is available.

Appendix B - Kd Values for Far-field Sediment Conditions

Appendix B. Kd Values for Far-field Sediment Conditions[a]				
Radio-nuclide	Reasonably Conservative Kd (mL/g)	"Best" Kd (mL/g)	Kd Range (mL/g)	Justification/References[b]
^{3}H, Cl, Tc	0	0	0 to 0.6	Tc exists predominantly as TcO_4^-. A review of Hanford sediment Tc-Kd values showed a range of -2.8 to 0.6 mL/g for 15 observations; median was 0.1 mL/g (1). Later studies did not change this range but did decrease the median slightly to -0.1 mL/g (2). Negative Kd values are physically possible and may not be an experimental artifact (2). ^{3}H is expected to move along with water. Cl is expected to behave as a dissolved anionic species. Most recent results using ILAW specific borehole sediments [299-E17-21] yielded Tc-Kd of 0 mL/g. See Kaplan et al. (18) for details.
Ac, Am, Ce, Cm, Eu	60	300	60 to 1300	Am-Kd: 67 to >1200 mL/g (3). Am-Kd: 125 to 833 mL/g (4)
C	0.5	5	0.5 to 1000	Assumed dominant species: HCO_3^-. Three processes will be acting on the ^{14}C to take it out of solution: adsorption onto the calcite surface, volatilization as CO_2 gas, and precipitation into the calcite structure. The latter process is largely irreversible, therefore it is not well represented by the K_d construct (K_d assumes that adsorption occurs as readily as desorption). Volatilization is entirely removed from the definition of the K_d construct. In systems that contain higher concentrations of carbonate minerals, such as the calcrete layer in the 200 West Area, an appreciably higher Kd should be used to account for the isotopic dilution/precipitation reaction that may occur. A Kd of 100 mL/g would be appropriate for such a system. Since most of the 100 and 200 plateau areas contain <1% carbonate, lower Kd values are warranted for these areas, such as 0.5 mL/g. K_d values of ^{14}C of >250 mL/g have been measured in calcite ([5]). At 100K, the C-14 is widely distributed down gradient from a major source (crib) associated with reactor operations. (Additional references: 6, 7, 8, 9, 10). Estimated range.
Co	1000	2000	1000 to 12500	Na system, 1290 to 2120 mL/g (11) Ca system, 2000 to 3870 mL/g (11) Hanford sediment/groundwater system 11600 to 12500 mL/g (12)
Cs	500	2000	500 to 4000	Na system, 1410 to 1590 mL/g (11) Hanford sediment/groundwater system, 540 to 3180 mL/g (12).). Most recent results using ILAW specific borehole sediments [299-E17-21] yielded Kd of 2,030 ± 597. See Kaplan et al. (18) for details.
I	0	0.1	0.0 to 15	A review of Hanford sediment I-Kd values showed a range of 0.7 to 15 mL/g for 9 observations; median was 0.7 mL/g (1). Later studies increased this range to 0.2 to 15 mL/g; the median was decreased to 0.3 mL/g (2). Most recent results using ILAW specific borehole sediments [299-E17-21] yielded Kd of 0 mL/g (18).

Ni, Sn, Nb	50	300	50 to 2500	Ni: Hanford sediment/groundwater system, 440 to 2350 mL/g (12) Ni: A study of a broad range of sediments, including those from Hanford had Ni-Kd's of 50 to 340 mL/g (13).
Np	2	15	2 to 25	A review of Hanford sediment Np-Kd values showed range of 2.4 to 21.7 mL/g for 4 observations; median was 17.8 mL/g (1). Later studies increased the slightly to 2.2 to 21.7 mL/g; the median was slightly lowered, 15 mL/g (2).
Pb	8000	10,000	8000 to 80000	pH 6 and no competing ions: 13,000 to 79,000 mL/g (14)
Pu	50	150	50 to 2000	Pu(V, VI): pH 4 to 12: 80 to >1980 mL/g (15)
Ra, Sr	5	14	5 to 200	Sr Kd values: Na system, 173 mL/g, 49 to 50 mL/g (11) Ca system, 8 to 13 mL/g, 5 to 19 mL/g (11) 5 to 120 mL/g (15) 19.1 to 21.5 mL/g (12) Na system, pH 7 to 11, 14.9 to 25.1 mL/g (16) Most recent data using ILAW borehole sediment [299-E17-21] yielded 14.3 ± 1.6. See (18).
Ru	10	20	10 to 1,000	Estimated (17 as cited in 11)
Se	3	7	3 to 15	Hanford groundwater/sediment system: -3.44 to 0.78 mL/g (12). Most recent data using ILAW borehole sediment [299-E17-21] yielded Kd values ranging from 3.75 to 10.85 mL/g and had an average of 6.7 ± 1.9 mL/g (18).
Th, Zr	40	1000	40 to 2500	Estimated. Zr: pH 6 to 12 : 90 to >2000 mL/g (15)
U	0.5	0.6	0.1 to 80	A review of Hanford sediment U-Kd values showed range of 0.1 to 79.3 mL/g for 13 observations; median was 0.6 mL/g (1). Results from later studies support the range (2). In all reported data, some U was adsorbed by Hanford sediments and >90% of the values were between 0.6 and 4 mL/g. Most recent work with the ILAW Borehole sediment [299-E17-21] yielded Kd of 0.6 ± 0.1. See (18).

[a] Kd values in this table describe sorption of radionuclides to Hanford sediment-dominated sequence under far field conditions. The aqueous phase is assumed to be untainted Hanford groundwater except for trace levels of radionuclide and the solid phase is assumed to be natural Hanford sand-dominated sequence sediment. The literature values upon which the values were based upon had an aqueous phase near neutral pH, ionic strength between ~0 to 0.01, trace radionuclide concentrations.

Appendix C - Discussion on Double Layer and Film Thickness

Double Layer Thickness vs. Film Layer Thickness

The double layer thickness was estimated from the Debye-Huckel Parameter (K) (Hiemenz and Rajagopalan 1997):

$$K = \left[\left(\frac{1000 e^2 N_A}{\varepsilon k_B T} \right) \sum_i z_i^2 M_i \right]^{1/2} \qquad \text{(A)}$$

Where K^{-1} (m) is sometimes used to estimate the double layer thickness, e is the electric charge (or charge of an electron, units = C), N_A is Avogadro's number, ε is fluid permittivity (C V^{-1} m^{-1}), k_B is Boltzmann's constant (J K^{-1}), z is the valence of the electrolyte, and M is the electrolyte concentration (M).

Assuming Ca^{2+} and SO_4^{2-} are the dominant ions at an ionic strength of 10 mM, the **double layer thickness based on Equation A is 1.5e-9 m.**

The film thickness was calculated with the following equation taken from Hillel (1980):

$$\lambda = \frac{\theta}{\rho_b A_{ss}} \qquad \text{(B)}$$

Where λ is the film thickness (cm), θ is the volumetric water content, A_{ss} is the specific surface area (cm^2/g) and ρ_b is the bulk density (g/cm^3). Using θ = 0.6, ρ_b = 1.25 g/cm^3, and A_{ss} of 2000 cm^2/g in Equation B, the **film thickness (λ) = 2.4 μm**.

Appendix D - Information Requested For Near Field Geochemical Transport Modeling

Reactive transport modeling of the waste form leaching and near field is being performed using the computer code STORM that is described in the Waste Form Leaching Data Package (McGrail et al. 1999).

The STORM code requires that the user provide the chemical formulas for the reactions needed to form the solid minerals that constitute the sediments and engineered barriers surrounding the glass waste forms. The Geochemical Data Package provides guidance in this appendix. The mineralogy of the Hanford sand sediments that might be used for backfill and the native Hanford formation sands and gravels have not been characterized at the ILAW site. However some quantitative mineralogy of Hanford formation sediments taken from outcrops and from the sides of other solid waste disposal facilities in the 200E and 200W areas have been reported. The data in Serne et al. (1993) pages 5-28 list detailed mineralogical, geochemical, hydrologic and physical characterization information for four sediments. This information can be used as input to STORM.

In FY00 about ten of the 21 samples from the ILAW borehole [299-E17-21] drilled in FY98 will be characterized for quantitative mineralogy and perhaps amorphous hydrous oxide content using the same techniques discussed in Serne et al. (1993). The 21 samples were used to obtain site specific K_d values, cation exchange capacities, particle sizes and hydrologic parameters in FY98-99. These data have been documented in topical reports [Kaplan et al. 1998 and Reidel et al. 1998] and companion 2001 Data Packages [Khaleel 1999 and Reidel and Horton 1999].

Mineralogy data needed for the STORM code reactive transport calculations for cement and concrete and are available in the following topical reports [Criscenti and Serne 1990, Criscenti et al. 1996, and Krupka and Serne 1996} and references cited therein. Hydrologic and physical properties of cement and concrete are discussed in the Near Field Hydrology 2001 Data Package [Myer and Serne 1999] and references cited therein.

For the 2001 ILAW PA all chemical dissolution/precipitation reactions for the backfill sediments, natural sediments, cements and concrete are assumed to reach equilibrium in each time step during the transport modeling. There is limited kinetic data available for the dissolution/precipitation reactions for these minerals/materials but the geochemists could not tabulated the information in time for the 2001 data packages. However kinetic data will be tabulated and made available to the STORM transport modelers in time for the 2003 PA activity. The amount of effort expended in tabulating kinetic information will be determined based on the importance of kinetics deciphered from critically analyzing the results of the near field transport modeling in the 2001 PA.

Exposure Scenarios and Unit Dose Factors for the Hanford Immobilized Low-Activity Tank Waste Performance Assessment

by Paul D. Rittmann PhD CHP

Performance assessment (PA) dose calculations involve models and parameters from many disciplines to predict the migration of radioactive material from low-level disposal sites and the potential impacts this may have on members of the public in the future. Of particular interest is the dose calculation assumptions employed for the Hanford Immobilized Low-Activity Tank Waste (ILAW) Performance Assessment (PA). Exposure scenarios and model parameters must be selected which will be acceptable to the DOE as well as local technical experts on the Hanford Environmental Dose Overview Panel (HEDOP).

The particular combination of activities by which an individual accumulates radiation dose from a disposal site is known as an exposure scenario. For the ILAW PA the exposure scenarios are constructed from the land use scenarios (HNF-EP-0828, Rev 2), of which there are three general categories.

(1) The water infiltration rate at the disposal site is very low due to an engineered barrier. Ground water contamination is expected to be very small, or even non-existent. The main contaminants leaving the waste site are gases and vapors which diffuse upward through the soil to the ground surface. Potential exposure scenarios involve individuals living 100 meters downwind from the waste, or directly above the waste, where the contaminant emission rate is greatest.

(2) The water infiltration rate at the disposal site remains similar to present natural infiltration rates. Large scale irrigation for commercial farming is excluded. Potential exposure scenarios include people living 100 meters from the waste once contamination has reached the groundwater, and individuals living above the waste who drill a well through it.

(3) The water infiltration rate at the disposal site is much larger than the present natural infiltration rate due to widespread irrigation of the central plateau of the Hanford Site. Potential exposure scenarios involve ways that water from a well 100 meters from the disposal site may be used. Onsite exposures are precluded by the active irrigation.

Since many waste disposal site performance assessments have been prepared, both for the Hanford Site and other DOE-managed facilities, there is a body of knowledge associated with these assessments. Future PA documents must be consistent with previous PA documents to a considerable degree. However, there is always room for improvement. One such area is the range of potential doses to individuals who may live on or near the disposal site some time in the future. The reason for doing this is to ensure that potential doses are not underestimated. The low end of the dose range will be zero. The high end depends on the assumed exposure scenarios and the model parameters selected to describe the scenario. This report describes possible exposure scenarios, selects average (or typical) model parameters, and calculates unit dose factors for these scenarios. This approach enables meaningful comparisons between scenarios, and provides assurance that bounding cases have indeed been considered.

1.0 EXPOSURE SCENARIO DESCRIPTIONS

The potential exposure scenarios are divided into two general categories, offsite and onsite. These originated by considering the delays in exposure which can be generally expected from waste disposal sites on the Hanford Site. The offsite location receives the majority of the dose after contaminants have migrated from the disposal site into the groundwater and are brought to the surface through a well. Exposure of the offsite individual requires considerable delay between site closure and the eventual appearance of radioactivity in the ground water. Only radionuclides with long half lives, such as plutonium, will be significant hazards. Radionuclides with shorter half lives, such as cesium-137 and strontium-90, normally will decay to insignificant amounts before becoming part of the groundwater contamination. In order for the short half life nuclides to be significant exposure hazards, someone must actively expose themselves to the buried waste by moving onto the disposal site and digging into it. Hence the onsite scenarios were developed.

The general features of the exposure scenarios used in performance assessments are shown in Table 1.

Table 1. General Features of Performance Assessment Exposure Scenarios.

Feature	Onsite Receptor	Offsite Receptor
Time delay following site closure	no less than 100 years	any time after site closure
Receptor location	directly over the waste disposal site	no closer than 100 meters from the edge of the buried waste
Contamination sources	(1) gases & vapors - migrate upward from the waste (2) well water (3) exhumed waste	(1) gases & vapors carried by the wind to the offsite location (2) well water
Exposure scenarios	(1) well driller - person actually drilling through the waste (2) residential - person living near the well	(1) industrial - people working at some commercial enterprise (2) residential - person living near the well (3) farmer - subsistence farming operation (4) native American Indian

The offsite exposures occur as a result of the environmental transport of radioactive contamination to locations near the waste disposal site. The usual location is 100 meters from the edge of the buried waste, or wherever the ground water contamination would be greatest. The principal transport mechanism is the migration of contaminants from the waste through the vadose soil and into the ground water. For most nuclides this involves a considerable time delay (i.e., hundreds of years) between site closure and arrival of the contamination. In addition, different nuclides travel at different rates through the soil, so they arrive at the well at times which may differ by more than the 70 year lifetime of the offsite individual. The offsite individual is also exposed to any airborne emissions from the waste disposal site. The airborne emissions result from the upward migration of certain radionuclides. The airborne emissions normally lead to less dose than the ground water contamination.

The onsite exposures are the result of human activity directly over the buried waste, for example, a residence or business. Since local regulations would prohibit such activities, the onsite exposure scenarios are assumed to be delayed for 100 years following site closure. After this delay, it is assumed that knowledge of the disposal site location is lost or ignored, and individuals unknowingly trespass. To establish bounding doses for this individual, it is assumed that a well is drilled through the waste. The waste materials brought to the surface are not recognized as waste. It is assumed that the appearance of the exhumed waste differs little from the native soil, and it becomes part of a garden.

The intent of these exposure assumptions is to establish reasonable bounds on the potential doses resulting from the waste disposal site. The exposure scenarios result from consideration of how the radioactivity can move, where it moves, and how people might be exposed to it in future years.

1.1 No Water Infiltration Exposure Scenarios

Since the water infiltration rate is expected to be very low due to the presence of an engineered barrier, little contamination will reach the ground water. However, gases and vapors will diffuse from the waste through the soil. These gaseous contaminants enter the air above the disposal site and may be carried by the wind to receptors located near the site. In addition, there may be inadvertent intrusion into the disposal site.

Table 2 summarizes the various exposure scenarios analyzed for the no water infiltration case. Note that skin absorption refers to radioactive materials on the skin being absorbed into the body by passage through the skin. Note also that the first scenario (Offsite Farmer) applies any time after site closure, while the remaining scenarios require a minimum of 100 years delay before they can occur.

One exposure scenario requires modeling the average dilution and dispersion of gases released from the surface as they travel downwind to someone living nearby. Since the airborne emission from the disposal site is in the form of gases and vapors, there will be no appreciable deposition of radioactivity on ground. However, plants and animals do absorb certain gases

directly from the air, leading to an ingestion dose to individuals consuming such produce. The emission rate from the ground surface may vary with time as the waste ages and radioactivity decays. The bounding doses for this scenario are achieved sometime after site closure.

A second exposure scenario involves a residence located above the disposal site with a porous floor. Gas concentrations in the dwelling would depend on the emission rate from the soil and the assumed ventilation rate in the dwelling. For an individual to be living above the disposal site, all knowledge of the site must have been lost. The dose calculation cannot begin until 100 years have elapsed from site closure.

Table 2. Exposure Scenarios for the No Water Infiltration Case.

Offsite Farmer -- gas/vapor emanations from the disposal site are carried downwind to a subsistence farm
▸ inhalation of plume ▸ ingestion (plants & animals) ▸ external radiation exposure from plume ▸ skin absorption from air
Onsite Resident -- gas/vapor emanations into a residence over the disposal site
▸ inhalation (higher concentrations in a dwelling) ▸ external radiation exposure (from soil and air) ▸ skin absorption (from air)
Intruder -- individual present while a well is being drilled through the waste disposal site
▸ inhalation (resuspended dust & gaseous emissions) ▸ ingestion (trace amounts of soil) ▸ external radiation exposure ▸ skin absorption (contact with soil)
Post-intrusion Resident -- lives near the exhumed waste
▸ inhalation (resuspended dust & gaseous emissions) ▸ ingestion (trace amounts of soil & garden produce) • external radiation exposure (working in garden) • skin absorption (contact with soil)

Notes: "Skin absorption" refers to radioactivity on the skin being absorbed into the body by passage through the skin. The first scenario applies any time after site closure, while the other three require a delay of at least 100 years before they can occur.

The third and fourth exposure scenarios listed on Table 2 assume the waste is unintentionally disturbed by human activity such as drilling a well through it. It is assumed that such intrusion is prevented for the first 100 years following site closure. After this period, it is assumed that knowledge of the disposal site becomes unavailable or is ignored. In addition, any markers or warnings are ignored. Compliance with performance objectives for the intruder (HNF-EP-826, Rev 2) is measured through reasonable exposure scenarios during and after the inadvertent intrusion.

Exposure scenario development begins with listing various ways the intruder can be exposed to the exhumed waste. These include inhalation of resuspended dust & gaseous emissions, ingestion of trace amounts of soil in the course of other activities, ingestion of garden produce, external radiation exposure, and absorption of contaminants that come in contact with skin.

There are two primary exposure scenarios for the intruder. The first describes the exposure to an individual digging a well through the disposal site. The second describes the exposure to an individual residing near the well afterward. Other forms of intrusion, such as digging footings for buildings, are considered unlikely due to the depth of the waste.

In this scenario, one or more individuals are exposed to the waste because the waste site has been returned to the public and no restrictions on land use prevent such an event. The drilling of water wells is a fairly common occurrence. However, the likelihood of a driller actually encountering the buried waste is low, since there are many places to drill, but few are over the buried waste.

The well extends from the ground surface to the unconfined aquifer. The diameter of the well could range from 4 inches up to 12 inches. The larger the diameter, the more waste will be brought to the surface. Prior Hanford performance assessments assumed that the well diameter is 12 inches (30 cm). This value certainly establishes an upper bound on the volume exhumed by a well-drilling operation. A more common diameter for a well is 6 inches (15 cm). This average diameter (15 cm) will be assumed in this report.

The total volume of soil produced by the well drilling is the product of the well cross sectional area and the thickness of soil between the unconfined aquifer and the ground surface. In the 200 Areas, for example, this thickness is about 80 meters. In this example, the total volume of soil excavated is 1.4 m^3.

Soil volume from well = $(3.14159)(0.15m/2)^2(80\ m) = 1.4\ m^3$

The volume of waste exhumed is the product of the well cross sectional area and the waste thickness. The disposal facility design will determine the waste thickness. By way of example, if the waste is 8 meters thick, then the total volume of waste excavated by the drilling operation would be 0.14 m^3. For comparison, the Grouted Waste PA (WHC-SD-WM-EE-004) used a waste volume of 0.64 m^3.

The individuals doing the drilling are exposed to the waste through inhalation of resuspended dust and gaseous emissions, ingestion of trace amounts, external exposure to the contamination, and dermal contact with the contaminated soil. The total exposure time is assumed to be 5 working days, or 40 hours. A portion of the waste at the time of drilling may still be in a form that cannot be resuspended and inhaled. An example is waste in the form of glass beads which are corroding slowly with time.

The dose to the driller depends on the area over which the contamination is spread. In the Grouted Waste performance assessment (WHC-SD-WM-EE-004, Rev 1) the area used was 100 m^2. This value will also be used in the present calculations. The 200 West Area Burial Ground performance assessment (WHC-EP-0645, Rev 0) did not consider doses to the driller in detail, since for all nuclides, the dose to the driller is less than the dose to the post-drilling resident. Previous PAs that calculate dose to the driller also assumed the activity is uniformly mixed in the top 15 cm of soil. Thus the exhumed waste is diluted to a total volume of $(100\ m^2)(0.15\ m)=15\ m^3$.

After the drillers leave, the mound of exhumed material is assumed to be spread around to level the ground for a garden. It will be assumed that the waste appears no different than the normal soil and thus is treated just like soil would be. Three important parameters affect the eventual dose received by the individual who works the garden. These are the depth of contamination in the soil, the area over which the contamination is spread, and the portion of the person's diet which comes from the garden. This section discusses these parameters and establishes values for them.

The customary tilling to prepare the soil for planting is assumed to only affect the top 15 cm (6 inches) of soil. This 15 cm tilling depth has been used in prior Hanford Site performance assessments. The greatest tilling depth likely to be encountered is about 60 cm, while the most shallow depth would be no tilling at all. The deeper the soil is tilled, the more dilute the waste becomes in the surface layer. The 15 cm depth is typical for root systems of garden vegetables. The nuclide concentration in plants due to root uptake is based on the average concentration to which the roots are exposed. If the tilling depth were greater than the root depth, the concentration in the material inhaled and ingested would be reduced. This would also lower the resulting doses. The 15 cm tilling depth will be assumed in the base analysis case. The upper bound on the soil concentration will be assumed to be the 10 cm depth, while the lower bound will be assumed to be the 60 cm depth. Many garden plants have root systems which penetrate deeper than 15 cm. However, it will be assumed that most of the nutrients taken from the soil will come from the top 15 cm, so that corrections for root depth will not be necessary.

Having chosen a tilling depth, the dose received by the gardener is proportional to the product of the soil concentration and the quantity of garden produce consumed. The proportionality with soil concentration assumes the contaminants are present in trace amounts which neither affect the growth of the plant, nor exceed solubility limits in the plant tissues. This relationship is summarized in the equation below.

Gardener Dose $\propto$ (Soil Conc)(Quantity Eaten) (1)

In general, the soil concentration is inversely proportional to the area over which the waste is spread. For estimating soil concentration in the garden, the smallest and largest areas can be tied to reasonable spreading thicknesses. The smallest reasonable thickness is 1 cm, because thinner layers require excessive effort to achieve. The largest useful thickness is the tilling depth, 15 cm. The garden area is the total volume of soil exhumed by drilling divided by the assumed thickness. In the 200 Area example where 1.4 m^3 is exhumed, the range of distributed thicknesses gives rise to a range of garden areas from 10 m^2 to 140 m^2. For areas between these limits, the soil concentration is inversely proportional to the area over which the material taken from the well is spread. Larger areas are possible, but the distribution of waste activity will be non-uniform.

The quantity of food derived from the garden is proportional to the garden size. To estimate food production per unit garden area, two approaches are used. The first is commercial food production in Washington State (WA Department of Agriculture 1994). Using the statewide food production per acre figures, the estimated garden area can be computed. The computed total garden area (194 m^2) is mostly for production of grain.

The second approach to estimating garden size uses garden production estimates published by the Washington State University (WSU) Cooperative Extension (1980). The document provides estimates of pounds of produce per 10 foot row in a garden. In addition, it gives recommended row spacings. The spacing was treated as the row width to compute production per unit area. The WSU production estimates are higher than the commercial production averages hence the needed garden area is smaller (161 m^2). These were assumed to be optimum values under excellent growing conditions.

Thus an efficiently planned and maintained garden of 200 m^2 can be assumed to supply most of one average person's garden produce needs. The quantity of food obtained from the garden by one person is proportional to the area of the garden up to a maximum of 200 m^2. Beyond 200 m^2 there is more food than the individual can eat. With more than one person in the household, the needed garden area increases proportionately. However, since the typical gardener obtains about 25% of his vegetable diet from a garden (see Section 2.2.3) a family of four would have a garden no larger than 200 m^2.

Recall that (1) the soil concentration is inversely proportional to the garden area, and (2) the quantity eaten is directly proportional to the garden area. Thus, the gardener's ingestion dose is largely independent of the garden area up to a maximum area of about 200 m^2. Once the garden area exceeds this maximum area, the ingestion dose decreases in proportion to the area. This maximum garden area will be assumed in the ILAW PA.

The chosen garden area of 200 m^2 differs considerably from prior Hanford performance assessments (eg., WHC-SD-WM-EE-004 and WHC-EP-0645) which have used a garden area of

2500 m^2. The more realistic area of 200 m^2 leads to ingestion doses which are 12.5 times greater than before for the same volume of waste exhumed. One justification for the larger area assumption used in prior performance assessments is that after a few hundred years the waste has not yet decomposed into fine particles suitable for uptake into plants. The large particles cannot be resuspended into the air, and prevent the plants from absorbing as much. In effect, the dilution factor is one or more orders of magnitude greater. In the present performance assessment, the unavailable portion will be estimated from glass corrosion characteristics.

For the post-intrusion resident, the range of possible contaminated garden sizes will be taken to be 10 m^2 to 200 m^2. Not all of the larger garden could be contaminated by the exhumed waste, but the individual collects food from all parts of the garden so the effect is the same.

The tilling assumption affects the dose calculations only by making the surface soil concentrations more uniform. Without tilling, the nuclide concentrations in the surface soil could range from that of the waste matrix to zero (background radioactivity is not considered). Conceivably some plants might be unable to grow in certain parts of the garden due to the high waste concentration. The tilling assumption ensures that the vegetable pathways will contribute to the overall dose to the gardener. In practice, the exhumed waste will not be uniformly spread over the garden area. However, the gardener roams the garden and averages out the exposure rate and soil ingestion. The produce grown in the garden will have varying levels of contamination, but the individual consumes portions grown in various parts of the garden, so that assuming an average soil concentration approximates the average produce concentration.

1.2 Low Water Infiltration Exposure Scenarios

In this land use category, the natural water infiltration causes contaminants in the disposal site to migrate into the ground water. Any human activities directly over the waste disposal site are assumed to be delayed at least 100 years. Human activities related to radiation exposure offsite begin after site closure, but really don't become interesting until the ground water plume reaches a well located 100 meters from the disposal site. Although there could be two general categories for the exposure scenarios, human intrusion and offsite scenarios, only the offsite scenarios will be considered (HNF-EP-0828).

The offsite scenarios establish compliance with performance objectives at the point of highest projected dose or concentration beyond a 100 meter buffer zone surrounding the disposal site (HNF-EP-0826). Exposure scenario development begins with listing various ways the well water could be used and selecting those activities that could lead to significant radiation exposure. Table 3 lists potential dose contributors. Some of the listed pathways turn out to be insignificant. Because the irrigation activities are not directly over the disposal site water infiltration at the disposal site is not affected. Also note that skin absorption refers to radioactive materials on the skin being absorbed into the body by passage through the skin.

The per capita water withdrawal rate from domestic wells mentioned in Miller (1980) (page 27), is 65 gallons per day, or 90,000 liters per year. This figure covers the principal domestic uses, namely, washing and bathing, drinking and cooking for one person.

Table 3. Exposure Pathways for the Low Water Infiltration Case.

(1) Drinking the well water (also cooking with it)
▸ ingestion
(2) Showering and bathing with the well water
▸ inhalation (sprays) • ingestion (small amounts) • external radiation exposure (immersion) • skin absorption (contact with water)
(3) Irrigating a garden
▸ inhalation (sprays & resuspended dust) ▸ ingestion (produce & trace amounts of soil) ▸ external radiation exposure (while in garden) • skin absorption (contact with soil)
(4) Drinking water for house pets and livestock
▸ ingestion (eggs, poultry, milk) ▸ external radiation exposure (proximity to animal)
(5) Irrigating livestock pastures
▸ inhalation (sprays & resuspended dust) ▸ ingestion (beef & milk) ▸ external radiation exposure (while in pasture)
(6) Sleeping on soil contaminated by irrigation
▸ inhalation (resuspended dust) ▸ external radiation exposure (while on ground) ▸ skin absorption (contact with soil)
(7) Sweat lodge/wet sauna
▸ inhalation (steam) ▸ skin absorption (contact with steam) ▸ external radiation exposure (soil, walls, steam)

As ground water enters the Columbia River, it is diluted by the large flow of surface water. From 1989 to 1999 the average flow rate measured at Priest Rapids Dam is about 3360 cubic meters per second (PNNL-6415). Radioactive contamination in the ground water would then be transported to various water intakes for use as irrigation and public drinking supplies. Doses to an individual irrigating from the Columbia River would be orders of magnitude smaller than doses to the same farmer irrigating from a well which penetrates the aquifer down gradient from the waste site. For this reason, the dose to an individual irrigating from the Columbia River will not be considered. However, since a large number of people would be affected by contamination in the river, a total population dose will be estimated.

As in prior performance assessments (eg., WHC-SD-WM-EE-004 and WHC-EP-0645) a total population of 5 million people between the Hanford Site and the Pacific Ocean will be assumed to derive all of their drinking water from the Columbia River. The population estimate is an upper bound. The lower bound is the population at an earlier time, assumed to be 1 million persons.

In addition, the average irrigation rate along the river will be assumed to be 25 cm/y (WHC-SD-WM-EE-004). This value was obtained as an average in counties along the Columbia River, and thereby differs from the irrigation rate assumed for individuals living near the Hanford Site. Again, this average over a large population will have an insignificant range.

Offsite exposure scenarios will use one or more of the listed pathways. Some pathways may be ruled out by characteristics of the environmental setting. For example, irrigation of a garden from a well is reasonable, but irrigation of pastures may not be possible, depending on the bounding pumping rate from the well. Possible exposure scenarios have been selected to represent future uses of the land. They are listed in Table 4.

The exposure scenarios listed in Table 4 use the naming convention of DOE/RL-91-45, *Hanford Site Risk Assessment Methodology* (HSRAM), Revision 3. The customary disposal site performance assessment all-pathways scenarios is included as an alternate for the agricultural scenario. Differences in modelling assumptions are discussed in later sections.

The native american subsistence resident (NASR) is based on discussions presented in DOE/RL-96-16. This individual represents a bounding case whose intakes of contaminated foodstuffs and exposures to environmental contamination are maximized.

Table 4. Exposure Scenarios for the Low Water Infiltration Case.

Industrial Scenario - represents potential doses to workers in a commercial industrial setting. Drinking water comes from the well (1), as does water used in showering (2), but no other pathway applies.
Residential Scenario - represents potential doses to individuals living in a community near the disposal site. These individuals drink from the well (1), shower regularly (2), irrigate a garden (3), give it to their pets (4), water a lawn and sleep on it occasionally (6).
Agricultural Scenario - represents potential doses to individuals who may take up residence on the Hanford Site to operate a subsistence farm. These individuals drink from their well (1), shower regularly (2), irrigate a garden (3), give it to their pets and livestock (4), irrigate a pasture for their cow (5), water a lawn and sleep on it occasionally (6). This scenario includes all of the pathways listed in Table 3 except the sauna.
Native American Subsistence Resident (NASR) Scenario - represents potential doses to individuals practicing the traditional subsistence lifestyle of the native American Indian. This includes hunting, fishing, gathering wild produce, and using a sweat lodge. These individuals also have a well for drinking, bathing, irrigating, and providing water for pets and livestock. All of the pathways listed on Table 3 are used.

1.3 High Water Infiltration Exposure Scenarios

In this land use category, the water infiltration rate at the disposal site is much larger than the present natural infiltration rate due to widespread irrigation of the central plateau of the Hanford Site. The higher infiltration rate changes the rate at which radioactivity is released from the disposal site as well as the rate at which it travels through the vadose zone. In addition, it acts to dilute the radioactivity entering the ground water. Thus the resulting ground water concentrations could be higher or lower than in the low infiltration case.

As with the low infiltration case, compliance with performance objectives is measured at the point of highest projected dose or concentration beyond a 100 meter buffer zone surrounding the disposal site (HNF-EP-0826). The offsite exposure scenarios discussed for the low water infiltration case also apply here. The only difference is the contaminant concentration in the ground water pumped from the well. Since water concentrations determine the dose, it is essential to have a credible model for the release and transport of waste contaminants through the soil.

2.0 EXPOSURE PATHWAY PARAMETERS

This section summarizes the recommended parameters and models to be used in calculating the radiation doses for the various scenarios in the ILAW PA. What follows is a description of each parameter, typical values, and the justification for the values chosen for this performance assessment. Where these parameters differ from prior performance assessments for Hanford disposal sites, the differences are explained. The mathematical models are described to illustrate how the parameters are used in calculations.

For the most part this is simply an expanded version of a previous supporting document (WHC-SD-TI-707). The discussion of data and models is divided into several topical areas, namely, nuclear properties, human activities, animal, plant, and soil characteristics.

An additional consideration is the potential effects on special groups of individuals who may be exposed in unique ways not normally considered. Information relevant to the modeling of dose to these special groups is included in each section.

2.1 Nuclear Parameters

The first parameters of interest are basic nuclear properties of the radionuclides which may be found in waste buried on the Hanford Site. The two main selection criteria for these nuclides is the radioactive half-life and the projected inventory in typical N-Reactor fuel. Radionuclides with half-lives greater than approximately one year are considered.

Table 5 shows the decay half-life and the decay chain branching ratios. A branching ratio is the fraction of decays of a parent nuclide which produce a given progeny nuclide. These parameters are needed to determine the amount of a nuclide, and any radioactive progeny, which is present as a function of time. Values are taken from the Evaluated Nuclear Data File, Release VI (ENDF/B-VI). The conversion from seconds to years was carried out using the value 365.25 days per year. Also shown on this table are the short-lived progeny which are assumed to be in secular equilibrium with the parent. These short half-life progeny are also called "implicit daughters" because their radioactive emissions are not considered separately, but combined with the parent nuclide.

As noted in DOE/RL-97-69, *Hanford Immobilized Low-Activity Tank Waste Performance Assessment* (section 3.4.7.4), new measurements of the half lives for Se-79 and Sn-126 show substantial increases. The newer values have been used in Table 5.

Note: Parentheses show (1) half-lives that are normally given in days, and (2) branching ratios that differ from 1.00.

Table 6 shows the radioactive decay chains which will be computed prior to and during the exposure scenarios. Radioactive decay normally reduces the dose that a receptor could receive. However, in the cases shown on Table 6, the ingrowth of the progeny nuclides with time may increase the dose from the parent nuclide. One example of this is Th-232, which has a very long half-life so that there is essentially no change in its activity during the year of exposure. Since the initial activity of the progeny nuclides (Ra-228 and Th-228) is assumed to be zero any increase will have maximum effect on the Th-232 doses. In addition, since the progeny

accumulate according to their much shorter half-lives, they are able to increase the dose from Th-232 significantly.

The decay chains used in these calculations are limited to four radioactive members by the assumption that the decay times will be less than 1000 years.

Notes:

Decay times are assumed to be less than 1000 years so that the ingrowth of progeny with long half-lives can be ignored.

There is a slight increase in the Pu-238 and U-234 for the Am-242m decay chain that is not shown. This is a result of the low-probability alpha decay of Am-242m. The complete chain is, Am-242m(0.00455)--->Np-238--->Pu-238--->U-234.

2.2 Human Parameters

Parameters for humans represented in the various exposure scenarios are the internal and external dose factors, and the food types and consumption rates for typical humans currently living near the Hanford Site.

2.2.1 Internal Dose Factors

Internal dose factors specify the effective dose equivalent (EDE) from a unit intake (ingested or inhaled) of a radionuclide. The dose is accumulated over a period of 50 years, known as the dose commitment period. This dose commitment period was set by the ICRP in Publication 26 (1977) when determining internal dose and relating it to whole body exposure.

If the nuclide has radioactive progeny with short half-lives, then the internal dose factors for these progeny are included with the parent isotope. It is assumed that the progeny are in secular equilibrium with the parent nuclide.

Currently, internal dose factors are based on the methods and assumptions of the International Commission on Radiological Protection (ICRP) prior to 1990. In 1990, the ICRP published Report Number 60 which revised these methods. Regulatory bodies in the United States have not yet adopted the improved methods, so they are not included here.

There are three internal dose factor collections which will be considered. The first is widely used in performance assessments for the United States Department of Energy (DOE/EH-0071). The second was prepared under the sponsorship of the United States Environmental Protection Agency (EPA-520/1-88-020). This set is also acceptable for use in performance assessments at DOE sites (DOE/LLW-93 and DOE M 435.1-1 Implementation Guide Chapter IV). The third was computed for the GENII software (PNNL-6584), which is often used at the Hanford Site. The GENII internal dose factors were recently revised (WHC-SD-WM-TI-596).

The dose factors from the three collections have been converted to the common units of mrem per pCi intake in Tables 7 and 8 below. For the ingestion dose factors, Table 7 shows the assumed values for f1, which is the fraction of the activity ingested that enters body fluids. "DF" is an abbreviation for dose factor. For the inhalation dose factors, Table 8 lists the assumed lung model category. The "V" for tritium stands for vapor, and includes a 50 percent increase due to absorption through the skin. The "Org" for C-14 means that the carbon is assumed to have an organic chemical form. The "D", "W", and "Y" mean the material clears the lungs in a matter of days, weeks, or years, respectively.

Comparison ratios of the GENII and DOE dose factors divided by the EPA dose factors are shown in Tables 7 and 8. Dose factors that differ less than 5% from the EPA numbers are not shown in the ratio columns. The only nuclides with differences greater than 25 percent are

Co-60, Nb-94, Tc-99, Ru-106, Ag-108m, In-115, Sn-126, Re-187, Bi-207, Ra-226, Ra-228, Th-228, Np-237, Pu-241, and Bk-247.

The internal dose factors for Nb-91 are not listed in any dose factor collection and were assumed to be bounded by the values for Nb-93m. Both nuclides emit low energy electrons and photons, as shown on the nuclear decay data summary of Table 9. For Nb-91, there is a continuous spectrum of low energy photons associated with the electron capture and positron decay. However, this continuous spectrum is a minor addition to the photon spectrum. The total electron plus photon energy for Nb-91 (15 keV) is less than that for Nb-93m (26 keV). Therefore, the internal dose factor for Nb-91 should be less than that for Nb-93m.

An additional consideration is the half-life of the two isotopes compared with expected residence times in the body. Inhalation class Y niobium is retained in the lungs for a considerable length of time. Most is removed during the first several years, but some is retained indefinitely. The organ with the largest dose for class Y Nb-93m is the lungs. Most (87%) of the dose from Nb-93m accrues during the first 10 years after inhalation. Thus, the effect of Nb-93m's shorter half-life is small. It will be assumed that the internal dose factors for Nb-91 are bounded by those for Nb-93m.

In addition to Nb-91, the internal dose factors for Po-209 are not listed in any dose factor collection and had to be computed by comparison with Po-210. Corrections were made for the energy of the alpha particles emitted, and the decay half-life using the equation shown below.

$$\text{Dose Factor} \propto \frac{E_\alpha}{\lambda_{eff}}\left[1 - e^{-\lambda_{eff} T_d}\right] \qquad (2)$$

where,

$E\alpha$ = total alpha energy per decay. For Po-209 this is 4.882 Mev per decay, while for Po-210 this is 5.3045 Mev per decay.

λ_{eff} = effective removal constant, which combines both the biological elimination and the radioactive decay of the nuclide.

T_d = dose commitment period used in the dose factor collections shown in Tables 7 and 8, namely, 50 years.

The biological removal half time for polonium is 50 days (ICRP 30). The decay half-life of Po-209 is 102 year, thus its λ_{eff} is 0.01388 per day. The decay half-life of Po-210 is 138 days, thus its λ_{eff} is 0.01889 per day. Since these are so large, the dose integration term in brackets is nearly 1 after 50 years. The ratio of Po-209 to Po-210 internal dose factors is shown below. This ratio was applied to the Po-210 inhalation and ingestion dose factors to arrive at the Po-209 internal dose factors.

$$\frac{\text{Po-209 Dose Factor}}{\text{Po-210 Dose Factor}} = \frac{4.882 \text{ Mev} * 0.01889 \text{ per day}}{5.3045 \text{ Mev} * 0.01388 \text{ per day}} = 1.252$$

The dose factor collection from the EPA (EPA-520/1-88-020) will be used in the ILAW PA. These are the only internal dose factors currently approved by the DOE for use in performance assessments (DOE M 435.1-1). The differences with the other collections is minor. Ratios of the GENII and EPA internal dose factors to the DOE dose factors are shown in Table 8.

Special groups of people such as children and diabetics, will have different internal dose factors due to differences in organ mass and retention times in the various tissues of the body. Internal dose factors for different age groups have been computed by the ICRP in Publication 56 (1989). However, these dose factors are for a limited number of nuclides. Unit dose factors for individuals whose metabolic characteristics differ considerably from those of the reference individual will also differ from those presented in Tables 7 and 8. As explained in DOE M 435.1-1 Chapter IV, the use of dose factors for representative members of the public is desirable to avoid overly conservative results. A bounding case exposure scenario evaluates possible upper limits.

Absorption through the skin, and injection from an injury are not considered since they are not likely to add significantly to the doses computed in the intruder and irrigation scenarios. These may be computed using an internal dosimetry program such as CINDY (PNNL-7493). Values have been published (PNNL-10190) and are basically the ingestion dose factor divided by the internal transfer factor (f1).

Any special exposure pathways associated with extended dermal contact with contaminated soil or vegetation will require appropriate dermal absorption dose factors. Dermal absorption methods for radionuclides were recently included in a revision to the MEPAS[1] program (PNNL-10523).

Notes:

(1) GENII Internal DF are from the July 1999 library revision by PDR. EPA Inhalation & Ingestion dose factors from Federal Guidance Report Number 11, EPA-520/1-88-020, Sept 1988. DOE Ingestion & Inhalation dose factors from DOE/EH-0071, (DE88-014297), July 1988. All are 50 year committed EDE.

(2) "DF" means dose factor. "Lung" refers to the ICRP lung model classification, "H2O" is tritium vapor (which includes skin absorption), "Organic" means organic carbon, "D" is days, "W" is weeks, and "Y" is years.

(3) The short-lived radioactive progeny shown on Table 5 are assumed to be in secular equilibrium with their parent nuclide. The dose factors for implicit daughters have been added to the parent dose factor to give the values shown.

(4) The last two columns show ratios of GENII and DOE inhalation dose factors to the EPA dose factors. Ratios of dose factors within 5% of the EPA value are not shown.

Table 9. Nuclear Decay Data for Nb-91 and Nb-93m.

Nb-91 (680 y)	Particle energy, keV	fraction of decays	Weighted energy, keV
EC	1254.6	0.99836	417.51
positron	232.6	0.00164	0.13
electron	13.47	0.2348	3.16
photon	15.69	0.18319	2.87
	15.77	0.35027	5.52
	17.66	0.10136	1.79
	511	0.00328	1.68
Total for electrons + photons:			15 keV
Nb-93m (16.13 y)	Particle energy, keV	fraction of decays	Weighted energy, keV
IT	30.77	1	30.77
electron	11.78	0.1440	1.70
	14.15	0.0365	0.52
	28.07	0.1340	3.76
	28.31	0.0262	0.74
	28.40	0.4710	13.38
	30.39	0.1360	4.13
photon	16.52	0.0310	0.51
	16.61	0.0590	0.98
	18.61	0.0175	0.33
	30.77	5.5 E-06	0.00
Total for electrons + photons:			26 keV

Note: The last column shows the product of the particle energies and the fraction of decays with this energy particle. Although the Nb-93m half life is short enough that the total retained in the body (and hence the dose) decreases partly by radioactive decay, its total electron plus positron energy is large enough to make up for the loss by decay. Data from ENDF/B-VI.

2.2.2 External Dose-Rate Factors

External dose-rate factors give the expected dose equivalent rate to an individual standing in the center of a large contaminated area. The dose rate factors have units of dose equivalent rate per unit soil concentration. The contamination is assumed to be uniformly spread over a very large area. The dose rate factors are derived for infinite sources of varying thickness. If the area becomes smaller than a few hundred square meters, then the dose rate factors must be adjusted downward. The thickness of the contaminated layer affects the dose rate and must be considered. For typical exposure scenarios the soil thickness is 15 cm. Radionuclides are assumed to be uniformly distributed through this thickness as a result of cultivating the soil for the purpose of growing a garden.

External dose rates from a layer of contaminated surface soil are available from various sources. Three sources that have been used on the Hanford Site are the DOE surface gamma dose-rate conversion factors (DOE/EH-0070), the EPA values in Federal Guidance Report Number 12 (EPA-402-R-93-081), and the external dose factors recently computed for the GENII program. The three sets of external dose rate factors are shown in Table 10. They have been converted to the common units of mrem/hour per Ci/m^2 for purposes of comparison.

The DOE surface gamma conversion factors (DOE/EH-0070) are derived from an assumed contamination thickness of zero. The contamination lies on top of the soil surface in a layer which is infinitely thin, perfectly flat, and infinite in extent. These assumptions necessarily exaggerate the dose rates for the ILAW PA. Strong beta-emitting nuclides such as Sr-90 produce no external dose since the bremsstrahlung radiation was ignored.

The GENII external dose rate factors (PNNL-6584) were computed using a version of the ISOSHLD program known as EXTDF which is part of the GENII software package. Bremsstrahlung radiation is computed for all beta emitters. The dose rate factors assume the contamination is distributed through the top 0.15 meters (6 inches) of soil. The surface soil is given a density of 1.5 grams per cubic centimeter. Again the surface layer is perfectly flat and infinite in extent. The finite thickness adds realism, since the contamination is worked into the soil during normal tilling operations. These dose rate factors have been used in prior Hanford Site performance assessments.

The EPA external dose rate factors (EPA-402-R-93-081) were computed using a Monte Carlo approach with the best available input data and dosimetric models, except that ICRP 30 organ weighting factors rather than ICRP 60 weighting factors were used. These are considered to be the best external dose rate factors currently available and will be used in the ILAW PA.

The EPA values are for a soil contamination thickness of 15 cm. The number shown for Eu-150 is listed as Eu-150b in the EPA compilation. The reference does not give values for Nb-91 and Po-210. Therefore, the values computed by EXTDF were used instead.

Notes:
(1) GENII external DRF were computed using the EXTDF program. EPA external DRF are from Federal Guidance Report Number 12, EPA 402-R-93-081 (Sept 1993). DOE external DRF are from DOE/EH-0070 (July 1988).
(2) Short-lived radioactive progeny included in the "+D" nuclides are in secular equilibrium with their parent nuclide.
(3) The conversion to area units from volume units assumes a thickness of 0.15 meters. The density correction applied to the EPA (1993) dose rate factors is 1.067. Because Nb-91 and Po-209 are not part of the EPA compilation, the GENII values were used.
(4) The last two columns show ratios of GENII and DOE external dose rate factors to the EPA dose rate factors. Ratios within 10% of the EPA value are not shown.

The GENII and EPA external dose rate factors are listed as dose rate per unit concentration in the soil. The unit concentration was converted to a unit area by multiplying by the contamination thickness of 15 cm. The DOE dose rate factors are already in area units. Note that the EPA dose rate factors were developed for a soil density of 1.6 g/cc. However, the ILAW PA will use a soil density for the surface layer of 1.5 g/cc. Therefore, the EPA dose rate factors were multiplied by the density correction factor of 1.067 to give the values shown on Table 10.

The three external dose factor collections are compared in Table 10. What is shown on this table are ratios of the GENII and DOE collections divided by the EPA collection. Differences less than 10 percent are not shown. Ratios for dose rate factors which are zero were not computed.

The GENII external dose rate factors agree fairly well (within 26%) for nuclides that emit penetrating gamma rays and have the largest dose rate factors. Examples are Na-22, Ti-44, Mn-54, Co-60, Nb-94, Ag-108m, Sn-126, Cs-134, Cs-137, Eu-150, Eu-152, Eu-154, Ho-166m,

Bi-207, Ra-226, Ra-228, and Th-228. The disagreement between GENII and the EPA collections is over the low energy photon emitters. However, for these nuclides the internal doses are typically much greater than the external, so the disagreement would not affect the total doses.

In general, the DOE external dose rate factors are larger than the EPA dose rate factors by more than a factor of 4. The exceptions (Be-10, C-14, Si-32, Cl-36, Se-79, Rb-87, Sr-90, Tc-99, Cd-113m, In-115, Sn-121m, Cs-135, and Pm-147) are for nuclides which produce most of their photons through bremsstrahlung. For these nuclides, the DOE external dose rate factors are much too small.

In all three references used in Table 10 the dose rates were computed at a height of 1 meter above the soil. The actual height has little effect on the dose rate. Table 11 demonstrates this by comparing dose rate factors computed by the EXTDF program at 100 cm and 10 cm. The table shows the ratios of the 10 cm dose rate divided by the 100 cm dose rate for nuclides where the difference between dose rate factors was greater than 10 percent. It must be noted that all these nuclides have external dose rates which are insignificant compared with the internal. The exclusively low energy photons emitted by these nuclides are noticeably attenuated by the additional 90 cm of air.

Table 11. Ratios of Dose Rate Factors at Two Elevations.

Nuclide	Ratio	Nuclide	Ratio
H-3	1.61	U-236	1.26
Fe-55	1.61	Pu-236	1.35
Ni-59	1.18	Pu-238	1.27
Ni-63	1.18	Pu-240	1.37
Zr-93	1.20	Pu-242	1.46
Nb-93m	1.61	Cm-242	1.46
Mo-93	1.61	Cm-244	1.48
Pd-107	1.52	Cm-246	1.52
Sm-151	1.21	Cm-248	1.46
Pb-205	1.61	Cf-248	1.55
Th-232	1.12	Cf-250	1.36
U-232	1.13	Cf-252	1.42
U-234	1.16		

Note: The ratios are the dose rate factor (DRF) at 10 cm above the soil surface divided by the dose rate factor at 1 meter above the soil.
Nuclides having DRFs within 10% at the two elevations are not shown. DRFs were computed using the EXTDF program, which is part of the GENII software package.

External dose rate factors for immersion in contaminated air are listed in Table 12 below. Values are from Federal Guidance Report Number 12 (EPA-402-R-93-081). The dose rate factors were computed assuming the individual is located at the center of a hemisphere of infinite extent. Hence these are also referred to as semi-infinite cloud dose rate factors. Values for Nb-91 and Po-209 are from the EXTDF program of the GENII software package. The columns labeled "Ratio" compare the external dose from submersion in contaminated air with the inhalation dose that accrues during the same period. The inhalation dose is computed as the product of the air concentration, the exposure time, the breathing rate, and the inhalation dose factor. The submersion dose is computed as the product of the air concentration, the exposure time, and the submersion dose rate factor. Thus the ratio of inhalation dose to submersion dose is the product of the breathing rate and the inhalation dose factor divided by the submersion dose factor. This ratio is shown in Table 12 for the daily average breathing rate (0.95 m^3/h) and EPA inhalation dose factors. The light activity breathing rate could also be used, but leads to larger ratios. For the nuclides used in this report (Table 5), the smallest ratio is 5.06 for Na-22. Nuclides notable for large inhalation doses, like insoluble transuranic (TRU) isotopes, have ratios greater than 1 million. Because the activity inhaled by the individual is considerably smaller than the activity ingested, the inhalation dose for non-TRU isotopes is a small part of the total. Therefore, the submersion dose will not be included in the dose calculation.

Notes:
(1) External DRF for submersion in contaminated air are from Federal Guidance Report Number 12, EPA 402-R-93-081 (Sept 1993). Because Nb-91 and Po-209 are not part of the EPA compilation, the GENII values were used. Short-lived radioactive progeny included in the "+D" nuclides are in secular equilibrium with their parent nuclide. The nuclide is dispersed uniformly in a hemisphere of infinite extent. The receptor is at the center of the hemisphere.
(2) The "Ratio" columns are computed as the inhalation dose factor times the daily average breathing rate (0.95 m^3/h) divided by the submersion dose rate factor.

2.2.3 Ingestion Rates for People

In this section the ingestion rates for all types of produce for all exposure scenarios are presented and compared. In addition, consumption rates for water and trace amounts of soil are given. Finally, garden size is discussed because the assumed garden size controls soil concentration in the garden of the post-intrusion resident.

The diets compiled by the EPA to represent averages in different parts of the United States have been used in prior Hanford Site disposal facility performance assessments. The consumption parameters for the "West" region in a national survey were used (Yang and Nelson 1986). These are listed in Table 13 below, under the column "g/d". In contrast, a somewhat different set of values has become established for Hanford dose assessments. These are found in DOE/RL-91-45 Revision 3, *Hanford Site Risk Assessment Methodology* (HSRAM). The consumption parameters listed in that document for the industrial, residential and agricultural scenarios are presented in Table 14.

In Table 13 the last two columns of numbers are computed from the first column using 365 days per year consumption. Note that the usual 365.25 d/y has been rounded to simplify calculations. The values shown in the second column under "Observed Intakes" are the same as the values in the first column, except that the units have been changed from grams per day to kilograms per year.

The last column gives the consumption rates used for an average individual in the residential and all-pathways farmer scenarios. These have been adjusted for the fraction of the individual's diet which is locally produced based on the fractions given in the EPA Exposure Factors Handbook (EPA/600/8-89/043). The adjustment for garden produce is that 25 percent of the vegetable diet actually comes from the garden, and is contaminated. The other 75 percent is assumed to be obtained from uncontaminated sources. For animal products, it is assumed that 50 percent of the animal products (except for fish) are locally produced and thus contaminated.

Table 13. Human Food Consumption: Traditional Models.

Item Consumed	Observed Intakes		Residential & Farmer Intakes kg/y
	g/d	kg/y	
Leafy produce	45.3	16.53	4.1
Other veg. (protected)	152.5	55.66	13.9
Fruit (exposed + misc)	105.3	38.43	9.6
Cereal (grain)	202.6	73.95	18.5
Meat (beef & pork)	115.0	41.98	21.0
Milk	283.5	103.48	51.7
Poultry	28.9	10.55	5.3
Eggs	29.1	10.62	5.3
Fish	18.5	6.75	6.75
Drinking Water	1480	540	540
Trace Soil Ingestion	0.1	0.0365	0.0365

Notes: Annual intakes are computed as 365 days of daily intakes. Values in the last column are adjusted for average diet fraction locally produced, namely, 25% for garden produce and 50% for animal products.

"Leafy" refers to vegetables whose leafy parts are normally eaten, such as lettuce, cabbage and spinach. "Other veg." are termed "protected" produce because the edible portion is underground or has some type of non-edible covering. Examples of protected produce are potatoes, onions, peanuts, and sweet corn. "Fruit" is termed "exposed" produce because airborne contaminants may deposit on the edible portion, but the surface area is small compared to leafy vegetables. Examples of exposed produce are apples, asparagus, cherries, grapes, snap beans,

squash, and tomatoes. "Grains" refers to cereals consumed by humans, such as corn (for meal), oats, soybeans, and wheat.

The next grouping of foods, namely, "Meat", "Milk", "Poultry", and "Eggs" refers to animal products that may be contaminated because the animals ingest contaminated feed and drink. The various animals raised for foods are separated into the two categories "Meat" and "Poultry". If the animal resembles a cow (e.g. goats or pigs), it is "Meat". If the animal resembles a bird (e.g. ducks and turkeys), it is "Poultry". The names simply refer to the most likely animal. In addition, no distinction is made between goat's milk and cow's milk. The method for estimating animal product concentrations is too coarse.

Other animal products can be postulated, such as wild animals or commercial food items (not grown locally). However, neither is contaminated by exhumed waste or ground water, so no dose accrues from them. Wild animals that are hunted for food, such as deer and waterfowl, would acquire some contamination once the ground water reaches the Columbia River. These are not explicitly included, because only the population dose is of interest from the Columbia River. Game animals are a small part of the total population dose.

The non-dairy beverage consumption rates measured by the EPA (Yang and Nelson 1986) for the western region is 1.48 liters per day (1480 g/d). The grouted waste performance assessment used 1.84 liters per day (Roseberry and Burmaster 1992). The traditional assumption commonly used in other performance assessments is 2 liters per day, which is 35 percent higher than the EPA average and 9 percent higher than the grouted waste PA. The EPA value (540 L/y) will be used for the residential and all-pathway farmer cases, while the 2 L/d value is considered the bounding value.

Inadvertent soil ingestion is assumed to occur at the rate of 100 mg per day for adults, and at twice this rate for children (EPA/600/8-89/043). This is a trace amount associated with hand-mouth contact, licking the lips, and similar motions. Deliberate soil ingestion is not considered. A survey of measurements of soil ingestion is presented in NUREG/CR-5512, Section 6.3.2.

In the drilling scenario, the worker is exposed for a period of 5 days. At 100 mg/d, the worker ingests 500 mg soil. Since 0.14 m^3 waste was spread over a 15 m^3 soil volume [(15 m^3)=(100 m^2)(0.15 m)], the amount of waste ingested is shown in the calculation below.

Driller soil ingestion = (100 mg/d)(5 d) = 500 mg soil

Driller waste ingestion = (500 mg)(0.14 m^3)/(15 m^3) = 4.7 mg waste

In the post-intrusion gardening scenario, the resident is exposed for a period of 365 days. At 100 mg/d, the resident ingests 36,500 mg soil. Since 0.14 m^3 waste was spread over a 30 m^3 soil volume [(30 m^3)=(200 m^2)(0.15 m)], the amount of waste ingested is shown in the calculation below.

Gardener soil ingestion = (100 mg/d)(365 d) = 36,500 mg soil

Gardener waste ingestion = (36,500 mg)(0.14 m^3)/(30 m^3) = 170 mg waste

Note that the amount ingested by the post-intrusion resident is substantially larger than the amount ingested by the driller. In addition, the ingestion amounts can be normalized to unitless fractions, the activity ingested per unit activity exhumed. This is illustrated below using an area density of 225 kg/m^2 based on a soil density of 1500 kg/m^3 and a tilling depth of 0.15 cm. This method of comparison avoids the need to know the waste thickness and well diameter.

Driller ingestion fraction = (500 mg)/(225 kg/m^2)/(100 m^2)
= 2.22 x 10^{-8} Ci ingested per Ci exhumed

Gardener ingestion fraction = (36,500 mg)/(225 kg/m^2)/(200 m^2)
= 8.11 x 10^{-7} Ci ingested per Ci exhumed

For exposure of the population along the Columbia River, parameters are scaled up by the assumed total population of 5 million. Two exceptions are water intake and fish consumption. The average drinking rate of 540 L/y per person (Yang and Nelson 1986) will be used. About half of this number is water, while the rest is various other beverages, most of which are derived from drinking water supplies.

The quantity of fish consumed by the population is limited by what the river is able to produce. The total mass of fish harvested from the Columbia River annually and consumed locally is approximately 15 metric tons (PNNL-9823). The average amount of fish consumed by 5 million people is thus 3 grams per year per person.

The range of consumption rates for a large population is small since the individual differences are averaged out. Thus the total food consumed by the population depends primarily on the size of the population. The one exception is fish consumption, which is assumed to remain constant at 15 metric tons per year.

The HSRAM ingestion rates are shown in Table 14 for the industrial and agricultural scenarios. The ingestion rates for the residential scenario are the same except that the meat and milk pathways are absent. Game meat (deer) and fish are listed even though they would not be contaminated by exhumed soil, or by the irrigation of a subsistence farm from a well. The game rate is based on one 45 kg deer per year. Half the mass is edible, and is divided among a family of four.

Estimated food intake rates are from DOE/RL-96-16 (April 1997 draft) for the Native American Subsistence Resident (NASR) (Table 5.7). The total vegetable intake rate was divided among the four types of produce using the same relative proportions as shown in Table 13. The animal protein intake rate (150 g/d) was assumed to be made of meat (120 g/d) and deer (30 g/d).

Note that the deer intake rate is assumed to be twice the game intake rate given in the HSRAM. In DOE/RL-96-16 a value for organ intake rate is given as 54 g/d. This has been added to the meat to give the total shown. Values for waterfowl (70 g/d), upland game birds (18 g/d), and wild bird eggs (45 g/d) have been added to the deer assumption to give the total game intake rate shown (163 g/d). These daily intake rates are converted to annual intake rates using 365 days per year.

Overall, the native american food intake rates are roughly twice the all-pathways farmer intake rates. Thus the resulting scenario dose factors will be roughly twice as great also.

Table 14. Human Food Consumption: New Models.

Item Consumed	Industrial	Agricultural	NASR
Leafy produce	0	3.7	20
Other veg. (protected), kg/y	0	11.0	67
Fruit (exposed + misc), kg/y	0	15.3	46
Cereal (grain), kg/y	0	14.6	108
Meat (beef & pork), kg/y	0	21.9	42
Milk, L/y	0	110	219
Poultry, kg/y	0	5.5	11
Eggs, kg/y	0	0	11
Fish, kg/y	0	9.9	197
Game (deer & birds), kg/y	0	5.5	59
Water, L/y	250	730	1095
Soil, kg/y	0.0125	0.0365	0.073

The industrial and agricultural are from HSRAM (DOE/RL-91-45). The HSRAM residential scenario has the same intake rates as the agricultural except that the meat, milk, poultry and egg intakes are zero. The HSRAM vegetable intake rate of 80 g/d has been separated into 10 g/d leafy, 30 g/d other vegetables, and 40 g/d grain. The HSRAM meat intake rate of 75 g/d has been separated into 60 g/d meat and 15 g/d poultry. The HSRAM daily intakes were converted to annual intakes using 365 days per year.

The native american subsistence resident (NASR) intakes are from DOE/RL-96-16 (April 1997). The daily vegetable intake rate of 660 g/d has been divided into 55 g/d leafy, 184 g/d other vegetables, 127 g/d fruit, and 295 g/d grains based on the distribution shown in Table 13. Similarly, the animal protein intake rate of 150 g/d has been separated into 135 g/d meat and 15 g/d deer. The organ intake of 54 g/d has been added to the meat intake for a total of 189 g/d. Daily intakes are converted to annual intakes using 365 days per year.

Garden Area Determination: From the estimated annual intakes of garden produce it is possible to estimate the minimum garden area needed to supply an individual. This area is needed for intruder calculations in which the exhumed waste is spread over a garden.

The quantity of food derived from the garden is proportional to the garden size. To estimate food production per unit garden area, two approaches were considered. The first is commercial food production in Washington State (WA Department of Agriculture 1994). Values for production per acre and per square meter are shown on Table 15. "cwt" means 100 pounds. Bushels of grain were assumed to have a density 70 percent that of water (700 kg/m^3). Thus a bushel of grain is assumed to weigh about 54 lb. The categories used for human consumption are from Table 13. The average person consumes the amount shown, in kg/y. Based on the average food production rate, the necessary garden area is 194 m^2. This total area is mostly needed for production of grains. This area also requires an efficient gardening operation to succeed.

The second approach to estimating garden size uses garden production estimates published by the Washington State University (WSU) Cooperative Extension (1980). Values are listed in Table 16. The document provides estimates of pounds of produce per 10 foot row in a garden. In addition, it gives recommended row spacings. The spacing was treated as the row width to compute production per unit area. The same average annual consumption rates from Table 13 were used to determine garden area needs. The WSU production estimates are higher than the commercial production averages hence the needed garden area is smaller (161 m^2). These were assumed to be optimum values under excellent growing conditions.

For performance assessment gardens, an efficiently planned and maintained garden of 200 m^2 will be assumed to supply 100% of the garden produce needs of a single adult over a year's time, or 25% of the garden produce needs of a family of four. Note that this represents a marked decrease from previous performance assessments. Ingestion doses from the post-intrusion garden are thus expected to increase due to the higher soil concentration.

Table 15. Commercial Food Production as a Basis for Garden Size.

Type of Produce	Yield per acre	Yield kg/m^2	Garden Area
Leafy Vegetables	**16.5 kg/y**	**2.35**	**7.0 m^2**

Notes: Food production data from *Home Gardens*, WSU Cooperative Extension Report EB-422. Average consumption rates are from Yang and Nelson, 1986.

2.2.4 Inhalation Rates for People

To determine the internal dose from the inhalation of resuspended particulate matter, one must be able to compute the total activity inhaled. Values are needed for the average air concentration, the time exposed at that concentration, and the average breathing rate during the exposure period.

A mass loading approach is used to estimate airborne concentrations of radionuclides for scenarios involving resuspension of contaminated soil as well as scenarios involving aerosolization of contaminated water. It is assumed that the air contains some average amount of contaminated soil or water per unit volume. This is then inhaled at a characteristic breathing rate for a length of time appropriate to the activity to calculate the total inhalation intake.

Radionuclides Dispersed in Soil: For scenarios with inhalation of radionuclides dispersed in soil, the average mass loading in air depends on what is happening to the contaminated soil. Active gardening produces the largest average mass loading, at 0.5 mg/m³. Routine activities outdoors are assume to take place at an average air concentration of 0.1 mg/m³. Indoor activities are assumed to take place at the lowest air concentration, 0.05 mg/m³. The basis for these air concentrations is presented very effectively in NUREG/CR-5512, Section 6.3.1.

In the well-drilling scenario, the individual is assumed to be exposed for 40 hours, spread over 5 days. This is the time needed to drill the well. During this time the individual breathes at the light activity rate for reference man (ICRP 23), 1.2 cubic meters per hour. The actual inhalation scenario is highly variable. The worker can be exposed to a high concentration when the waste material comes out of the hole. However, this material is soon buried by clean material coming from farther down the hole. In addition, the material is likely wetted as part of the drilling operation and to minimize fugitive dust emissions. Another modeling approach is to average the contamination over the assumed spreading area and compute the total inhaled over the 40 hour work period.

In the Grouted Waste performance assessment (WHC-SD-WM-EE-004) the well-drilling worker inhales resuspended dust at a concentration of 0.1 mg/m³ for one hour. However, the air concentration was not based on the waste concentration, but rather on the average soil concentration after spreading. In effect, the 0.64 m³ of exhumed waste is diluted to a total volume of 15 m³. These assumptions lead to the inhalation of 0.12 mg soil containing 0.0051 mg of waste, as shown in the calculations below.

Soil Inhaled (Grout PA) = (1 h)(1.2 m^3/h)(0.1 mg/m^3)
= 0.12 mg soil inhaled

Waste Inhaled (Grout PA) = (0.12 mg soil)(0.64 m^3)/(15 m^3)
= 0.0051 mg waste inhaled

If the well-driller's dust is undiluted waste, the worker would inhale 0.12 mg of waste. However, the actual inhalation time is probably greater than one hour. Since the waste layer is about 10% of the total well volume, and the well takes 40 h to drill, the time of exposure to the waste is (40 h)(0.10)=4 h. This would mean the worker inhales 4.8 mg of soil containing 0.48 mg of waste, as shown in the calculations below.

Soil Inhaled (ILAW PA) = (40 h)(1.2 m^3/h)(0.1 mg/m^3)
= 4.8 mg soil inhaled

Waste Inhaled (ILAW PA) = (4.8 mg soil)(0.14 m^3)/(1.4 m^3)
= 0.48 mg waste inhaled

For estimating inhalation exposure in the post-drilling residential scenario, the individual spends the entire year living in the contaminated area. The Grouted Waste performance assessment (WHC-SD-WM-EE-004) used an average inhalation rate of 8520 m³ per year and an average air concentration of 0.1 mg/m³. The annual amount of soil inhaled was 852 mg. The 200 West Area Burial Ground performance assessment (WHC-EP-0645) used more detailed inhalation assumptions based on PNNL-6312. The inhalation dose was based on an annual inhalation of 445 milligrams.

Inhalation dose for the ILAW PA will be based on a refinement of the model used for the 200 West Area Burial Ground. It is also very similar to the method discussed in NUREG/CR-5512.

The air concentrations shown in Table 17 are used to estimate the equivalent time of exposure to an average air concentration of 0.1 mg/m³. The actual air concentrations used in the table are discussed at length in NUREG/CR-5512, Section 6.3.1. The values chosen represent

conservative bounds on likely concentrations for the activities indicated. The exposure times are also based on the NUREG/CR-5512, although the document is not as explicit as to the assumptions behind the time periods used. It appears that NUREG/CR-5512 includes a vacation period of 2 weeks away from the residence. This is a minor (3%) reduction in the mass inhaled, and is not included in the ILAW PA. The combinations shown on Table 17 for the residential scenario lead to the annual inhalation of 573 milligrams of soil, which lies between the values used in the prior Hanford Site performance assessments. This value will also be used for the all-pathways farmer scenario.

The Columbia River population average is based on an exposure of 12 hours per day at the daily average breathing rate. This leads to an annual inhalation of 416 milligrams of soil, as shown below. In the 200 West Area Burial Ground PA (WHC-EP-0645) the annual inhalation was twice as great based on wide-spread irrigation leading to contaminated airborne material over a much larger region. This is unrealistically high, since the air concentration of contaminated material is bounding. There are other sources of airborne material that are not contaminated. Hence the lower estimate will be used in the ILAW PA for population dose.

(8766 h/y)(0.5)(0.95 m3/h)(0.1 mg/m3) = 416 mg/y

In Table 17 the 2920 hour period asleep is 8 hours per day, 365 days per year. For 180 days the individual works in or near his fields for 10 hours, making a total of 1800 hours outdoors. Of this 1800 hours, 100 hours is spent in dusty conditions. The remainder of the year (4046 hours) is spent indoors. The breathing rates shown on the table are from ICRP Report Number 23 on Reference Man (ICRP 23). No adjustment is made for the finite area of the contamination because the individual spends most of the year close to the emission source. Adjustment for a 4 week period away from home would reduce the annual inhalation intake by less than 10 percent. Therefore, the above value will be used for both the post-intrusion garden as well as the irrigated farm.

Table 17. Calculation of the Inhalation Time for the Residential Gardener.

Activity	Air Concentration (mg/m^3)	Exposure Time (h/y)	Breathing Rate (m^3/h)	Mass Inhaled (mg/y)
Asleep	0.05	2,920	0.45	65.7
Indoors	0.05	4,046	1.2	242.8
Outdoor	0.1	1,700	1.2	204.0
Gardening	0.5	100	1.2	60.0
Away		0		0.0
	Total Time:	8,766		572.5
	Averages:	6,030	0.95	573

Note: The individual spends 8 hours per day, 365 days per year asleep. For 180 days the individual spends 10 hours each day in the fields. Of this time, 100 hours are spent in relatively dusty conditions.

For routine exposure calculations, a daily average breathing rate (0.95 m^3/hr or 22.8 m^3/d) and air concentration (0.1 mg/m^3) must be used. Using these values, the annual intake of 573 mg requires an inhalation exposure time of 6030 hours, as shown in the last line of Table 17. Note also that the amount of waste actually inhaled depends on the garden size. If 0.14 m^3 of waste are exhumed and spread over a 200 m^2 garden that is tilled to a depth of 0.15 meter, then the 573 mg of soil contains 2.7 mg of waste. This assumes the densities of the waste and soil are nearly the same.

$$\text{Waste Inhaled} = (573 \text{ mg soil})(0.14 \text{ m}^3)/(200 \text{ m}^2)/(0.15 \text{ m}) = 2.7 \text{ mg}$$

The result for the post-intrusion resident is substantially larger than the amount inhaled by the driller. In addition, the inhaled masses can be normalized to a unitless fraction, the activity inhaled per unit activity exhumed. This is illustrated below using an area density of 225 kg/m^2 based on a soil density of 1500 kg/m^3 and a tilling depth of 0.15 cm. This method of comparison avoids the need to know the waste thickness and well diameter.

$$\text{Driller inhalation fraction} = (4.8 \text{ mg})/(225 \text{ kg/m}^2)/(100 \text{ m}^2)$$
$$= 2.13 \times 10^{-10} \text{ Ci inhaled per Ci exhumed}$$

Gardener inhalation fraction = (573 mg)/(225 kg/m^2)/(200 m^2)
= 1.27 x 10^{-8} Ci inhaled per Ci exhumed

In the HSRAM scenarios, the average air concentration is 50 μg/m^3. The daily inhalation rate is 20 m^3/d. Thus the individuals inhale 1.0 mg soil each day. In the industrial scenario, the annual inhalation time is 250 days so that the total annual inhalation is 250 mg soil. In the residential and agricultural scenarios the annual inhalation time is 365 days so that the total annual inhalation is 365 mg soil. The HSRAM inhalation intakes are therefore lower than the residential gardener commonly used in Hanford Site performance assessments.

The native american subsistence resident scenario (DOE/RL-96-16 Table 5.7) has the individual inhaling 30 m^3/d at an average concentration of 100 μg/m^3. Thus the daily intake rate is 3.0 mg/d, and the annual intake is 1095 mg soil. As with the food pathways, this is roughly twice the intake of the all-pathways farmer. Therefore, the inhalation dose from resuspended soil should be roughly twice as great also.

Radionuclides Suspended in Water: For scenarios with inhalation of radionuclides suspended in water, two situations are modeled. The first is the inhalation of spray created by a shower. The second is inhalation of steam in a wet sauna or "sweat lodge". A mass loading approach is used to estimate intakes for both cases.

The two parts of the mass loading approach are droplet suspension in air, and evaporation of water. The average water droplet concentration in air during these activities is about 10 mg liquid/m^3, a value characteristic of fogs (Hinds 1982). The evaporation of the contaminated water leads to partially saturated water vapor (a gas) in the shower or sauna. The assumed temperature and relative humidity determines the water vapor concentration. Note that only a small fraction of the radioactivity in the evaporating water becomes airborne. In *Airborne Release Fractions/Rates and Respirable Fractions for Nonreactor Nuclear Facilities, Volume 1* (DOE-HDBK-3010-94) data for the sudden depressurization of superheated aqueous solutions is presented in Table 3-5 for various initial pressures and volumes. With a source volume of 0.35 L at a pressure of 60 psig, the respirable release fraction is 0.006. A somewhat larger value of 0.01 will be used to represent the resuspension from pouring water on hot rocks in the sweat lodge, and for the spray of a shower. (The only exception to this is tritium. Since it is assumed to be oxidized, 100% of the tritium becomes airborne.) From data cited in DOE-HDBK-3010-94, it will be assumed that 99% of the radioactive contaminants (except for tritium) are not aerosolized when the water evaporates. The assumed temperatures and relative humidities for the shower and sweat lodge are listed in Table 18 below. Values for ambient conditions at the irrigation site are calculated from the average temperature and relative humidity at the Hanford Site (PNNL-12087) during the irrigation months (April through September). The evaporative entrainment fraction is assumed to be an order of magnitude smaller, again based on data cited in DOE-HDBK-3010-94 for lower temperature conditions without spray sources.

Also shown in Table 18 are the vapor concentrations calculated from the vapor pressure and relative humidity for the assumed temperature. The percents are by volume. The row labeled "Evaporated Water" is the concentration of water in the air. It is calculated using the formula weight for water (18.0153 g/gmole) and the ideal gas law, as shown below. Note that the temperature is in degrees kelvin rather than celsius, and also that Table 18 uses cubic meters (m^3) as the unit for volume.

Mass of water vapor per unit volume =
(18.0153 g/gmole)(Vapor Conc)/(0.08057 L·atm/gmole/°K)/(Temperature)

The line labeled "Entrained Water" is 1% of the "Evaporated Water" line to reflect the fact that evaporation leaves most of the contaminants behind. The line labeled "Droplets" is the bounding droplet concentration of a fog. Under ambient conditions normally found at the irrigation site there is no fog. The fog is only found in the shower and sauna.

Table 18 shows the effective total concentration of ground water in the air in the line labeled "Total Water". This line is the sum of the "Entrained Water" and "Droplets" lines. The line labeled "Tritium Total" is the sum of the "Evaporated Water" and "Droplets" lines.

The "Dilution Adjustment" is for the ambient humidity exposure only. It divides the year into two halves: irrigation and no irrigation. During the irrigation season the ground water is diluted by natural precipitation. As discussed in Section 2.5, this leads to a factor of 94%. During the remainder of the year (without irrigation) the contaminated fraction of the humidity is assumed to be reduced to 50%. Activities such as cooking and cleaning supply the contaminated portion of the humidity. For ambient conditions, the adjustment is calculated as shown below.

Ambient Dilution Adjustment = (94%)(0.5) + (50%)(0.5) = 72%

The annual exposure times depend on the exposure scenario, and determine the annual inhalation intake. Parameters for the ILAW PA are listed in the lower half of Table 18. The last lines in the table are calculated as the product of the "Annual Count", the "Event Duration", the "Breathing Rate", the "Dilution Adjustment", and the total water intake. Values are given for both tritium and all other nuclides. The assumed density of the irrigation water is 1.0 kg/L.

Table 18. Airborne Ground Water Intakes.

Parameter	Ambient	Shower			Sauna
Temperature	19.3°C (66.8°F)	40°C (104°F)			50°C (122°F)
Relative Humidity	39.8%	80%			80%
Water Vapor Concentration	0.87%	5.82%			9.74%
Evaporated Water, g/m^3	6.5	41			66
Entrained Contaminants, g/m^3	0.0065	0.41			0.66
Droplets, g/m^3	0	0.01			0.01
Total Water, g/m^3	0.0065	0.42			0.67
Tritium Total, g/m^3	6.5	41			66
Dilution Adjustment	72%	100%			100%
Breathing Rate, m^3/h	0.95	1.2			1.2
Exposure Scenario	All-Pathways and NASR	All-Pathways	HSRAM Industrial	HSRAM Residential, Agricultural	NASR
Event Duration, h/d	24	0.25	0.167	0.167	1
Annual Count, d/y	365	365	250	365	180
Total Inhaled, L/y	0.039	0.046	0.021	0.031	0.14
Total Tritium, L/y	39	4.5	2.1	3.1	14

Notes:

Ambient conditions are those found at the irrigation site. The average temperature and relative humidity during the irrigation season (April through September) are from PNNL-12087. No aerosol droplets are present. The "Dilution Adjustment" is based on the presence of natural precipitation during the irrigation season and half the normal during the remainder of the year.

The shower temperature is based on typical hot water settings. The relative humidity during the shower is a value selected from the likely range of 60% to 100%.

The sauna or sweat lodge experience lasts one hour and is repeated approximately every other day during the year. The temperature and relative humidity are reasonable assumptions.

The evaporative entrainment from ambient sources is assumed to be 0.1%, while the entrainment during showers and saunas (sweat lodge) is assumed to be 1%.

The listed breathing rates are from ICRP 23. The assumed density of the ground water is 1.0 kg/L.

Because the total groundwater inhaled is considerably smaller than the total groundwater ingested during the year the moisture inhalation dose should be smaller also. These moisture inhalation pathways were not used in prior Hanford performance assessments.

The "Sauna" for the NASR is also the "Sweat Lodge" used in DOE/RL-96-16. The assumed exposure conditions for the ILAW PA scenario leads to an inhalation of 0.14 L/y. The exposure conditions in DOE/RL-96-16 lead to the much larger inhalation of about 57 L/y. The reason for the difference is the extreme exposure conditions found in DOE/RL-96-16. For example, the sweat lodge temperature is 60 °C (140 °F) with a relative humidity of 100%, which means the air in the sauna is 20% water vapor. The sudden 20% reduction in oxygen concentration would certainly result in labored breathing, possibly fainting. The exposure to high temperature at saturated conditions for one hour would lead to skin burns over most of the body. Most of the difference is due to the assumption that 100% of the dissolved impurities become airborne when the water evaporates.

2.2.5 External Exposure Times

During the drilling operation, the worker is exposed to varying dose rates. Until the waste is exhumed this dose rate is zero. While the waste comes from the hole, the dose rate is high. Since the radiation source is small (about 0.14 m^3), the dose rate varies inversely with the square of the worker's distance from the waste. The waste is soon covered with clean soil from deeper in the well, which reduces the dose rate. To represent the potential dose to the worker, the waste is assumed to be spread into a layer 15 cm thick over an area of 100 m^2. The external dose rate factors of Table 10 are used to estimate the dose from 40 hours of exposure. This is the same approach used in the Grouted Waste performance assessment.

It should be noted that this assumption for the drilling operation exaggerates the external dose to the worker. If a flattened mound is placed 2 meters to the side of the worker, the dose rates are actually less than those from a 100 m^2 slab, even though the nuclide concentration is higher. With a general area contamination, the worker is standing on a portion of the contamination and receives higher dose rates.

The external dose rate factors of Table 10 apply to the center of the contaminated area. As one moves away from the center the dose rate decreases sharply with distance, unlike the resuspended dust concentration in the air. The airborne dust concentration decreases by diffusion and turbulent mixing rather slowly with distance, falling to half the peak value at a distance of about 100 m. By contrast, external dose rates at the edge of the contaminated area are half the value at the center of the contaminated area. At a distance of 10 meters from the edge of the contamination the dose rates are less than 10 percent of the center value.

For the post-intrusion resident, only the garden is contaminated, while for the irrigation scenarios most of the area near the person's dwelling is contaminated. The extent of the contaminated areas will affect the calculation of external dose in the two exposure situations. The exposure to soil contamination is divided into two time periods during the year. The first

period is the time actually spent standing in the contamination. The second period is the total time near the contamination, or indoors.

In the post-intrusion garden scenario, the external exposure time is taken to be half the total time outdoors, or 900 hours. In other words, the individual spends a time equivalent to 900 hours during the year standing in the center of his garden. Since the dose rate decreases rapidly with distance from the small garden, the time away from the garden has zero exposure.

In the irrigation scenarios, it is assumed that the entire time outdoors (1800 hours) is spent in exposure conditions similar to the center of an irrigated field. However, the dose rate indoors is reduced by a factor of 3. This factor of 3 is discussed in detail in NUREG/CR-5512, Section 6.7.4. Therefore the effective time of exposure at the unshielded dose rate is 4120 hours, as shown below.

$$(1800 \text{ hr}) + (6966 \text{ hr})/3 = 4120 \text{ hours}$$

Prior Hanford Site performance assessments used different values. The Grouted Waste performance assessment used an effective time of 4383 hours for both the post-intrusion gardener, the all-pathways irrigator, and the populations. The 200 West Area Burial Ground performance assessment used an effective time of 3260 hours for individuals and 4383 hours for populations. The effective exposure times selected for the ILAW performance assessment differ from the values used in prior Hanford performance assessments. Note that the average exposure time for the Columbia River population is chosen to be 4383 hours to be consistent with prior calculations.

For the HSRAM scenarios, the external exposure in the industrial scenario is 8 h/d, 146 d/y for an annual total time of 1,168 h. The residential and agricultural scenarios use an exposure time of 24 h/d, 365 d/y for an annual total of 8760 h/y. All external doses are reduced using the factor 0.8 to account for shielding from building walls. Therefore, the annual exposure time for the industrial scenario is 934 hours, and for the residential/agricultural scenarios is 7008 hours. The NASR also uses 7008 h/y for the effective external annual exposure time.

Comparison of the Driller and Post-Intrusion Resident. To compare the driller and the post-intrusion resident, note that the intake parameters are directly proportional to the dose from each pathway. For a few nuclides there are additional differences due to removal processes such as radioactive decay or leaching from the surface layer. Ignoring these details, Table 19 summarizes the important parameters for comparing doses. The inhaled and ingested amounts are in terms of the grams of waste exhumed. (Waste density is assumed to be the same as surface soil density.) The external exposure time has been adjusted by the waste volume to garden volume ratio to correct for the different garden sizes. In each pathway, the intake by the Driller is significantly smaller than the intake by the Gardener. Thus the dose to the Driller will be less than the dose to the Gardener for all nuclides.

Table 19. Comparison of the Intake Parameters for the Intruders.

Pathway	Driller	Gardener	Ratio
Waste Ingested	4.7 mg	170 mg	0.03
Vegetables ingested	0.0	43 kg	0.00
Waste Inhaled	0.48 mg	2.7 mg	0.18
External factor	(40h)(0.14m³)/(15m³) = 0.37 h	(900h)(0.14m³)/(30m³) = 4.2 h	0.09

Note: The above values assume 0.14 m³ of waste are exhumed and spread over 100 m² for the Driller and 200 m² for the Gardener. In both scenarios the soil mixing depth is 0.15 meter.

Some of the external exposure pathways noted in Table 3 are much smaller than internal pathways that accompany the external exposure. For example, the external exposure to an individual whose livestock and household pets drink contaminated well water is much smaller than the internal dose resulting from the consumption of animal products (milk, meat, poultry, and eggs). This follows from the observation that the dose resulting from a given amount of radioactivity outside the body (leading to an external dose) is orders of magnitude lower than the dose resulting from the same amount of radioactivity ingested or inhaled (leading to an internal dose). Admittedly, the individual will not eat all of the radioactivity present in an animal, since the radioactivity will be present in organs and tissues that are not normally eaten. However, the use of all four animal pathways combined with the observation that the individual is in close proximity to the animal for only short periods during the day gives assurance that this external pathway can be ignored.

A more detailed evaluation of the external dose from submersion in contaminated air is needed in order to eliminate it from further consideration. Table 12 shows the submersion dose rate factor as well as the ratio between the inhalation dose and the submersion dose. The smallest ratio is 5.06 for Na-22. Hence the submersion dose can be ignored since it will never be a significant part of the total dose.

2.2.6 Absorption Through the Skin

Each exposure scenario includes dermal contact with the contaminated medium. The driller and post-intrusion resident get the contaminated soil on their skin. The ground water scenarios have contaminated water being used for showers and saunas. These two will be treated separately to demonstrate that the likely intake from contamination being absorbed through the skin into body fluids is negligible compared to other ingestion pathways.

An exception is for tritium as water vapor. The inhalation dose factor for tritium includes absorption through the skin in addition to the lungs by increasing the value by 50%. The ingestion dose factor is not modified.

Internal dose factors for radionuclides absorbed through the skin can be calculated from the numbers given in Table 7 by dividing the ingestion dose factor by the gut-to-body-fluid transfer fraction (f1). This is somewhat inexact because the material in the gut is wet and has a variety of chemicals secreted by the body to aid in the absorption of nutrients. In addition, the interior surface area of the small intestine is larger than the skin area of the entire body to aid in the absorption of nutrients.

For both soil and water in contact with the skin, the transfer from the skin to the body fluids is assumed to be proportional to the f1 parameter. The f1 transfer fraction thus cancels out of the calculation, and dermal contact becomes another ingestion dose.

Contaminated Soil. Soil adheres to the skin, which is one reason people take showers. Typical soil adherence values range from 0.1 mg/cm^2 to 5 mg/cm^2. The adult body has a skin area of about 20,000 cm^2. The hands and arms have about 20% of the total area. A small fraction of the contamination present on the skin will be absorbed into the body through the skin. This fraction is assumed to be one percent of the f1 value. Table 20 summarizes the affected skin areas, soil adherence, and annual contact events for each of the exposure scenarios. The product of these factors gives the effective soil ingestion due to dermal contact. The values shown are small compared to the values for direct ingestion of soil presented in Tables 13 and 14. Hence the approach taken in DOE/RL-91-45 to neglect dermal absorption of radionuclides will be adopted in the ILAW PA also.

Contaminated Irrigation Water. Waterborne contaminants in contact with the skin may potentially be absorbed through the skin into the body fluids. The leading dermal contact events are showers and the sauna or sweat lodge. Since these expose the entire skin surface, the potential for significant absorption exists. However, contact time is limited to 15 minutes for showers and 1 hour for the sauna or sweat lodge. Based on typical values for the dermal absorption constant (0.001 cm/h or less) and the dermal absorption method described in PNNL-10523 (Section 2.2), it is concluded that effective intakes per shower or sauna are less than 20 cm^3. With up to 180 saunas per year, the annual ingestion intake increases by less than 1 percent. Therefore, the dermal absorption of radionuclides in irrigation water will not be explicitly included in the calculations for the ILAW PA.

Table 20. Effective Soil Ingestion Due to Dermal Contact With Soil.

	Intruder	Post-Intrusion Resident and Irrigated Farm	HSRAM Industrial	HSRAM Residential and Agricultural	NASR
Skin Surface Fraction	0.25	0.2	0.25	0.25	0.25
Soil Adherence, mg/cm^2	0.25	0.25	0.20	0.20	1.0
Contact Frequency, d/y	5	100	146	180	365
Effective Annual Ingestion, g/y	0.063	1.0	1.5	1.8	18

Notes:

The total skin surface area for an adult is 20,000 cm^2. It is assumed that 1% of the soil adhering to the skin is available for absorption into the body.

The effective annual ingestion is the product of the total skin area, the skin surface fraction, 1% of the soil adherence, and the contact frequency. The NASR has the greatest intake.

HSRAM - Hanford Site Risk Assessment Methodology
NASR - Native American Subsistence Resident

2.3 Animal Parameters

The animal parameters discussed here are those pertaining to the eventual concentration of radioactivity in animal products consumed as food, such as fish, milk, meat, poultry, and eggs. The equilibrium model used to represent various animals assumes that they take in radioactivity by inhalation, ingestion, and dermal absorption at a rate which changes slowly during the year. The concentration in the animal reaches a steady-state maximum related to the concentration in its environment. Note that the radiation doses received by the animals are assumed to be low enough to not affect their health or metabolism. The contaminant concentration in food products is proportional to the level of contamination in the animal's environment, particularly in the food it consumes. The constants of proportionality are called bioaccumulation factors, or transfer factors.

Not all animals have transfer factors developed for them. It is assumed that other aquatic animals such as bottom-dwelling fish, crustaceans and mollusks are consumed in minimal amounts. If a group of people is identified who consume significant quantities of these creatures

then efforts will be made to quantify the transfer factors which would apply to them. Other land animals such as pigs or goats are assumed to have transfer factors which differ very little from cattle.

The contaminant concentration in cattle and poultry depends on the rate at which the contaminant is consumed. The cattle and poultry diets are discussed in the next section. The equilibrium transfer factors for these animals are discussed afterward.

2.3.1 General Animal Parameters

The daily intake rates assumed for cattle and poultry are listed in Table 21. These are from NUREG/CR-5512, Section 6.5.1. No distinction is made between the diets of poultry raised for food and egg-laying hens. For comparison with prior Hanford Site performance assessments, the default intake rates used by the GENII program (PNNL-6584) are also shown in Table 21. The water intake rates are the same for both. Note that the GENII program does not distinguish between the two types of stored feed (i.e. hay or grain), nor does it allow the animals to ingest soil directly.

To calculate the radionuclide concentrations in the animal foods, it is necessary to introduce a "dry-to-wet ratio". The "dry-to-wet ratio" is a unitless quantity measured as the ratio of the dry weight of the item to its wet weight. The "dry-to-wet ratio" for stored hay applies at the time of harvest. In practice the hay is dried before being fed to cattle. Thus the "dry-to-wet ratio" for sun-cured hay is reported as approximately 0.9, similar to stored grain. All of the wet weights shown on Table 21 are at the time of harvest or when the animal is grazing.

The intake rates found in NUREG/CR-5512 will be used in the current performance assessment. The principal reason for this change from prior Hanford performance assessments is the extra detail provided on the diet. Previous performance assessments relied on the GENII software, which is unable to accommodate this detail. The ILAW PA for the low-level waste glass form will utilize hand calculations that incorporate the added detail.

The exposure of special groups living near waste sites or near locations where the ground water enters the Columbia River would probably include the consumption of some type of native game animals. These animals could acquire radioactivity from drinking and grazing near locations were ground water enters the river. The larger examples of these, such as deer, would graze over a large area. Thus only a small portion of the deer would be contaminated. Similarly, the smaller animals might derive all of their nourishment from a contaminated area. However, such animals would have to be harvested from many locations over the course of a year. The average concentration from all such animals would be much lower due to the large forage area needed for hunting and gathering. It will be assumed that the game animals are contaminated at such a low level compared with the domesticated animals that the dose from game animals can be ignored.

Table 21. Animal Feed, Water, and Soil Intake Rates

Values from NUREG/CR-5512 for use in the ILAW PA							
Type of Feed	dry-to-wet ratio	Beef, kg/d		Milk, kg/d		Poultry, kg/d	
		dry	wet	dry	wet	dry	wet
Fresh Forage	0.22	3	14	8	36	0.0275	0.13
Stored Hay	0.22	6	27	6	29	0	0
Stored Grain	0.91	3	3	2	2	0.0825	0.09
Total Feed, kg/d:		12	44	16	67	0.110	0.22
Soil Ingestion Rate:		0.6 kg/d		0.8 kg/d		0.011 kg/d	
Drinking Water:		50 L/d		60 L/d		0.3 L/d	
Values from GENII (PNNL-6584) used in previous Hanford Site PAs							
Type of Feed	dry-to-wet ratio	Beef, kg/d		Milk, kg/d		Poultry, kg/d	
		dry	wet	dry	wet	dry	wet
Fresh Forage	0.20	10	51	8	41	0	0
Stored Hay	0.18	3	17	2	14	0.022	0.12
Stored Grain	NA	NA	NA	NA	NA	NA	NA
Total Feed, kg/d:		13	68	10	55	0.022	0.12
Soil Ingestion Rate:		NA		NA		NA	
Drinking Water:		50 L/d		60 L/d		0.3 L/d	

The wet weights are at the time of harvest or grazing. The GENII software does not distinguish between stored hay and stored grain. In addition, GENII does not consider ingestion of soil by grazing animals.

It should be noted that animals killed by native hunters would be more efficiently scavenged than common farm animals. Some of the internal organs would be eaten. The animal skins could be used for clothing, and larger bones could be used as tools or ceremonial items. The more extensive use of animal parts could increase the exposed person's radiation dose. Nevertheless, it will be assumed that this dose is small compared with that from farm animals.

2.3.2 Equilibrium Transfer Factors

The equilibrium transfer factors for cattle and poultry relate the rate of intake of a contaminant to the eventual steady-state concentration in meat or milk or eggs. These parameters are the ratio of the equilibrium concentration of a nuclide in the animal product to the daily intake by the animal. For beef, poultry and eggs the units are Ci/kg per Ci/d (equivlent to d/kg), while for milk the units are Ci/L(milk) per Ci/d (equivalent to d/L). Values obtained from NUREG/CR-5512 (1992) are listed in Table 22. Transfer factors for organs such as liver or brain are not available. Since some elements may be found in higher concentrations in these tissues, individuals who consume the organs would receive higher doses from the radioactive isotopes of the elements.

The concentration of waterborne contaminants in fish is assumed to be proportional to the concentration of the contaminant in the water environment of the fish. The constant of proportionality for fish is called a "bioaccumulation" factor. It is the average concentration of the contaminant in the edible portion of the fish divided by the concentration in the water. This parameter has units of L/kg. Values for fresh-water fish from NUREG/CR-5512 (1992) and PNWD-2023 (1994) are listed in Table 22 under the column labelled "Fish". The NUREG/CR-5512 values have been used in prior Hanford Site performance assessments. The Hanford Environmental Dose Reconstruction (HEDR) values are recently published and have not been used in prior performance assessments. There are only two bioaccumulation factors which are affected by the HEDR research. The first is for sodium (100 in NUREG/CR-5512 became 8) and neptunium (250 in NUREG/CR-5512 became 21). These are marked in Table 22.

Table 22. Transfer Factors for Cows, Chickens, and Fish

*Beef, milk, poultry, and egg transfer factors for H-3 and C-14 were computed from the equilibrium model described in the text. Fish bioaccumulation factors for sodium and neptunium are from PNWD-2023. Other transfer factors are from NUREG/CR-5512. Above transfer factors are based on the wet weights.

Transfer factors for tritium (H-3) and C-14 are computed from an equilibrium model. The ratio of radioactive H-3 (or C-14) to the non-radioactive hydrogen (or carbon) in the animal's diet is assumed to be reproduced in the food product. The equilibrium transfer factor is then the fraction of hydrogen (or carbon) in the food product divided by the daily intake of hydrogen (or carbon). The assumed element fractions are listed in Table 23 below. Values in this table were taken from NUREG/CR-5512.

Table 23. Hydrogen and Carbon Fractions for Equilibrium Models

Food Pathway Item	Hydrogen Fraction	Carbon Fraction
Garden Soil	0.022	0.03
Leafy Vegetables	0.10	0.09
Other Vegetables	0.10	0.09
Fruit	0.10	0.09
Grain	0.068	0.40
Fresh Forage	0.10	0.09
Stored Hay	0.10	0.09
Stored Grain	0.068	0.40
Beef	0.10	0.24
Milk	0.11	0.07
Poultry	0.10	0.20
Eggs	0.11	0.15

Notes: All fractions listed above are based on the wet weight of the item. All fractions are taken from NUREG/CR-5512, except for the hydrogen fraction in garden soil, which is calculated as the soil porosity (30%) times the density of water (1.0 kg/L) divided by the soil density (1.5 kg/L) times 9. Hydrogen fractions include organically bound hydrogen as well as water. The effective water fraction is the hydrogen fraction times 8.94, which is the ratio of molecular weights for water and hydrogen.

The bioaccumulation factors shown in Table 22 are used to estimate total population dose from fish consumption to people living near the Columbia River. The edible portion of fish is the muscle normally cooked and consumed. The rest of the fish is assumed to be discarded. If there are individuals who eat or otherwise use other parts of the fish they could receive additional dose.

Although not important for the ILAW PA, a subject requiring research is the equilibrium transfer factors for wild animals consuming native vegetation. These species may be "harvested" by humans for food. In addition, since standard uptake factors are for muscle tissue only, there would need to be organ-specific uptake factors for those internal organs which may be consumed by special groups of people.

2.4 Plant Parameters

Living plants supplying food for people fall into two broad categories, aquatic plants and terrestrial plants. It will be assumed that aquatic plants contribute very little to the typical human diet -- either directly or indirectly. If exceptions are identified then a suitable set of parameters and models for contaminant uptake by aquatic plants and subsequent consumptions by humans will be utilized. All plants eaten are assumed to be terrestrial rather than aquatic.

The calculation of radionuclide concentrations in living terrestrial plants uses three main routes, (1) root uptake, (2) resuspension to leaves (also called "rain splash"), and (3) direct deposition of irrigation water on foliage. Each of these will be considered separately below. The three uptake routes are then combined to obtain the total concentration in edible portions of plants.

2.4.1 Root Uptake

The model for root uptake of a contaminant into terrestrial plants assumes that the concentration in the edible portion is proportional to the concentration in the soil at the time of harvest. The constants of proportionality are known as the soil-to-plant concentration ratios. These concentration ratios are measured as the concentration of the dry produce item divided by the soil concentration. They have no units, since the soil and food items have the same mass-based concentration units, eg. pCi/kg.

Because the human consumption rates shown in Tables 13 and 14 are the wet weights, it is necessary to select suitable constants to convert from dry weight to wet weight. These constants are known as "dry-to-wet ratios". They are simply the dry weight of the food item divided by the wet weight of the item. The "dry-to-wet ratios" from three sources are listed in Table 24. The values chosen for the ILAW PA are from PNWD-2023 for leafy vegetables and NUREG/CR-5512 for the others. The chosen values for the ILAW PA appear in the last column of Table 24. The values under the "GENII" column have been used in prior Hanford Site performance assessments.

The GENII dry-to-wet ratios for grains differ greatly from the other collections. However, it has been assumed in prior performance assessments that grains would be unlikely to become contaminated in the intruder or irrigation scenarios. The intruder would probably not raise grains in his home garden, and the principal grain crop in this area (dry-land wheat) would not be irrigated. For the ILAW PA grains are included as contaminated vegetable intakes. The basis for this approach is that some grains (e.g. corn) are irrigated. In addition, the 25% contamination fraction incorporates the presence of non-irrigated grains (e.g. wheat) in the individual's diet.

Table 24. Dry-to-Wet Ratios for Vegetation Consumed by Humans

Type of Produce	GENII	ORNL-5786	ILAW PA
Leafy Vegetables	0.10	0.067	0.09
Other (protected)	0.25	0.222	0.25
Fruit (exposed)	0.18	0.126	0.18
Grains	0.18	0.888	0.91

ILAW PA values are from PNWD-2023 and NUREG/CR-5512.

Root uptake will be calculated using concentration ratios listed in Table 25. The ratios for four types of vegetables are given on this table. The definition of the four types were given in Section 2.2.3. Most of the values are from NUREG/CR-5512 (1992). The value for the iodine concentration ratio in leafy vegetables is from the more recent HEDR assessment (PNWD-2023 1994). The values for hydrogen were calculated using an equilibrium assumption. The ratio of tritium to hydrogen in the soil is assumed to be duplicated in the plant. Thus the effective soil-to-plant transfer factor is the hydrogen concentration in the plant divided by the hydrogen concentration in the soil and the dry-to-wet ratio for the plant.

*Concentration ratios shown for hydrogen were calculated from the equilibrium model. The concentration ratio for iodine is from PNWD-2023. Other concentration ratios are from NUREG/CR-5512. The above transfer factors are based on the dry weights.

The Hanford Site is very dry and sandy, so that plant uptake factors would likely differ from the generic values used in literature reviews such as NUREG/CR-5512 and ORNL-5786. However, the preparation of the soil for a garden changes the properties of surface layer. The tilling, watering and addition of fertilizers and organic material produces soil which resembles the generic garden soil of NUREG/CR-5512 and ORNL-5786. It is therefore assumed that the concentration ratios found in these documents are adequate to describe plant uptakes in possible future gardens on the Hanford Site.

Groups of people gathering native vegetation for nourishment and other household needs may require special consideration. The soil-to-plant transfer factors could differ considerably

from the values shown on Table 25. Soils deficient in some mineral will have much higher uptake factors for radionuclides which are chemically similar to what is missing. The converse is also true. In addition, the distribution of the contaminant in the native vegetation during the growth of the plant is important. For example, Native American Indians use various parts of the cattail over its growth stages (CTUIR 1995). However, the ILAW PA deals with localized areas of contaminated soil resulting from intrusion or irrigation with contaminated ground water. The transfer factors for native plant species is not needed because the contaminated portion is an insignificant part of the overall diet.

2.4.2 Rain Splash

The term "rain splash" refers to all the processes which cause soil to deposit on the surfaces of plants. It includes the transport of soil by the irrigation water, rain drops, and the wind. The standard model (NRC 1977) then includes a "translocation" factor which is the fraction of activity deposited on plant surfaces which ends up in the edible portions of the plant. There are two basic approaches to estimating the concentration in plants due to resuspension of contaminated soil. The standard approach begins with an estimate of the average air concentration and then computes the activity deposition rate on the plant. The other approach (NUREG/CR-5512 1992) simply treats rain splash in a manner similar to root uptake.

In NUREG/CR-5512 the amount of rain splash is characterized by a "mass loading" factor which is the ratio of foliage contamination due to rain splash divided by the concentration in the soil nearby. It is similar to the root uptake concentration ratio described in the previous section. The value recommended in NUREG/CR-5512, Section 6.5.2 is 0.1 Ci/kg (dry produce) per Ci/kg soil for all plant types. In addition, this value "includes consideration of translocation of activity in soil from plant surfaces to edible parts of the plant." The only other parameter used to estimate the actual plant concentration from rain splash is the dry-to-wet ratio.

The more commonly used approach begins with an average air concentration due to rain splash and computes a deposition rate on plant surfaces. The RESRAD program (Yu et al. 1993) has a default mass loading air concentration of 0.1 mg/m^3. The default value in GENII is 0.225 mg/m^3. Both of these use a deposition speed of 0.001 m/sec which is suitable for respirable particles. However, both of these assumptions lead to rain splash transfers which are two or three orders of magnitude below the experimental data referenced in NUREG/CR-5512.

For the ILAW PA the standard transport model will be used rather than the effective mass loading approach of NUREG/CR-5512. However, the average air concentration for rain splash will be 1 mg/m^3 with a deposition speed of 0.01 m/sec. These parameters lead to mass loading values which are consistent with the data reported in NUREG/CR-5512.

Other parameters which are part of the standard model for foliar deposition are the interception fraction, the crop yield (biomass), the translocation factor, the weathering half-life, and the growing period.

The interception fraction is the portion of the airborne contamination depositing in a unit area which initially attaches to vegetation. It includes the fraction of the ground surface which is covered by vegetation. Values for interception fraction for various crops are given in ORNL-5786. More recent publications described in PNNL-6584 will be used as the basis of the interception fractions for this performance assessment. The empirical relationship between interception fraction and standing biomass (dry weight) is shown below.

$$\text{Interception Fraction} = 1.0 - \text{Exp}[-(P)(\text{Dry Yield})] \quad (3)$$

The parameter P depends on the type of vegetation. For leafy vegetables, grains, grass and hay the measured value for P is 2.9 m^2/kg, while for fruits and other plants the measured value for P is 3.6 m^2/kg. The "Dry Yield" is the mass per unit area of the standing biomass at the time of harvest, adjusted for water content. The "Dry Yield" is calculated as the product of the dry-to-wet ratio and the crop yield (wet). Values for biomass and interception fraction are shown on the Table 26.

Table 26. Various Crop-Specific Parameters

Type of Produce	Dry-to-wet Ratio	Crop Yield kg(wet)/m^2	Interception Fraction[2]	Translocation Factor	Growing Period
Leafy Vegetables	0.09[1]	2.0	0.407	1.0	45 d
Other (protected)	0.25	2.0	0.835	0.1	90 d
Fruit (exposed)	0.18	3.0	0.857	0.1	90 d
Grains	0.91	0.8	0.371	0.1	90 d
Fresh Forage - Cow	0.22	1.5	0.616	1.0	30 d
Stored Hay - Cow	0.22	1.0	0.472	1.0	45 d
Stored Grain - Cow	0.91	1.0	0.472	0.1	90 d
Forage - Poultry	0.22	1.0	0.472	1.0	30 d
Grain - Poultry	0.91	1.0	0.472	0.1	90 d

[1]Value shown is from PNWD-2023. All other values are from NUREG/CR-5512 Section 6.5.7.
[2]Interception fractions are calculated using the formula described in the text (PNNL-6584 Section 4.7.4).

The translocation factor is the fraction of what deposits on the foliage that reaches the edible parts of the plant. The values are shown on Table 26 are widely used in calculations of this type (NRC 1977; PNNL-6584 1988; NUREG/CR-5512 1992) and will be used in the ILAW PA.

The weathering half-life is the time required for half the contamination initially deposited on plant foliage to be removed by the action of wind, rain and irrigation. The value chosen for all nuclides is 14 days, based on the recommendations of NRC (1977) and the review given in ORNL-5786.

The growing period is the time that a plant is subject to the mechanical action of weathering prior to be harvested. The growing period varies with crop type. It is the time needed to produce one crop. During the growing season more than one crop may be harvested.

2.4.3 Direct Deposition

The models for root uptake and rain splash contributions to growing plants depend only on the soil concentration at the time of harvest. Direct deposition is unique to overhead irrigation. It refers to the transfer of contamination from irrigation water to the foliage intercepting the water as it falls.

A key parameter to model the contamination of foliage by direct deposition is the interception fraction. The value recommended for all plant types by the NRC (1977) will be used, 0.25. This value is not well documented, but is widely used in other reviews (PNNL-6584 1988; NUREG/CR-5512 1992).

The other parameters determining plant concentrations exposed to contaminated irrigation water are the translocation factors, the weathering half-life, and the growing periods. The same parameters used for describing rain splash will also be used for direct deposition. The translocation factors and growing periods are shown on Table 26, while the weathering half-life is 14 days.

If a special group of people were using overhead irrigation to increase growth density and crop yield, then the same parameters used for the standard group would apply to them also. No special modeling would be required unless the group were using the crop in some manner which could produce more dose than simply eating it.

2.5 Soil Parameters

The soil parameters of interest are those pertaining to the delivery of radiation exposure to someone living over, or growing food crops in contaminated soil. The two main types of exposure are from external and internal sources. In addition, the internal exposure can be divided into inhalation and ingestion intakes. Each of these routes of exposure will be discussed below.

The principal effect of the soil on the external exposure received by someone living nearby is through the soil density, chemical composition, and roughness. As described in Section 2.2.2, the surface soil density is assumed to be 1.5 g/cc. The contamination of interest is distributed through the top 15 cm. The assumed composition is primarily silicon dioxide, with various

additions, such as water. Over time the radioactive contaminants have been observed to migrate into deeper layers. The radioactive elements are affected by the average flow of water through the surface layer into deeper layers. Some elements, such as hydrogen and iodine are very soluble and leach from the surface layer in a few years. Other elements, such as cesium and plutonium hardly move at all.

The principal relationship between soil contamination and inhalation dose is through the ease with which contaminants in the soil become airborne. The presence of ground cover and moisture reduces the air concentration. Hand-tilling activities increase the air concentration. The gradual leaching of radioactive contamination to deeper layers of soil reduces the air concentration as well.

The principal relationship between soil contamination and ingestion dose is through the ease with which contaminants in the soil become incorporated in plant and animal produce. It is assumed that the effects of tilling and fertilizers lead to soils that are similar to those for which the concentration ratios shown in Table 25 were derived. The gradual leaching of radioactive contamination to deeper layers of soil (below the root zone) reduces the concentration in plant and animal products as well.

Soil-specific parameters related to leaching are the soil composition (sand, clay, silt and organic), the distribution coefficients, the density, porosity, and the water content. These parameters determine the rate at which radionuclides leach from the surface layer into deeper layers, the magnitude of the external dose rate factors, and the expected ratios of radioactive elements to non-radioactive elements in those cases where equilibrium models can be applied, namely, for tritium.

The composition of the surface layer is assumed to be sandy, where sandy is defined to have greater than 70 percent sand-sized particles. With few exceptions this is what lies near the surface of the entire Hanford Site. The soil-to-plant concentration ratios and distribution coefficients depend on this assumption. However, the preparation of the soil for a garden changes the properties of surface layer. The tilling, watering and addition of fertilizers and organic material produces soil which resembles the generic garden soil of NUREG/CR-5512. It is therefore assumed that the leaching coefficients found in this document is adequate to describe possible future gardens on the Hanford Site.

The distribution coefficients are taken from NUREG/CR-5512 (1992) and are listed in Table 27. The values in NUREG/CR-5512 were obtained from experiments using four different soil types (sand, loam, clay, and organic). The smallest distribution coefficients (representing the most mobile condition) was reported in NUREG/CR-5512. While this approach may underestimate soil concentrations, the effect of leaching from the surface layer during the growing season is small for most nuclides.

The thickness of the surface soil of interest in the dose calculations is the top 15 centimeters. This thickness represents typical cultivation depths for mechanical mixing of

deposited activity. In addition, it represents typical root depths. This thickness has been used in all prior Hanford Site performance assessments.

The density and thickness of the affected surface layer determine the external dose rate factors discussed in Section 2.2.2, as well as the leaching coefficients computed for the surface layer. Leaching is the process by which contaminants migrate from the surface layer of soil into deeper layers below. The driving force behind the leaching process is the application of water to the soil. Leaching is treated as a removal rate constant giving the fraction of the material in the surface layer which is removed per unit of time. It is calculated using equation (4) shown below.

$$\lambda_s = \frac{P + I - E}{\theta\, d\, (1 + \rho/\theta\, K_d)} \qquad (4)$$

where,

λ_s= average soil leaching coefficient, fraction removed from a soil layer of thickness "d" during the time that irrigation occurs.

P = total precipitation, in centimeters, during the irrigation period. Over the period 1961 to 1990, the precipitation during the 6 month irrigation season (April to September) has been 5.23 cm (PNNL-12087).

I = total irrigation, assumed to be 82.3 cm per year (32.4 inches/y). Nearly all of this is deposited during a 6 month period.

E = total evapo-transpiration, in centimeters per year. Assumed to be 77.5 cm per year so that the total over-irrigation (P+I-E) is 10 cm/y. This over-irrigation assumption is consistent with PNWD-2023, which assumed that farmers over-irrigate by 10 percent.

d = thickness of soil from which nuclides migrate, in centimeters. This is assumed to be 15 cm (5.9 inches).

ρ = bulk density of the surface soil, in grams per cubic centimeter. The value normally used at Hanford is 1.5 g/cc.

θ = volumetric water content of the surface soil, milliliters of water per cubic centimeter of soil. A value of 0.3 ml/cc is assumed. The irrigated soil is assumed to be nearly saturated with water.

K_d= distribution coefficient in surface soil for an element, in milliliters per gram. Values from NUREG/CR-5512 are shown on Table 27.

The values assigned to the variables in the above equation were used in prior Hanford performance assessments. The annual irrigation total (82.3 cm/y) is based on the Specific Information on the Terrestrial Environment (SITE) database referenced ORNL-5786. The SITE database reports that a large percentage of the drier western states falls into the range from 70 to 85 cm/y. The values chosen in NUREG/CR-5512 is 76 cm/y, while the value more appropriate to Hanford is 82.3 cm/y (WHC-SD-WM-EE-004). The Hanford value is based on irrigation rates in the counties surrounding the site. Note that the amount of irrigation is assumed to be the same for all plant types including grains.

Leaching coefficients computed from the equation (4) are listed in Table 27. The numerator represents the excess water added each year. It is taken to be about 10 cm during the irrigation season based on the discussion in PNWD-2023.

Table 27. Leaching Factors for Garden Soil

Element	Leach per year	Kd	Atomic Number	Element	Leach per year	Kd	Atomic Number

Soil distribution coefficients are from NUREG/CR-5512. The leaching factors were calculated using Equation (4).

The soil moisture is used in the special equilibrium model for tritium. The tritium is chemically bound in a water molecule and thus goes with the water. The transfer from soil or irrigation water to vegetation is best described with an equilibrium model. The concentration of tritium in irrigation water, for example, is similar to the concentration in the water in the soil or a plant or the cow's milk. The soil hydrogen fraction is 0.022 kg hydrogen per kg soil. Thus the effective moisture content of the soil is calculated as shown below. The density of water is 1.0 kg/L.

$$(8.94\ g\ H_2O/g\ H_2)(0.022\ kg\ H_2/kg\ soil)/(1.0\ kg/L)=0.197\ L\ H_2O/kg\ soil$$

This value is consistent with the assumed value for the volumetric water content of soil (0.3 ml/cc) and its density (1.5 kg/L). Note that the value reported in NUREG/CR-5512 is 0.1 L/kg. A higher value is therefore being used in the ILAW PA, which leads to higher tritium concentrations in irrigated soil.

In the exposure scenario where the glass waste matrix is brought to the surface, it will be assumed that the glass is still largely unchanged from the time of disposal. Most of the radionuclides are assumed to remain in the glass brought to the surface. Leaching from the surface layer for the nuclides trapped in the glass will not be considered.

Because the expected irrigation application rate of 82.3 cm/year (32.4 inches/year) is applied over a minimum area of 2 hectare (5 acres), the total annual water need for the farmer is at least 1.7×10^7 liters. This value was assumed in prior Hanford performance assessments. The ability of a well to supply water at this rate must be confirmed before dose calculations based on it are carried out.

The Hanford Environmental Dose Reconstruction Project (HEDR) found the irrigation rate in the counties surrounding the Hanford Site ranged from 61 cm/y to 98 cm/y (PNWD-2023, Rev 1). This range leads to leaching coefficients that range from 0 to 2.5 times the chosen values. This range has little effect on the resulting doses for most nuclides because the leaching coefficients are generally small.

A two-part removal rate from the soil has been adopted for use in the ILAW PA. It is assumed that significant irrigation occurs during 6 months of the year. The rest of the year has very little water infiltration. During the no-irrigation period there is no leaching from the surface layer. The one exception is tritium. Tritium is removed from the surface layer during this period by evaporation. Since the natural precipitation normally is 10.69 cm water during the no-irrigation period, this is also the evaporation rate. Evaporation of tritiated water thus leads to the effective leaching coefficient shown below.

$$\lambda_{s,H3} = (10.69 \text{ cm/y})/(0.3 \text{ ml/cc})/(15 \text{ cm}) = 2.38 \text{ per year}$$

Natural precipitation acts to dilute contaminated irrigation water slightly. It adds water that is not contaminated. The formula below shows the dilution factors [i.e., I/(I+P)] used in these calculations during the irrigation season.

$$\text{Dilution Adjustment (individual)} = (82.3 \text{ cm})/(82.3 + 5.23 \text{ cm}) = 0.940$$

$$\text{Dilution Adjustment (population)} = (63.5 \text{ cm})/(63.5 + 5.23 \text{ cm}) = 0.924$$

3.0 MATHEMATICAL MODELS AND DOSE CALCULATIONS

The mathematical models used for the ILAW PA unit dose factors are described in this section. The selection of the various pathway parameters discussed in the previous section can be best understood through the formulas that apply the parameters. The presence of radioactive decay chains complicates this discussion, and the subsequent calculations. But the use of decay chains is necessary because some progeny nuclides are more significant than the parent nuclide.

To facilitate calculations with the large number of nuclides that may be found at the Hanford Site, the hand calculations were automated using commercial spreadsheet software. Spreadsheet calculations have been verified by hand calculations presented in Appendix A and Appendix B.

Doses to humans exposed to exhumed contamination or irrigation water include both internal and external radiation exposures. The internal dose comes from the inhalation of resuspended dust and the ingestion of contaminated water, soil, and foodstuffs. The external dose comes primarily from being near the contaminated soil. The sections below describe how the human dose is computed from the parameters of Section 2 together with standard models for estimating this dose. First, the time dependence of soil concentrations are presented. Second, the external and inhalation doses received from contaminated soil are described. Third, the concentrations and doses for various plant types are described. Finally, the concentrations and doses for animal products are described. The role of radioactive decay and daughter ingrowth is discussed in each section.

3.1 Time Dependence of Soil Concentrations

The soil concentrations are of two types. The first type of soil contamination results from drilling a hole through the waste site and spreading the contamination in a garden. In this case there is some initial concentration of a nuclide in the surface layer that decreases with time due to radioactive decay and leaching from the surface layer. The second type of soil concentration results from irrigating with contaminated water. In this case the contamination increases with time due to the added radioactivity. However, this increase is offset by radioactive decay and leaching from the surface layer.

In the description of progeny ingrowth, it will be assumed that only the parent nuclide is present initially. Each nuclide in the chain must be treated independently. This enables the calculation of unit dose factors for each of the principal nuclides in a decay chain. In the case of irrigation water, it is also assumed that the progeny are not accumulating in the water prior to irrigation. Only the parent nuclide is coming from the well and being deposited on the soil. In addition, it is assumed that the water concentration is constant during the year of irrigation. As before, this enables the calculation of unit dose factors for each of the principal nuclides in a decay chain.

The discussion below is divided into three parts. The first describes the decay of a nuclide and progeny ingrowth with time due to nuclear decay alone, i.e., without leaching or additions from contaminated irrigation water. The second part adds decay in the presence of leaching from the surface layer. The third includes irrigation with contaminated water. In all cases, the decay chains shown in Table 6 are used. The longest decay chain has just four members because decay times less than 1000 years are assumed.

3.1.1 Decay Without Leaching or Irrigation Deposition

The radioactive decay constants will be represented as λ_{1r}, λ_{2r}, λ_{3r}, λ_{4r}, and so forth until λ_{nr}, which is the last member of the chain. The leaching coefficients describing removal from the surface layer by water infiltration will be represented as λ_{1s}, λ_{2s}, λ_{3s}, λ_{4s}, and so forth. The sum of these the radioactive and leaching constants for a given nuclide will be represented as λ_1, λ_2, λ_3, λ_4, and so forth. In other words, λ_2 is defined by the equation $\lambda_2 = \lambda_{2r} + \lambda_{2s}$. Radioactive decay constants are computed by dividing the half life of the nuclide (Table 5) into the logarithm of 2 (Ln 2 = 0.69314718). Leaching coefficients are listed in Table 27.

The following demonstrates the general form of the customary decay chain formula to describe the ingrowth of the "nth" progeny from the first member of the chain. In other words, the only member of the chain with any activity to begin with is the first nuclide. The equations below describe the ingrowth of a specific progeny nuclide, the "nth" member of the chain in the absence of leaching and irrigation with contaminated water. These equations also describe the activity in contaminated vegetables or animal products after they are harvested.

$$C_{sn} = C_{s1}^{0} \left(\prod_{k=1}^{n-1} B_{k,k+1} \right) \left(\prod_{k=2}^{n} \lambda_{kr} \right) DR_{1n} \tag{5}$$

$$DR_{1n} = \sum_{k=1}^{n} \frac{e^{-\lambda_{kr} t}}{PD_{1,kr,n}} \tag{6}$$

where

$$PD_{1,kr,n} = \prod_{\substack{i=1 \\ i \neq k}}^{n} \left(\lambda_{ir} - \lambda_{kr} \right) \tag{7}$$

C_{s1}^{0} is the initial soil concentration of the first member of the chain. C_{sn} is the concentration of the "nth" member of the chain after the time "t" has elapsed. C_{sn} is assumed to be zero initially, and to increase with time. Both concentrations have units of Ci/kg.

The term $B_{k,k+1}$ is the fraction of decays of nuclide number "k" which produce nuclide number "k+1". $B_{k,k+1}$ is also known as the branching ratio for nuclear transition from k to k+1. Most branching ratios are simply 1.0. Non-unit branching ratios are given in Table 6.

The term DR_{1n} contains the time dependent functions for each nuclide in the chain from nuclide "1" down to nuclide "n". For convenience in writing the denominator, the product of decay constant differences is defined as shown in Equation (7).

The decay equations are presented as Equation (8) for the first four nuclides. In a four-step decay chain, nuclide 1 (the parent) decays to nuclide 2, which then decays to nuclide 3, which then decays to nuclide 4.

$$C_{s1} = C_{s1}^{0} \, \mathrm{Exp}(-\lambda_{1r} T) \tag{8}$$

$$C_{s2} = C_{s1}^{0} \, \lambda_{2r} \left\{ \mathrm{Exp}(-\lambda_{1r} T)/(\lambda_{2r} - \lambda_{1r}) + \mathrm{Exp}(-\lambda_{2r} T)/(\lambda_{1r} - \lambda_{2r}) \right\}$$

$$\begin{aligned} C_{s3} = C_{s1}^{0} \, \lambda_{2r} \lambda_{3r} \{ & \mathrm{Exp}(-\lambda_{1r} T)/[(\lambda_{2r} - \lambda_{1r}/(\lambda_{3r} - \lambda_{1r})] \\ & + \mathrm{Exp}(-\lambda_{2r} T)/[(\lambda_{1r} - \lambda_{2r})(\lambda_{3r} - \lambda_{2r})] + \mathrm{Exp}(-\lambda_{3r} T)/[(\lambda_{1r} - \lambda_{3r})(\lambda_{2r} - \lambda_{3r})] \} \end{aligned}$$

$$\begin{aligned} C_{s4} = C_{s1}^{0} \, \lambda_{2r} \lambda_{3r} \lambda_{4r} \{ & \mathrm{Exp}(-\lambda_{1r} T)/[(\lambda_{2r} - \lambda_{1r})(\lambda_{3r} - \lambda_{1r})(\lambda_{4r} - \lambda_{1r})] \\ & + \mathrm{Exp}(-\lambda_{2r} T)/[(\lambda_{1r} - \lambda_{2r})(\lambda_{3r} - \lambda_{2r})(\lambda_{4r} - \lambda_{2r})] \\ & + \mathrm{Exp}(-\lambda_{3r} T)/[(\lambda_{1r} - \lambda_{3r})(\lambda_{2r} - \lambda_{3r})(\lambda_{4r} - \lambda_{3r})] \\ & + \mathrm{Exp}(-\lambda_{4r} T)/[(\lambda_{1r} - \lambda_{4r})(\lambda_{2r} - \lambda_{4r})(\lambda_{3r} - \lambda_{4r})] \} \end{aligned}$$

where,

C^0_{s1} = initial concentration of nuclide 1 (i.e. at T=0), in Ci/kg. The initial concentrations of all other members of the chain are assumed to be zero.

C_{s1},C_{s2}, C_{s3},C_{s4} = concentration of nuclides 1, 2, 3, and 4 at time T, in Ci/kg.

λ_{1r},λ_{2r}, λ_{3r},λ_{4r} = radioactive decay constants for nuclides 1, 2, 3, and 4. Note that the decay constant is the natural logarithm of 2 divided by the half-life of the nuclide. Note also that the decay constants in a decay chain are all different so the denominators will never be zero.

3.1.2 Decay With Leaching but Without Irrigation Deposition

For the case where leaching from the surface layer is allowed, there is an additional removal mechanism, which has the effect of increasing the size of the removal terms. Leaching coefficients were discussed in Section 2.5 and are listed in Table 27. The addition of leaching only changes Equations (6) and (7) by replacing λ_k for λ_{kr}. For these equations the radioactive decay constant, in effect, increases. The new equations for decay with leaching are shown below as Equations (9), (10), and (11). Note that the product of radioactive decay constants in Equation (9) is unchanged from Equation (5).

$$C_{sn} = C^0_{s1} \left(\prod_{k=1}^{n-1} B_{k,k+1} \right) \left(\prod_{k=2}^{n} \lambda_{kr} \right) DS_{1n} \tag{9}$$

$$DS_{1n} = \sum_{k=1}^{n} \frac{e^{-\lambda_k t}}{PD_{1,k,n}} \tag{10}$$

where

$$PD_{1,k,n} = \prod_{\substack{i=1 \\ i \neq k}}^{n} (\lambda_i - \lambda_k) \tag{11}$$

The term C^0_{s1} is the same as in Equation (5). It is the initial soil concentration of the parent nuclide in the chain. The $B_{k,k+1}$ terms are also the same as in Equation (5). The change in the definition of the time-dependent function DS_{1n} increases the exponents, so the decline in soil concentration is faster. Note that the subtractions in the $PD_{1,k,n}$ term do not eliminate the leaching factor. Therefore Equations (7) and (11) are not the same.

In the post-intrusion gardening scenario, the dose received during the first year is greatest for most nuclides. However, a few nuclides with long half lives, little leaching, and progeny with large unit dose factors, the dose in some later year may be the largest. This will be discussed when the post-intrusion unit dose factors are described. An additional consideration for the glass waste matrix is degradation of the glass leading to increased availability for plant uptake and resuspension into the air.

3.1.3 Decay With Leaching and Irrigation Deposition

The sources of contaminated irrigation water are either groundwater or Columbia River water. The instantaneous rate of addition of contamination to the soil is given by the equation below. The conversion factor shown in the equations changes centimeters of water applied to the soil to liters applied per square meter.

$$ID_p = C_w I (10 \text{ L m}^{-2} \text{ cm}^{-1}) / T_{irr}$$

where

ID_p = instantaneous activity deposition rate during the irrigation of areas growing plant type p, in curies per square meter per year (Ci y^{-1} m^{-2}).

C_w = irrigation water concentration, in curies per liter (Ci/L). This concentration is assumed to be constant (no decay) during the 6 month application period.

I = irrigation water applied to plants during the irrigation period. For the maximum individual cases, this value is 82.3 cm. For the population dose, this value was lowered to 63.5 cm due to less irrigation in humid areas along the Columbia River (Kincaid 1993).

T_{irr} = irrigation period in years. The value 0.5 yr is used since the irrigation is assumed to take place 6 months per year.

The instantaneous rate of increase in the soil concentration is computed from Equation (12) below.

$$ID^0_{s1} = ID_p / (\rho \, d) \qquad (12)$$

where

ID^0_{s1} = instantaneous rate of increase in the soil concentration during the irrigation season, in curies per kilogram per year.

ID_p = instantaneous activity deposition rate during the irrigation of soils growing plant type p, in curies per square meter per year (Ci y^{-1} m^{-2}).

ρ = bulk density of the surface soil, in grams per cubic centimeter. The value normally used in Hanford Site PA work is 1.5 g/cc.

d = thickness of soil from which nuclides migrate, in centimeters. This is assumed to be 15 cm (5.9 inches).

Using contaminated irrigation water, the concentration of radioactivity in the surface layer of soil increases with time. The equations to represent this turn out to be the time integral of Equations (9), (10), and (11). This activity accumulation is shown in Equations (13) and (14), below. Equation (11), which defines $PD_{1,k,n}$, is not affected by the integration. The term ID^0_{s1} is the rate at which the concentration of the parent nuclide increases due to irrigation deposition. Note that irrigation is assumed for a 6 month period, followed by 6 months in which the precipitation essentially matches the evapo-transpiration, so that the leaching coefficients during the last 6 months are zero. Note the addition of the irrigation time (t) to the equation to make the DI decay term a unitless fraction representing accumulation in the soil of contaminants that decay or are leached from the surface layer. At the end of the irrigation period, $t=T_{irr}$.

$$C_{sn} = t \cdot ID^0_{s1} \left(\prod_{k=1}^{n-1} B_{k,k+1} \right) \left(\prod_{k=2}^{n} \lambda_{kr} \right) DI_{1n} \tag{13}$$

$$DI_{1n} = \sum_{k=1}^{n} \frac{1 - e^{-\lambda_k t}}{\lambda_k t \, PD_{1,k,n}} \tag{14}$$

Equations (5), (6), and (7) apply to soil with no leaching at all. Whatever water falls on the soil evaporates without forcing contamination through the surface layer into deeper layers. The key to represent this ordinary decay is the term DR_{1n}. Equations (9), (10), and (11) apply to soil with some leaching taking place. This might be due to excess natural precipitation or irrigation with uncontaminated water. The key to represent this decay with leaching is the term DS_{1n}. Equations (13) and (14) apply to soil being irrigated with contaminated water. Leaching from the surface layer is also occurring. The key to represent this combination of decay, leaching, and accumulation is the term DI_{1n}. These key terms will be used in the next section to describe the soil concentration after many years of irrigation with contaminated water. The soil concentration after 50 years of irrigation with a constant nuclide concentration can be computed for evaluation purposes.

One exception to the above is for tritium in the irrigation water applied to the soil. An equilibrium approach is used. The tritium concentration in the soil moisture is assumed to equal the tritium concentration in the applied irrigation water, adjusted for natural precipitation. This is calculated using the formula below.

$$C_{s,H3} = 8.94\ F_{Hs}\ C_{w,H3}\ I/(I+P) \quad (15)$$

where

$C_{s,H3}$ = concentration of tritium in the surface soil, in curies per kilogram.

8.94 = factor to convert the hydrogen weight fraction into a water fraction. It comes from the ratio of molecular weights for hydrogen (2.0159 g/gmole) and water (18.0153 g/gmole).

F_{Hs} = fraction of hydrogen in garden soil, 0.022 g hydrogen per gram of soil (from Table 23).

$C_{w,H3}$ = concentration of tritium in the irrigation water, in pCi/L.

I = total irrigation water applied to the soil during the irrigation season, 82.3 cm/y (63.5 cm/y for the population).

P = total natural precipitation water reaching the soil during the irrigation period, 5.23 cm/y (PNNL-12087).

The ratio I/(I+P) incorporates the dilution of contaminated irrigation water with natural precipitation. The values chosen for "I" and "P"lead to dilution ratio of 94%.

3.1.4 Activity Concentration at the End of the First Year

To describe the concentration of a nuclide in the soil at the end of the first year, one must combine the equations of the previous section into the physically allowable sequences. During the first 6 months of the year irrigation takes place. The leaching coefficients are as shown in Table 27. Then the irrigation ceases and the precipitation rate is assumed to match the evapo-transpiration rate, so that the leaching factors are all zero. During the second half of the year there is only radioactive decay.

Initial Soil Contamination. In the post-intrusion garden scenario, for the first member of a decay chain, the soil concentration at the end of the year is the initial concentration multiplied by factors for decay and leaching during the irrigation season followed by simple decay during the remainder of the year. This is shown in Equation (16) below. The Y_{11} term is introduced to simplify later equations.

$$C_{s1}(1) = C^0_{s1} \cdot DS_{11} \cdot DR_{11} = C^0_{s1} \cdot Y_{11} \quad (16)$$

In general, the term $C_{sn}(Ti)$ is the soil concentration of the "nth" member of the decay chain after Ti years. As before, C^0_{s1} is the initial soil concentration of the first member of the chain. The DS_{11} factor applies for the first 6 months. The DR_{11} factor controls the second 6 months. The DS_{11} and DR_{11} terms are normally preceded by factors for branching ratios and products of decay constants. However, for the first member of the chain, these terms are 1.

The first daughter of nuclide "1" is produced during the irrigation period and then decays during the rest of the year. It also is produced from the decay of the parent nuclide that is present at the end of the irrigation season. This is shown in Equation (17) below. The term BP_{12} contains the branching ratio and product of decay constants found in Equations 5 and 9.

$$C_{s2}(1) = C_{s1}^{0} \cdot BP_{12} \cdot (DS_{12} \cdot DR_{22} + DS_{11} \cdot DR_{12}) = C_{s1}^{0} \cdot BP_{12} \cdot Y_{12} \tag{17}$$

The concentration of the third and fourth nuclides in the chain at the end of the first year is calculated using Equation (18) below. Longer chains are computed in a similar fashion. Note that all possible decay paths must be considered. This leads to as many terms as there are members in the decay chain.

$$\begin{aligned} C_{s3}(1) &= C_{s1}^{0} \cdot BP_{13} \cdot (DS_{13} \cdot DR_{33} + DS_{12} \cdot DR_{23} + DS_{11} \cdot DR_{13}) \\ &= C_{s1}^{0} \cdot BP_{13} \cdot Y_{13} \\ C_{s4}(1) &= C_{s1}^{0} \cdot BP_{14} \cdot (DS_{14} \cdot DR_{44} + DS_{13} \cdot DR_{34} + DS_{12} \cdot DR_{24} + DS_{11} \cdot DR_{14}) \\ &= C_{s1}^{0} \cdot BP_{14} \cdot Y_{14} \end{aligned} \tag{18}$$

Irrigation. In the irrigation scenarios, for the first member of the chain, the concentration at the end of the year is the product of the accumulated activity at the end of the irrigation season and the decay factor resulting from decay without irrigation or leaching for the remainder of the year. This is shown in Equation (19) below. Note the similarity between Equations (16) and (19). This will be seen again in the next few equations.

$$C_{s1}(1) = T_{irr} \cdot ID_{s1}^{0} \cdot DI_{11} \cdot DR_{11} \tag{19}$$

In general, the term $C_{sn}(Ti)$ is the soil concentration of the "nth" member of the decay chain after Ti years. As before, ID_{s1}^{0} is the instantaneous rate of increase in the soil concentration for the first member of the chain. The DI and DR terms are normally preceded by factors for branching ratios and products of decay constants. However, for the first member of the chain, these terms are 1.

The first daughter of nuclide "1" is produced during the irrigation period and then decays during the rest of the year. It also is produced from the decay of the parent nuclide that is present at the end of the irrigation season. This is shown in Equation (20) below. Note that the assumed amount of the daughter in the irrigation water is zero. The term BP_{12} contains the branching ratio and product of decay constants found in Equations (9) and (13).

$$C_{s2}(1) = T_{irr} \cdot ID^0_{s1} \cdot BP_{12} \cdot (DI_{12} \cdot DR_{22} + DI_{11} \cdot DR_{12}) \quad (20)$$

The concentration of the third and fourth nuclides in the chain at the end of the first year is calculated using Equation (21) below. Longer chains are computed in a similar fashion. Note that all possible decay paths must be considered. This leads to as many terms as there are members in the decay chain, as shown below.

$$\begin{aligned} C_{s3}(1) &= T_{irr} \cdot ID^0_{s1} \cdot BP_{13} \cdot (DI_{13} \cdot DR_{33} + DI_{12} \cdot DR_{23} + DI_{11} \cdot DR_{13}) \\ C_{s4}(1) &= T_{irr} \cdot ID^0_{s1} \cdot BP_{14} \cdot (DI_{14} \cdot DR_{44} + DI_{13} \cdot DR_{34} + DI_{12} \cdot DR_{24} + DI_{11} \cdot DR_{14}) \end{aligned} \quad (21)$$

In practice, it is better to calculate the decay factors for each nuclide, since these are unitless fractions whose value is near 1.0 for nuclides with long half lives. The calculation of media concentrations and dose can be carried out ignoring decay. A decay factor can then be added.

3.1.5 Soil Concentration after Many Years of Irrigation

After the first year of irrigation, there is residual contamination which must be taken into account when computing the total activity at the end of the year under consideration. The activity after N years is the sum of (1) the activity after (N-1) years decaying for 1 year, plus (2) the activity which normally accumulates during the year. Note that the residual activity from (N-1) years of prior irrigation is first subjected to decay with leaching during the first portion of the year and then decay without leaching for the remainder (Y_{11}). As a reminder, it is assumed that the water concentration of the parent nuclide remains constant and that none of the progeny nuclides accumulate in the water. This permits separate unit dose factors for each of the principal nuclides in a decay chain. The concentration of progeny nuclides in the irrigation water will be determined by the release and transport codes.

For the first member of the decay chain, the soil concentration at the end of N years is shown in Equation (22). The Y and Z terms are introduced to simplify later equations. The Z term is analogous to an exponential term in the usual decay equations. Equation (22) applies to scenarios in which irrigation with contaminated water occurs.

$$\begin{aligned} C_{s1}(N) &= C_{s1}(N\text{-}1) \cdot Y_{11} + C_{s1}(1) \\ &= C_{s1}(1) \cdot (1 - Y_{11}^N)/(1 - Y_{11}) = C_{s1}(1) \cdot Z_1 \end{aligned} \quad (22)$$

where, $Z_1 = (1 - Y_{11}^N)/(1 - Y_{11})$

The activity concentration of the first daughter after N years of accumulation and decay is shown below. The soil concentration after N years is the sum of (1) the activity added during the

Nth year and the activity present at the end of N-1 years after one more year of leaching and decay.

The YZ combination term shown in Equation (23) is introduced to simplify later equations. The YZ term has a form similar to that of the standard decay equations. The product of decay constants represented as the PD term in Equations (6), (10) and (14) has a reversed order compared to these equations.

$$\begin{aligned} C_{s2}(N) &= C_{s1}(N\text{-}1)\cdot BP_{12}\cdot Y_{12} + C_{s2}(N\text{-}1)\cdot Y_{22} + C_{s2}(1) \\ &= C_{s2}(1)\cdot Z_2 + C_{s1}(1)\cdot BP_{12}\cdot Y_{12}\cdot(Z_1 - Z_2)/(Y_{11} - Y_{22}) \\ &= C_{s2}(1)\cdot Z_2 + C_{s1}(1)\cdot BP_{12}\cdot YZ_{12} \end{aligned} \tag{23}$$

The activity concentration of the third member of the decay chain after N years of accumulation and decay is shown below.

$$\begin{aligned} C_{s3}(N) &= C_{s1}(N\text{-}1)\cdot BP_{13}\cdot Y_{13} + C_{s2}(N\text{-}1)\cdot BP_{23}\cdot Y_{23} + C_{s3}(N\text{-}1)\cdot Y_{33} + C_{s3}(1) \\ &= C_{s3}(1)\cdot Z_3 + C_{s2}(1)\cdot BP_{23}\cdot Y_{23}\cdot(Z_2 - Z_3)/(Y_{22} - Y_{33}) + \\ &\qquad C_{s1}(1)\cdot BP_{13}\cdot Y_{13}\cdot(Z_1 - Z_3)/(Y_{11} - Y_{33}) + \\ &\qquad C_{s1}(1)\cdot BP_{13}\cdot Y_{12}\cdot Y_{23}\cdot\{Z_1/[(Y_{11} - Y_{22})(Y_{11} - Y_{33})] + \\ &\qquad Z_2/[(Y_{22} - Y_{11})(Y_{22} - Y_{33})] + Z_3/[(Y_{33} - Y_{11})(Y_{33} - Y_{22})]\} \\ &= C_{s3}(1)\cdot Z_3 + C_{s2}(1)\cdot BP_{23}\cdot YZ_{23} + C_{s1}(1)\cdot BP_{13}\cdot[YZ_{13} + YZ_{123}] \end{aligned} \tag{24}$$

The activity concentration of the fourth member of the decay chain after N years of accumulation and decay is shown below.

$$\begin{aligned} C_{s4}(N) &= C_{s1}(N\text{-}1)\cdot BP_{14}\cdot Y_{14} + C_{s2}(N\text{-}1)\cdot BP_{24}\cdot Y_{24} + C_{s3}(N\text{-}1)\cdot BP_{34}\cdot Y_{34} + \\ &\qquad C_{s4}(N\text{-}1)\cdot Y_{44} + C_{s4}(1) \\ &= C_{s4}(1)\cdot Z_4 + C_{s3}(1)\cdot BP_{34}\cdot YZ_{34} + C_{s2}(1)\cdot BP_{24}\cdot[YZ_{24} + YZ_{234}] \\ &\qquad C_{s1}(1)\cdot BP_{14}\cdot[YZ_{14} + YZ_{124} + YZ_{134} + YZ_{1234}] \end{aligned} \tag{25}$$

where

$$\begin{aligned} YZ_{1234} = Y_{12}\cdot Y_{23}\cdot Y_{34}\cdot\{&Z_1/[(Y_{11} - Y_{22})(Y_{11} - Y_{33})(Y_{11} - Y_{44})] + \\ &Z_2/[(Y_{22} - Y_{11})(Y_{22} - Y_{33})(Y_{22} - Y_{44})] + \\ &Z_3/[(Y_{33} - Y_{11})(Y_{33} - Y_{22})(Y_{33} - Y_{44})] + \\ &Z_4/[(Y_{44} - Y_{11})(Y_{44} - Y_{22})(Y_{44} - Y_{33})]\} \end{aligned}$$

Fortunately, chains with more than 4 members do not need to be considered because the accumulation time is 50 years. For the nuclides of interest, four member chains will be adequate for 1000 years. There is a similarity between the above equations for decay and leaching of an initial soil contamination over time and the ordinary decay equations.

The initial soil contamination may be due to well-drilling or to irrigation with contaminated water in prior years. Thus irrigation calculations involving prior irrigation with contaminated water are calculated as the sum of an initial soil concentration case and an irrigation case. The initial soil concentration is computed according to the method shown in equations (22) through (25).

3.2 Emanation of Gaseous Nuclides from the Soil Surface

Two cases are described in the "No Infiltration Scenarios" of Table 2. The first is the "Offsite Farmer" who is downwind of the disposal site. The second is the "Onsite Resident" who lives in a dwelling affected by the gaseous emission. These scenarios are presented in more detail below. In addition, the two are compared to show that the offsite dose is always lower than the onsite dose.

The nuclides of concern for these emissions are H-3, C-14, Rn-220, and Rn-222. The H-3 is normally found as water and would be released as water vapor. The C-14 has been assumed to be bound to an organic compound. Presumably the organic compound could be volatile as well. The most likely carbon compound to be emitted is carbon dioxide. However, the inhalation dose factor for carbon dioxide is about 90 time smaller than for organically bound C-14. Finally, the inhalation dose from radon compounds depends on the ease with which the particulate progeny of the inert gas become attached to dust particles in the air, as well as the relative amounts of the short half life progeny. For this reason, the radon emission is limited to 20 pCi m^{-2} s^{-1} (HNF-EP-0826).

3.2.1 Effect on the Offsite Farmer

Radioactivity released into the air is carried by the wind to locations some distance from the emission source. As the airborne material travels it is diluted, so that the potential doses are lessened. However, the radioactive material may settle on crops and pastures, leading to ingestion pathway doses as well as the initial inhalation dose as the plume passes the receptor location. The inhalation dose to an individual downwind is calculated using the formula shown below.

$$H_{bt} = Q_{emit}\, X/Q'\, BR\, DF_{inh} \qquad (26)$$

where,

H_{bt} = inhalation dose at a downwind location, mrem

Q_{emit} = activity released into the air as a gas or respirable particles, Ci

X/Q' = air transport factor, 1.0E-4 s/m^3

BR = breathing rate, 2.64E-4 m^3/s

DF_{inh} = inhalation dose factor for a nuclide emanating from the ground surface, in mrem per pCi inhaled. Values are given in Table 8.

Because the emission from the ground surface is assumed to take place over the course of a year, the parameters in Equation (26) are chosen to represent the annual average. Thus the annual average breathing rate is 0.95 m^3/h, or 2.64E-4 m^3/s. In addition, the activity released into the air is the total released over the course of one year. Finally, the air transport factor (1.0E-4 s/m^3) is a bounding value for an annual emission (WHC-SD-WM-TI-616). It includes the normal variation in wind direction, wind speed, and atmospheric stability.

Inserting values for inhalation dose factor, and assuming a 1 Ci emission over the course of a year, leads to unit dose factors of 0.0025 mrem per Ci H-3, and 0.055 mrem per Ci C-14.

An additional method for estimating the offsite dose, that takes into account the ingestion pathways is the CAP88-PC software from EPA (402-B-92-001). The software predicts that the total doses are 0.0237 mrem per Ci H-3, and 1.32 mrem per Ci C-14. The program output is listed in Appendix C. Note that the air transport factors used by CAP88-PC was 7.98E-6 s/m^3 because a distance of 1000 m was input. The doses reported by CAP88-PC were then adjusted upward by the ratio of air transport factors, namely, (1.0E-4)/(7.98E-6)=12.5 to give the values reported above. An additional difference with the simple inhalation dose method is the assumed chemical form of the carbon. In CAP88-PC the carbon is in the form of carbon dioxide, while in the simple inhalation calculation, the organic form is used. Although the organic form of carbon leads to larger inhalation doses, the ingestion pathways in CAP88-PC give most of the dose. It should be noted that the various consumption parameters in CAP88-PC are larger. For example the fraction of contaminated vegetables is 100% in CAP88-PC. The value of CAP88-PC is that is can be used to demonstrate compliance with the 10 mrem/y performance objective for airborne emissions.

3.2.2 Effect on the Onsite Resident

For modeling the effect of contaminants emanating from the soil into a ventilated building, the equilibrium air concentration is the product of the emanation rate (activity per unit area per unit time) and the floor area divided by the building ventilation rate (volume per unit time). The ratio of ventilation rate to floor area is characteristic of classes of building construction. Typical ratios are less than 0.003 m/s. The individual exposed to gaseous emanations from the disposal site is located in a ventilated dwelling. For a constant emanation rate with a constant ventilation rate, the concentration starts at zero and rises according to the formula shown below.

$$C = (C_{eq})\cdot\{1-\mathrm{Exp}[-(F)(t)/(V)]\}$$

$$C_{eq} = (E)/(F/A) \qquad (27)$$

where,

C = time-dependent air concentration inside the building, Ci/m³

C_{eq} = steady-state (or equilibrium) air concentration, Ci/m³

E = contaminant emanation rate, Ci m^{-2} s^{-1}

A = building floor area, m²

F = building ventilation rate, m³/s

V = building volume, m³

The ratio F/A is characteristic of certain dwellings. Two examples are listed below. Typical values will need to be established for dose calculation purposes. For radon, the DOE uses an emanation limit. For gases such as tritium (as water vapor) and carbon-14, a dose calculation can be performed.

house: F/A = (10 cfm)/(100 ft²) = 1/600 ft/s = 5.08E-4 m/s

office: F/A = (100 cfm)/(200 ft²) = 1/120 ft/s = 2.54E-3 m/s

Using the smaller value to maximize the equilibrium air concentration, and assuming a unit emanation rate (1 pCi m^{-2} s^{-1}) leads to an equilibrium air concentration of 2000 pCi/m³, or 2 pCi/L in the dirt-floor house.

The inhalation dose received by exposure to radionuclides emanating from the soil into a dwelling is the product of the steady-state air concentration, the volume of air inhaled during the year, and the inhalation dose factor as shown in Equation (28). Any decay factor is expected to be nearly one, since the nuclides that contribute to this pathway (tritium, C-14, Rn-220 and Rn-222) are expected to see very little change in the emanation rate due to radioactive decay.

$$H_{be} = Q_{ab}\, C_{eq}\, D_{inh}\, T_{inh} \qquad (28)$$

where

H_{be} = inhalation dose from the emanation of gaseous nuclides during one year, in mrem.

Q_{ab} = quantity of air inhaled by the person while in the dwelling, in m³/y. The value used is 6170 m³/y based on the sleeping and indoor data in Table 17.

C_{eq} = steady-state concentration of gaseous nuclides in the dwelling, in pCi/L.

D_{inh} = inhalation dose factor for a nuclide, in mrem per pCi inhaled. Values are given in Table 8.

T_{inh} = inhalation exposure time of the individual, 1 y.

For H-3 and C-14, the inhalation doses are calculated as shown below. They are based on a unit emanation rate, 1 pCi m^{-2} s^{-1}.

H-3: (6170 m^3/y)(2000 pCi/m^3)(9.60E-8 mrem/pCi)(1 y) = 1.18 mrem

C-14: (6170 m^3/y)(2000 pCi/m^3)(2.09E-6 mrem/pCi)(1 y) = 25.8 mrem

3.2.3 Comparison of Offsite and Onsite Doses

A basic difference between the two dose calculations is the input radioactivity. For the offsite dose calculation, the total released into the air during one year must be estimated. For the onsite dose calculation, the rate at which activity enters the air per unit area of floor space is needed. To put the two on a comparable level, assume the ground surface directly above the waste site has a surface area of 31,690 m^2. A uniform emanation rate of 1 pCi m^{-2} s^{-1} for one year will release 1 Ci of activity into the air.

(1 pCi m^{-2} s^{-1})(31,690 m^2)(3.156x10^7 s/y)(1 y) = 1 Ci

Because the offsite dose is smaller than the onsite dose for unit emission rates (Table 28), the waste site area needs to be increased to raise the offsite dose, which depends on the total emitted during the year. Table 28 shows the calculated doses and required disposal site area for the two doses to be equal. Because the disposal site surface area will be significantly less than a square kilometer (1.0E+6 m^2), the onsite dose will always be greater than the offsite dose.

Table 28. Comparison of Onsite and Offsite Doses.

Volatile Nuclide	Onsite Resident (per pCi m^{-2} s^{-1})	Offsite Farmer (per Ci released)	Disposal Facility Surface Area
H-3	1.18 mrem	0.0237 mrem	1.58E+6 m^2
C-14	25.8 mrem	1.32 mrem	1.08E+6 m^2

Disposal Site Area is calculated as the Onsite dose multiplied by 31,690 m^2 and divided by the Offsite dose.

3.3 External and Inhalation Dose

The inhalation dose that is received by exposure to airborne water during showering or a sauna or under ambient conditions is simply the product of the volume of water inhaled during

the year, the water concentration, and the inhalation dose factor as shown in equation (29). No consideration of radioactive decay or progeny ingrowth is needed, because the water concentration is assumed to be constant during the year, and no progeny are allowed to accumulate in the water.

$$H_{bw} = Q_{wb}\, C_w\, D_{inh}\, T_{inh} \tag{29}$$

where

H_{bw} = inhalation dose from airborne moisture during one year, in mrem.

Q_{wb} = quantity of contaminated water inhaled by the person while in the shower or sauna, in L/y. Values are given in Table 18.

C_w = concentration of a nuclide in the contaminated water, in pCi/L.

D_{inh} = inhalation dose factor for a nuclide, in mrem per pCi inhaled. Values are given in Table 8.

T_{inh} = inhalation exposure time of the individual, 1 y.

The external and inhalation dose due to exposure to contaminated soil are accumulated over the course of a year for all exposure scenarios except the waste intruder (driller). The amount accumulated per day depends on the soil concentration on that day. The external dose rate and the inhalation dose rate are proportional to the soil concentration. The total accumulated over the year is proportional to the time integral of the soil concentration. The external dose and inhalation doses are shown in equation (30). To obtain the total dose from the parent nuclide it is necessary to include the contributions from each progeny nuclide. Hence the sum over nuclides in a decay chain. Note that radioactive decay is not considered for the waste intruder because the exposure time is so brief (5 days) compared to the half lives of the nuclides selected for analysis.

$$H_{xs} = \sum_{i=1}^{n} \int_0^{1y} \rho\, d\, C_{si}\, D_{ext,i}\, dT$$

$$H_{bs} = \sum_{i=1}^{n} \int_0^{1y} M_{sb}\, C_{si}\, D_{inh,i}\, dT \tag{30}$$

where

H_{xs} = external dose accumulated during the year from one radionuclide and its progeny due to radioactivity in the soil, mrem

H_{bs} = inhalation dose accumulated during the year from one radionuclide and its progeny due to radioactivity in the soil, mrem

I = index over the decay chain. I=1 refers to the first member, or parent nuclide; I=2 refers to the second member of the decay chain; I=3 refers to the third member; I=4 refers to the fourth member.

ρ = bulk density of the surface soil, in grams per cubic centimeter. The value normally used in Hanford Site PA work is 1.5 g/cc.

d = thickness of soil from which nuclides migrate, in centimeters. This is assumed to be 15 cm (5.9 inches).

C_{si} = time-dependent soil concentration of the ith nuclide during the year, in Ci/kg. It is affected by radioactive decay and leaching from the surface layer of soil.

$D_{ext,i}$ = external dose rate factor for exposure to radiation from nuclide "I" in contaminated soil, in mrem/h per Ci/m^2. Values are given in Table 10.

M_{sb} = mass of soil inhaled annually by the individual, in mg/y. Values are discussed in Section 2.2.4.

$D_{inh,i}$ = inhalation dose factor for nuclide "I", in mrem per pCi inhaled. Values are given in Table 8.

The only term in the integrals with any time dependence is the soil concentration. Thus the accumulated dose at time T is the time integral of the activity equations. These integrations are simply the integral of each exponential. Each of the exponential terms in the decay equations (6) and (10), namely, Exp(-λT), are replaced with the time integral shown in Equation (31). Note that the integral of the DS term in equation (10) is the same as the DI term in equation (14).

$$\text{Time Integral} = \int_0^T \text{Exp}(-\lambda t)\, dt = [1 - \text{Exp}(-\lambda T)]/\lambda \qquad (31)$$

If the product λT is less than 0.0002, a loss of numeric accuracy is experienced. To overcome this, the integral in equation (31) is replaced with the equivalent polynomial to improve the numeric precision of the calculation. The polynomial used is shown in equation (32).

$$[1 - \text{Exp}(-\lambda T)]/\lambda = T\cdot[1 - \lambda T/2 + (\lambda T)^2/6 - (\lambda T)^3/24] \qquad (32)$$

Notice that if the product λT is very small, the time integral approaches the decay period. For this reason, the time integral of the decay equation is sometimes referred to as an effective time period. In effect, it is a particular time period adjusted for radioactive decay. To consistently work with unitless decay periods, all time integrals are divided by the integration period. Thus the integration period must be made a factor in the calculation.

For the irrigated farm scenario, the concentration of nuclides in the soil increases with time due to the activity accumulating in the soil as shown in equation (14). The soil concentration follows the time integral formula of equations (31) and (32). The accumulated intake or dose at time T is the time integral of the equation (14). In other words, each exponential term in the decay equation (10), namely, $\text{Exp}(-\lambda T)$ is replaced with its second integral, shown in equation (33).

$$\text{Second Integral} = [\lambda T - 1 + \text{Exp}(-\lambda T)]/\lambda^2 \tag{33}$$

If the product λT is less than 0.001, a loss of numeric accuracy is experienced. To overcome this, the integral in equation (33) is replaced with the equivalent polynomial to improve the numeric precision of the calculation. The polynomial used is shown in equation (34).

$$[\lambda T - 1 + \text{Exp}(-\lambda T)]/\lambda^2 = T^2 \cdot [1 - \lambda T/3 + (\lambda T)^2/12 - (\lambda T)^3/60]/2 \tag{34}$$

Notice that if the product λT is very small, the time integral in equations (33) and (34) approaches the decay period squared. Again, to only work with unitless decay factors, the second integral is divided by the integration period squared. This time must then be made a factor in the dose equation.

Using the two-part irrigation model, the dose accumulated during the first 6 months depends only on the DS or DI integration. The dose during the second 6 months (without irrigation) depends only on the DR integration. This idea is summarized in the equations below. Equation (35) shows the time integral of equations (16) through (18) for an initial soil contamination (e.g. the post-intrusion garden), while equation (36) shows the time integral of equations (19) through (21) for irrigation with contaminated water. Constant factors have been omitted to simplify the equations. In both equations the first integral represents the dose from the nth member of the decay chain during the first 6 months. During the first 6 months the only source of this nuclide is the decay of the parent nuclide. After 6 months of decay and ingrowth, each member of the decay chain will be present in the soil. Thus the second time integral on the right has contributions from decay of the parent as well as decay of the other members of the chain.

Initial Soil Contamination: (from Equation 16)

$$\int_0^{1y} Y_{1n}(T)\,dT = \int_0^{T_{irr}} DS_{1n}(T)\,dT + \sum_{k=1}^{n} DS_{1k}(T_{irr}) \int_0^{T_{no}} DR_{kn}(T)\,dT$$

$$\int_0^{1y} Y_{1n}(T)\,dT = T_{irr}\, IDS_{1n}(T_{irr}) + T_{no} \sum_{k=1}^{n} DS_{1k}(T_{irr})\, IDR_{kn}(T_{no}) \tag{35}$$

Irrigation with Contaminated Water: (from Equation 19)

$$\int_0^{1y} C_{s1}\,dT = \int_0^{T_{irr}} DI_{1n}(T)\,dT + \sum_{k=1}^{n} DI_{1k}(T_{irr}) \int_0^{T_{no}} DR_{kn}(T)\,dT$$

$$\int_0^{1y} C_{s1}\,dT = T_{irr}\, IDI_{1n}(T_{irr}) + T_{no} \sum_{k=1}^{n} DI_{1k}(T_{irr})\, IDR_{kn}(T_{no}) \qquad (36)$$

The above equations show the decay factors that represent each integral. Additional terms needed in later calculations are defined below. Note that the integration period becomes a factor in the equation because the decay factors are designed to be unitless quantities between 0 and 1.

$$\int_0^{T_{irr}} DS(T)\,dT = T_{irr}\, IDS(T_{irr}) \qquad \int_0^{T_{no}} DR(T)\,dT = T_{no}\, IDR(T_{no})$$

$$\int_0^{T_{irr}} DI(T)\,dT = T_{irr}\, IDI(T_{irr}) \qquad T_{no} = 1y - T_{irr} \qquad (37)$$

$$\int_0^{T_{veg}} DR(T)\,dT = T_{veg}\, IDR(T_{veg}) \qquad \int_0^{T_{beef}} DR(T)\,dT = T_{beef}\, IDR(T_{beef})$$

note that

T_{irr} = irrigation period in years. The value of 0.5 yr is assumed based on current practices near the Hanford Site.

T_{no} = interval during which no irrigation takes place, $T_{no} = 1y - T_{irr}$

T_{veg} = consumption period for garden produce, assumed to be 90 days

T_{beef} = consumption period for beef after slaughter, assumed to be 120 days.

3.4 Ingestion Dose

Human ingestion dose comes from the pathways discussed earlier, such as contaminated drinking water, trace intakes of soil, vegetables grown on contaminated soil, and animal products. Each of these is discussed below. The basic dose calculation is the product of three factors, (1) the quantity consumed, (2) the radionuclide concentration in what is consumed, and (3) the ingestion dose factor. The addition of radioactive decay and progeny ingrowth is discussed with each pathway.

3.4.1 Soil and Water Ingestion

The ingestion dose from drinking water is shown in equation (38). The drinking water has no progeny. The concentration of each nuclide in a chain is treated separately.

$$H_{ew} = Q_{we}\, C_w\, D_{ing}\, T_{ing} \tag{38}$$

where

H_{ew} = ingestion dose from drinking water, in mrem.

Q_{we} = quantity of contaminated drinking water ingested by the person, in L/y. See Tables 13 and 14 for values.

C_w = concentration of a nuclide in the contaminated water, in pCi/L.

D_{ing} = ingestion dose factor for a nuclide, in mrem per pCi ingested. Values are given in Table 7.

T_{ing} = ingestion exposure time of the individual, 1 y.

The ingestion dose from the intake of trace amounts of soil is shown in equation (39). The soil concentration does include leaching, decay and progeny ingrowth. Because the soil is consumed in small amounts during the year, the total dose is represented as the time integral of the daily intake. As before, the time integral must accommodate the change in infiltration rates during the year, just as was done for the inhalation and external doses using equations (35) and (36).

$$H_{es} = \sum_{i=1}^{n} \int_{0}^{1y} M_{se}\, C_{si}\, D_{ing,i}\, dT \tag{39}$$

where

H_{es} = ingestion dose accumulated during the year from one radionuclide and its progeny due to radioactivity in the soil, mrem

I = index over the decay chain. I=1 refers to the first member, or parent nuclide; I=2 refers to the second member of the decay chain; I=3 refers to the third member; I=4 refers to the fourth member.

M_{se} = mass of soil ingested annually by the individual, in mg/y.

C_{si} = time-dependent soil concentration of the ith nuclide during the year, in Ci/kg. It is affected by radioactive decay and leaching from the surface layer of soil.

$D_{ing,i}$ = ingestion dose factor for nuclide "I", in mrem per pCi ingested. Values are given in Table 7.

3.4.2 Garden Produce

The ingestion dose from garden produce grown in contaminated soil is the product of the quantity of vegetables eaten, the concentration of radioactivity in the vegetables, and the ingestion dose factor. The ingestion dose factors are given in Table 7. Quantities eaten are given in Tables 13 and 14. The calculation of radionuclide concentrations in living plants uses three main routes, (1) root uptake, (2) resuspension to leaves (also called "rain splash"), and (3) direct deposition of irrigation water on foliage. Each of these will be considered separately below. The three uptake routes are then combined to obtain the total ingestion dose from the garden produce.

The equations presented below apply to both garden produce and cattle feed in the sense that the quantity eaten and the ingestion dose factor can be removed to give the nuclide concentration in the cattle feed. These concentrations are needed to calculate dose from ingestion of contaminated animal products.

The garden produce intakes are based on the two situations. The first applies to leafy vegetables. It is assumed that leafy vegetables are produced more-or-less continuously during the growing season. They are consumed shortly after being collected. Thus the continuous model uses a time integral to represent the accumulated dose from leafy vegetables during the growing season. It is further assumed that leafy vegetables are not raised after the growing season has ended. Any leafy vegetables consumed after the growing seasons ends are assumed to have been imported from uncontaminated areas. The 25% of a person's diet that comes from contaminated sources is then assumed to be 50% during the irrigation period and 0% during the remainder of the year.

The second garden produce model applies to the other types of garden produce. These foods are assumed to be grown and harvested twice during the growing season. The plant concentration depends on the soil concentration at the time of harvest. For an initial soil contamination (e.g. post-intrusion garden or prior irrigation) this time is taken to be midway through the irrigation season. For the irrigation scenarios harvest is assumed to occur at the end of the irrigation season. Because these foods may be stored and eaten over a period of time, radioactive decay during the storage and consumption periods needs to be taken into account. The amount of radioactive contamination eaten during the consumption period is the time integral of the ordinary decay equations (5) through (7). The average consumption period for non-leafy vegetables is taken to be 90 days. Some products do not keep well, and have shorter consumption periods. Others keep very well and have longer consumption periods. The value selected for the ILAW PA (90 days) simplifies the calculations in that all non-leafy vegetables have the same period. Note that for long half life nuclides the actual value has no effect on the final doses.

Root uptake is calculated using concentration ratios. These ratios are listed in Table 25. The ingestion dose from garden produce due to root uptake into the various types of vegetation is described with equation (40). The first equation shows the continuous model for leafy

vegetables. Note that the integral is over half the year so the assumed annual intake from garden must be adjusted upward to compensate. Hence the ratio (1 y)/(T_{irr}). The second equation shows the harvest model for the other vegetables. In both equations the sum over radionuclides in a decay chain is needed to obtain the total dose from the parent nuclide.

$$H_{epr}(\text{leafy}) = \sum_{i=1}^{n} \frac{1\,y}{T_{irr}} \int_{0}^{T_{irr}} R_p\, B_{pi}\, Q_{vp}\, C_{si}\, D_{ing,i}\, dT$$

$$H_{epr}(\text{others}) = \sum_{i=1}^{n} R_p\, B_{pi}\, Q_{vp}\, C_{si}\, IDR_i(T_{veg})\, D_{ing,i}\, T_{ing} \qquad (40)$$

where

H_{epr} = ingestion dose from plant type p due to root uptake, in mrem.

p = type of plant. There are 4 types of garden produce. The first equation covers leafy vegetables (p=1). The second equation covers other vegetables, fruit, and grain (p=2,3,4).

R^p = dry to wet ratio for plant type p. See Table 24 for values.

B_{pi} = soil to plant concentration ratio, as Ci/kg dry weight of vegetables to Ci/kg of soil. See Table 25 for values.

Q_{vp} = quantity of plant type p eaten by the person, in kg/y. See Tables 13 and 14 for values.

C_{si} = soil concentration of the ith nuclide, in Ci/kg. It is affected by radioactive decay and leaching from the surface layer of soil during the irrigation season. In the second equation it is the soil concentration at the time of harvest.

T_{irr} = irrigation period in years. The value of 0.5 yr is assumed based on current practices near the Hanford Site.

IDR_i = decay factor that accounts for radioactive decay of the ith nuclide during the consumption of garden produce

T_{veg} = consumption period for garden produce, assumed to be 90 days

T_{ing} = ingestion exposure time of the individual, 1 y.

$D_{ing,i}$ = ingestion dose factor for nuclide "I", in mrem per pCi ingested. Values are given in Table 7.

The resuspension of dust by wind, or water drops splashing soil onto the foliage leads to some contamination of the edible portion of the plant. The ingestion dose from this source of contamination is calculated using equation (41). The first equation shows the continuous model for leafy vegetables. Note that the integral is over half the year so the assumed annual intake from garden must be adjusted upward to compensate. Hence the ratio (1 y)/(T_{irr}). The second

equation shows the harvest model for the other vegetables. Note the sum over radionuclides in a decay chain to obtain the total dose from the parent nuclide.

$$H_{epf}(\text{leafy}) = \sum_{i=1}^{n} \frac{1\,y}{T_{irr}} \int_{0}^{T_{irr}} R^{a} V_{d} \frac{F_{fp} F_{tp} T_{w}}{Y_{p}} Q_{vp} C_{si} D_{ing,i}\, dT$$

$$H_{epf}(\text{others}) = \sum_{i=1}^{n} R^{a} V_{d} \frac{F_{fp} F_{tp} T_{w}}{Y_{p}} Q_{vp} C_{si} IDR_{i}(T_{veg}) D_{ing,i} T_{ing} \quad (41)$$

where

H_{epf} = ingestion dose from plant type p due to resuspension of contaminated soil onto plant surfaces (rain splash), in mrem.

p = type of plant. There are 4 types of garden produce. The first equation covers leafy vegetables (p=1). The second equation covers other vegetables, fruit, and grain (p=2,3,4).

R^{a} = average concentration of soil in the air near the foliage due to rain splash, 1.0 mg/m³. See Section 2.4.2 for further discussion.

V_{d} = diffusion attachment speed, or ground deposition speed that represents rain splash soil, 0.01 m/s or 864 m/d. See Section 2.4.2 for further discussion.

F_{fp} = interception fraction for plant type p. The fraction of what falls to the earth that lands on the plant. Computed using equation (3). Values are listed in Table 26.

F_{tp} = translocation factor, i.e. the fraction of what deposits on the foliage that ends up in the edible portions of the plant. Values are listed in Table 26.

T_{w} = effective exposure period for foliar deposition, in days. The values are computed using a foliage weathering time of 14 days. Values are shown in Table 29.

Y_{p} = harvest yield of crop type p, in kg/m² (wet weight). Also called the standing biomass. Values are listed in Table 26.

Q_{vp} = quantity of plant type p eaten by the person during the year, in kg/y. See Tables 13 and 14 for values.

C_{si} = time-dependent soil concentration of the ith nuclide, in Ci/kg. It is affected by radioactive decay and leaching from the surface layer of soil during the irrigation season. In the second equation it is the soil concentration at the time of harvest.

T_{irr} = irrigation period in years. The value of 0.5 yr is assumed based on current practices near the Hanford Site.

IDR_{i} = decay factor that accounts for radioactive decay of the ith nuclide during the consumption of garden produce

T_{veg} = consumption period for garden produce, assumed to be 90 days

T_{ing} = ingestion exposure time of the individual, 1 y.

$D_{ing,i}$ = ingestion dose factor for nuclide "I", in mrem per pCi ingested. Values are given in Table 7.

One effect of wind, rain, and irrigation is to remove deposited contamination from plant surfaces. This effect is included using a weathering term shown in equation (42). Values for the effective growing period are only slightly affected by the radioactive half life of the isotope for the long half lives shown in Table 5. Therefore, the decay effects were not considered (λ_w=0). Values for T_w are given in Table 29 for the growing periods shown in Table 26.

$$T_w = \{ 1 - Exp[-(\lambda_w + \lambda_r)T_p^f] \} / (\lambda_w + \lambda_r) \quad (42)$$

where

T_w = effective exposure period for foliar deposition, in days. Values are shown in Table 29.

λ_w = weathering removal coefficient, 0.0495105 per day, or 18.0713 per year, which corresponds to a 14 day half time.

λ_r = radioactive decay constant, namely, the natural logarithm of 2 divided by the radioactive decay half life in days. Values are listed in Table 5.

T_p^f = exposure time of the plant type p to the airborne contamination depositing on the foliage, in days (also called growing period). Values are shown in Table 26.

The previous two avenues by which contamination reaches the edible portions of the plants apply only to activity which is present in the soil. This section discusses direct deposition of contaminants in irrigation water onto the foliage. The ingestion dose due to radioactivity in the edible portion of the plants due to direct deposition on foliage is given in equation (43).

Table 29. Effective Exposure Times for Foliar Deposition

Growing Period	T_w
30 days	15.6 days
45 days	18.0 days
90 days	20.0 days

The effective exposure times are computed assuming radioactive decay is negligible for the nuclides of Table 5.

$$H_{epd}(leafy) = ID_p \frac{0.25\, F_{tp}\, T_w}{Y_p} Q_{vp}\, D_{ing}\, T_{ing}$$

(43)

$$H_{epd}(others) = \sum_{i=1}^{n} ID_p \frac{0.25\, F_{tp}\, T_w}{Y_p} Q_{vp}\, IDR_i(T_{veg})\, D_{ing,i}\, T_{ing}$$

where

H_{epd} = ingestion dose from plant type p due to deposition of a nuclide in contaminated irrigation water onto plant surfaces, in mrem.

p = type of plant. There are 4 types of garden produce. The first equation covers leafy vegetables (p=1). The second equation covers other vegetables, fruit, and grain (p=2,3,4).

ID_p = instantaneous activity deposition rate due to irrigation of soils growing plant type p, in Ci/yr/m^2. Only the parent nuclide is present. Any progeny nuclides are assumed to be absent.

0.25 = interception fraction for contaminants in irrigation water. The fraction of what falls to the earth that lands on the plant.

F_{tp} = translocation factor, i.e. the fraction of what deposits on the foliage that ends up in the edible portions of the plant. Values are listed in Table 26.

T_w = effective exposure period for foliar deposition, in days. The values are computed using a foliage weathering time of 14 days. Values are shown in Table 29.

Y_p = harvest yield of crop type p, in kg/m^2 (wet weight). Also called the standing biomass. Values are listed in Table 26.

Q_{vp} = quantity of plant type p eaten by the person during the year, in kg/y. See Tables 13 and 14 for values.

IDR_i = decay factor that accounts for radioactive decay during the consumption of garden produce

T_{veg} = consumption period for garden produce, assumed to be 90 days

T_{ing} = ingestion exposure time of the individual, 1 y.

$D_{ing,i}$ = ingestion dose factor for the ith nuclide, in mrem per pCi ingested. Values are given in Table 7.

The ingestion dose from garden produce due to direct deposition depends on the rate at which water is applied. In the previous two pathways, root uptake and rain splash, the determining factor is the total amount of water (and thus activity) applied to the soil. A summary of the essential calculation and the decay corrections is presented in Table 30.

Table 30. Summary of Ingestion Dose from Garden Produce

Essential Dose Calculation for an Initial Soil Contamination	
Root Uptake:	$R_p B_p C_s Q_{vp} D_{ing} T_{ing}$
Rain Splash:	$R^a V_d F_{fp} (F_{tp} T_w / Y_p) C_s Q_{vp} D_{ing} T_{ing}$
Correction for Radioactive Decay and Progeny Ingrowth	
Leafy Vegetables:	$IDS(T_{irr})$
Other Vegetables, Fruit, and Grain:	$DS(T_h) \cdot IDR(T_{veg})$
Essential Dose Calculation for Irrigation with Contaminated Water	
Root Uptake:	$R_p B_p C_s Q_{vp} D_{ing} T_{ing}$
Rain Splash:	$R^a V_d F_{fp} (F_{tp} T_w / Y_p) C_s Q_{vp} D_{ing} T_{ing}$
Direct Deposition:	$ID_p (0.25) (F_{tp} T_w / Y_p) Q_{vp} D_{ing} T_{ing}$
Correction for Radioactive Decay and Progeny Ingrowth	
Leafy Vegetables:	Root Uptake & Splash: $IDI(T_{irr})$ Direct Deposition: no decay
Other Vegetables, Fruit, and Grain:	Root Uptake & Splash: $DI(T_{irr}) \cdot IDR(T_{veg})$ Direct Deposition: $IDR(T_{veg})$

Notes: Leafy vegetables are consumed continuously during growing season (T_{irr}) only. Other produce is harvested and consumed over a period of time (T_{veg}). The decay factors are unitless fractions shown in Equation (37). Progeny ingrowth is computed using the method shown in Section 3.1.4.

Explanation of Symbols Used in Table 30.

B_p = soil to plant concentration ratio, as Ci/kg dry weight of vegetables to Ci/kg of soil. See Table 25 for values.

C_s = soil concentration of a nuclide, in Ci/kg. It is affected by radioactive decay and leaching from the surface layer of soil during the irrigation season.

D_{ing} = ingestion dose factor for a nuclide, in mrem per pCi ingested. Values are given in Table 7.

F_{fp} = interception fraction for plant type p. The fraction of what falls to the earth that lands on the plant. Computed using equation (3). Values are listed in Table 26.

F_{tp} = translocation factor, i.e. the fraction of what deposits on the foliage that ends up in the edible portions of the plant. Values are listed in Table 26.

ID_p = instantaneous activity deposition rate due to irrigation of soils growing plant type p, in Ci/yr/m².

p = type of plant. There are 4 types of garden produce. The first equation covers leafy vegetables (p=1). The second equation covers other vegetables, fruit, and grain (p=2,3,4).

Q_{vp} = quantity of plant type p eaten by the person during the year, in kg/y. See Tables 13 and 14 for values.

R^a = average concentration of soil in the air near the foliage due to rain splash, 1.0 mg/m³. See Section 2.4.2 for further discussion.

R_p = dry to wet ratio for plant type p. See Table 24 for values.

T_h = time at which harvest occurs. For initial soil contaminations, harvest is assumed to occur halfway through the growing season, $T_h=T_{irr}/2$. For irrigation with contaminated water, the harvest occurs at the end of the irrigation season to maximize the soil contamination.

T_{ing} = ingestion exposure time of the individual, 1 y.

T_{irr} = irrigation period in years. The value of 0.5 yr is assumed based on current practices near the Hanford Site.

T_{veg} = consumption period for garden produce, assumed to be 90 days

T_w = effective exposure period for foliar deposition, in days. The values are computed using a foliage weathering time of 14 days. Values are shown in Table 29.

V_d = diffusion attachment speed, or ground deposition speed that represents rain splash soil, 0.01 m/s or 864 m/d. See Section 2.4.2 for further discussion.

Y_p = harvest yield of crop type p, in kg/m² (wet weight). Also called the standing biomass. Values are listed in Table 26.

The one special case nuclide is tritium in contaminated irrigation water. Tritium present in an initial soil contamination is handled using the same method as any other nuclide. The soil-to-plant concentration ratio shown in Table 25 is used. Tritium in irrigation water leads to an equilibrium situation in which the concentration of tritium in the water is reproduced throughout the plant. Since the equilibrium is established rather quickly, the decay corrections are simpler than for other nuclides. The calculation of dose from tritium in irrigation water is shown in Equation (44) below. Note that the tritium model assumes that loss of tritium by evaporation of water from soil or plants is not important.

$$H_{epH}(\text{leafy}) = \frac{I\,C_{w,H3}}{I + P}(8.94\,F_{Hp})\,Q_{vp}\,D_{ing,H3}\,T_{ing}$$

(44)

$$H_{epH}(\text{others}) = \frac{I\,C_{w,H3}}{I + P}(8.94\,F_{Hp})\,Q_{vp}\,IDR(T_{veg})\,D_{ing,H3}\,T_{ing}$$

where

H_{epH} = ingestion dose from plant type p due to tritium (H-3) in the irrigation water, in mrem.

p = type of plant. There are 4 types of garden produce. The first equation covers leafy vegetables (p=1). The second equation covers other vegetables, fruit, and grain (p=2,3,4).

I = total irrigation water applied to the soil during the irrigation season, 82.3 cm/y (63.5 cm/y for populations).

$C_{w,H3}$ = concentration of tritium in the irrigation water, in pCi/L.

P = total natural precipitation water applied to the soil during the irrigation period, 5.23 cm/y (PNNL-12087).

F_{Hp} = fraction of hydrogen in plant type p. Values are listed in Table 23. The factor of 8.94 converts the hydrogen fraction to an effective water fraction that includes organically bound hydrogen.

Q_{vp} = quantity of plant type p eaten by the person during the year, in kg/y. See Tables 13 and 14 for values.

IDR = decay factor that accounts for radioactive decay during the consumption of garden produce

T_{veg} = consumption period for garden produce, assumed to be 90 days

T_{ing} = ingestion exposure time of the individual, 1 y.

$D_{ing,H3}$ = ingestion dose factor for tritium, in mrem per pCi ingested. Value is given in Table 7.

3.4.3 Animal Products Eaten

The simplest animal product to evaluate is fish. The dose from fish consumption is shown in equation (45). It is the product of the quantity of fish consumed during the year, the concentration in the fish, and the ingestion dose factor. The fish harvested is consumed over the next few days, so there is no need to correct for radioactive decay and progeny ingrowth.

$$H_{ef} = Q_{fe}\,C_w\,B_f\,D_{ing}\,T_{ing} \quad (45)$$

where

H_{ef} = ingestion dose from contaminated fish, in mrem.

Q_{fe} = quantity of contaminated fish consumed by the person during the year, in kg/y. See Tables 13 and 14 for values.

C_w = concentration of a nuclide in the contaminated water, in pCi/L.

B_f = bioaccumulation factor in fish, in L/kg. It is the ratio of the contamination in the edible parts of the fish to the concentration in the water. Values are shown in Table 22.

T_{ing} = ingestion exposure time of the individual, 1 y

D_{ing} = ingestion dose factor for a nuclide, in mrem per pCi ingested. Values are given in Table 7.

The ingestion dose from foods obtained from land animals is computed using equilibrium transfer factors shown in Table 22. These relate the total radioactive material ingested by the animal each day to the concentration in the animal product consumed by a person. The total diet of the animal must be taken into account. The animal may drink contaminated water, ingest contaminated soil, graze on contaminated grass and be fed stored material that is also contaminated. Each of these will be presented in turn. The total ingestion dose from animal products is the sum of these.

Just as with garden produce there is a continuous production model and a harvest model in which the animal is slaughtered for later consumption. The beef cattle model illustrates the latter, while the milk cow illustrates the former. The chicken (meat) and egg are treated as continuous because these are produced at regular intervals during the year and then consumed shortly thereafter.

The ingestion dose from contaminated water consumed by the animal is shown in equation (46). Because the progeny nuclides are not allowed to form in the water supply, the dose from each nuclide in a chain will be calculated separately. When the beef cattle is slaughtered (i.e. harvested), there is a large quantity of beef available. This food is then consumed over a period of time during which radioactive decay and progeny ingrowth occurs. The quantity of contaminated beef consumed during the year is from Tables 13 and 14. These values have already been adjusted for the fraction of the year that contaminated beef is consumed. Hence, the factor (T_{ing}/T_{beef}) is included.

$$H_{eqw}(\text{beef}) = \sum_{i=1}^{n} \int_{0}^{T_{beef}} Q_{wq}\, C_w\, F_{qi}\, Q_{aq} \left(\frac{T_{ing}}{T_{beef}} \right) D_{ing,i}\, DR_i\, dT$$

$$H_{eqw}(\text{others}) = Q_{wq}\, C_w\, F_q\, Q_{aq}\, D_{ing}\, T_{ing} \qquad (46)$$

where

H_{eqw} = ingestion dose from animal product q due to contaminated drinking water, in mrem.

q = index for animal products. There are 4 types of animal products, beef, milk, poultry, and eggs.

Q_{wq} = quantity of contaminated drinking water ingested by the animal associated with animal product q each day, in L/d. See Table 21 for values.

C_w = concentration of the parent nuclide in a decay chain in the contaminated water, in pCi/L. The progeny nuclide concentrations are assumed to be zero in the water.

F_{qi} = equilibrium transfer factor for animal product q for the ith nuclide in a decay chain, in d/kg (or d/L for milk). Values are given in Table 22. F_q is the transfer factor of the first nuclide.

Q_{aq} = quantity of animal product q consumed by the person during the year, in kg/y (or L/y for milk). See Tables 13 and 14 for values.

T_{beef} = consumption period for beef cattle, assumed to be 120 days

T_{ing} = ingestion exposure time of the individual, 1 y

$D_{ing,i}$ = ingestion dose factor for the ith nuclide in a decay chain, in mrem per pCi ingested. Values are given in Table 7. D_{ing} is the ingestion dose factor of the first nuclide in the chain.

The other contributors to the overall contamination of an animal product are summarized in Table 31. For the case of an initial soil contamination, the two components are vegetable foods consumed by the animal and the soil ingestion shown in Table 21. The animal foods are contaminated by root uptake and rain splash. There are three main kinds of food: fresh fodder (grass), stored hay (grass that is harvested and stored), and stored feed (grain that is harvested and stored). For the case of irrigation with contaminated water, additional components are direct deposition on the animal foods, and direct ingestion of the irrigation water.

Table 31. Summary of Ingestion Dose from Animal Products

Essential Dose Calculation for an Initial Soil Contamination. The activity intake rates are computed using the formulas below. These are converted to annual dose equivalent by means of the factor, $F_q Q_{aq} D_{ing} T_{ing}$.	
Trace Soil Ingestion:	$C_s Q_{sq}$
Fodder -- Root Uptake:	$R_p B_p C_s Q_{pq}$
Fodder -- Rain Splash:	$R^a V_d F_{fp} (F_{tp} T_w / Y_p) C_s Q_{pq}$

Correction for Radioactive Decay and Progeny Ingrowth -- Beef	
Soil Ingestion and Fresh Grass:	$DS(T_h)\cdot IDR(T_{beef})$
Stored Hay (grass) and Stored Grain:	$DS(T_h)\cdot DR(T_s)\cdot IDR(T_{beef})$
Correction for Radioactive Decay and Progeny Ingrowth -- Milk, Poultry, Eggs	
Soil Ingestion and Fresh Grass:	$[T_{irr}\cdot IDS(T_{irr}) + T_{no}\cdot DS(T_{irr})\cdot IDR(T_{no})]/T_{ing}$
Stored Hay (grass) and Stored Grain:	$DS(T_h)\cdot DR(T_s)\cdot IDR(T_{an})$
Essential Dose Calculation for Irrigation with Contaminated Water. The activity intake rates are computed using the formulas below. These are converted to annual dose equivalent by means of the factor, $F_q Q_{aq} D_{ing} T_{ing}$.	
Trace Soil Ingestion:	$C_s Q_{sq}$
Fodder -- Root Uptake:	$R_p B_p C_s Q_{pq}$
Fodder -- Rain Splash:	$R^a V_d F_{fp} (F_{tp} T_w / Y_p) C_s Q_{pq}$
Fodder -- Direct Deposition:	$ID_p (0.25) (F_{tp} T_w / Y_p) Q_{pq}$
Drinking Water Ingestion:	$C_w Q_{wq}$
Correction for Radioactive Decay and Progeny Ingrowth -- Beef	
Trace Soil Ingestion:	$DI(T_{irr})\cdot IDR(T_{beef})$
Fresh Grass:	Root & Splash: $DI(T_{irr})\cdot IDR(T_{beef})$ Direct Deposition: $IDR(T_{beef})$
Stored Hay and Grain:	Root & Splash: $DI(T_{irr})\cdot DR(T_s)\cdot IDR(T_{beef})$ Direct Deposition: $DR(T_s)\cdot IDR(T_{beef})$
Drinking Water:	$IDR(T_{beef})$
Correction for Radioactive Decay and Progeny Ingrowth -- Milk, Poultry, Eggs	
Trace Soil Ingestion:	$[T_{irr}\cdot IDI(T_{irr}) + T_{no}\cdot DI(T_{irr})\cdot IDR(T_{no})]/T_{ing}$

Fresh Grass:	Root Uptake & Rain Splash: $[T_{irr} \cdot IDI(T_{irr}) + T_{no} \cdot DI(T_{irr}) \cdot IDR(T_{no})]/T_{ing}$ Direct Deposition: no decay
Stored Hay and Grain:	Root & Splash: $DI(T_{irr}) \cdot DR(T_s) \cdot IDR(T_{an})$ Direct Deposition: $DR(T_s) \cdot IDR(T_{an})$
Drinking Water:	no decay

Notes: Beef is harvested and consumed over a period of time. Milk, poultry, and eggs are consumed continuously during the year. The decay factors are unitless fractions shown in Equation (37). Progeny ingrowth is computed using the method shown in Section 3.1.4.

Explanation of Symbols Used in Table 31.

B_p = soil to plant concentration ratio, as Ci/kg dry weight of vegetables to Ci/kg of soil. See Table 25 for values.

C_s = soil concentration of a nuclide, in Ci/kg. It is affected by radioactive decay and leaching from the surface layer of soil during the irrigation season.

C_w = concentration of a nuclide in the contaminated water, in pCi/L. Any progeny nuclide concentrations are assumed to be zero.

D_{ing} = ingestion dose factor for a nuclide, in mrem per pCi ingested. Values are given in Table 7.

F_q = equilibrium transfer factor for animal product q for a nuclide, in d/kg (or d/L for milk). Values are given in Table 22.

F_{fp} = interception fraction for plant type p. The fraction of what falls to the earth that lands on the plant. Computed using equation (3). Values are listed in Table 26.

F_{tp} = translocation factor, i.e. the fraction of what deposits on the foliage that ends up in the edible portions of the plant. Values are listed in Table 26.

ID_p = instantaneous activity deposition rate due to irrigation of soils growing plant type p, in Ci/yr/m^2.

p = index for animal fodder. There are 3 types of animal fodder, fresh grass, stored hay, and stored grain.

q = index for animal products. There are 4 types of animal products, beef, milk, poultry, and eggs.

Q_{aq} = quantity of animal product q eaten by the person during the year, in kg/y (or L/y for milk). See Tables 13 and 14 for values.

Q_{pq} = quantity of fodder type p eaten by the animal during the year, in kg/y. See Table 21 for values.

Q_{sq} = quantity of contaminated soil ingested by the animal associated with animal product q each day, in kg/d. See Table 21 for values.

Q_{wq} = quantity of contaminated drinking water ingested by the animal associated with animal product q each day, in L/d. See Table 21 for values.

R^a = average concentration of soil in the air near the foliage due to rain splash, 1.0 mg/m³. See Section 2.4.2 for further discussion.

R_p = dry to wet ratio for plant type p. See Table 23 for values.

T_{an} = time period over which stored hay and grain are consumed by the milk cow and chickens. Assumed to be the same as T_{veg}, 90 d.

T_{beef} = consumption period for beef cattle, assumed to be 120 days.

T_h = time at which harvest occurs. For initial soil contaminations, harvest is assumed to occur halfway through the growing season, $T_h=T_{irr}/2$. For irrigation with contaminated water, the harvest occurs at the end of the irrigation season to maximize the soil contamination.

T_{ing} = ingestion exposure time of the individual, 1 y.

T_{irr} = irrigation period in years. The value of 0.5 yr is assumed based on current practices near the Hanford Site. $T_{no} = 1y - T_{irr}$

T_s = storage time for the stored feed (hay and grain), 90 d.

T_w = effective exposure period for foliar deposition, in days. The values are computed using a foliage weathering time of 14 days. Values are shown in Table 29.

V_d = diffusion attachment speed, or ground deposition speed that represents rain splash soil, 0.01 m/s or 864 m/d. See Section 2.4.2 for further discussion.

Y_p = harvest yield of crop type p, in kg/m² (wet weight). Also called the standing biomass. Values are listed in Table 25.

The one special case nuclide is tritium in contaminated irrigation water. Tritium present in an initial soil contamination is handled using the same method as any other nuclide. The equilibrium transfer factors shown in Table 22 are used. Tritium in irrigation water leads to an equilibrium situation in which the concentration of tritium in the water is reproduced throughout the animal product. Since the equilibrium is established rather quickly, the decay corrections are simpler than for other nuclides. The calculation of dose from tritium in irrigation water is shown in Table 32 below. Note that the tritium model assumes that loss of tritium by evaporation of water from soil or plants is not important.

Table 32. Ingestion Dose from Animal Products from Tritium

Essential Dose Calculation for Irrigation with Contaminated Water. The activity intake rates are computed using the formulas below. These are converted to annual dose equivalent by means of the factor, $C_{w,H3} F_q Q_{aq} D_{ing,H3} T_{ing}$.	
Trace Soil Ingestion:	$8.94 F_{Hs} I/(I+P) Q_{sq}$
Fodder -- Root Uptake:	$8.94 F_{Hp} I/(I+P) Q_{pq}$
Drinking Water Ingestion:	Q_{wq}
Correction for Radioactive Decay and Progeny Ingrowth -- Beef	
Trace Soil Ingestion:	$IDR(T_{beef})$
Fresh Grass:	$IDR(T_{beef})$
Stored Hay and Grain:	$DR(T_s) \cdot IDR(T_{beef})$
Drinking Water:	$IDR(T_{beef})$
Correction for Radioactive Decay and Progeny Ingrowth -- Milk, Poultry, Eggs	
Trace Soil Ingestion:	$[T_{irr} + T_{no} \cdot IDR(T_{no})]/T_{ing}$
Fresh Grass:	$[T_{irr} + T_{no} \cdot IDR(T_{no})]/T_{ing}$
Stored Hay and Grain:	$DR(T_s) \cdot IDR(T_{an})$
Drinking Water:	no decay

Notes: Beef is harvested and consumed over a period of time. Milk, poultry, and eggs are consumed continuously during the year. The decay factors are unitless fractions shown in Equation (37). Progeny ingrowth is computed using the method shown in Section 3.1.4.

Explanation of Symbols Used in Table 32.

$C_{w,H3}$ = concentration of tritium (H-3) in the irrigation water, in pCi/L.

$D_{ing,H3}$ = ingestion dose factor for tritium, in mrem per pCi ingested. Value is given in Table 7.

F_q = equilibrium transfer factor for animal product q for tritium, in d/kg (or d/L for milk). Value is given in Table 22.

F_{Hs} = fraction of hydrogen in garden soil. The value used is listed in Table 23. The factor of 8.94 converts the hydrogen fraction to an effective water fraction that includes organically bound hydrogen.

F_{Hp} = fraction of hydrogen in plant type p. Values are listed in Table 23. The factor of 8.94 converts the hydrogen fraction to an effective water fraction that includes organically bound hydrogen.

I = total irrigation water applied to the soil during the irrigation season, 82.3 cm/y (63.5 for populations).

p = index for animal fodder. There are 3 types of animal fodder, fresh grass, stored hay, and stored grain.

P = total natural precipitation water reaching the surface soil during the irrigation period, 5.23 cm/y (PNNL-12087).

q = index for animal products. There are 4 types of animal products, beef, milk, poultry, and eggs.

Q_{aq} = quantity of animal product q eaten by the person during the year, in kg/y (or L/y for milk). See Tables 13 and 14 for values.

Q_{pq} = quantity of fodder type p eaten by the animal during the year, in kg/y. See Table 21 for values.

Q_{sq} = quantity of contaminated soil ingested by the animal associated with animal product q each day, in kg/d. See Table 21 for values.

Q_{wq} = quantity of contaminated drinking water ingested by the animal associated with animal product q each day, in L/d. See Table 21 for values.

T_{an} = time period over which stored hay and grain are consumed by the milk cow and chickens. Assumed to be the same as T_{veg}, 90 d.

T_{beef} = consumption period for beef cattle, assumed to be 120 days.

T_{ing} = ingestion exposure time of the individual, 1 y.

T_{irr} = irrigation period in years. The value of 0.5 yr is assumed based on current practices near the Hanford Site. $T_{no} = 1y - T_{irr}$

T_s = storage time for the stored feed (hay and grain), 90 d.

4.0 SCENARIO DOSE FACTORS

The tables in this section provide unit dose factors for each exposure scenario. The intrusion scenarios (no water infiltration) are given in Tables 33 and 34. The ground water scenarios are given in Tables 35 to 39. The population dose from use of contaminated drinking water is given in Table 40. Finally, Table 41 provides a comparison of the total dose to the drinking water dose for each scenario. The dose from the drinking water is the largest contributor for most nuclides.

The intrusion scenarios separate the external and internal doses to facilitate calculation of doses for an exhumed waste matrix that retains a portion of the radioactivity in a form that is not able to produce inhalation or ingestion doses (i.e., pieces of glass). The external dose depends only the amount exhumed. The internal dose also depends on the fraction that has decomposed and is available to produce inhalation and ingestion doses.

The irrigation scenarios are bounded by the NASR (Table 39). The next largest dose factors are for the HSRAM Agricultural and All Pathways Farmer (Tables 37 and 38). The traditional All Pathways Farmer doses are generally lower than those for the HSRAM Agricultural. Exceptions are for Gd-152, Ac-227, Th-229, Th-230, Th-232, and U-232, largely due to the strong inhalation dose component.

The comparison ratios in Table 41 are the total dose divided by the drinking water dose for each of the irrigation scenarios. The HSRAM Industrial scenario is not listed in Table 41 because the largest ratio was for Gd-152 (1.13). All other nuclide ratios were less than 1.06.

As indicated in DOE M 435.1-1 Chapter IV, the use of representative exposure scenarios is desired to avoid overly conservative assumptions. Thus the Post-Intrusion Resident (Table 34) should be used for evaluating compliance with the performance objectives for intruders. In addition, the All Pathways Farmer (Table 38) should be used for the groundwater performance objectives.

To bound the uncertainties associated with the various scenario parameters, the Native American Subsistence Residence case was created. Unit dose factors for this individual should be used to indicate an upper bound on the potential doses resulting from ground water contamination.

Units are mrem per Ci exhumed.
The "Internal" column is the sum of the "Inhale" and "Ingest" columns. External and internal doses are separated because the glass waste matrix will prevent a portion of the exhumed activity from contributing to the internal dose.

Units are mrem per Ci exhumed.
The "Internal" column is the sum of the "Garden", "Inhale", and "Ingest" columns. External and internal doses are separated because the glass waste matrix will prevent a portion of the exhumed activity from contributing to the internal dose.

Units are mrem per pCi/L in the ground water.
The "Total" column is the sum of the "Ingest" and "Inhale" columns.

Appendix A

Hand Calculations for Tritium

HAND CALCULATIONS FOR TRITIUM

A.1 No Water Infiltration Exposure Scenarios

Each of the exposure scenarios listed in Table 2 will be evaluated. The external exposures are not computed for tritium because the external dose rate factor for tritium is zero. Absorption through the skin is included in the inhalation dose factor for tritium.

Normally, three significant digits are kept during calculations. Because the spreadsheet software keeps several digits, agreement with the spreadsheet can only be obtained if 4 or 5 significant digits are retained. This is particularly true in the calculation of decay factors.

A.1.1 Offsite Farmer

Assume 1 curie H-3 is released into the air during the year. The bounding annual average air transport factor is 1.0E-04 s/m^3.

Inhalation Dose: From Table 28, 0.0237 mrem

A.1.2 Onsite Resident

Assume the H-3 emanation rate is 1 pCi/m^2/s. The average air concentration in a dwelling with an air exchange to floor area ratio of 5.0E-04 m/s is computed as shown below.

C_{eq} = (1 pCi/m^2/s)/(5.0E-04 m/s) = 2000 pCi/m^3

The individual is present in his dwelling about 6966 h/y from Table 17. The total volume of air inhaled during this period is computed as shown below.

V_{air} = (2920 h/y)(0.45 m^3/h) + (4046 h/y)(1.2 m^3/h) = 6170 m^3/y

Inhalation Dose:

(2000 pCi/m^3)(6170 m^3)(9.60E-08 mrem/pCi) = 1.18 mrem

A.1.3 Intruder (Well Driller)

Assume 1 curie H-3 is exhumed from the well shaft during the 5 day operation. The soil is spread over an area of 100 m^2 so the average soil concentration is computed as shown below.

C_s = (1 Ci)(1E12 pCi/Ci)/(100 m^2)/(225 kg/m^2) = 4.444E+7 pCi/kg

A mass loading approach is used, so that the driller inhales a total of 4.8 mg (4.8E-06 kg) of soil. He ingests a total of 500 mg (5.0E-4 kg) soil. The inhalation and ingestion dose calculations are shown below.

Inhalation Dose:

(4.8E-06 kg inhaled)(4.444E+7 pCi/kg)(9.60E-08 mrem/pCi) = 2.05E-05 mrem

Ingestion Dose:

(5.0E-04 kg ingested)(4.444E+7 pCi/kg)(6.40E-08 mrem/pCi) = 1.42E-03 mrem

External Dose:

(40 h)(4.444E+7 pCi/kg)(225 kg/m²)(0 mrem/h per Ci/m²) = 0 mrem

Total Dose to Driller:

2.05E-05 + 1.42E-03 mrem = 1.44E-03 mrem per Ci exhumed

A.1.4 Post-Intrusion Resident (Gardener)

Assume 1 curie H-3 is exhumed from the well shaft and spread over an area of 200 m². The average soil concentration is computed as shown below.

C_s = (1 Ci)(1E12 pCi/Ci)/(200 m²)/(225 kg/m²) = 2.222E+7 pCi/kg

This concentration decreases with time due to leaching from the surface layer during the irrigation season and radioactive decay. Decay factors used in the dose calculations are computed below (Table 30).

λ_r = (0.69315)/(12.33 y) = 0.056216 y^{-1} λ_l = 2.22 y^{-1} (Table 27)
$\lambda_t = \lambda_r + \lambda_l$ = 2.27622 y^{-1}

$\lambda_t T_{irr}$ = (2.27622 y^{-1})(0.5 y) = 1.13811
$DS(T_{irr})$ = Exp(-1.13811) = 0.32042
$IDS(T_{irr})$ = [1 - Exp(-1.13811)]/(1.13811) = 0.59711

$\lambda_r T_{no}$ = (0.056216 y^{-1})(0.5 y) = 0.028108
$IDR(T_{no})$ = [1 - Exp(-0.028108)]/(0.028108) = 0.98608

$T_{irr} \cdot IDS(T_{irr}) + T_{no} \cdot DS(T_{irr}) \cdot IDR(T_{no})$ =
(0.5y)(0.59711) + (0.5y)(0.32042)(0.98608) = 0.45653 y

$DS(T_h)$ = Exp[-(2.27622 y^{-1})(0.25 y)] = 0.56606

$\lambda_r T_{veg}$ = (0.056216 y^{-1})(90 d)/(365.25 d/y) = 0.013852

$IDR(T_{veg}) = [1 - Exp(-0.013852)]/(0.013852) = 0.99311$

$DS(T_h) \cdot IDR(T_{veg}) = (0.56606)(0.99311) = 0.56216$

A mass loading approach is used, so that the resident inhales a total of 573 mg (5.73E-04 kg) of soil over the course of a year. He also ingests a total of 0.0365 kg soil during the year. The inhalation and ingestion doses from these sources are shown below.

Inhalation Dose: (resuspended soil)
(5.73E-4 kg/y)(2.222E+7 pCi/kg)(9.60E-8 mrem/pCi)(0.45653 y) = 5.58E-4 mrem

Ingestion Dose: (soil only)
(0.0365 kg)(2.222E+7 pCi/kg)(6.40E-8 mrem/pCi)(0.45653 y) = 0.0237 mrem

External Dose:
(900 h/y)(2.222E+7 pCi/kg)(225 kg/m²)(0 mrem/h per Ci/m²)(0.45653 y) = 0 mrem

The vegetable produce from the garden is contaminated by root uptake and rain splash. Doses from each are shown below. The contaminated food consumption rate is combined with the ingestion period (1 year) so that the column of consumption rates has units of kg rather than kg/y. The product of soil concentration and ingestion dose is combined into a single quantity to simplify the calculation.
(2.222E+7 pCi/kg)(6.40E-8 mrem/pCi)=1.4221 mrem/kg

Ingestion Dose: (root uptake only)
(1.4221 mrem/kg)(51)(0.09)(4.1 kg)(0.59711) = 16.0 mrem
(1.4221 mrem/kg)(18)(0.25)(13.9 kg)(0.56216) = 50.0 mrem
(1.4221 mrem/kg)(25)(0.18)(9.6 kg)(0.56216) = 34.5 mrem
(1.4221 mrem/kg)(3.4)(0.91)(18.5 kg)(0.56216) = 45.8 mrem
Total from root uptake: 146.3 mrem

Ingestion Dose: (rain splash only)
To simplify the calculation, the mass loading, ground deposition speed, soil concentration and ingestion dose factor are combined in a single factor.
(1 mg/m³)(0.01 m/s)(1.4221 mrem/kg)(86,400 s/d) = 1.229E-3 mrem/d/m²

(1.229E-3mrem/d/m²)(18d)(0.407)(1.0)/(2.0kg/m²)(4.1kg)(0.59711) = 0.0110mrem
(1.229E-3mrem/d/m²)(20d)(0.835)(0.1)/(2.0kg/m²)(13.9kg)(0.56216) = 0.0080mrem
(1.229E-3mrem/d/m²)(20d)(0.857)(0.1)/(3.0kg/m²)(9.6kg)(0.56216) = 0.0038mrem
(1.229E-3mrem/d/m²)(20d)(0.371)(0.1)/(0.8kg/m²)(18.5kg)(0.56216) = 0.0119mrem
Total from rain splash: 0.0347mrem

Total Dose to Gardener:
5.58E-04 + 0.0237 + 146.3 + 0.0347 mrem = 146 mrem per Ci exhumed

A.1.5 Post-Intrusion Resident (HSRAM Residential)

Assume 1 curie H-3 is exhumed from the well shaft and spread over an area of 200 m^2. The average soil concentration is computed as before. The same decay factors used for the Gardener also apply here. Doses from each pathway are shown below.

Inhalation Dose: (resuspended soil)
(3.65E-4 kg/y)(2.222E+7 pCi/kg)(9.60E-8 mrem/pCi)(0.45653 y) = 3.55E-4 mrem

Ingestion Dose: (soil only)
(0.0365 kg)(2.222E+7 pCi/kg)(6.40E-8 mrem/pCi)(0.45653 y) = 0.0237 mrem

External Dose:
(7008 h/y)(2.222E+7 pCi/kg)(225 kg/m^2)(0 mrem/h per Ci/m^2)(0.45653 y) = 0 mrem

Ingestion Dose: (root uptake only)
(1.4221 mrem/kg)(51)(0.09)(3.7 kg)(0.59711) = 14.4 mrem
(1.4221 mrem/kg)(18)(0.25)(11.0 kg)(0.56216) = 39.6 mrem
(1.4221 mrem/kg)(25)(0.18)(15.3 kg)(0.56216) = 55.0 mrem
(1.4221 mrem/kg)(3.4)(0.91)(14.6 kg)(0.56216) = 36.1 mrem
Total from root uptake: 145.1 mrem

Ingestion Dose: (rain splash only)
(1.229E-3mrem/d/m^2)(18d)(0.407)(1.0)/(2.0kg/m^2)(3.7kg)(0.59711) = 0.0099mrem
(1.229E-3mrem/d/m^2)(20d)(0.835)(0.1)/(2.0kg/m^2)(11.0kg)(0.56216) = 0.0063mrem
(1.229E-3mrem/d/m^2)(20d)(0.857)(0.1)/(3.0kg/m^2)(15.3kg)(0.56216) = 0.0060mrem
(1.229E-3mrem/d/m^2)(20d)(0.371)(0.1)/(0.8kg/m^2)(14.6kg)(0.56216) = 0.0094mrem
Total from rain splash: 0.0317mrem

Total Dose to HSRAM Residential:
3.55E-04 + 0.0237 + 145.1 + 0.0317 mrem = 145 mrem per Ci exhumed

A.2 Low Water Infiltration Exposure Scenarios

Each of the exposure scenarios listed in Table 4 will be evaluated. The external exposures are not computed for tritium because the external dose rate factor for tritium is zero. Absorption through the skin is included in the inhalation dose factor for tritium. The main dose pathway in every case is the drinking water pathway.

It will be assumed in each exposure scenario that the well water concentration is 1 pCi/L. Thus the doses computed are per pCi/L.

Normally, three significant digits are kept during calculations. Because the spreadsheet software keeps several digits, agreement with the spreadsheet can only be obtained if 4 or 5 significant digits are retained. This is particularly true in the calculation of decay factors.

A.2.1 Industrial (HSRAM)

The worker inhales 2.1 L/y during routine showering and ingests 250 L/y of drinking water (untreated). The soil pathways do not apply because the soil is not contaminated.

Inhalation Dose: (showering)
(2.1 L/y)(1 pCi/L)(9.60E-08 mrem/pCi)(1 y) = 2.02E-7 mrem

Ingestion Dose: (drinking)
(250 L/y)(1 pCi/L)(6.40E-08 mrem/pCi)(1 y) = 1.60E-5 mrem

Total Dose to Industrial Worker:
2.02E-7 + 1.60E-5 mrem = 1.62E-5 mrem per pCi/L

A.2.2 Residential (HSRAM)

The soil concentration decreases with time due to leaching from the surface layer during the irrigation season and radioactive decay. Decay factors used in the dose calculations are computed below (Table 30). Equilibrium model assumptions lead to somewhat different decay factors than in the no-infiltration cases.

$\lambda_r T_{no} = (0.056216\ y^{-1})(0.5\ y) = 0.028108$
$IDR(T_{no}) = [1 - Exp(-0.028108)]/(0.028108) = 0.98608$

$T_{irr} + T_{no} \cdot IDR(T_{no}) = (0.5y) + (0.5y)(0.98608) = 0.99304\ y$

$\lambda_r T_{veg} = (0.056216\ y^{-1})(90\ d)/(365.25\ d/y) = 0.013852$
$IDR(T_{veg}) = [1 - Exp(-0.013852)]/(0.013852) = 0.99311$

Inhalation of well water during showers amounts to 3.1 L/y. Inhalation of resuspended soil amounts to 365 mg (3.65E-04 kg) of soil over the course of a year. The individual also ingests a total of 0.0365 kg soil and 730 L water during the year. The soil concentration is based on the soil moisture having the same tritium concentration as the well water (adjusted for natural precipitation by Equation 15). The soil concentration and the resulting inhalation and ingestion doses from the soil and water are shown below.

$C_{s,H3} = (8.94)(0.022)(1\ pCi/L)(82.3\ cm)/(82.3 + 5.23\ cm)/(1\ kg/L)$
$C_{s,H3} = 0.1849\ pCi/kg$

Inhalation Dose: (showering)
(3.1 L/y)(1 pCi/L)(9.60E-08 mrem/pCi)(1 y) = 2.98E-7 mrem

Inhalation Dose: (resuspended soil)
(3.65E-4 kg/y)(0.1849 pCi/kg)(9.60E-8 mrem/pCi)(0.99304 y) = 6.43E-12 mrem

Ingestion Dose: (drinking)
(730 L/y)(1 pCi/L)(6.40E-08 mrem/pCi)(1 y) = 4.67E-5 mrem

Ingestion Dose: (soil)
(0.0365 kg/y)(0.1849 pCi/kg)(6.40E-8 mrem/pCi)(0.99304 y) = 4.29E-10 mrem

External Dose:
(7008 h/y)(0.1849 pCi/kg)(225 kg/m²)(0 mrem/h per Ci/m²)(0.99304 y) = 0 mrem

The vegetable produce contamination is based on the plant moisture having the same tritium concentration as the well water (adjusted for natural precipitation by Equation 15). The contaminated food consumption rate is combined with the ingestion period (1 year) so that the column of consumption rates has units of kg rather than kg/y. The product of plant water concentration and ingestion dose factor is combined into a single quantity to simplify the calculation.

(0.94)(1 pCi/L)(6.40E-8 mrem/pCi)=6.016E-8 mrem/L

The factors 0.894 L/kg and 0.6079 L/kg in the calculations below are the volume of water per kilogram of plant. They are calculated from the hydrogen fractions shown in Table 23 multiplied by 8.94 kg water per kg hydrogen, and divided by the density of water, 1.0 kg/L.

Ingestion Dose: (garden produce)
(6.016E-8 mrem/L)(0.894 L/kg)(3.7 kg)(1.00) = 1.99E-7 mrem
(6.016E-8 mrem/L)(0.894 L/kg)(11.0 kg)(0.99311) = 5.88E-7 mrem
(6.016E-8 mrem/L)(0.894 L/kg)(15.3 kg)(0.99311) = 8.17E-7 mrem
(6.016E-8 mrem/L)(0.6079L/kg)(14.6 kg)(0.99311) = 5.30E-7 mrem
Total from garden produce: 2.13E-6 mrem

Total Dose to Resident:
2.98E-7+6.43E-12+4.67E-5+4.29E-10+2.13E-6 mrem = 4.92E-5 mrem per pCi/L

A.2.3 Agricultural (HSRAM)

Both inhalation doses as well as the ingestion doses for drinking water, soil, and garden produce are the same as the HSRAM Residential case. They are listed below.

Inhalation Dose: (showering)
(3.1 L/y)(1 pCi/L)(9.60E-08 mrem/pCi)(1 y) = 2.98E-7 mrem

Inhalation Dose: (resuspended soil)
(3.65E-4 kg/y)(0.1849 pCi/kg)(9.60E-8 mrem/pCi)(0.99304 y) = 6.43E-12 mrem

Ingestion Dose: (drinking)
(730 L/y)(1 pCi/L)(6.40E-08 mrem/pCi)(1 y) = 4.67E-5 mrem

Ingestion Dose: (soil)
(0.0365 kg/y)(0.1849 pCi/kg)(6.40E-8 mrem/pCi)(0.99304 y) = 4.29E-10 mrem

External Dose:
(7008 h/y)(0.1849 pCi/kg)(225 kg/m^2)(0 mrem/h per Ci/m^2)(0.99304 y) = 0 mrem

Ingestion Dose: (garden produce)
Total from garden produce: 2.13E-6 mrem

Total from the above pathways = 4.915E-05 mrem

The agricultural scenario adds the dose from animal products that are contaminated by ingestion of well water, contaminated fodder and soil. The decay factors are based on Table 32 and are shown below.

$\lambda_r T_s = (0.056216\ y^{-1})(90\ d/365.25\ d/y) = 0.013852$
$DR(T_s) = Exp(-0.013852) = 0.98624$

$\lambda_r T_{beef} = (0.056216\ y^{-1})(120\ d)/(365.25\ d/y) = 0.018469$
$IDR(T_{beef}) = [1 - Exp(-0.018469)]/(0.018469) = 0.99082$

$DR(T_s) \cdot IDR(T_{beef}) = (0.98624)(0.99082) = 0.97719$

$\lambda_r T_{an} = (0.056216\ y^{-1})(90\ d)/(365.25\ d/y) = 0.013852$
$IDR(T_{an}) = [1 - Exp(-0.013852)]/(0.013852) = 0.99311$

$DR(T_s) \cdot IDR(T_{an}) = (0.98624)(0.99311) = 0.97944$

$\lambda_r T_{no} = (0.056216\ y^{-1})(0.5\ y) = 0.028108$
$IDR(T_{no}) = [1 - Exp(-0.028108)]/(0.028108) = 0.98608$

$T_{irr} + T_{no} \cdot IDR(T_{no}) = (0.5y) + (0.5y)(0.98608) = 0.99304\ y$

The dose for each pathway is the sum of contributions to the animal's diet. In particular, there is fresh feed, stored hay, stored grain, soil, and drinking water. Each of these has a common factor made of the annual amount consumed by the individual, the ingestion dose factor, the equilibrium transfer factor, the water concentration, and the ingestion period.

Ingestion Dose: (beef)

(21.9 kg/y)(6.40E-8 mrem/pCi)(0.01 d/kg)(1 pCi/L)(1 y) = 1.402E-8 mrem·d/L

(1.402E-8 mrem·d/L)(0.94)(0.894 L/kg)(14 kg/d grass)(0.99082) = 1.63E-7 mrem
(1.402E-8 mrem·d/L)(0.94)(0.894 L/kg)(27 kg/d hay)(0.97719) = 3.11E-7 mrem
(1.402E-8 mrem·d/L)(0.94)(0.6079L/kg)(3 kg/d grain)(0.97719) = 2.35E-8 mrem
(1.402E-8 mrem·d/L)(0.94)(0.1967L/kg)(0.6 kg/d soil)(0.99082) = 1.54E-9 mrem
(1.402E-8 mrem·d/L)(1.00) (50 L/d water)(0.99082) = 6.95E-7 mrem
Total from beef: 1.19E-6 mrem

Ingestion Dose: (milk)

(110 L/y)(6.40E-8 mrem/pCi)(0.0082 d/L)(1 pCi/L)(1 y) = 5.773E-8 mrem·d/L

(5.773E-8 mrem·d/L)(0.94)(0.894 L/kg)(36 kg/d grass)(0.99304) = 1.73E-6 mrem
(5.773E-8 mrem·d/L)(0.94)(0.894 L/kg)(29 kg/d hay)(0.97944) = 1.38E-6 mrem
(5.773E-8 mrem·d/L)(0.94)(0.6079L/kg)(2 kg/d grain)(0.97944) = 6.46E-8 mrem
(5.773E-8 mrem·d/L)(0.94)(0.1967L/kg)(0.8 kg/d soil)(0.99304) = 8.48E-9 mrem
(5.773E-8 mrem·d/L)(1.00)(60 L/d water)(1.00) = 3.46E-6 mrem
Total from milk: 6.65E-6 mrem

Ingestion Dose: (poultry)

(5.5 kg/y)(6.40E-8 mrem/pCi)(1.9 d/kg)(1 pCi/L)(1 y) = 6.688E-7 mrem·d/L

(6.688E-7 mrem·d/L)(0.94)(0.894 L/kg)(0.13 kg/d grass)(0.99304) = 7.26E-8 mrem
(6.688E-7 mrem·d/L)(0.94)(0.894 L/kg)(0.0 kg/d hay)(0.97944) = 0.0 mrem
(6.688E-7 mrem·d/L)(0.94)(0.6079L/kg)(0.09 kg/d grain)(0.97944) = 3.37E-8 mrem
(6.688E-7 mrem·d/L)(0.94)(0.1967L/kg)(0.011 kg/d soil)(0.99304) = 1.35E-9 mrem
(6.688E-7 mrem·d/L)(1.00)(0.3 L/d water)(1.00) = 2.01E-7 mrem
Total from poultry: 3.08E-7 mrem

Total Dose to HSRAM Agricultural:

4.915E-5+1.19E-6+6.65E-6+3.08E-7 mrem = 5.73E-5 mrem per pCi/L

A.2.4 All Pathways

The doses for each pathway are calculated in the same manner as the HSRAM Agricultural case except most of the exposure parameters are different. The revised doses are listed below.

Inhalation Dose: (showering and ambient humidity)

(4.5+39 L/y)(1 pCi/L)(9.60E-08 mrem/pCi)(1 y) = 4.18E-6 mrem

Inhalation Dose: (resuspended soil)

(5.73E-4 kg/y)(0.1849 pCi/kg)(9.60E-8 mrem/pCi)(0.99304 y) = 1.01E-11 mrem

Ingestion Dose: (drinking)
(540 L/y)(1 pCi/L)(6.40E-08 mrem/pCi)(1 y) = 3.46E-5 mrem

Ingestion Dose: (soil)
(0.0365 kg/y)(0.1849 pCi/kg)(6.40E-8 mrem/pCi)(0.99304 y) = 4.29E-10 mrem

External Dose:
(4120 h/y)(0.1849 pCi/kg)(225 kg/m²)(0 mrem/h per Ci/m²)(0.99304 y) = 0 mrem

Ingestion Dose: (garden produce)
(6.016E-8 mrem/L)(0.894 L/kg)(4.1 kg)(1.00) = 2.21E-7 mrem
(6.016E-8 mrem/L)(0.894 L/kg)(13.9 kg)(0.99311) = 7.42E-7 mrem
(6.016E-8 mrem/L)(0.894 L/kg)(9.6 kg)(0.99311) = 5.13E-7 mrem
(6.016E-8 mrem/L)(0.6079L/kg)(18.5 kg)(0.99311) = 6.72E-7 mrem
Total from garden produce: 2.15E-6 mrem

The dose for each pathway is the sum of contributions to the animal's diet. In particular, there is fresh feed, stored hay, stored grain, soil, and drinking water. Each of these has a common factor made of the annual amount consumed by the individual, the ingestion dose factor, the equilibrium transfer factor, the water concentration, and the ingestion period.

Ingestion Dose: (beef)
(21 kg/y)(6.40E-8 mrem/pCi)(0.01 d/kg)(1 pCi/L)(1 y) = 1.344E-8 mrem·d/L

(1.344E-8 mrem·d/L)(0.94)(0.894 L/kg)(14 kg/d grass)(0.99082) = 1.57E-7 mrem
(1.344E-8 mrem·d/L)(0.94)(0.894 L/kg)(27 kg/d hay)(0.97719) = 2.98E-7 mrem

(1.478E-6 mrem·d/L)(1.00)(0.3 L/d water)(1.00) = 4.43E-7 mrem
Total from eggs: 6.81E-7 mrem

Total of all animal pathways = 1.68E-5 mrem

Total Dose for the NASR:
5.09E-6+1.93E-11+7.01E-5+8.58E-10+1.10E-5+1.68E-5 mrem
= 1.03E-4 mrem per pCi/L

A.2.6 Columbia River Population

The collective doses for each pathway are calculated in the same manner as the All Pathways Irrigator case scaled up for a population of 5 million, with a lower irrigation rate, and reduced by a factor of 1000 to convert from mrem to rem. The inhalation and ingestion doses are adjusted for the population and unit conversion as shown below. The new soil concentration is shown also.

Inhalation: (9.60E-8 mrem/pCi)(5.0E+6)(0.001 rem/mrem) = 4.80E-4 rem/pCi
Ingestion: (6.40E-8 mrem/pCi)(5.0E+6)(0.001 rem/mrem) = 3.20E-4 rem/pCi

$C_{s,H3}$ = (8.94)(0.022)(1 pCi/L)(63.5 cm)/(63.5 + 5.23 cm)/(1 kg/L)
$C_{s,H3}$ = 0.1817 pCi/kg

Inhalation Dose: (showering and ambient humidity)
(4.5+39 L/y)(1 pCi/L)(4.80E-4 rem/pCi)(1 y) = 2.09E-2 rem

Inhalation Dose: (resuspended soil)
(4.16E-4 kg/y)(0.1817 pCi/kg)(4.80E-4 rem/pCi)(0.99304 y) = 3.60E-8 rem

Ingestion Dose: (drinking)
(540 L/y)(1 pCi/L)(3.20E-4 rem/pCi)(1 y) = 0.1728 rem

Ingestion Dose: (soil)
(0.0365 kg/y)(0.1817 pCi/kg)(3.20E-4 rem/pCi)(0.99304 y) = 2.11E-6 rem

External Dose:
(4383 h/y)(0.1817 pCi/kg)(225 kg/m²)(0 mrem/h per Ci/m²)(0.99304 y) = 0 mrem

With a lower irrigation rate, the irrigation dilution factor changes to become (63.5

cm)/(63.5+5.23cm)=0.924. The common factor used in the garden produce calculation is shown below.

(0.924)(1 pCi/L)(3.20E-4 rem/pCi)=2.957E-4 rem/L

Ingestion Dose: (garden produce)

(2.957E-4 rem/L)(0.894 L/kg)(4.1 kg)(1.00) = 1.08E-3 rem
(2.957E-4 rem/L)(0.894 L/kg)(13.9 kg)(0.99311) = 3.65E-3 rem
(2.957E-4 rem/L)(0.894 L/kg)(9.6 kg)(0.99311) = 2.52E-3 rem
(2.957E-4 rem/L)(0.6079L/kg)(18.5 kg)(0.99311) = 3.30E-3 rem
Total from garden produce: 1.06E-2 rem

The dose for each pathway is the sum of contributions to the animal's diet. In particular, there is fresh feed, stored hay, stored grain, soil, and drinking water. Each of these has a common factor made of the annual amount consumed by the individual, the ingestion dose factor, the equilibrium transfer factor, the water concentration, and the ingestion period.

Ingestion Dose: (beef)

(21 kg/y)(3.20E-4 rem/pCi)(0.01 d/kg)(1 pCi/L)(1 y) = 6.720E-5 rem·d/L

(6.720E-5 rem·d/L)(0.924)(0.894 L/kg)(14 kg/d grass)(0.99082) = 7.70E-4 rem
(6.720E-5 rem·d/L)(0.924)(0.894 L/kg)(27 kg/d hay)(0.97719) = 1.46E-3 rem

Hand Calculations for Carbon-14

HAND CALCULATIONS FOR CARBON-14

B.1 No Water Infiltration -- Post-Intrusion Resident

Only two of the exposure scenarios listed in Table 2 will be evaluated, the post-intrusion gardener and the all-pathways irrigator. These two exercise all of the relevant calculations. The other scenarios are very similar to previous calculations with tritium, or are very similar to the calculations shown for C-14.

Normally, three significant digits are kept during calculations. Because the spreadsheet software keeps several digits, agreement with the spreadsheet can only be obtained if 4 or 5 significant digits are retained. This is particularly true in the calculation of decay factors.

It will be assumed that 1 curie C-14 is exhumed from the well shaft and spread over an area of 200 m^2. The average soil concentration is computed as shown below.

C_s = (1 Ci)(1E12 pCi/Ci)/(200 m^2)/(225 kg/m^2) = 2.222E+7 pCi/kg

This concentration decreases with time due to leaching from the surface layer during the irrigation season and radioactive decay. Decay factors used in the dose calculations are computed below (see Table 30).

λ_r = (0.69315)/(5730 y) = 1.210E-4 y^{-1} λ_l = 0.0644 y^{-1} (Table 27)
$\lambda_t = \lambda_r + \lambda_l$ = 0.064521 y^{-1}

$\lambda_t T_{irr}$ = (0.064521 y^{-1})(0.5 y) = 0.032261
$DS(T_{irr})$ = Exp(-0.032261) = 0.96825
$IDS(T_{irr})$ = [1 - Exp(-0.032261)]/(0.032261) = 0.98404

$\lambda_r T_{no}$ = (1.21E-4 y^{-1})(0.5 y) = 6.05E-5
$IDR(T_{no})$ = [1 - Exp(-6.05E-5)]/(6.05E-5) = 0.99997

$T_{irr} \cdot IDS(T_{irr}) + T_{no} \cdot DS(T_{irr}) \cdot IDR(T_{no})$ =
(0.5y)(0.98404) + (0.5y)(0.96825)(0.99997) = 0.97613 y

$DS(T_h)$ = Exp[-(0.064521 y^{-1})(0.25 y)] = 0.98400

$\lambda_r T_{veg}$ = (1.21E-4 y^{-1})(90 d)/(365.25 d/y) = 2.98E-5
$IDR(T_{veg})$ = [1 - Exp(-2.98E-5)]/(2.98E-5) = 0.99999

$DS(T_h) \cdot IDR(T_{veg})$ = (0.98400)(0.99999) = 0.98399

A mass loading approach is used, so that the resident inhales a total of 573 mg, or 5.73E-04 kg (Table 17) of soil over the course of a year. He also ingests a total of 0.0365 kg soil (Table 13) during the year. The inhalation and ingestion doses from these sources are shown below. Note that the C-14 internal dose factors for inhalation and ingestion are the same.

Inhalation Dose: (resuspended soil)

(5.73E-4 kg/y)(2.222E+7 pCi/kg)(2.09E-6 mrem/pCi)(0.97613 y) = 0.0260 mrem

Ingestion Dose: (soil only)

(0.0365 kg)(2.222E+7 pCi/kg)(2.09E-6 mrem/pCi)(0.97613 y) = 1.65 mrem

External dose is computed from the external dose rate factor for C-14, the soil concentration and the exposure time (900 h from Section 2.2.5). A modified form of the soil concentration is used to simplify the calculation. This is shown below.

External Dose:

(900 h/y)(1 Ci)/(200 m^2)(6.82E-3 mrem/h per Ci/m^2)(0.97613 y) = 0.0300 mrem

The vegetable produce from the garden is contaminated by root uptake and rain splash. Doses from each are shown below. The contaminated food consumption rate is combined with the ingestion period (1 year) so that the column of consumption rates has units of kg rather than kg/y. The product of soil concentration and ingestion dose is combined into a single quantity to simplify the calculation.

(2.222E+7 pCi/kg)(2.09E-6 mrem/pCi)=46.44 mrem/kg

Ingestion Dose: (root uptake only)

(46.44 mrem/kg)(0.7)(0.09)(4.1 kg)(0.98404) = 11.8 mrem
(46.44 mrem/kg)(0.7)(0.25)(13.9 kg)(0.98399) = 111.2 mrem
(46.44 mrem/kg)(0.7)(0.18)(9.6 kg)(0.98399) = 55.3 mrem
(46.44 mrem/kg)(0.7)(0.91)(18.5 kg)(0.98399) = 538.5 mrem
Total from root uptake: 716.7 mrem

Ingestion Dose: (rain splash only)

To simplify the calculation, the mass loading, ground deposition speed, soil concentration and ingestion dose factor are combined in a single factor.

(1 mg/m^3)(0.01 m/s)(46.44 mrem/kg)(86,400 s/d) = 0.04012 mrem/d/m^2

(0.04012mrem/d/m^2)(18d)(0.407)(1.0)/(2.0kg/m^2)(4.1kg)(0.98404) = 0.593mrem
(0.04012mrem/d/m^2)(20d)(0.835)(0.1)/(2.0kg/m^2)(13.9kg)(0.98399) = 0.458mrem
(0.04012mrem/d/m^2)(20d)(0.857)(0.1)/(3.0kg/m^2)(9.6kg)(0.98399) = 0.217mrem
(0.04012mrem/d/m^2)(20d)(0.371)(0.1)/(0.8kg/m^2)(18.5kg)(0.98399) = 0.677mrem
Total from rain splash: 1.945mrem

Total Dose to Gardener:

0.0260 + 1.65 + 0.0298 + 716.7 + 1.945 mrem = 720 mrem per Ci exhumed

B.2 Low Water Infiltration -- All Pathways Farmer

It will be assumed in each exposure scenario that the well water concentration is 1 pCi/L. Thus the doses computed are per pCi/L. The main dose pathway in every case is the drinking water pathway.

Normally, three significant digits are kept during calculations. Because the spreadsheet software keeps several digits, agreement with the spreadsheet can only be obtained if 4 or 5 significant digits are retained. This is particularly true in the calculation of decay factors.

Inhalation of well water during showers amounts to 0.045 L/y (Table 18). Inhalation of evaporated well water under ambient conditions amounts to 0.39 L/y. The individual ingests a total of 540 L/y of drinking water (Table 13). The doses from these pathways are shown below. Because the ground water comes from the well and is ingested or inhaled shortly after, no decay factors are needed.

Inhalation Dose: (showering and ambient humidity)

(0.046+0.039 L/y)(1 pCi/L)(2.09E-06 mrem/pCi)(1 y) = 1.76E-7 mrem

Ingestion Dose: (drinking)

(540 L/y)(1 pCi/L)(2.09E-06 mrem/pCi)(1 y) = 1.13E-3 mrem

The soil concentration at the end of the year (apart from decay corrections) is based on 82.3 cm of irrigation water applied to the garden and pasture (Section 2.5). The soil concentration is shown below in two units. Both are used in the calculations that follow.

C_s = (82.3 cm/y)(10,000 cm²/m²)(0.001 L/cm³)(1 pCi/L) = 823 pCi/m²

or

C_s = (823 pCi/m²)/(225 kg/m²) = 3.6578 pCi/kg

The soil concentration decreases with time due to leaching from the surface layer during the irrigation season and radioactive decay. Additional decay factors used in the dose calculations for the all pathways irrigation scenario are shown below (see Tables 30 and 31).

$\lambda_1 T_{irr}$ = (0.064521 y^{-1})(0.5 y) = 0.032261

$DI(T_{irr})$ = [1 - Exp(-0.032261)]/(0.032261) = 0.98404

$IDI(T_{irr})$ = [0.032261 - 1 + Exp(-0.032261)]/(0.032261)² = 0.49471

$T_{irr} \cdot IDI(T_{irr}) + T_{no} \cdot DI(T_{irr}) \cdot IDR(T_{no}) =$
$(0.5y)(0.49471) + (0.5y)(0.98404)(0.99997) = 0.73936$ y

$\lambda_r T_{veg} = (1.21E\text{-}4\ y^{-1})(90\ d)/(365.25\ d/y) = 2.98E\text{-}5$
$IDR(T_{veg}) = [1 - Exp(-2.98E\text{-}5)]/(2.98E\text{-}5) = 0.99999$

$DI(T_{irr}) \cdot IDR(T_{veg}) = (0.98404)(0.99999) = 0.98403$

$\lambda_r T_{beef} = (1.21E\text{-}4\ y^{-1})(120\ d)/(365.25\ d/y) = 3.98E\text{-}5$
$IDR(T_{beef}) = [1 - Exp(-3.98E\text{-}5)]/(3.98E\text{-}5) = 0.99998$

$DI(T_{irr}) \cdot IDR(T_{beef}) = (0.98404)(0.99998) = 0.98402$

$DR(T_s) = Exp[-(1.21E\text{-}4\ y^{-1})(90\ d)/(365.25\ d/y)] = 0.99997$

$DR(T_s) \cdot IDR(T_{beef}) = (0.99997)(0.99998) = 0.99995$

$DI(T_{irr}) \cdot DR(T_s) \cdot IDR(T_{beef}) = (0.98404)(0.99997)(0.99998) = 0.98399$

$\lambda_r T_{an} = (1.21E\text{-}4\ y^{-1})(90\ d)/(365.25\ d/y) = 2.98E\text{-}5$
$IDR(T_{an}) = [1 - Exp(-2.98E\text{-}5)]/(2.98E\text{-}5) = 0.99999$

$DI(T_{irr}) \cdot DR(T_s) \cdot IDR(T_{an}) = (0.98404)(0.99997)(0.99999) = 0.98400$

$DR(T_s) \cdot IDR(T_{an}) = (0.99997)(0.99999) = 0.99996$

Inhalation of resuspended soil amounts to 573 mg (5.73E-04 kg) of soil over the course of a year. The individual also ingests a total of 0.0365 kg soil during the year. The time of exposure to external radiation is 4120 h/y. The inhalation, ingestion, and external doses from the soil are shown below.

Inhalation Dose: (resuspended soil)
(5.73E-4 kg/y)(3.6578 pCi/kg)(2.09E-6 mrem/pCi)(0.73936 y) = 3.24E-9 mrem

Ingestion Dose: (soil)
(0.0365 kg/y)(3.6578 pCi/kg)(2.09E-6 mrem/pCi)(0.73936 y) = 2.06E-7 mrem

External Dose:
(4120 h/y)(8.23E-10 Ci/m²)(6.82E-3 mrem/h per Ci/m²)(0.73936 y) = 1.71E-8 mrem

The vegetable produce contamination is calculated as shown below. The contaminated food consumption rate is combined with the ingestion period (1 year) so that the column of consumption rates has units of kg rather than kg/y. The product of the soil concentration and the ingestion dose factor is computed below and used in the calculations to simplify the equations.

(3.6578 pCi/kg)(2.09E-6 mrem/pCi)=7.645E-6 mrem/kg

Separate dry-to-wet ratios and consumption amounts are needed for each plant type. The soil-to-plant concentration ratio is 0.7 for all plant types (Table 25). The ingestion doses from root uptake and rain splash are shown below.

Ingestion Dose -- Garden Produce: (root uptake only)

(7.645E-6 mrem/kg)(0.7)(0.09)(4.1 kg)(0.49471) = 9.77E-7 mrem
(7.645E-6 mrem/kg)(0.7)(0.25)(13.9 kg)(0.98403) = 1.83E-5 mrem
(7.645E-6 mrem/kg)(0.7)(0.18)(9.6 kg)(0.98403) = 9.10E-6 mrem
(7.645E-6 mrem/kg)(0.7)(0.91)(18.5 kg)(0.98403) = 8.87E-5 mrem
Total from root uptake: 1.17E-4 mrem

Ingestion Dose -- Garden Produce: (rain splash only)

To simplify the calculation, the mass loading, ground deposition speed, soil concentration and ingestion dose factor are combined in a single factor.

(1 mg/m³)(0.01 m/s)(7.645E-6 mrem/kg)(86,400 s/d) = 6.605E-9 mrem/d/m²

(6.605E-9mrem/d/m²)(18d)(0.407)(1.0)/(2.0kg/m²)(4.1kg)(0.49471)=4.91E-8mrem
(6.605E-9mrem/d/m²)(20d)(0.835)(0.1)/(2.0kg/m²)(13.9kg)(0.98403)=7.54E-8mrem
(6.605E-9mrem/d/m²)(20d)(0.857)(0.1)/(3.0kg/m²)(9.6kg)(0.98403)=3.56E-8mrem
(6.605E-9mrem/d/m²)(20d)(0.371)(0.1)/(0.8kg/m²)(18.5kg)(0.98403)=1.12E-7mrem
Total from rain splash: 2.72E-7mrem

Ingestion Dose -- Garden Produce: (direct deposition)

To simplify the calculation, the activity addition rate and ingestion dose factor are soil concentration and ingestion dose factor are combined in a single factor.

(823 pCi/m²)/(0.5 y)/(365.25 d/y)(2.09E-6 mrem/pCi) = 9.419E-6 mrem/d/m²

(9.419E-6mrem/d/m²)(18d)(0.25)(1.0)/(2.0kg/m²)(4.1kg)(1.00)=8.69E-5mrem
(9.419E-6mrem/d/m²)(20d)(0.25)(0.1)/(2.0kg/m²)(13.9kg)(0.99999)=3.27E-5mrem
(9.419E-6mrem/d/m²)(20d)(0.25)(0.1)/(3.0kg/m²)(9.6kg)(0.99999)=1.51E-5mrem
(9.419E-6mrem/d/m²)(20d)(0.25)(0.1)/(0.8kg/m²)(18.5kg)(0.99999)=1.09E-4mrem
Total from direct deposition: 2.44E-4mrem

Total Dose from Garden Produce:

1.17E-4 + 2.72E-7 + 2.44E-4 mrem = 3.61E-4 mrem

The animal pathways add the dose from animal products that are contaminated by ingestion of well water, contaminated fodder and soil. The dose for each pathway is the sum of contributions to the animal's diet. In particular, there is fresh feed, stored hay, stored grain, soil, and drinking water. Each of these has a common factor made of the annual amount consumed by the individual, the ingestion dose factor, the equilibrium transfer factor, the water concentration, and the ingestion period.

Common Factor for Beef:
(0.049 d/kg)(21 kg/y)(2.09E-6 mrem/pCi)(1 y) = 2.151E-6 mrem·d/pCi

Ingestion Dose from Beef: (drinking water ingestion)
(2.151E-6 mrem·d/pCi)(50 L/d)(1 pCi/L)(0.99998) = 1.08E-4 mrem

Ingestion Dose from Beef: (soil ingestion)
(2.151E-6 mrem·d/pCi)(0.6 kg/d)(3.6578 pCi/kg)(0.98402) = 4.65E-6 mrem

Ingestion Dose from Beef: (root uptake into feed)
(2.151E-6 mrem·d/pCi)(3.6578 pCi/kg) = 7.868E-6 mrem·d/kg

(7.868E-6 mrem·d/kg)(0.7)(0.22)(14 kg/d grass)(0.98402) = 1.67E-5 mrem
(7.868E-6 mrem·d/kg)(0.7)(0.22)(27 kg/d hay)(0.98399) = 3.22E-5 mrem
(7.868E-6 mrem·d/kg)(0.7)(0.91)(3 kg/d grain)(0.98399) = 1.48E-5 mrem
Total from root uptake: 6.37E-5 mrem

Ingestion Dose from Beef: (rain splash onto feed)
(1 mg/m^3)(0.01 m/s)(7.868E-6 mrem·d/kg)(86,400 s/d) = 6.798E-9 mrem/m^2

(6.798E-9mrem/m^2)(15.6d)(0.616)(1.0)/(1.5kg/m^2)(14kg/d)(0.98402)=6.00E-7mrem
(6.798E-9mrem/m^2)(18.0d)(0.472)(1.0)/(1.0kg/m^2)(27kg/d)(0.98399)=1.53E-6mrem
(6.798E-9mrem/m^2)(20.0d)(0.472)(0.1)/(1.0kg/m^2)(3kg/d)(0.98399)=1.89E-8mrem
Total from rain splash: 2.15E-6mrem

Ingestion Dose from Beef: (direct deposition onto feed)
To simplify the calculation, the activity addition rate and ingestion dose factor are soil concentration and ingestion dose factor are combined in a single factor.
(823 pCi/m^2)/(0.5 y)/(365.25 d/y)(2.151E-6 mrem·d/pCi) = 9.693E-6 mrem/m^2

(9.693E-6mrem/d/m^2)(15.6d)(0.25)(1.0)/(1.5kg/m^2)(14kg/d)(0.99998)=3.53E-4mrem

(3.587E-9mrem/m²)(18.0d)(0.472)(1.0)/(1.0kg/m²)(29kg/d)(0.98400)=8.70E-7mrem
(3.587E-9mrem/m²)(20.0d)(0.472)(0.1)/(1.0kg/m²)(2kg/d)(0.98400)=6.66E-9mrem
Total from rain splash: 1.49E-6mrem

Ingestion Dose from Milk: (direct deposition onto feed)
To simplify the calculation, the activity addition rate and ingestion dose factor are soil concentration and ingestion dose factor are combined in a single factor.
(823 pCi/m²)/(0.5 y)/(365.25 d/y)(1.135E-6 mrem·d/pCi) = 5.115E-6 mrem/m²

(5.115E-6mrem/m²)(15.6d)(0.25)(1.0)/(1.5kg/m²)(36kg/d)(1.00)=4.79E-4mrem
(5.115E-6mrem/m²)(18.0d)(0.25)(1.0)/(1.0kg/m²)(29kg/d)(0.99996)=6.67E-4mrem
(5.115E-6mrem/m²)(20.0d)(0.25)(0.1)/(1.0kg/m²)(2kg/d)(0.99996)=5.11E-6mrem
Total from direct deposition: 1.15E-3mrem

Total Dose from Milk: 1.26E-3 mrem

Common Factor for Poultry:
(4.2 d/kg)(5.3 kg/y)(2.09E-6 mrem/pCi)(1 y) = 4.652E-5 mrem·d/pCi

Ingestion Dose from Poultry: (drinking water ingestion)
(4.652E-5 mrem·d/pCi)(0.3 L/d)(1 pCi/L) = 1.40E-5 mrem

Ingestion Dose from Poultry: (soil ingestion)
(4.652E-5 mrem·d/pCi)(0.011 kg/d)(3.6578 pCi/kg)(0.73936) = 1.38E-6 mrem

Ingestion Dose from Poultry: (root uptake into feed)

(4.652E-5 mrem·d/pCi)(3.6578 pCi/kg) = 1.702E-4 mrem·d/kg

(1.702E-4 mrem·d/kg)(0.7)(0.22)(0.13 kg/d grass)(0.73936) = 2.52E-6 mrem
(1.702E-4 mrem·d/kg)(0.7)(0.22)(0.0 kg/d hay)(0.98400) = 0.0 mrem
(1.702E-4 mrem·d/kg)(0.7)(0.91)(0.09 kg/d grain)(0.98400) = 9.60E-6 mrem
Total from root uptake: 4.05E-5 mrem

Ingestion Dose from Poultry: (rain splash onto feed)

(1 mg/m³)(0.01 m/s)(1.702E-4 mrem·d/kg)(86,400 s/d) = 1.471E-7 mrem/m²

(1.471E-7mrem/m²)(15.6d)(0.616)(1.)/(1.5kg/m²)(.13kg/d)(0.73936)=9.06E-8mrem
(1.471E-7mrem/m²)(18.0d)(0.472)(1.)/(1.0kg/m²)(.0 kg/d)(0.98400)=0.0 mrem
(1.471E-7mrem/m²)(20.0d)(0.472)(.1)/(1.0kg/m²)(.09kg/d)(0.98400)=1.23E-8mrem
Total from rain splash: 1.03E-7mrem

Ingestion Dose from Poultry: (direct deposition onto feed)

To simplify the calculation, the activity addition rate and ingestion dose factor are soil concentration and ingestion dose factor are combined in a single factor.

(823 pCi/m²)/(0.5 y)/(365.25 d/y)(4.652E-5 mrem·d/pCi) = 2.096E-4 mrem/m²

(2.096E-4mrem/m²)(15.6d)(0.25)(1.)/(1.5kg/m²)(.13kg/d)(1.00)=7.08E-5mrem
(2.096E-4mrem/m²)(18.0d)(0.25)(1.)/(1.0kg/m²)(0.0kg/d)(0.99996)=0.0 mrem
(2.096E-4mrem/m²)(20.0d)(0.25)(.1)/(1.0kg/m²)(.09kg/d)(0.99996)=9.43E-6mrem
Total from direct deposition: 8.03E-5mrem

Total Dose from Poultry: 1.08E-4 mrem

Common Factor for Eggs:

(3.1 d/kg)(5.3 kg/y)(2.09E-6 mrem/pCi)(1 y) = 3.434E-5 mrem·d/pCi

Ingestion Dose from Eggs: (drinking water ingestion)

(3.434E-5 mrem·d/pCi)(0.3 L/d)(1 pCi/L) = 1.03E-5 mrem

Ingestion Dose from Eggs: (soil ingestion)

(3.434E-5 mrem·d/pCi)(0.011 kg/d)(3.6578 pCi/kg)(0.73936) = 1.02E-6 mrem

Ingestion Dose from Eggs: (root uptake into feed)

(3.434E-5 mrem·d/pCi)(3.6578 pCi/kg) = 1.256E-4 mrem·d/kg

(1.256E-4 mrem·d/kg)(0.7)(0.22)(0.13 kg/d grass)(0.73936) = 1.86E-6 mrem
(1.256E-4 mrem·d/kg)(0.7)(0.22)(0.0 kg/d hay)(0.98400) = 0.0 mrem
(1.256E-4 mrem·d/kg)(0.7)(0.91)(0.09 kg/d grain)(0.98400) = 7.09E-6 mrem
Total from root uptake: 8.94E-6 mrem

Ingestion Dose from Eggs: (rain splash onto feed)

(1 mg/m³)(0.01 m/s)(1.256E-4 mrem·d/kg)(86,400 s/d) = 1.085E-7 mrem/m²

(1.085E-7mrem/m²)(15.6d)(0.616)(1.)/(1.5kg/m²)(.13kg/d)(0.73936)=6.68E-8mrem
(1.085E-7mrem/m²)(18.0d)(0.472)(1.)/(1.0kg/m²)(.0 kg/d)(0.98400)=0.0 mrem
(1.085E-7mrem/m²)(20.0d)(0.472)(.1)/(1.0kg/m²)(.09kg/d)(0.98400)=9.07E-9mrem
Total from rain splash: 7.59E-8mrem

Ingestion Dose from Eggs: (direct deposition onto feed)

To simplify the calculation, the activity addition rate and ingestion dose factor are soil concentration and ingestion dose factor are combined in a single factor.

(823 pCi/m²)/(0.5 y)/(365.25 d/y)(3.434E-5 mrem·d/pCi) = 1.548E-4 mrem/m²

(1.548E-4mrem/m²)(15.6d)(0.25)(1.)/(1.5kg/m²)(.13kg/d)(1.00)=5.23E-5mrem
(1.548E-4mrem/m²)(18.0d)(0.25)(1.)/(1.0kg/m²)(0.0kg/d)(0.99996)=0.0 mrem
(1.548E-4mrem/m²)(20.0d)(0.25)(.1)/(1.0kg/m²)(.09kg/d)(0.99996)=6.97E-6mrem
Total from direct deposition: 5.93E-5mrem

Total Dose from Eggs: 7.96E-5 mrem

Total of All Animal Pathways = 3.17E-3 mrem

Total Dose from All Pathways:

1.76E-7 + 1.13E-3 + 3.24E-9 + 2.06E-7 + 1.70E-8 + 3.61E-4 + 3.17E-3 mrem
= 4.67E-3 mrem per pCi/L

Appendix C

Output from CAP88-PC for H-3 and Carbon-14

OUTPUT FROM CAP88-PC FOR H-3 AND CARBON-14

From the SYNOPSIS report, the worst-case wind direction was east southeast (ESE). From the CHI/Q TABLE report, the air transport factor for this direction is 7.980E-6 s/m³. From the SUMMARY report, the effective dose equivalent for H-3 is 0.00189 mrem, and for C-14 0.105 mrem.

At a location where the air transport factor is 1.0E-4 s/m³, the CAP88-PC dose is computed as shown below. These values are listed in Table 28.

H-3: (0.00189 mrem)(1.0E-4 s/m³)/(7.98E-6 s/m³) = 0.0237 mrem

C-14: (0.105 mrem)(1.0E-4 s/m³)/(7.98E-6 s/m³) = 1.32 mrem

The EPA default parameter file was used as input to the CAP88-PC calculations rather than the Hanford-specific parameter file.

Quality Assurance Considerations

Quality Assurance Considerations

For analysis of data and calculations in this report, a peer review procedure was established and followed. The peer reviewers were selected based on their experience and knowledge of specific subject areas. The internal peer review was provided per Fluor Daniel Northwest (FDNW) internal procedures. PNNL provided the Hanford Environmental Dose Overview (HEDOP) technical review for this report.

Example hand calculations are provided in Appendices A and B to illustrate in detail the methods used. Reviewer checklists are attached.

Evaluation of the Potential for Agricultural Development at the Hanford Site

R. G. Evans[a]

Executive Summary

By 2050, when cleanup of the Hanford Site is expected to be completed, large worldwide demands to increase the global production of animal/fish protein, food, and fiber are anticipated, despite advancements in crop breeding, genetic engineering, and other technologies. World population is projected to double to more than 12 billion people, straining already stressed worldwide agricultural resources. The current world surpluses in many commodities will not last when faced with increasing population, decreasing ocean fisheries, and rapid loss of productive lands from soil salination and erosion. The production of pharmaceuticals from bioengineered plants and animals will undoubtedly add more pressure on the already limited (and declining) arable land base. In addition, there will be pressure to produce crops that can help reduce the world's dependence on petroleum and be used for chemical plant feedstock.

These external, formidable pressures will necessitate increasing investments in irrigation infrastructures in many areas of the world to increase productivity. Intensive greenhouse culture and aquaculture also will be greatly expanded. There will be large economic and social pressures to expand production in areas such as the Pacific Northwest. Agricultural exports will continue to be important

The most likely large areas for expanded irrigation in the Pacific Northwest are the undeveloped East High areas of the Columbia Basin Project and non-restricted areas within the Hanford Site in south-central Washington State. Both of these are potentially highly productive areas for producing food and export capital. The environmental concerns will be large; however, the favorable growing conditions, high-quality (low-salinity) abundant water supplies and minimal problems with salination of soils make the Pacific Northwest a very desirable region for economically sustainable expansion from a world perspective.

The area known as the Hanford Site has all the components that favor successful irrigated farming. This semi-arid desert steppe area has deep soils, long summer days, a long growing season, good drainage, mild winters, and an abundant, high-quality, and dependable potential water supply from the Columbia River. Economically, the Hanford Site benefits from excellent transportation systems (roads, rail, and barge), extensive power systems, and the already well developed agricultural processing, supply, and service infrastructure that supports the regions agriculture.

Constraints to agricultural development of the Hanford Site are political and social, not economic or technical. Obtaining adequate water rights for any irrigated development will be a major issue.

Analysis of the land use data shows that the total irrigable area (not including buffer areas), including both the north (wildlife refuge areas) and south side of the river, is about 120,380 hectares (297,442 acres). Excluding the wildlife refuges, 6300 hectares (15576 acres) are classified for tree and vine crops, and 62,640 hectares (154775 acres) are classified for field crops. Over the entire site, not including buffer areas, 27,160 hectares (67116 acres) were classified as unsuitable for irrigation. One-kilometer-wide

buffers were excluded from all rivers and lakes (20,100 hectares [49,681 acres]) and currently restricted areas (16,280 hectares [40239 acres]). State and federal wildlife reserves account for 35,740 hectares (88315 acres).

Potential land use and economic scenarios on the Hanford Site favor intensive, large-scale agricultural development growing high-value orchard, vineyard, and vegetable crops. Such large enterprises would be able to afford to import clean water and use high-level water management to minimize deep drainage. Irrigation technologies would be limited to highly efficient methods such as center pivots and microirrigation. Any suburban or small ranchette developments should be examined carefully in light of safety concerns and the associated generally poor levels of water management.

Numerous anticipated future advances in irrigation and resource conservation techniques will greatly minimize the negative environmental impacts of agricultural activities. These include precision agriculture techniques, improved irrigation systems, and controls. It is believed that such improved systems will be the norm for farming in 50 years.

Scientific irrigation scheduling and a network of supporting weather stations must be part of the total system for water and pest management of any future agricultural development on the Hanford Site. It is highly probable that any future irrigation development on the Hanford Site would be pressurized irrigation systems because of the site's very sandy soils and undulating topography. Water would be supplied to the fields by pressurized pipelines rather than canals or ditches. Because of the light soils and widely variable topography of new lands such as the Hanford Site, new advances in microirrigation and self-propelled irrigation (i.e., linear move and center pivot systems) will probably have the most promise for future irrigation.

A reasonable estimate of deep percolation in 50 years would be the current best achievable levels of the best technology: from 2% to 15% of the applied water, not including water applied for frost protection or other non-irrigation uses. Recharge from irrigation would probably range from 50 to 500 mm/yr compared to historical estimated natural recharge rates, even with the expected improved technologies and systems. Wine grapes would have the least recharge, while field crops would potentially have the greatest deep percolation losses. Small acreage, irrigated ranchette development would probably contribute about twice the recharge to the unconfined aquifer systems as large scale irrigation.

Acknowledgments

Pat Daly with the Franklin County Conservation District and Jeff Godfrey with the Grant County Conservation District by providing GIS files on agricultural land use in their counties. Ms. Cindy Mead and Tammy Killian did the land use mapping needs for this project. Mr. Chas Scripter with the USDA-NRCS in Spokane provided GIS soils maps and needed othrophotos for the analysis. Dr. Mary J. Hattendorf conducted the GIS analysis of the combined data sets. Dr. Charles Kincaid and Dr. Michael Fayer with PNNL provided valuable assistance by providing maps and documentation and thoughtful review.

1.0 Introduction

In the early 1940s, the U.S. Department of Defense used the right of eminent domain to acquire about 1520 square kilometers (586 square miles) in Benton and Grant Counties of Washington State as part of the Manhattan Project to develop the atomic bomb. Until the late 1980s, the Hanford Site in south-central Washington continued to be involved in the production of weapons-grade fissionable materials (Figure 1.1). More recently, the primary mission of the Hanford Site has focused on the cleanup and disposal of hazardous waste and radioactive materials resulting from this previous industrial endeavor.

Cleanup efforts are estimated to be completed around 2050. A small fraction of the total Hanford Site will be reserved by the U.S. Department of Energy (DOE) for waste disposal and protection from residual radiation sources. The remainder of the land is anticipated to be declared as excess and gradually returned to other uses until all excess lands are returned at the end of the DOE mission. There are tremendous regional and national pressures to establish the future use of these excess lands.

A substantial portion of the Hanford Site is ideally suited to the type of high-value production agriculture currently practiced in the mid-Columbia region. Agricultural development of portions of this area could have a large impact in both regional and state economies, providing new employment opportunities and growth. Consequently, there are intense regional political and economic pressures to release at least some of these lands for agricultural uses.

On the other hand, the portion of the Columbia River flowing past the Hanford Site, known as the Hanford Reach, is the last section of the lower Columbia River unaffected by dams. In addition, the Hanford Site is part of the oldest and largest remaining old-growth desert ecology community in Eastern Washington. Thus, there are equally fierce proponents for protecting the Hanford Site from any future development and maintaining it as an ecologically sensitive reserve.

The DOE released the Hanford Site Comprehensive Land Use EIS (DOE 1999), which suggests future cropping patterns, agricultural land use, and associated water issues. This study and the information will be the basis for agricultural land use scenarios used to estimate risk and radiation dose to future inhabitants of the Hanford Site. These scenarios will become part of assessments conducted to evaluate remedial actions and disposal alternatives at the Hanford Site until the cleanup is completed within the next 50 years.

This particular study is not related to any existing DOE study of potential future land use. Likewise, this study does not consider existing proposals by the Benton County Planning Commission or other agencies, public, or private groups, or currently restricted non-industrial lands (i.e., the Arid Lands Ecology Reserve). Similarly, endangered species, biological diversity and wildlife management, global climate change, potential concerns by lending organizations to finance development, effect on utility systems, waste management and refuse disposal, waste water (septic tanks, livestock containment) treatment, hazardous waste management, public health concerns with hazardous waste and exposure, or the affects of agricultural development on specialized installations such as the Laser Interferometer Gravitational-Wave Observatory (LIGO) were not part of this evaluation. The purpose of this report is

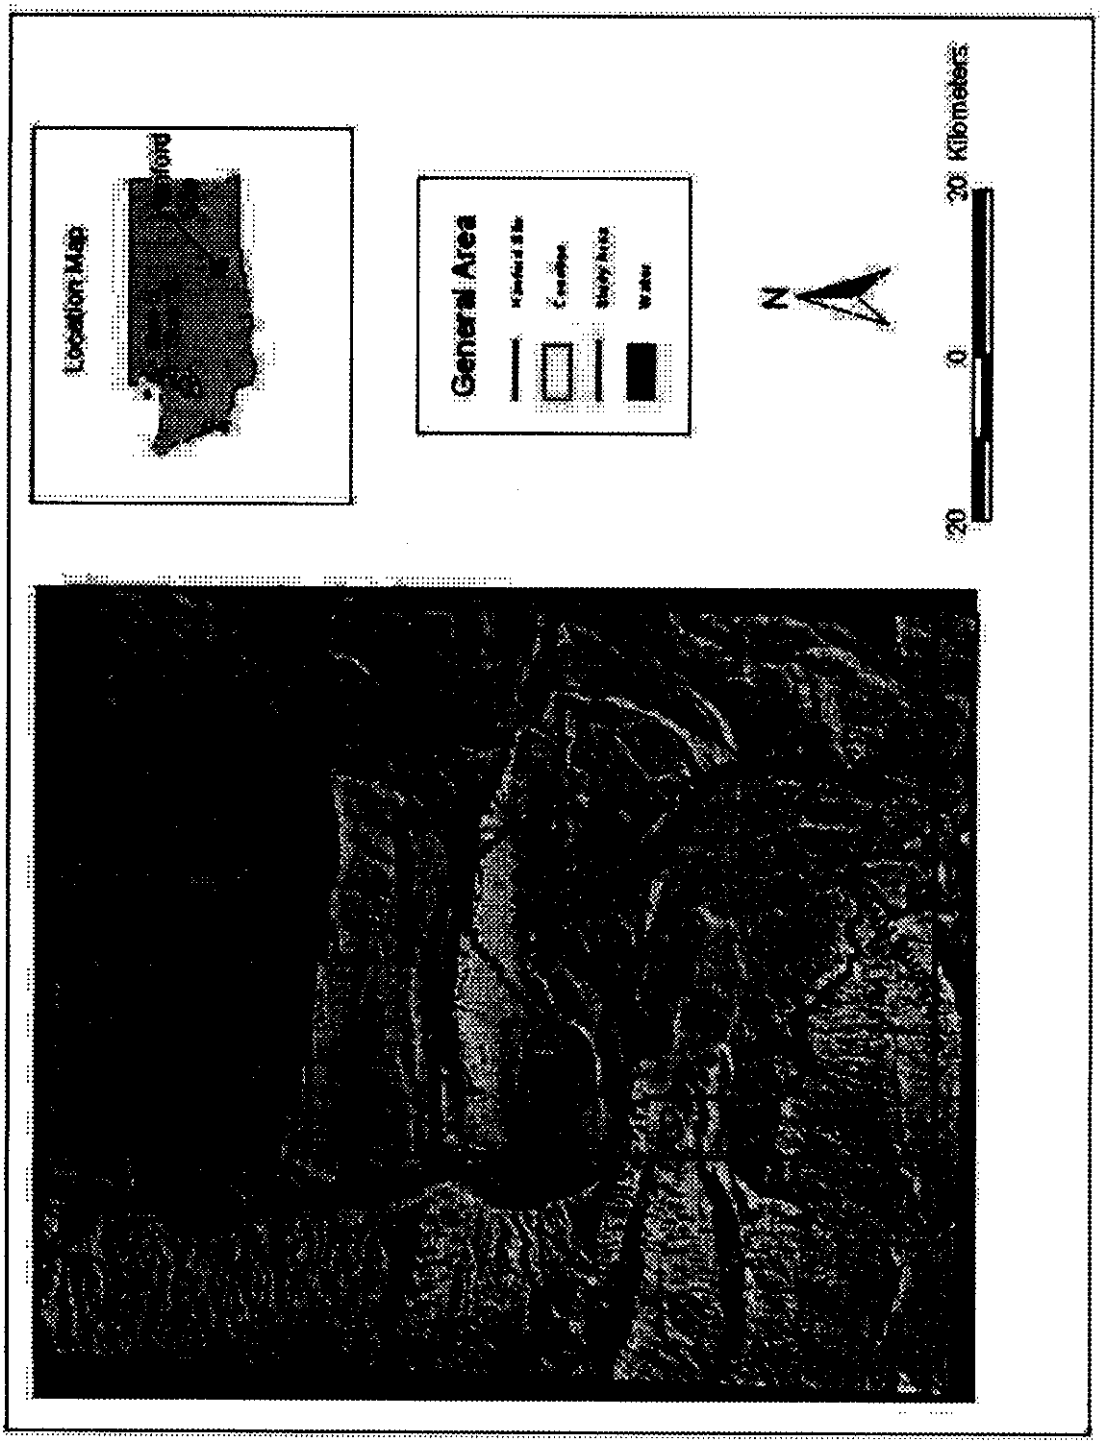

Figure 1.1. Map Showing the General Location of the Hanford Site and the Study Area

to suggest potential cropping patterns and related water requirements after closure of the Hanford Site in the event that some lands are opened to *irrigated* agricultural development. Potential future agricultural land uses were based on current irrigation and cultural practices that will continue to be improved and developed over the next 50 years. While there is some speculation, the intent is only to suggest reasonable future uses of Hanford lands in the event they become available for agricultural development based on *current* farming practices.

This is an attempt to characterize the attributes of the Hanford Site that are appropriate for agricultural development and determine the potential for future agricultural land use given current irrigation technology, crops, and crop rotation scenarios. It was assumed that development must be economically sustainable using current agricultural enterprises as a basis. Anticipated future advances in irrigation and resource conservation techniques, water rights issues, and impacts of possible shifts in agricultural production are discussed. Also examined are crop water use needs per unit area, potential advances in irrigation technology that would impact irrigation efficiencies, and issues of environmental stewardship.. Anticipated average irrigation rates and amounts for various crops and net infiltration rates (groundwater recharge) also are part of the analysis.

Rainfed or "dryland" agriculture was not included as part of this analysis because such operations might not be sustainable due to low annual precipitation and low commodity prices. The economics may change in the future, and these options should be re-evaluated at that time. A potential exists to use various areas of the Hanford Site for dryland livestock grazing or winter wheat production. However, these uses present challenges because of the large acreage requirements per animal, perceived incompatibility with various ecosystems, and the Hanford Site's lower natural precipitation relative to nearby lands where winter wheat is grown.

The analysis is based on comparison of the acreage and water requirements of the current farming community and trends in Franklin, Grant, and Adams counties. The year 1996 was used as the baseline because of the availability of orthoquad maps for that year and data from the 1997 Census of Agriculture. The lands used as the study area were approximately bounded on the north by the Frenchman Hills (Royal Slope), on the east by Highway 395, and on the south by the Yakima River.

One particular goal was to obtain estimates of the amount of deep percolation and recharge that might result from development of irrigated agriculture on the Hanford Site. Deep percolation (also called deep drainage) is defined as the amount of water from natural or artificial sources that travels downward through the soil profile until it is below the plant's root zone and unavailable for crop use. Deep percolation is generally the result of infiltrated water that exceeds the soil's ability to hold it. However, small channels and other established flow pathways in the soil can carry substantial amounts of water directly to the groundwater (preferential flow), effectively bypassing the plant rooting zone. Preferential flow exists in almost all soils and is a major factor in soil water movement, but it is generally neglected because it is difficult to measure.

Recharge, on the other hand, is the flux of water that arrives at the upper boundary of the unconfined aquifer (water table). Deep percolation and recharge are assumed to be equal in magnitude when integrated over many years, but temporal distribution will be different because of the transit time through the

vadose zone towards the groundwater. Recharge can influence the elevation of the water table, but is generally viewed as a problem only when it carries excessive contaminants to the groundwater.

Existing data and geographic information system (GIS) software (ArcView) were used to make maps of soils and topography and to summarize 1996 crop use of the current irrigated lands surrounding the Hanford Site. These data were compared to soil and topographic conditions at the Hanford Site to assess suitability and/or limitations for various crop and irrigation system scenarios. All lands currently within the Hanford Site, except for disposal sites such as the central plateau (200 East and West Areas) and other industrialized sites that might be restricted in the future, were considered for their potential for agricultural development regardless of their current status.

2.0 Environmental Setting

This section briefly describes the physical and environmental setting of the Hanford Site to set the stage for the discussion on agriculture. Hanford Site geology, soils, topography, climate, potential evapotranspiration, recharge rates, and water resources (surface and subsurface) are discussed.

2.1 Geology

The geology and hydrology of the Hanford Site have been studied extensively over the past 50 years (Cole et al. 1997; Neitzel et al. 1997). Geologically, the Hanford Site lies within the Pasco Basin, a large structural depression that has collected a relatively thick sequence of fluvial, lacustrine, and glacio-fluvial sediments over the past several thousand years. The Pasco Basin and nearby anticlines and synclines are underlain by or composed of the Columbia River Basalt Group, a sequence of continental flood basalts covering more than 163,000 km^2 (63,000 mi^2) in Washington, Oregon, and Idaho that occurred over a period from 17 million to 6 million years ago.

Landslides have occurred along the northern portions of the Yakima Ridge folds of the Pasco Basin along basalt and sedimentary interfaces. They have also occurred along steep river embankments (i.e., White Bluffs) to the east of the Hanford Site and are primarily due to subsurface irrigation return flows that have saturated lower portions of the embankments, resulting in slumping.

The underlying basalt layers are often fractured, and numerous geologic faults run through the Hanford Site. The basalt flows are frequently separated by interbeds of epiclastic and volcaniclastic sedimentary layers and old residual soils. Overlying the basalts are fluvial and lacustrine sediments of the Ringold formation and the glacio-fluvial Hanford formation.

The sediments in the Hanford formation are primarily the result of cataclysmic flooding due to the periodic breaching of ice dams in western Montana and northern Idaho that caused huge volumes of water to spill across eastern and central Washington. These floods are among the largest ever documented anywhere in the world, the last of which occurred about 13,000 years ago. These sediments were channeled and alluvium was deposited between flood events. Later aeolian depositions of glacial till cover portions of the site. Recently, the sediments have been locally reworked by winds, and sand dunes are common in southern and eastern portions of the Hanford Site.

2.2 Soils

Hajek (1966) described 15 different general surface soil types on the Hanford Site, ranging from sand to silty and sandy loams. These same soils are found elsewhere in Benton, Grant, Adams, and Franklin counties, and most are being irrigated. Figure 2.1 shows the distribution of major soil types in the study area and the Hanford Site. As can be seen, the major agricultural soil types in the surrounding area are loamy sands, sandy loams, fine sandy loams, silt loams, and sands, all of which are common on the Hanford Site. These soils are characterized by relatively high infiltration rates, low water holding

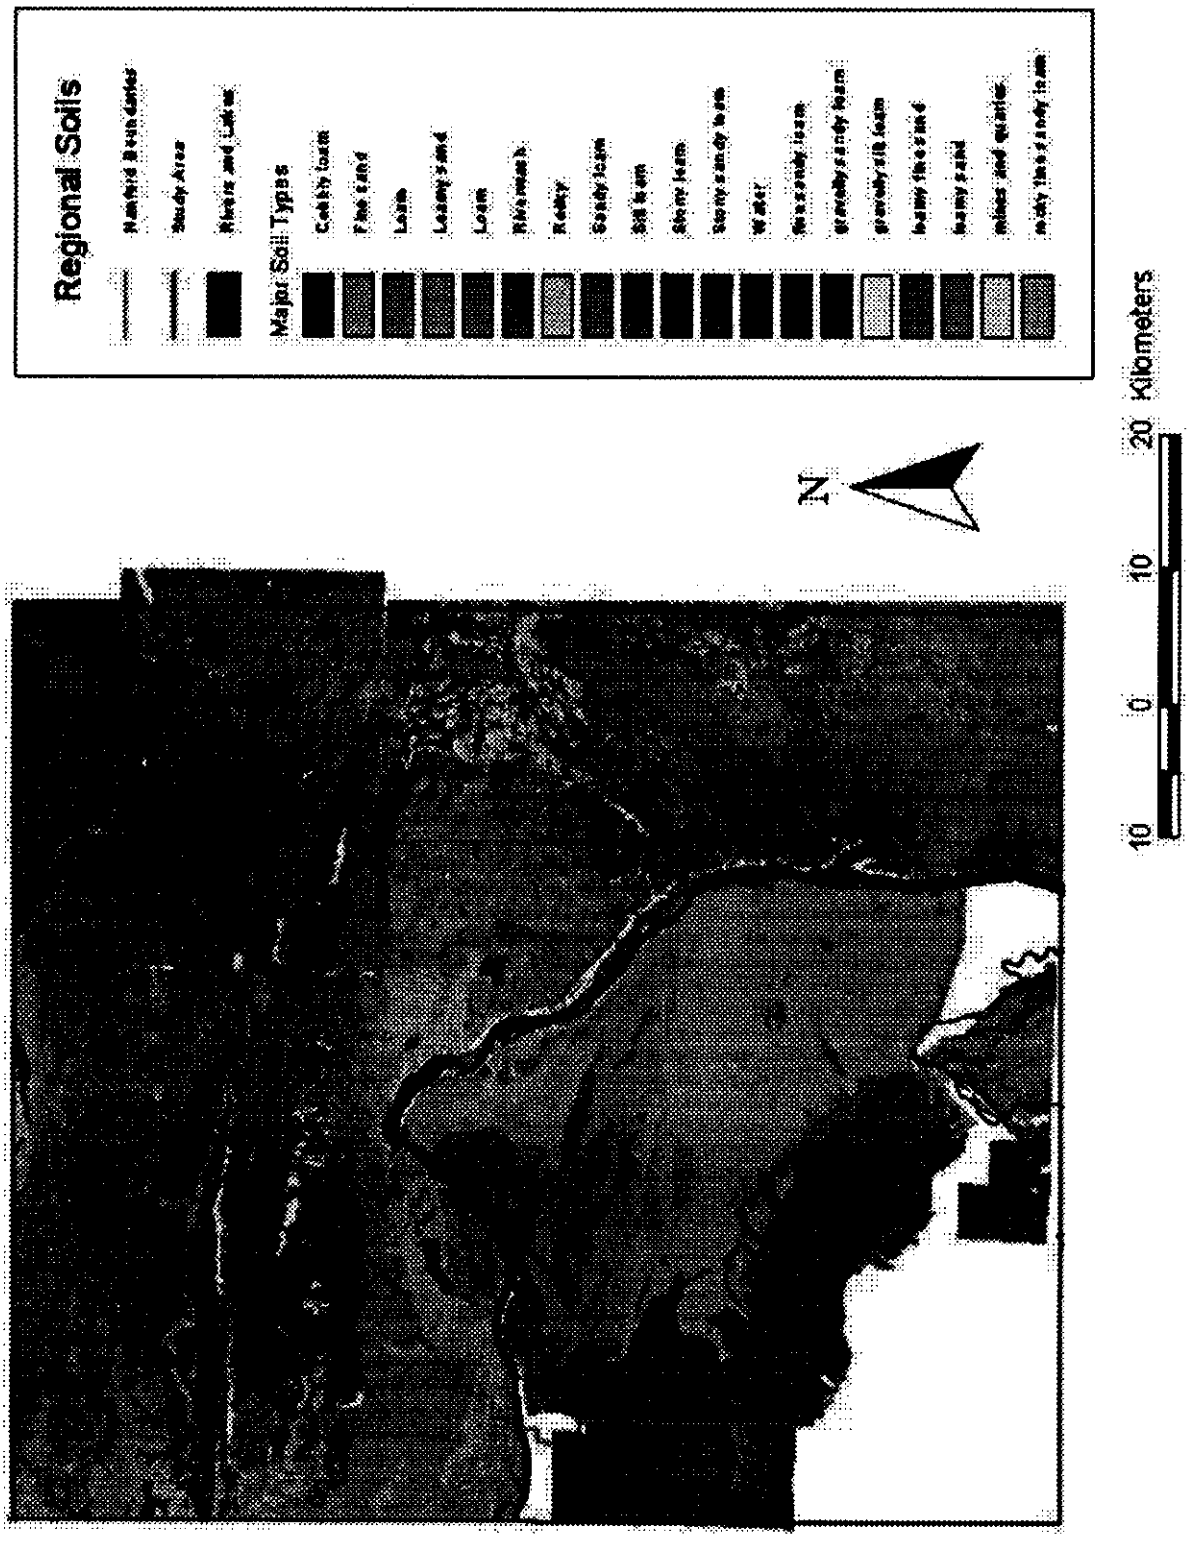

Figure 2.1. General Soils Map of the Study Area and the Hanford Site

capacities, and very low clay and organic matter contents. They are easily eroded by wind and water. Probable ranges of infiltration rates and available water holding capacity (AWC) for each soil type, based on texture from soil survey information, are presented in Table 2.1.

2.3 Topography

The Hanford Site occupies an area roughly 50 km (N-S) by 40 km (E-W) that is about 1517 km^2 (586 mi^2) in south-central Washington. It lies north of the confluence of the Yakima and Columbia Rivers. The Columbia River flows in an easterly direction across part of the northern boundary and, turning south, forms part of the eastern boundary of the Hanford Site. Rattlesnake Mountain, Yakima Ridge, and Umtanum Ridge form the southwestern and western boundary. The Saddle Mountains lie to the north of the Hanford Site. Adjoining lands to the west, north, and east are principally range and commercial agricultural land. The cities of Richland, Kennewick, and Pasco (the Tri-Cities) and West Richland are located southeast of the site and constitute the nearest population centers.

About 1100 km^2 (427 mi^2) of the Hanford Site are in Benton County. The remainder lies in Grant County, north of the Columbia River, and although it is part of the site, is primarily managed by the National Fish and Wildlife Service and the State of Washington as wildlife refuges and recreation areas. A large portion of land (30,900 hectares [76,300 acres]) in the southwest portion of the site on the eastern side of Rattlesnake Mountain is currently set aside as the Fitzner-Eberhardt Arid Lands Ecology Reserve. Only about 6% (about 90 km^2 [33 mi^2]) of the total area has been disturbed and is used for the production of special nuclear materials and the storage and disposal of wastes.

Figure 2.2 is a graphical representation of the diverse and widely varying topography in the region around the Hanford Site. Elevations within the Hanford Site vary from about 120 m (400 ft) above mean sea level near the Columbia River to more than 1060 m (3480 ft) at the top of Rattlesnake Mountain at the southern end of the site. Wahatis Peak in the Saddle Mountains at the north end of the Hanford Site reaches almost 800 m (2500 ft). However, most of the site is relatively flat and similar to many of the irrigated agricultural lands in the region.

2.4 Climate

Annual precipitation on the Hanford Site is only about 160 mm (6.3 in.), and irrigation is required for economic production of most crops. Average Class A pan evaporation for the area is about 1400 mm (4.6 ft) for the growing season. Winds are generally from the northwest although considerable winds from the southwest occur in the spring and fall. The record maximum temperature is 45°C (113°F), and the record minimum temperature -31°C (-23°F). Additional information on climate on the Hanford Site is contained in Hoitink and Burke (1997).

(a) BC is Benton County Soil Survey (USDA- Soil Conservation Service 1971), G is the Grant Count Soil Survey (USDA - Soil Conservation Service 1984).
(b) Data are the ranges of values found by Hagood et al. 1970.
(c) AWC is available water holding capacity of soil or the amount of soil water available for crop use. AWC is the difference between measured values of field capacity and permanent wilting point.

2.5 Potential Evapotranspiration

Potential evapotranspiration (ET) is basically the maximum amount of water that will be used by a crop, depending on growth stage and climatic conditions. For simplicity, these calculations are usually made for a "reference" crop such as well watered alfalfa (ET_r) or grass (ET_o). Actual water use of a particular crop is adjusted by decimal values of "crop coefficients" that are multiplied times the reference evapotranspiration. The Penman equation (Penman 1948) as modified by Wright (1982) and Allen et al. (1989) was used to calculate the reference potential evapotranspiration (ET_r) for the area.

Climatic records for several weather stations in the irrigated agricultural areas near the Hanford Site were analyzed to determine potential crop water use, also called potential evapotranspiration. The Public Agricultural Weather System (PAWS) station operated by Washington State University (WSU) near Mattawa is probably the most representative agricultural weather station for expected Hanford Site conditions. The average alfalfa reference evapotranspiration (ET_r) for the April through October growing

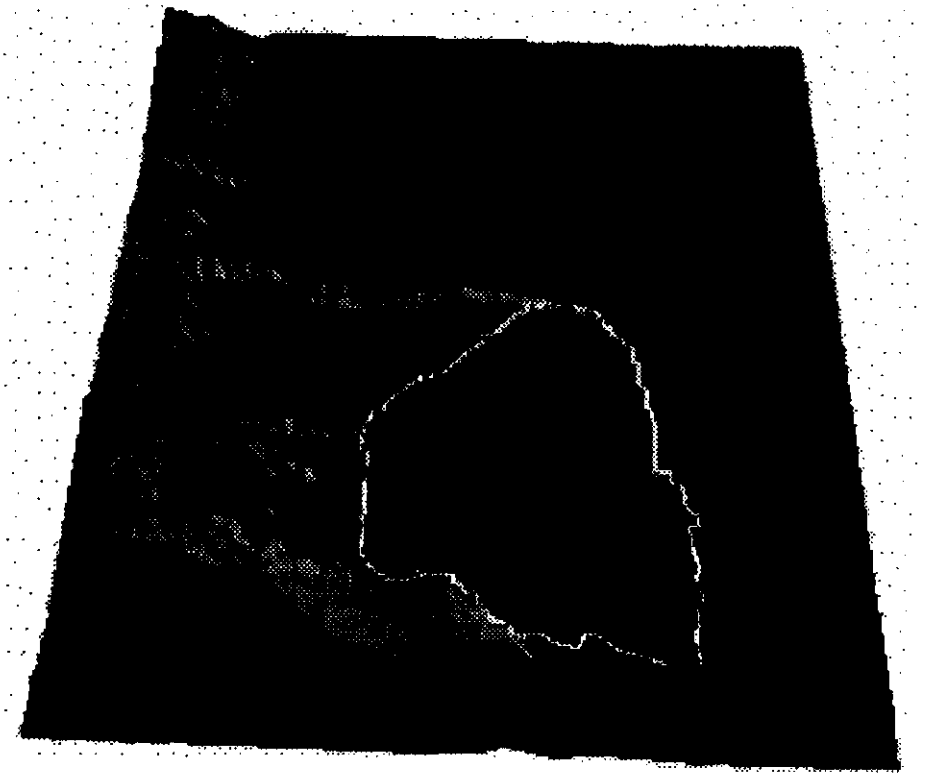

Figure 2.2. Three-Dimensional Map Showing Elevation Ranges for the Area Surrounding the Hanford Site (white line) and the Study Area (dark line) and the Columbia River in Central Washington

season is about 978 mm (38.5 in.) for all stations and 1060 mm (41.7 in.) for Mattawa. Figure 2.3 is a graph of the long-term average alfalfa ET_r for several PAWS weather stations around the Hanford Site, with the peak water use of about 225 mm (8.9 in) occurring in July. Crop water use can vary substantially from year to year depending on climatic conditions. Table 2.2 is a listing of the long-term average crop water use over the season from stored soil water (winter precipitation) and irrigation. Deficit irrigation or other management practices may reduce these values.

2.6 Recharge Rates

Determining recharge rates is critical to the long-term environmental cleanup efforts and management at the Hanford Site to ensure long-term protection of groundwater from industrial wastes. Gee et al. (1992) estimated that the time required for contaminants to travel through the thick unsaturated zone at the Hanford Site ranged from thousands of years, for recharge rates below 1 mm/yr, to tens of years for recharge rates above 50 mm/yr.

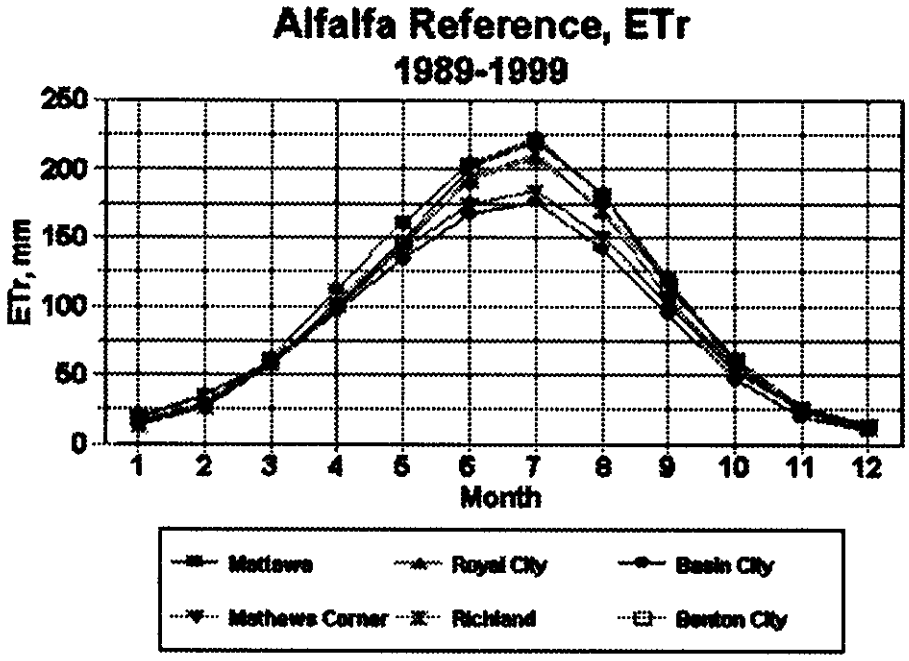

Figure 2.3. Annual Distribution of Potential Evapotranspiration of Alfalfa (ETr) for PAWS Weather Stations in Irrigated Agricultural Areas Near Hanford for 1989-1999

Currently, most of the recharge is from natural precipitation, although significantly higher recharge rates are estimated due to localized industrial activities (i.e., central plateau operational areas). Some artificial recharge to the Hanford Site that results from private irrigation development (from deep wells) lies to the north of the Site in the Cold Creek drainage. This amount is estimated to be small because the irrigation systems are efficient and the high cost of pumping water encourages good management. Estimated recharge from any future irrigated agriculture development on the Hanford Site will likewise depend on the types of irrigation systems used and their management.

The wide discrepancies in estimated recharge rates for the Hanford Site are attributed to variations in precipitation, vegetative cover, and surface soil textures. Gephart et al. (1979) analyzed data from long-term field studies at the Hanford Site and concluded that recharge from natural precipitation through thick unsaturated sections is almost negligible. Gee et al. (1992), using lysimeter data collected at a number of locations on the Hanford Site over a period of 20 years, found that recharge rates ranged from more than 100 mm/yr to rates near zero (i.e., no measurable drainage). Coarse-textured soils without plants yielded the most recharge, and fine-textured soils with or without plants yielded the least. Deep-rooted plants, such as sagebrush, were generally successful in limiting recharge on all soils on the Hanford Site to near-zero amounts, but shallow-rooted plants such as cheatgrass appeared unable to prevent recharge. Subsurface drainage (i.e., recharge) from a cheatgrass-covered lysimeter averaged about 35% of the total annual precipitation during a 3-yr test (1984 to 1986). Fayer and Walters (1995) estimated that annual recharge for the non-industrial areas of the Hanford Site typically averaged less than 10 mm/yr (i.e., "background recharge rates").

Table 2.2. Long-Term Average Crop Water Use in mm per Year at Various PAWS Weather Stations Near the Hanford Site

Crop	Mattawa	Royal City	Basin City	Mathews Corner	Richland	Benton City	Pasco

(a) Penman alfalfa is the calculated value of evaporation based on an alfalfa reference over the whole year. It is indicative of clear water pond evaporation over the year.
(b) Many orchard crops are grown with (w/) grass cover crops between rows, which requires additional water. Orchards without (w/o) cover crops would be representative of drip-irrigated blocks.

2.7 Water Resources

Water resources within the Columbia Plateau region must be considered in a regional and international framework. Withdrawals from the Columbia River may have a large impact on downstream water users (domestic, municipal, industrial, and agricultural) and on recreation, navigation, and hydropower production. Human activities have negatively affected surface and subsurface water quality over broad areas. Reservoir releases for power and other uses are jointly coordinated by the U.S. Bureau of Reclamation (USBR) and the U.S. Army Corps of Engineers to manage often competing demands. Withdrawals from deep confined aquifers affect piezometric levels in wells over large areas. In addition, specific recharge areas for the deep aquifers are largely unknown, but may be hundreds of kilometers from the withdrawal locations.

2.7.1 Surface Water

The Columbia River is the dominant surface water source at the Hanford Site. It rises in Canada along the western side of the Selkirk Mountains in British Columbia and enters Washington State north of Spokane before heading west and then south to the Hanford Site, where it makes a bend to the east before going south and to the west. It is the second largest river in the contiguous United States in terms of total flow. The Columbia River drains a total area of 680,000 km^2 (262,480 mi^2) and is about 2000 km (1243 mi) long. It flows into the Pacific Ocean and forms much of the boundary between Oregon and Washington. Major tributaries include the Snake and Yakima rivers, which join the Columbia River in the Tri-Cities area.

Average discharge at the mouth of the Columbia River is about 7250 m^3/s (256,000 ft^3/s). Irrigation diversions throughout the entire Columbia drainage area currently account for less than 5% of the total annual flow at the mouth of the river. Average daily flows of the Columbia River in the Hanford Reach range from 1000 to 7000 m^3/s (36,000 to 250,000 ft^3/s), which are largely controlled by upstream releases from Grand Coulee Dam.

Some communities and the Hanford Site use the Columbia River for municipal and industrial water supplies. However, the primary uses of the Columbia River are hydropower production and irrigation. In addition, recreational uses of the Columbia River include sport fishing, hunting, boating, sailboarding, swimming, water skiing, and diving. Considerations for threatened and endangered species of fish currently impact the total management of the Columbia River resource. The substantial amount of electrical power produced in the region from hydro, nuclear, and other sources also relies on water from the river system and has a major regional economic impact.

The Yakima River borders a short length of the southern boundary of the Hanford Site. Average annual flow is about 104 m^3/s (3712 ft^3/s). Approximately one-third of the Hanford Site is drained by the Yakima River system. Surface runoff from the Hanford Site is estimated to be about 3% of the total annual precipitation to the area.

2.7.2 Groundwater

Unconfined and confined aquifers underlie the Hanford Site, both of which would be available for future agricultural development of the area. Many small municipalities and industrial users that are not adjacent to the rivers use deep, confined aquifers as a water supply. The Tri-Cities communities use a mix of Columbia River and supplemental groundwater sources (confined and unconfined aquifers), whereas almost all rural domestic (homesteads and livestock) water comes from unconfined aquifers (<100 m deep). Groundwater from both aquifers systems is used for irrigation.

The Ringold and Hanford formations compose the unconfined system, which is directly connected to and discharges into the Columbia River. Unconfined groundwater flow direction at the Hanford Site is predominately from west to east. Specific yields for the Ringold formation typically range from 0.05 to 0.2 and from 0.1 to 0.3 for the Hanford formation. Effective porosity ranges from 0.01 to 0.37, with an average value estimated to be about 0.25. Groundwater quality is generally quite good with relatively low salt levels, although domestic wells usually require a water softener because of calcium carbonates precipitates. In addition, there are localized plumes of contaminants from past Hanford operations (i.e., tritium, iodine-129, uranium, technetium-99, strontium-90, trichloroethylene, chloroform, and carbon tetrachloride) in the unconfined aquifer system.

The saturated thickness of the unconfined aquifer system varies from close to zero near the basalt ridges and Rattlesnake Mountain to the west to more than 60 m near the Columbia River. Depth to groundwater ranges from less than 0.3 m near the river to more than 100 m elsewhere on the Hanford Site. Recharge to unconfined aquifers is from runoff from the elevated areas along the western side of the site (i.e., Rattlesnake Mountain), spring discharges from the extensive confined aquifer system, artificial recharge from processing waste water disposal, and local precipitation. There is a direct hydraulic connection to the Yakima and Columbia rivers.

Within the Pasco Basin, the Columbia River Basalt Group consists of the Saddle Mountain, Wanapum, and Grande Ronde basalts. These subsurface basalt groups contain numerous confined aquifers associated with the more permeable interflow and interbed zones generally located between the dense, columnar confining units. Yields range from quite small to quite large. The locations of recharge areas for these aquifers and hydraulic connections between the various confined aquifers are not well understood. Hydraulic connections between the confined and unconfined aquifers also exist due to substantial artesian pressures (from 300 to 400 m of head in some cases) in the confined aquifers. Some of these aquifers are extensively used for large-scale irrigation in areas not served by the various Columbia River Basin irrigation projects. Piezometric pressures are declining in some confined aquifers in some areas as a direct result of agricultural and municipal pumping. Water quality is good with low levels of total dissolved solids. However, most of the salts are sodium bicarbonates, which require that the water always be treated with acids to lower pH before any agricultural use. These deep aquifers would be available for future agricultural uses on the Hanford Site. However, because of recently observed declines in hydraulic head, their long-term sustainability for large-scale development is doubtful and needs more study.

An analysis of well data was derived from records on file with the Washington Department of Ecology (WDOE) in Spokane. The information contained in these records was very sparse in most instances. Domestic well data are likely incomplete, whereas the other categories are close to actual. Table 2.3 summarizes the characteristics of the domestic, industrial, irrigation, and municipal wells in the study area that were registered with the WDOE.

Table 2.3. Summary of Well Characteristics for all Wells by Major Use Category Within the Study Area Based on WDOE Well Permit Records (values in parenthesis are one standard deviation)

Use	Total Wells	Number of Wells with Screens or Perforations	Average Screened Length, m	Average Depth, m	Average Discharge, l/s
Domestic	116	19	6.6 (4.81)	86.1 (76.49)	4.54 (10.92)
Industrial	38	18	6.8 (9.39)	84.4 (72.75)	22.3 (31.75)
Irrigation	883	443	9.8 (7.04)	116.7 (126.14)	81.6 (78.85)
Municipal	57	18	20.8 (29.05)	182.5 (110.26)	36.4 (52.30)

The WDOE records for 1226 wells in the study area surrounding the Hanford Site were analyzed and characterized. There were 883 wells classified as irrigation, 116 as domestic, 38 as industrial, and 57 as municipal. Another 132 wells were registered as "fish" (11), "other" (24) or "test" (97). It is safe to assume that the domestic category may not be accurate because it is highly probable that numerous domestic wells in the area were not registered with WDOE and some domestic users are also using water classified as "irrigation."

Figure 2.4 is a frequency distribution of well depths in the study area based on the WDOE records. There is tremendous variability in these records, and statistical measures describing the distributions have limited use. The majority of wells (799), and the largest numbers in the bimodal distribution, are primarily located in the unconfined aquifers. However, a number of wells less than 60 m deep are high-volume wells located in unconsolidated gravel deposits near the Columbia River (i.e., 56% of all irrigation wells were less than 60 m deep). Figure 2.5 shows well depth distribution by use. Most of the wells deeper than 100 m (426) are withdrawing water from the confined aquifers in the basalts and are used for large irrigation (35% of irrigation wells) or municipal purposes (72% of municipal wells).

Many of the wells were only partially cased, leaving portions of the bore holes open, particularly in the basalt formations. Less than 41% (498) of all four major categories that were examined had screens, perforations or both.

Screen length is an indication of the thickness of the water bearing strata. There are 573 wells out of the 1226 and 498 from the four major categories that have screens and/or perforations. Figures 2.6 and 2.7 show the distribution of the length of screens (and/or perforations) for all wells and all categories by

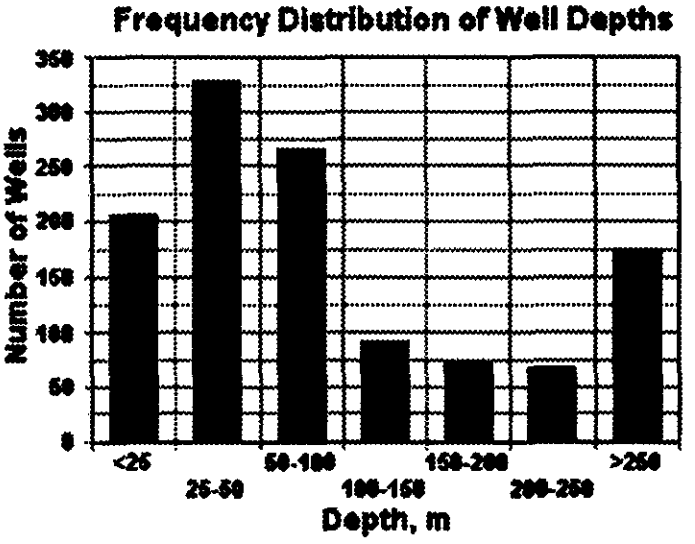

Figure 2.4. Frequency Distribution of Depths for 1225 Nearby Wells in the Areas North and East of the Hanford Site Based on WDOE Filed Well Records

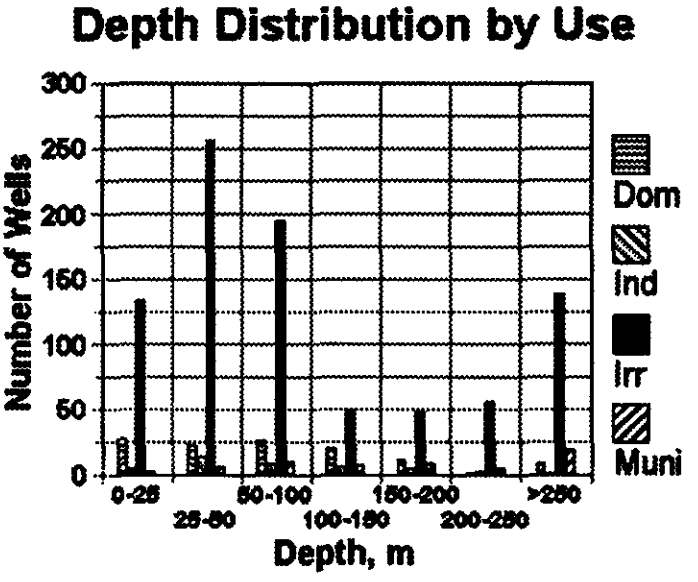

Figure 2.5. Frequency Distribution of the Depth of Wells by Use in the Study Area Based on WDOE Filed Well Records

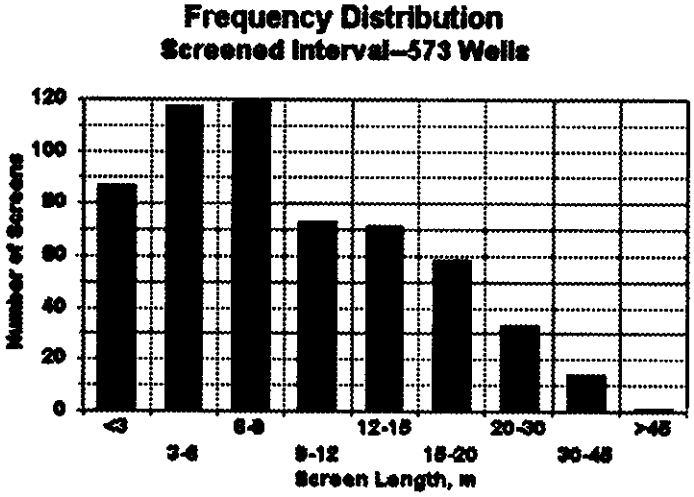

Figure 2.6. Frequency Distribution of the Length of Screens or Perforations of 573 Wells Near the Hanford Site

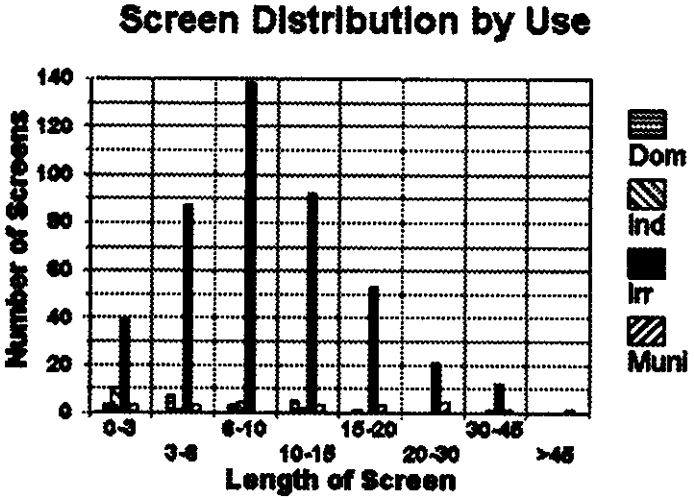

Figure 2.7. Distribution of the Length in Meters of Well Screens or Perforations by Major Use Category (498 wells since test and other miscellaneous types of wells are not included)

use from the permits that were examined. Fifty percent of the irrigation, 16.4% of the domestic, 43.6% of the industrial, and 32% of municipal wells are screened and/or perforated. The average length of screened interval for all wells of all types is 9.5 m, with 41% between 3 and 9 m. The majority of the wells in the unconfined aquifers have screens and/or perforated casings.

Three-fourths of the domestic and almost two-thirds of the irrigation wells are less than 100 m deep and most likely in the unconfined aquifers. Most of the water extracted by sustained, higher yielding wells in the unconfined aquifers is likely from irrigation return flows or direct hydraulic connections to the rivers. Natural recharge to the water tables is small. For wells less than 100 m (300 ft) deep, the average discharge for domestic wells is about 4.5 l/s (72 gpm), for irrigation wells 75 l/s (1200 gpm), for industrial users 23 l/s (360 gpm), and for municipal wells 26.4 l/s (420 gpm). Table 2.4 characterizes wells less than 100 m in the study area.

Table 2.4. Summary of Well Characteristics for Wells Less Than 100 m in Depth Within the Study Area Based on WDOE Well Permit Records. (Values in Parenthesis are one standard deviation)

Use	Number of Wells <100 m	Number of Wells <100 m with Screens or Perforations	Average Screened Length, m	Average Depth, m	Average Discharge, l/s
Domestic	76	13	6.17 (4.16)	40.3 (22.37)	5.24 (12.98)
Industrial	25	16	4.6 (3.77)	40.2 (19.52)	21.1 (33.29)
Irrigation	583	412	9.7 (7.01)	41.2 (19.82)	75.3 (83.74)
Municipal	18	6	7.2 (6.16)	58.0 (23.41)	24.7 (50.76)

3.0 Agricultural Development in the Region

Central Washington is one of the most productive and diverse agricultural areas in the world. Some of the highest yields ever measured for many crops have been reported there. Over 80 different crops are typically grown in the region every year including many high-value specialty crops. Because of the low annual rainfall in the region (from 150 to 200 mm/yr), development of high-value agriculture has depended on irrigation to supplement natural precipitation. In addition, the area has abundant, high-quality water from the Columbia River and low-salinity soils.

Soil erosion by wind and water is a significant problem, but can be minimized with appropriate agricultural practices. Waterlogging of soils tends to be localized in small areas because of subsurface bedrock topography, but is easily controlled by installing subsurface drainage systems.

A well developed infrastructure is in place to support large-scale agriculture in the region, including transportation (excellent road, rail, and river transport systems), strong electrical power network, service industries, equipment retailers, and research centers (WSU and the U.S. Department of Agriculture (USDA)-Agricultural Research Service). Large investments have been made in food processing and storage facilities, especially in the Tri-Cities area. This infrastructure would be available to support any future agricultural development of the Hanford Site.

Irrigated agriculture and its related industries (agricultural services, food processing, transportation, and retailing) is, and will continue to be, a fundamental part of the state's economy. Annual production from the state's irrigated lands exceeds $3.5 billion at the farm gate and is a major source of exports. A large infrastructure has been developed for processing, transporting, and retailing agricultural products with huge large economic effect on the regional economy. Secondary processing of agricultural products is estimated to add an additional $20-25 billion a year to the state's economy.

The region's agricultural industry affects almost all economic sectors, resulting in purchase of billions of dollars in goods and services every year. It provides a stable base for growth in other sectors as it quietly, steadily, and reliably produces a huge proportion of the state's income.

Yakima, Grant, Franklin, Benton, and Walla Walla Counties, which surround the Hanford Site, are the top five counties in Washington, respectively, in terms of the farm gate value of their agricultural production. Washington State currently ranks 15th nationally in the value of its total agricultural output (farm gate: livestock and crops) with a substantial portion of that output from irrigated agriculture in this region. Washington is ranked 8th nationally in total crop value, 3rd in vegetables, and 3rd in the production of fruit and nuts. The region's crop production is high, and it is reasonable to assume that irrigated agricultural production would be similar for the Hanford Site. The Appendix summarizes the current agricultural production in Grant, Adams, and Franklin Counties.

3.1 Irrigation Development

The main irrigated areas near the Hanford Site are the Yakima River Project and the Columbia Basin Project. Both of these projects were built by the U.S. Department of the Interior, Bureau of Reclamation. Several large-scale private irrigation developments also exist to the south and east of the Hanford Site on sandy soils, which are almost exclusively irrigated by center pivot machines.

Starting about 25 years ago, a relatively small irrigated area was developed adjacent to the northern boundary of the Hanford Site (along Cold Creek) for the production of wine grapes and fruit trees. Recent developments include center pivoted irrigated alfalfa and potatoes (however, these will likely be converted to drip irrigated wine grapes in the near future). These developments are significant to this study since they successfully demonstrate the types of crops that could be grown in many parts of the Hanford Site with similar slopes, aspects, and soil types.

3.1.1 Yakima River Project

The Yakima River Project is the oldest irrigation development in the region and contains about 182,000 actively irrigated hectares (450,000 acres). Six main irrigation districts operate in the project with about 20 small, private districts that typically irrigate less than 1000 hectares (2,500 acres). The Kittitas Irrigation District serves the Ellensburg area in the upper Yakima Basin. The Tieton, Roza, Sunnyside, and Wapato (Yakama Indian Reservation) irrigation districts serve lands in the lower Columbia Basin from near Yakima to the Tri-Cities. The Kennewick Irrigation District serves lands in the Badger Canyon and west Kennewick areas. Land ownership in the Columbia Basin is about 40% federal, 30% Native American, and 30% private.

The earliest irrigation recorded in the Yakima River drainage is in 1852 in the Ahtanum Creek near a Catholic Mission and in 1853 when construction of the Indian Ditch near Tampico began. Cattlemen and sheep herders were attracted by the abundance of bunch grass and wild game. Miners started arriving in 1854, leading to conflicts with Native Americans and the construction of Fort Simcoe. Settlers arriving as early as 1861 developed additional irrigation along the Naches River. Additional irrigation diversions near Prosser and Kiona were in existence around 1878. In 1886, completion of the Northern Pacific Transcontinental Railroad spurred new agricultural expansion in the region. The railroad company and several private land development companies made large investments in irrigation to aggressively attract settlers. By 1900, after construction of the early Sunnyside and Congdon Canal systems, the Yakima Valley was the largest irrigated area in the state with about 48,600 hectares (120,000 acres) irrigated.

In 1905, Congress authorized the 200,000 hectares (500,000 acres) Yakima Federal Reclamation Project to be built by the USBR). Construction funds for the Tieton and Sunnyside divisions were authorized in 1906. Over the next 20 years, construction of the Kittitas, Roza, and Kennewick divisions were authorized, and six reservoirs were constructed. Today, the USBR manages the surface water supply in the Yakima Basin through control of reservoir releases.

Starting in the late 1890s and completed in the 1950s, the Wapato Project was constructed and managed by the Bureau of Indian Affairs (BIA) on Yakama Indian Reservation lands south of the Yakima

River. The BIA contracted with the USBR to supply water for the Wapato Project. Most of the natural flows of Toppenish, Simcoe, and Satus Creeks are also captured and used within the district.

Many of the earliest irrigation developments were consolidated into the various federal Yakima Basin projects. A considerable amount of water is reused and shared within and between irrigation districts by capturing return flows and water markets.

An undefined amount of water is pumped from both shallow and deep wells inside and outside the irrigation district lands (estimated at an additional 20,000 hectares [50,000 acres]). The deep wells are in the confined aquifers in the basalt and relatively high yielding. Shallow wells in the unconfined aquifers are mostly for domestic use since they generally have low yields (<6 l/s), except for some localized gravel deposits in the Wapato Irrigation District that have high yielding wells.

Orchards were planted early in the agricultural development of the lower Yakima Valley. Railroads provided rapid transportation of produce to urban markets, and the fruit industry grew and continues to flourish. Hops were introduced into the area in the early 1900s. Wine grapes were planted before the turn of the century, and although the industry died due to prohibition, it has made a major resurgence starting in the late 1970s. Concord grapes have been grown for juice since the 1940s. In general, there is a high percentage of permanent crops.

Because of the limitations of available agricultural production technology before World War II and the high labor requirements of orchard, vine, and hop, the general tendency in the area is to maintain small individual fields (<15 hectares [<40 acres]). The rugged and/or steep topography combined with early irrigation methods that eroded the surface also mandated small fields in many areas, particularly on higher lands in the Roza and Sunnyside Districts. Crops grown in the Kittitas area are mostly small grains, Timothy hay, alfalfa, pasture and field corn, and a small number of orchards. Field sizes are also generally small for many of the same reasons.

Originally, all of the water was applied by furrow and ridge methods (gravity-flow surface irrigation), but presently less than 20% of the lands use these methods. Solid set sprinklers and microirrigation (drip and micro sprinklers) methods have largely replaced older methods. There are few center pivots. The initial shift to adopt pressurized irrigation methods was driven by the benefits of frost protection and erosion control (cover crops) for the rapidly increasing permanent crop industries (orchards and vineyards) in the area. However, current restrictions on return flows to the river imposed by the Endangered Species Act have resulted in many conversions of the remaining surface irrigated lands to pressurized methods. It is expected that within a few years, surface irrigation will be used in only a few small areas of the basin.

Currently, Yakima County is ranked tenth in the list of leading agricultural counties in the United States. It ranks first in the nation in the production of hops, apples, and mint. More than 80 crops are grown including wine and juice grapes, mint, asparagus, sweet corn for processing, cut flowers, and alfalfa hay. The county is a major center for beef cattle feeding in the state, and numerous large dairies have located in the area.

3.1.2 Columbia Basin Project

The Columbia Basin Project (CBP) has three irrigation districts: the Quincy District, the East District, and the South District, which are located to the north and east of the Hanford Site. The CBP service area contains portions of Grant, Adams, Lincoln, Franklin, and Walla Walla counties. The South District lands are adjacent to the Hanford Site (across the Columbia River to the east and north). Construction of the CBP began in 1933, and the first water was delivered in 1952. The last block to be developed was Block 26 in the Mattawa area, just north of the Hanford Site.

Congress initially authorized the CBP to irrigate about 405,000 hectares (1,000,000 acres); however, because of a subsequent moratorium on future development of the project, only about 60% of the original area is currently irrigated with project water. The East High canals were never constructed even though many of the head works and siphons needed to supply the water to the area were built. An estimated 30% of the original East High area is currently irrigated using water from deep wells in the confined aquifers that were privately developed; however, it is doubtful that this is sustainable due to pumping costs and the cumulative effects of using high-sodium groundwaters on soils.

Current acreage figures also include about 16,320 hectares (40,300 acres) being irrigated through "artificially stored groundwater" or subsurface return flows from other project lands in the Black Sands area near George, Washington that were not part of the original project Irrigation has expanded (about 32,000 hectares [80,000 acres]) to "marginal" lands in other parts of the CBP because of advancements in irrigation technologies (i.e., center pivots and drip) that were not available when the project was designed. Annual production from CBP lands contributes more than $800 million in direct and secondary income that benefits several counties.

Most CBP water comes from Grand Coulee Dam, located on the main stem of the Columbia River about 90 miles west of Spokane. Natural inflows from Crab Creek, Rocky Ford Creek, and other natural tributaries provide small contributions (generally <1% of total project needs) to the project's water supply. Irrigation canals and other project works extend southward from Grand Coulee Dam about 125 miles to the vicinity of Pacso, Washington near the confluence of the Columbia River with the Snake and Yakima rivers. The Columbia River forms the western boundary of the project.

The CBP diverts about 3% (standard deviation about 5%) of the annual inflows to Lake Roosevelt, 0.3-0.33 M ha-m (2.5-2.7 MAF), to irrigate more than 251,840 hectares (622,000 acres) of land. With return flows back to the Columbia, the net water withdrawal from the Columbia River is about 1% of the total annual runoff of the entire river basin, 24.4 M ha-m (198 MAF). The average on-farm delivery is about 1.13 ha-m/ha (3.7 acre-ft/acre). Average annual crop irrigation requirements are estimated at 0.83 ha-m/ha (2.71 af/a) (Montgomery Water Group 1997).

Water delivery to farms (per unit area) has decreased since the project began because of changes in irrigation practices and some changes in cropping patterns. Farmers have converted from less efficient gravity irrigation systems to more efficient pressurized methods such as center pivots and drip or micro-irrigation methods. Since 1969, the percentage of farmers using pressurized irrigation systems has increased from 40% to 70% across the entire project. About 90% of the South District uses pressurized

systems, as does the Wahluke Slope (Mattawa) irrigated areas. All three irrigation districts actively encourage and provide assistance to their growers to convert to pressurized systems, greatly accelerating this trend. Also, the rapid conversion in some areas to orchard and vine crops and specialty seed crops (i.e., carrot seed), which use much less water than do historical crops, has helped to reduce water requirements. The CBP is the most rapidly growing orchard and vine crop area in the Pacific Northwest.

In 1993, the USBR issued a moratorium on all further water development in the CBP in response to requests from the Northwest Power Planning Council and the National Marine Fisheries Service. At the same time, the water resources agencies in Washington, Idaho, and Oregon simultaneously announced that they would no longer issue permits for new diversions in the basin's salmon streams. Thus, it is highly likely the CBP irrigated acreage will remain at present levels in the future.

3.1.3 Historical Irrigation in the Hanford Site

In 1818, Fort Nez Perce was founded near present day Wallula to protect fur trappers and traders. It was later renamed Fort Walla Walla. The permanent non-Indian settlers in the area were largely cattle ranchers. The area's mild winters, sand grass, and white sage fattened cattle that were driven the Vancouver, Canada and other regional markets. However, extreme cold and heavy snowfalls during the winters of 1880-81 and again in 1886-87 decimated the cattle industry. Settlers then began building small dams and canal systems using gravity flow irrigation methods along the lower Yakima and the Columbia rivers. Most of the early irrigated crop produced on the Hanford Site was hay for feeding livestock. From 1880 until the early 1890s, numerous homestead claims were filed in the Wahluke Slope/Hanford Reach area.

During the early 1900s until 1943, the area continued to grow. The towns of White Bluffs, Hanford, and Richland flourished. Irrigated areas produced apples, cherries, pears, alfalfa, potatoes, and many other vegetables. Beef cattle, horses, chickens, pigs, dairy cattle, and large flocks of sheep were raised and grazed in the area. The average 160-mm (6.3-in.) annual precipitation made production of rainfed or dryland crops such as wheat and barley impractical. In 1954, the USDA rated the soils in the Hanford Site as marginally suited for cultivation, primarily because of the type of irrigation (gravity flow) available at the time (USDA 1954). However, with the advent of pressurized sprinkler and micro-irrigation technologies, these early classifications are no longer valid as has been convincingly demonstrated in many nearby areas.

In March 1943, all the private lands within the current Hanford Site boundaries were acquired by right of eminent domain by the U.S. Government for the Manhattan Project as part of the war effort. The land has passed from the U.S. Department of Defense to DOE, which now operates and maintains the Hanford Site. Since 1943, there has been no agriculture within the site.

4.0 Agricultural Technologies

It is an exciting time to be involved in agriculture. The state of the art of agricultural technology is advancing extremely rapidly. Crop production methods and management 50 years from now undoubtedly will be much different than today. Agrichemical restrictions, environmental concerns, and the need to be competitive in world markets are fueling tremendous strides along many fronts improvements. This section explores some of the more probable future developments in agriculture and examines current technologies and the economic impacts of irrigated agriculture in the region.

Future farm management and cultural practices will be much different from today. Bioengineered plants will be more common because they will be more resistant to insects and disease, more salt tolerant, and will use nutrients and water more efficiently (less water will be needed). The production of pharmaceuticals will be more common in agriculture in addition to food and fiber. Biologically based pest control combined with genetically engineered crops resistant to many plant diseases will continue to reduce agrichemical use.

The development of site-specific, integrated real-time precision irrigation, fertigation and pesticide systems is currently underway. Global positioning systems (GPS), detailed field-yield monitoring, GIS, computer models, extensive field sampling programs, and real-time monitoring of climate and field parameters make it possible to optimize crop management for spatial and seasonal variability. Inputs can be optimally matched to yields, greatly reducing costs and improving environmental stewardship. Advances in remote sensing, crop protection, precision planting, precision tillage, precision irrigation, and harvest mapping are changing agriculture. Collectively, these are referred to as precision agriculture.

4.1 Precision Agriculture

Precision agriculture means carefully tailoring soil and crop management to fit the different conditions found in each field using a wide variety of technologies. Precision agriculture is sometimes called precision farming, prescription farming, site-specific farming, site-specific crop management or variable rate technology. It involves aspects of remote sensing, crop protection, precision planting, precision tillage, precision fertilizer placement, precision irrigation, on-the-go yield monitoring and other emerging applications. Some of the emerging technologies undoubtedly will be part of future crop production systems in the Pacific Northwest (Evans 1997a,b). Emerging technologies have the potential for reducing inputs, and improving use of existing resources, improving environmental stewardship, and improving farm profitability.

Some believe that the potential consequences of precision agriculture technologies will have as great an impact on future agricultural production as the "green revolution" is having currently. However, at present the technology is ahead of the science to use it correctly. Research is currently underway by universities and the USDA to give farmers confidence that the use of these technologies is practical and potentially valuable for improving production of irrigated crops in the near future.

The U.S. Congress has published the following definition of precision agriculture:

"Gathering on-farm information pertaining to the variation and interaction of site-specific spatial and temporal factors affecting crop production. Use of that information to prescribe and deliver site-specific applications of agricultural management practices and inputs to maximize productive efficiency while minimizing negative environmental impacts." (House Bill 725, 105th Congress, 1st Session, February 12, 1997)

Congress extended this concept by defining precision agriculture technologies to be:

"Instrumentation and techniques ranging from sophisticated sensors and software systems to manual sampling and data collection tools that measure, record and manage spatial and temporal data. Technologies for data processing that produce valued information for farm management decisions. Machines that deliver information-based management practices and inputs to accomplish the objectives of precision agriculture."

Thus, precision agriculture is basically about information: its collection, management, and interpretation. It has been made possible by advances in computer and communications technologies that allow growers to use equipment and software to manage inputs in ways that account for the inherent yield variability across any field. Precision agriculture is a systematic way to look at the total farming operation.

The necessary "components" to implement precision agriculture on irrigated lands have recently become readily and economically available. These include: 1) GPS, 2) GIS, 3) improved techniques for real-time remote sensing of soil and crop status, and 4) improved computers, communications, "smart" sensors, and monitoring systems to provide adequate feedback and control capabilities. These improved techniques for remote sensing of soil and crop status, [already discussed above], [already discussed above], advanced crop growth and disease models, [already discussed above], and real-time data collection systems that provide adequate feedback and control capabilities make it possible to develop integrated, economically viable, site-specific crop management systems. These data must be used with software to statistically evaluate, enhance, and spatially combine with other GIS data layers to look at inter-relationships and causes of yield variability.

Yield monitors, grid sampling, and remotely sensed data are valuable tools that provide critical information on field variability and evaluate the results of a site-specific management program. The amounts of water (and nitrogen) applied by center pivot and drip irrigation systems can be carefully managed to match the spatial variability in water holding capacity and related nutrient availability. Yields and crop quality are affected by many factors. Variations in quality and quantity of yields are increased by weeds, pests, and pathogen effects on crop growth as well as microclimate changes across a field, which can cause further variability in water and nutrient usage. In addition, the method used to correct one problem may have unwanted side effects that create new, and possibly more serious, problems that must then be corrected.

The large potential of precision agriculture is recognized by fertilizer companies and major farm equipment companies such as Ag Chem, John Deere, Case-IH, Heston and others, who are making

significant efforts to develop various applications. Companies like CENEX-Land 'O Lakes, Simplot Soilbuilders, and others are making large investments in equipment and employee training to provide related services. Self-propelled irrigation system manufacturers are also very interested and conducting research in precision agriculture. Software for site-specific evaluation is becoming more available at low prices.

Research is underway around the world to fit the various components of precision agriculture together. These are 1) optimizing yields and quality from each area within a field, 2) reducing product variability, 3) protecting the environment, 4) reducing inputs, and 5) maximizing returns on investments. Ideally, processing and marketing parameters also should be included to form a holistic approach to agriculture.

Because growers must irrigate in the arid west and can control soil water, they can maximize the benefits of many precision agriculture technologies. The arid climate of the Hanford Site enhances management ability since uncontrolled natural precipitation is a minor factor, and its influence is easily included by adjusting irrigation management strategies/programs. This can greatly reduce drainage/deep percolation losses.

Advances in farm equipment and management capabilities that are part of precision agriculture or precision farming will undoubtedly influence all of the world's agriculture in the next century. The alternative management practices of precision agriculture technologies will be fundamental to profitable and sustainable farming in the future. Environmental issues, reduced water supplies, and reduced availability of chemicals/pesticides must be addressed, and components of precision agriculture will be a part of the solution. Precision agriculture can make U.S. producers more competitive, and agrichemical use will be reduced to minimum levels.

4.2 Irrigation Technologies

Irrigation technology has advanced significantly since World War II. Center pivots and microirrigation techniques were developed in the 1950s and 1970s, respectively. These technologies are continuing to evolve. Thus, future decisions must be based on the current and expected advances in irrigation technologies for application of water and agrichemicals as well as management. The best area on which to base future agricultural land use for the Hanford Site is the CBP lands that are adjacent to the site to the north and east.

To select the type of irrigation system to install, a number of different factors must be considered. These include the crop and crop water requirements; water supply; soil characteristics; topography, size, and shape of the field; climate of the area; and economic factors such as labor requirements, available capital, and resource costs. Many of these factors are interdependent, and while one factor may or may not indicate a definite need for a particular irrigation method (or even the need for irrigation), the relationships between these factors must be considered.

Many crop factors influence the irrigation system choice. For crop consumptive use, both the total seasonal water needs and the pattern of water needs during the season (relative to growth stages)

compared to rainfall amounts and patterns determine the net irrigation requirements. Net irrigation requirements (over and above rainfall) range from only 125 to 300 mm (5 to 12 in.) of moisture for short-season vegetable crops and wine grapes to 630-900 mm (25 to 35 in.) for orchard and forage crops. The actual amount depends strongly on crop and location. Average daily peak period water needs for most Eastern Washington crops and locations is from 5 to 7 mm (0.20 to 0.28 in.) per day. This translates to a required continuous supply of from 1 to 1.2 L/s/ha (4 to 6 U.S. gallons per minute per acre) to be supplied by irrigation. Wetting of the crop foliage or fruit may cause disease or pest control problems, and depending on the quality of the irrigation water, crop wetting may not be recommended to avoid quality or toxicity problems. Lack of aeration in the root zone over time may reduce plant performance. Cultivation requirements or other cultural practices may preclude the use of certain methods. The expected economic return of the crop in both quantity and quality must be analyzed to determine how much can be invested in irrigation.

Water supply factors include the quantity and quality of the source. The kinds and amounts of any salts dissolved in the water must be known. Central Washington has high- quality, abundant surface water supplies with low soil salinity. The availability of the water (timing and frequency) affect the design and management of an irrigation system, and boosts the required supply rate if the supply is not continuous. The size of the available stream may limit the choice of systems to only the most efficient. If water is not available during critical dry periods or critical growth stages, irrigation is moot.

Soil characteristics that must be assessed include the infiltration rate, water holding capacity, depth, drainage conditions, reaction to water and salts, and soil erodibility. The variability of these properties throughout a field must also be known. The rate at which soil accepts water (the infiltration rate) will often eliminate some methods of irrigation. The soil water holding capacity and the depth of the soil in conjunction with the crop rooting depth, the crop water requirements, and climatic conditions may actually indicate irrigation is not needed, i.e., enough water is held in the soil and available to the crop for the entire growing season or to carry the crop during dry intervals. Typically, this will only be the case for deeper rooted crops grown on finer textured soils, or where dry spells during the summer are of short duration. Soil drainage conditions are extremely important in western Washington. Soils that do not have adequate natural drainage may rapidly become waterlogged under irrigation. Applied irrigation water may be lost in runoff and valuable topsoil may be eroded.

Field size, shape, and topography require differing degrees of flexibility in the irrigation system. The topography of the field may require extensive land leveling to use certain methods. Certain irrigation methods are not recommended for steep slopes, and others require special design requirements. All these factors increase the cost of the system.

Climate is the driving factor in determining crop water requirements and the need for irrigation to provide the portion of the requirement not met by precipitation. Seasonal and annual variations in climate will often decide the need for irrigation to produce high yields of high-quality crops in environments that otherwise do not need irrigation. This is also the case when irrigation is used for environmental modification to protect the crop (e.g., frost protection).

Irrigation as a cultural practice adds costs to production. Initial capital costs vary widely from method to method. The method chosen also affects total costs for irrigation water, energy, labor, and land preparation. In considering the economics of irrigation systems, trade-offs exist between costs of capital, labor, water, energy, and land. The system yielding the highest return is a compromise between these resource costs. Table 4.1 shows the range of typical capital and annual costs of the various irrigation methods. Capital costs include materials and construction of the irrigation system but does not include the cost of land, land preparation, and water source development costs. Annual costs include labor, amortization of the irrigation system, and energy costs (to pressurize the system, if needed) but does not include the cost of water, taxes, interest charges or amortization of the water delivery system (e.g., pump and well).

Furrow irrigation is a limited option at the Hanford Site because of high sand soil texture classifications. The small amount of silt loams may be suitable but are subject to severe erosion. Soil erosion is being addressed successfully by growers using formulations of polyacrylamide (PAM) in small quantities essentially to halt furrow irrigation-induced erosion on thousands of acres in the Yakima Valley and the CBP (details are on the Internet at http://kimberly.ars.usda.gov/pampage.ssi).

Table 4.1. Comparative Approximate Range of Initial and Annual Costs per Hectare (Including Labor) of Various Irrigation Methods, Not Including Land Purchase, Taxes or Water Development Costs

Method		Capita Costs		Annual Costs	
		Low, $	High, $	Low, $	High, $
Surface:					
	Furrow (rill)	500	1000	250	450
	Furrow w/Land Leveling	600	1500	250	450
	Furrow w/Automation	750	1600	300	500
	Furrow w/Tailwater Reuse	750	1500	300	600
Sprinkle:					
	Aluminum hand-move	875	2000	375	600
	Wheel-move	875	1850	225	500
	Center pivot	1000	2000	375	1100
	Precision System	1250	2500	450	1200
	LEPA	1250	2500	450	1100
	Traveling gun	1000	2000	250	1250
	Solid set	1850	3700	250	1000
Microirrigation:					
	Drip/trickle	1850	3700	500	1000
	Micro-sprayers	1900	4500	500	1000

The most appropriate irrigation methods for most of the Hanford Site, based on current technology and expected advances, will probably be self-propelled center pivots, linear move irrigation systems, and microirrigation. These methods are discussed in more detail below.

The amount of water that can be saved depends on the ability of a particular type of irrigation system to improve management. However, the major factor is grower knowledge and the existence of incentives to adopt the improved management practices. A critical link in improved management is the implementation of scientific irrigation scheduling (SIS) techniques that will be required for any irrigation scheme.

4.2.1 Irrigation Scheduling

Irrigation scheduling is generally defined as deciding when to irrigate and how much water to apply. All irrigators schedule their irrigations differently. Some follow a calendar, while others irrigate because their neighbor is watering. Whatever criteria are used, relatively few irrigators currently use an approach based on sound scientific principles, or, SIS.

In general, a fairly large number of studies throughout the western United States shows that scientific irrigation scheduling can, in most cases, reduce the gross amount of water normally pumped from 15% to 44%. Water savings of about 20% seems to be a generally achievable level over "non-scientific" methods.

The concept of scientific irrigation scheduling (SIS) involves soil water holding capacity, volume balance, application efficiency, crop stress related to productivity and economic benefits, when and how much to irrigate, and how to apply the target amount of water. All SIS methods are based on two fundamental approaches, 1) monitoring soil and/or plant water status, and 2) predicting irrigation schedules from a computed soil water budget that estimates water depletion in the root zone. The first approach provides a direct reading of soil/plant status in the field and of water use since the last reading, but limits the potential for forecasting or planning. The second approach provides a planning element but alone does not have a "ground truthing" component as a baseline check to ensure accuracy. Thus, most SIS methods use a combination of the two approaches with wide variation in frequency and rigor of ground truthing activities and the development of new schedules.

Scientific irrigation scheduling is a concept that dates from the early 1950s. However, despite decades of promotion by public agencies and private consultants, its success and dissemination has been limited. As a result of recent droughts, groundwater contamination issues, and endangered species programs, growers are much more willing to look at SISSIS seriously as a viable part of their operations. Farmers in the Pacific Northwest are sensitive to the increased public demands that irrigated agriculture conserve more water and reduce agrichemical usage by using improved irrigation methods and better management. The shift away from low-energy surface irrigation methods to moderate to high-energy pressurized sprinkler and microirrigation techniques is accelerating, causing additional demand for electric energy and creating an even greater need to conserve electric power in the region. These factors, in addition to using irrigation systems for multiple purposes(e.g., frost protection and crop cooling) and adopting new irrigation methods is creating interest in and acceptance of SIS. SIS Irrigators are now more open to educational opportunities that will help them stay competitive. Recent successful SIS

projects in Washington have also contributed to growing local approbation. The major incentives for adopting SIS currently are related to the cost of SIS services/technology and the cost of water, which includes the expense of pumping. Environmental regulations seem certain to provide additional incentives in many areas throughout the Pacific Northwest.

Educational programs are the only way to address problems related to an irrigator's insufficient knowledge of 1) irrigated soil properties; 2) irrigation system application capacities, rates and efficiencies; 3) crop characteristics relative to water use and the patterns of water use; 4) climate and environmental effects on crop water demand and irrigation performance; and 5) economic benefits. In the near term, extension educational and demonstration programs can provide irrigators the necessary confidence and knowledge to integrate SIS successfully into their total farming system. Equally important, such educational and demonstration programs will also help train consultants, conservation district staff, and electric utility and other agency personnel in climate-plant-soil-irrigation interactions and proper scheduling techniques and processes so they can work more effectively with growers. In addition, an increasing number of farmers and their children are college-educated, many with advanced degrees, and these individuals are more open to technological approaches to farming than earlier generations.

The technical approaches to SIS are complex because they must be based on many factors related to crops, soils, climate, irrigation method and management objectives as well as local experience with constraints imposed by the water delivery system. In addition, generalized SIS procedures must be tailored to each situation since many of these factors are site-specific. SIS services must adequately integrate and support other farm management decisions perceived by growers to be more important than the irrigation decisions. To be successful in the long term, educational SIS programs must demonstrate the increased value of a range of improved farming practices, such as precision agriculture, that are supported by scheduling. This complexity generally requires consultants and others (e.g., specific employees of large corporate farms) to provide tailored SIS services since most agricultural producers do not have the time or expertise. Unfortunately, many consultants also lack the necessary knowledge to advise irrigators properly on these subjects. Nevertheless, large farming enterprises are more likely to adopt SIS practices because they are often better capitalized and generally more willing to make long-term investments in technology and training.

Remarkable progress has been made in recent years on sensor technologies and automation suitable for SIS, and the diversity is enormous. The economic and environmental incentives as well as the educational level of the farmer will dictate which technologies will be adopted for more accurate scheduling. These devices and tools must be tested and evaluated for use in specific situations, and the new information made available to growers, utilities, private consultants, and other interested parties for inclusion in on-farm SIS programs.

It is estimated that more than 300,000 acres in Washington currently use some aspects of SIS. The successes of past SIS education and demonstration efforts in the region have added to the general perception that SIS may actually be a beneficial and requisite practice rather than an inconvenience. The future availability of low-cost soil/plant sensors, currently unavailable, are crucial to expanding SIS adoption.

4.2.2 Weather Networks

Successful implementation of SIS requires the availability of a network of weather stations that provide timely climatic data for predicting crop water use. Two agricultural weather networks in the Pacific Northwest currently have fully instrumented stations. These networks must be maintained to support both SIS and integrated pest management programs that reduce agrichemical usage. Because of significant microclimate differences between the larger scale stations and farms, some growers have installed their own weather stations to assist in frost protection and pest/disease control programs.

AgriMet is a satellite communications-based network operated by the USBR out of Boise, Idaho. AgriMet provides climatic data at 4-hour intervals from sites near the Washington communities of George, Odessa, Lind, Goldendale, Harrah, LeGrow (on the Snake River near Burbank), and Omak, and in Oregon near Hermiston, Hood River, and Echo).

The second weather network is the PAWS operated by WSU Cooperative Extension out of WSU-Prosser. It is a network of 59 real-time weather stations primarily located in the irrigated areas of the Columbia Basin and Yakima Valley. Stations are also located in the Wenatchee and Omak drainages and a few stations are on the west side of the Cascade Mountains. All of these stations collect 15-minute data and communicate these data to the base station either once an hour over an rf transmission network or over the Internet. During the spring and fall, some of these stations transmit data at half-hour intervals to assist growers in frost protection.

4.2.3 Self-Propelled Center Pivot and Linear Move Irrigation

A center pivot or lateral move system basically consists of a pipeline (lateral) mounted on motorized structures (towers) with wheels for locomotion. A center pivot machine rotates around a "pivot" point in the center of the field, whereas a lateral move machine travels along a straight path and has a separate guidance system. Sprinkler outlets are installed on the top of a pipe supported by steel trusses between adjacent towers. The towers are usually from 30 to 60 m (90 to 200 ft) apart, and each tower has a 1-hp motor and sits on two large rubber or steel tires.

In the United States, approximately one-third of all irrigation, or about 60% of all sprinkler-irrigated lands, is by self-propelled irrigation systems, mostly center pivots. This is about 125,000 machines on approximately 7.9 million hectares (19.5 million acres), or about 29% of the total irrigated area., In Washington, center pivots account for more than 25% (about 190,000 out of 810,000 hectares) of the total irrigated lands, mostly in the Columbia Basin. These sprinkler irrigation systems have allowed agricultural development of "marginal" lands in central Washington unsuitable for surface irrigation, because of their mostly light sandy soils and large variations in field topography. These conditions are also typical of much of the potentially irrigable lands of the Hanford Site.

Worldwide use of these very adaptable water application methods has grown in recent years due to their 1) potential for highly efficient and uniform water applications, 2) high degree of automation requiring less labor than most other irrigation methods, 3) large areal coverage, and 4) ability to apply water and water-soluble nutrients economically over a wide range of soil, crop, and topographic

conditions. For these reasons, center pivot irrigation in the United States increased by more than 50% from 1986 to 1996.A standard 50-hectare(125-acre) center pivot system will cost from $35,000 to $45,000, excluding land and water supply development costs. Water development costs depend on the source of water and power (i.e., electric, diesel or natural gas). Generally, the largest annual costs for these machines are for power or fuel to pump water.

Because center pivot and lateral move systems operate semi-automatically, it is relatively easy to manage soil water levels carefully across a field. Almost all crops including sugar cane, orchard and vine crops, and more traditional field crops such as maize, potatoes, small grains, alfalfa, and vegetables have been successfully irrigated with center pivot water application systems under a wide range of conditions. Some center pivot irrigated crops require special cultural practices such as planting in circles or using small pits or reservoirs in the furrows to facilitate infiltration on heavy soils and prevent surface runoff. Application efficiencies higher than 80% are possible depending on management and a properly designed installation for the site. Center pivot and lateral move systems have the potential to be more than water application devices. They also provide an excellent vehicle to apply some chemicals and many fertilizers to match plant requirements exactly. In some areas of south-central Washington that have very light soils, as much as 80% of all nitrogen fertilizer used is applied through the center pivot system. Substantial crop quality and pest control benefits may accrue when using this method for applying chemicals.

In addition, center pivot systems provide an especially suitable platform on which to mount various types of sensors since the lateral system potentially passes over every part of the field every day. Color video and infrared and reflected wavelength specific sensors could be combined and coupled with pattern recognition software and GPS for early detection of stresses due to lack of water or nutrients, disease, and insects as well as potentially identify various weeds and other problems.

4.2.4 LEPA Systems

A special adaptation of self-propelled technology is the Low Energy Precision Application (LEPA) method that can be installed on both center pivot and linear move systems. LEPA has "drop" tubes spaced about every meter that extend to the soil surface where a low pressure bubbler is attached in place of a sprinkler. Water is applied directly to the furrow, minimizing evaporation losses because the canopy is not wetted. Although initial capital costs are higher than standard systems, with the right soil, topography, and management, these systems can be very efficient (e.g., 95-98%). Soil evaporation is generally less than 2% with alternate row irrigation, although runoff may be as much as 50% with poorly designed and operated systems. Wind drift losses also are eliminated. The best results with LEPA have been obtained on heavier clay soils, and use has been limited in the Pacific Northwest (used mostly on mint and alfalfa with shallow furrows) because of the light soils with poor lateral spreading.

Crops are usually planted in a circle so that the drops do not damage plants. Sometimes a canvas "sock" or other fabric energy dissipation device is used to prevent soil erosion in the furrows. A machine such as the Dammer-Diker™ is often used with both LEPA and regular center pivot and linear move application techniques to create small reservoirs that store water until it has infiltrated on heavy or steeply sloping soils. Typical quarter-mile-long (400 m) LEPA systems have from 350 to 450 heads. These systems could also be improved using precision irrigation technologies.

4.2.5 Precision Irrigation with Self-Propelled Irrigation Systems

The goal of irrigation designers is to have the most uniform water application pattern possible along the entire length of the center pivot or linear move, which is not necessarily ideal for crop quality and the environment. For example, our research and that of others (Evans and Han 1994; Han et al. 1995; Mulla et al. 1996; Mallawatantri and Mulla 1996) has shown that, in grossly simplified terms, about 75% of leaching occurs in about 25% of the area in many center pivot irrigated fields in the central Pacific Northwest.

Self-propelled irrigation systems such as center pivots and linear moves are particularly amenable to site-specific approaches because they are automated and cover a large area with a single lateral pipe. Microprocessor-controlled center pivot and linear move irrigation systems provide a unique control and sensor platform for economical and effective precision irrigated crop management. These technologies have made it potentially possible to vary agrichemical and water applications to meet the specific needs of a crop in each unique zone within a field to optimize crop yield and quality. There is less impact to the environment and reduced costs for input water and chemicals. The criteria for managing precision water and chemicals with these self-propelled systems is currently being developed by numerous universities, government research groups, and industry, and is expected to be commonly available within five years.

Despite the inherent high-frequency and fairly uniform applications of self-propelled center pivot irrigation systems, considerable yield variations still exist that are often attributed to spatial variability in soil water holding capacities and related nutrient availability. Variations in water availability across a field result in a farmer needing to 1) ensure that areas with the lowest water holding capacity maintain adequate water levels, 2) manage the whole field based on average soil water depletions, or 3) avoid overirrigation in wettest areas. All of these cases will cause overirrigation or underirrigation of some areas because current center pivot systems cannot differentially irrigate based on varying soil and plant factors within a single field. Some chemical leaching below the root zone, surface runoff, and potential yield decreases may occur in different areas under each management practice.

Thus, it is obvious that having high water application uniformities across an entire field is not necessarily the best in terms of crop quality and the environment. For example, research at WSU and the research of others has shown that, *in grossly simplified terms*, that about 75% of the leaching occurs in about 25% of the area in many center pivot irrigated fields in the central Pacific Northwest. It is evident that the ability to more precisely manage small areas of the field will be necessary to reduce groundwater degradation. *Therefore, the next advances in center pivot and lateral move irrigation will involve being able to vary water and chemical applications along the length of the pipe depending on its position in the field* (Evans and Harting 1999).

Center pivots are especially suitable for site-specific water application because one pipeline and 100+ sprinklers can irrigate 50+ hectares (125 acres). Automating a sprinkle irrigation system for precision water applications requires the ability to control the net application rate from each head individually depending on its location in the field. In addition to improved water management and reduced leaching, another obvious advantage of automating individual heads is that the very high application depths near the pivot point can be reduced to levels matching the rest of the system by using larger, non-plugging

heads with better water distribution characteristics. Reducing water applications near the pivot point would also reduce the incidence of fungal diseases. With appropriate sensors, software, feedback, and control systems, irrigation efficiencies of 85 to 95% are possible with precision irrigation using center pivots. Most water losses would be from evaporation and wind drift. Including precision irrigation hardware and control software adds about $250 per hectare ($100 per acre) to the cost of the machine. Agronomic input and monitoring equipment to support management decisions also will increase costs.

4.2.6 Microirrigation Technologies

Drip irrigation, also called trickle irrigation, bubblers, and localized small microsprinklers, micro-spinners and microsprayers are collectively referred to as microirrigation. Microirrigation includes any localized irrigation method that slowly and frequently provides water directly to the plant root zone. Applying water slowly at discrete locations at low pressure and irrigating only a portion of the soil volume in the field can result in relatively low-cost water delivery systems that divert less water than other irrigation methods. Drippers and bubblers are designed to apply water at atmospheric pressure, whereas microsprinklers apply water from about 50 to more than 250 kPa (7-40 psi).

Microirrigation has the potential for precise, high-level management and is an extremely flexible irrigation method to design. It can be adapted to almost any crop and climatic zone. Microirrigation can be used over a wide range of terrain conditions, and it has allowed irrigated crop production to expand into areas with problem soils (either very low or very high infiltration rates) and poor water quality that could not be used with other irrigation methods. It can be installed as either a surface or subsurface water application system. Application efficiencies above 90% are readily possible under good management with well-designed systems. These systems can cost from $1200 to $3700 per hectare (from $500 to $1500 per acre) depending on the field size and crop.

Microirrigation can be used on most agricultural crops, although it is most often used with high- value specialty crops such as vegetables, ornamentals, vines, berries, olives, avocados, nuts, fruits, and green-house plants. In many cases, it can also be used economically for field crops, golf greens and fairways, cotton, and sugar cane. Microirrigation is used almost exclusively on wine grapes in central Washington because of its potential to control soil water levels and influence winter hardiness.

Microirrigation is being used increasingly around the world and in the Pacific Northwest, and it is expected to continue to be a viable irrigation method for future agricultural production. With increasing demands on limited water resources and the need to minimize the environmental consequences of irrigation, microirrigation technology will undoubtedly be even more important in the future. Micro-irrigation provides many unique agronomic, water, and energy conservation benefits that address many of the challenges facing irrigated agriculture, now and in the future. Farmers and other microirrigation users (i.e., landscapers and golf course managers) are continually seeking new applications to microirrigation technologies, such as waste water reuse, that will continue to provide new challenges for designers and irrigation managers.

Microirrigation inherently offers tremendous benefits for chemical injection and application. Consistent soil water contents and wetted soil volumes tend to increase the efficiency of plant uptake of many

chemicals. Water-soluble nutrients can be injected to match crop requirements closely, increase efficiency of nutrient use, and reduce costs. Labeled systemic pesticides and some soil fumigants also may be injected with high efficacy.

Any irrigation system must be compatible with the cultural operations of a specific crop. Using microirrigation may require adapting to new or innovative cultural practices and even the development of new harvest and tillage equipment. For example, surface lateral lines can hinder traditional harvest operations by requiring pre-harvest removal of the tubing or development of a new harvester and harvesting techniques. Lateral lines can be buried, but this generally requires moving to minimal-tillage or permanent-bed systems for perennial crops.

An in-depth understanding of the unique benefits and limitations of microirrigation systems is needed to design and manage these systems successfully. As with all other irrigation methods, there are definite tradeoffs that impact irrigation scheduling, efficiency, uniformity, ecology, crop responses and economics.

4.2.7 Frost Protection in Orchards and Vineyards

In some years, many plants require at least some level of protection from cold temperature injury (frost protection) in Pacific Northwest fruit growing areas. Cold weather can occur during spring, fall or winter, although most cold protection activities for tree crops occur in the spring to keep buds, flowers, and small fruitlets above the critical temperatures at which they can be killed. On the other hand, it is often necessary to protect Pacific Northwest *vinifera* vineyards from frost in the fall to prevent leaf drop so sugar will continue to accumulate in the berries. Sometimes frost protection is needed on perennial trees (i.e., peaches, apricots) and vine crops. Very often only a few degrees rise in air temperature is sufficient to minimize cold damage. Applying water using under-tree and over-crop sprinklers to protect crops from cold temperature injury is common practice in central Washington.

Protecting orchards and vineyards from frost in spring and fall can require large volumes of water to be available for short periods of time, often creating major physical and legal problems for growers. Typical frost protection with under-tree sprinklers requires about 6.25 l s^{-1} ha^{-1} or 2.3 mm hr^{-1}. Over-tree sprinkling is more effective but requires about twice that amount.

Frost protection requires water to be delivered before it is normally required for irrigation, and many canal systems are not ready when frost occurs. In addition, most of the canal and on-farm delivery systems in the western United States are generally designed to deliver water at rates too slow to provide frost protection. They are designed to satisfy the requirements of surface furrow (rill) irrigation (max. delivery 1-1.5 l s^{-1} ha^{-1} [6-9 gpm/ac] continuous flow to farms based on total cropped area), which is also adequate for standard sprinkle systems. These flows are usually combined and used to irrigate smaller areas ("sets"), often at rates above 6.3 l s^{-1} or 5.3 mm hr^{-1} (100 gpm /ac or 0.21 in/hr). Water use is rotated over several days to cover the entire cropped area. For frost protection, many growers are drilling wells and building large ponds to hold supplemental water or unused allocations.

Water may be required for frost protection over 4 to 6 weeks in the spring. Growers may operate their systems from 20 to 30 nights for 6 to 10 hours per night in a frost protection season. As much as 250 to 500 mm of water can be applied during a single frost protection season.

Because the water is applied in large amounts at times when trees are using very little, groundwater contamination can result by leaching of chemicals and nutrients from saturated soils. Most of the applied water from frost protection is either runoff or deep percolation.

4.3 Economic Impacts of Irrigated Crop Production

The economic impacts of irrigated agriculture are large. It is well documented that irrigation increases yields and provides stability in food production over rainfed agricultural systems. Irrigated lands constitute less than 17% of the world's cultivated farmland but produce 40% of the total food and fiber.

Table 4.2 presents approximate net returns per hectare for some typical crops grown in the area surrounding the Hanford Site. For example, if 50,000 hectares (125,000 acres) were equally split between potatoes, apples, and wine grapes, the gross return based on representative current prices would be more than $430 million per year. When the economic income/employment multipliers are used, the annual value easily exceeds $1 billion.

Income/employment multipliers of 1.7 are commonly used for irrigation sector impacts. At the state level (1997 data), the total direct agricultural industry employment multiplier generated per job ranges from 1.4 to 2.5 with about 5.4 jobs generated per food processing job. By comparison, the total employment multiplier for the aerospace industry is about 2.3, for the computers and electronics industry from 2.4 to 2.7, for business services 1.7, and for fisheries 1.2.

4.4 Future Pressures for Expanded Agricultural Development

By 2050, world wide demands for increased production of animal/fish protein, food, and fiber are anticipated, despite advancements in crop breeding, genetic engineering, and other technologies. World population is projected to double to more than 12 billion people, straining already stressed agricultural resources. Current world surpluses in many commodities will not last when faced with increasing population, decreasing ocean fisheries, and the rapid loss of productive lands from soil salination and erosion. The production of pharmaceuticals from bioengineered plants and animals will undoubtedly add more pressure on the already limited (and declining) arable land base. In addition, there will be pressure to produce crops that can help reduce the world's dependence on petroleum and be used for chemical plant feedstock.

These external, formidable pressures to increase productivity will necessitate increased investments in irrigation infrastructure in many areas of the world. Intensive greenhouse culture and aquaculture also will be greatly expanded. There will be large economic and social pressures to expand production in areas such as the Pacific Northwest. Agricultural exports will continue to be important.

The most likely large areas for expanded irrigation in the Pacific Northwest are the undeveloped East High areas of the CBP and non-restricted areas within the Hanford Site. Both of these are potentially highly productive food and export capital producing areas. The environmental concerns will be large; however, the favorable growing conditions, high-quality (low-salinity) abundant water supplies, and low soil salinity make the Pacific Northwest, from a world perspective, a very desirable region for economically sustainable expansion of agriculture.

The economics of developing each area will have to be assessed. The Hanford Site may be less expensive to develop, even though much of the infrastructure is already in place for the East High area, because of easy access to water (surface and groundwater) and power. However, [public? local? regional?] pressure to develop both areas will mount as existing agricultural resources are stretched in the future. Much of any new agricultural development in these areas probably would be private rather than public.

Table 4.2. Estimated Current Yields and Value Received for Selected Irrigated Crops That Could be Produced on Hanford Site Lands Based on Approximate State Averages of Yields (Metric), Prices Paid, and Net Returns Based on Washington Agricultural Statistics Data (Chase et al. 1993)

Crop	Yield/ha	Unit Price, $	Gross, $/ha	Net, $/ha
Alfalfa	13.5 M Tons	97	1,310	230
Apples	100 bins[a]	116	11,600	1,110

Wine Grapes	9 M Tons	1,012	9,110	1,560
Average Return			6,382	734

(a) A bin of apples is approximately 450 kg (1000 lbs).

5.0 Viability of Agriculture on the Hanford Site

This section presents the procedures and results of evaluating the potential for agricultural development of the Hanford Site. In general, the site's semi-arid desert steppe climate offers deep soils, long summer days because of the northern latitude, low altitude and its attendant long growing season, good drainage, mild winters, and the easy proximity of high quality, dependable water in the Columbia River.

Rattlesnake Mountain, Yakima Ridge, and Umtanum Ridge are significant sources of cold air drainage that will have considerable impact on agronomic and horticultural crops selected to be grown in the Hanford Site because of the danger of cold temperature injury to orchard and vine crops. However, the general winds from the Pacific Ocean coming up the Columbia River Gorge to the southwest during the spring and fall have a large moderating effect on low temperatures throughout a substantial part of the region, making it a very desirable location for high-value orchard, vineyard, and vegetable crops.

The area's suitability to produce high-value crops is evident in the irrigated areas around the Hanford Site, which are primarily devoted to producing high-value, high-yielding fruit and vegetable crops. According to the 1997 Census of Agriculture, 4% of the crops produced in the United States are fruits and vegetables, but they account for more than 30% of the total farm income. Lands released for irrigated agriculture in the Hanford Site undoubtedly would also produce high-value crops that would have a major impact on the region's economy since soils and climatic conditions are similar.

Any irrigated agricultural development of the Hanford Site will undoubtedly be integrated with wildlife and ecosystem reserves and permanently restricted disposal or old reactor sites. However, making the very big assumption that water rights and environmental concerns will not be overpowering issues, three different scenarios may be envisioned for future irrigated agricultural development of the Hanford Site. These are: 1) small acreages (< 10 hectares [20 acres]) primarily used for pasture and small home gardens with most of the income from off-site sources, 2) large-scale intensive commercial agricultural developments similar to the privately developed large corporate farms that pump water directly from the Snake and Columbia rivers, or 3) a combination of the two. The large scale agriculture might also be integrated with highly intensive production in greenhouses (irrigated) and/or aquaculture.

The small farms and ranchettes near Benton City and the West Richland area probably would be typical of the types of small acreage (suburban) farming operations on the Hanford Site, if permitted. Currently, these 0.5 to 10-hectare (1 to 20-acre) operations are mostly devoted to pasture, small gardens, and landscaping, with a few small vineyards and orchards. Irrigation efficiencies are generally quite low because of poor water management due to a number of factors, but mostly due to the lack of time by the owners because of other commitments and the fact that their livelihood does not depend on the production efficiency or profitability. The poor irrigation efficiencies tend to result in excessive water moving toward the groundwater and the leaching of chemicals from septic tanks, fertilizers, and other soluble materials used on the properties.

The national trend in commercial agriculture is toward larger farms and vertical integration of farming operations with processing and marketing due to rising input costs, declining commodity prices,

and the cost of environmental regulations. Global competitiveness and the regional economics of agriculture suggest that this pattern would also be the norm for future large-scale commercial agriculture at the Hanford Site.

If the Hanford Site was developed for irrigated agriculture today, it would likely consist of large, vertically integrated farming enterprises using center pivots and microirrigation techniques. Based on current trends, the most probable crops grown on the Hanford Site would include:

1. Alfalfa, pasture, and forage crops
2. Premium varietal wine and juice (Concord) grapes
3. Tree fruits such as apples, pears, and sweet cherries
4. Field crops such as dry beans and feed corn
5. Sugar beets
6. Vegetables crops such as potatoes, asparagus, sweet corn, carrots, and onions.

Groundwater flow direction under the Hanford Site is predominately from west to east. As water is removed from the unconfined aquifers (Hanford and Ringold), groundwater flow velocities may decline in some regions of the acquifer and perhaps reverse, greatly slowing or even reversing the migration rate of various contaminant plumes, possibility allowing more time for treatment and/or radioactive decay before they reach the river systems. Excessive groundwater pumping in the interior of the Hanford Site and/or locating pumps near the river could enable surface water to be drawn directly from the Columbia River into the acquifer and the wells.

Groundwater development will require careful management and implementation of specific water withdrawal strategies (spatial and temporal distribution of the volume of pumped water) with water applied to agricultural crops. Carefully managed groundwater use potentially can be part of the contaminant control and treatment programs. Irrigation diversions should probably be a mix of surface and groundwater supplies. One scenario is that areas directly above contaminant plumes and between the plumes and the river would use river water (or deep wells in the confined aquifers), while areas to the sides could use shallow groundwater to manage hydraulic gradients. The mix of surface water and shallow groundwater pumping might avoid potential contamination of crops and keep contaminated groundwater plumes away from the river. This type of program would need to be supported by monitoring and sophisticated computer modeling of the system.

A realistic potential development scenario involving contaminated groundwater will depend on: 1) stewardship or security of the waste disposal sites, 2) health and environmental considerations to protect people in the area, and 3) use of the water in unconfined aquifers in light of contaminant movement for domestic, industrial or irrigation uses. Based in these criteria and the undesirable consequences of poor irrigation efficiencies common to most small farms/ranchettes, it was decided to base most of this analysis on only the second option of large commercial agriculture (no greenhouses) that is typical of the region.

5.1 Analysis

Determination of reasonable future agricultural uses was based on review and analysis of existing data, maps, reports and observations from DOE, Pacific Northwest National Laboratory (PNNL), WDOE, USBR, USDA-Natural Resources Conservation Service, WSU Cooperative Extension, local governmental agencies, and other sources. No new data were collected as part of this study. The analysis of potential agricultural land use patterns for the Hanford Site was generated using a GIS to collect and compare existing data.

Existing electronic digital elevation maps (DEM), digital line graphics (DLG), digital orthoquads (regional satellite and aerial photographs that have been processed to include coordinates) and other available data on soils, crops, field sizes, climate, and housing information were entered into a GIS data base. Topographic data were based on digital elevation maps in the GIS to extract information (layers) on slope, aspect, and elevation (see Figure 2.2).

Land use data were collected by viewing the orthoquads, digitizing, and entering them into the GIS data base on current land use. Land use data were somewhat verified by limited field inspections to check crop types. A 1996 baseline was selected for the land use comparisons because it was the latest date for which many data were available including orthoquads and the 1997 U.S. Census of Agriculture information.

The orthoquads covering the study area were either purchased from the U.S. Geological Survey-Earth Resources Observation Systems (USGS-EROS) Data Center or obtained from the USDA-NRCS and entered into the ArcView GIS program. Crop types and other types of land use were digitized from the orthoquads although some ground verification of crops was required. Some land use information on Franklin and Grant Counties was provided in ArcView format by the Franklin Count Conservation District and the Grant County Conservation District, respectively. The land use data were used to help create GIS layers on existing land use.

Soils data were entered into the GIS using digital copies of the existing Hanford soil survey (Hajek 1966) and USDA Soil Surveys for Grant (1984) and Franklin Counties (draft information 1999). Parts of Adams and Benton County soil surveys (1967 and 1971, respectively) were digitized and entered into the GIS. The soil classifications were merged, and a GIS soils layer was developed.

The GIS data bases were used to develop the summary of characteristics of irrigated and rainfed agriculture in the surrounding area from Royal Slope, Wahluke Slope, Cold Creek, the north slope of Rattlesnake Mountain, the southwest corner of Adams County, and the western portions of Franklin County. GIS layers of soils, slope, aspect, topography, land use, etc. were used to generate areas of common characteristics. These characteristics were used in conjunction with other reported data and observations to evaluate various land use scenarios for the Hanford Site based on comparisons from surrounding agricultural areas.

Comparisons of land use by soil classification and topography were made by overlaying the GIS layers. The information was then sorted by crop type, soil classification, aspect, slope, and elevation.

Slope is given in percent gradient as a length (i.e., meters) per 100 of the same unit lengths. Aspect, also often called exposure, is the direction is which the land is primarily facing. This is normally presented as a circle in degrees from true north (0 to 360). For example, an area that has a southern exposure, would have an aspect of approximately 180 degrees, whereas a northern exposure would be 0 or 360 degrees.

No information was directly collected on the types of irrigation systems used. However, the assumptions and much of the discussion is based on experience and current published data on the various types of irrigation systems used in central Washington and is not specific to the study area. It was assumed that the types of irrigation systems in the study area followed the regional distributions.

5.1.1 Selection of Lands for Comparison

It was assumed that basing future land use on the Hanford Site and other areas in central Washington on current agricultural development was reasonable and appropriate. It was also assumed that the current trend toward large field sizes will continue, and the management capability of growers will be substantially improved in 50 years.

Yakima Project lands were not used for comparisons in this study because the relatively small field sizes, exposures (slope, topography, and aspect) and cropping patterns are not representative of expected potential agricultural situations in the Hanford Site. CBP lands were used as the major source of data for developing land use scenarios for this project due to cropping patterns and other physical similarities to the Hanford Site. In addition, much of the CBP irrigation development is more recent than the Yakima Basin Project lands and reflects modern agricultural development strategies: they are highly capitalized with large fields and professional managers.

The Royal Slope area of the CBP has similar aspect, topography and slopes common to many areas of the Yakima Valley, but its more recent development is probably more indicative of the types of development that would occur in the Hanford Site. The Wahluke Slope (Mattawa) is a particularly appropriate example of the expected types of development because of its proximity and recent irrigation development. In addition, the Wahluke Slope has similar geology and pumps from the same unconfined aquifers. Consequently, the South District of the CBP contains most of the lands used for comparison in this study to predict likely potential future agricultural land use patterns on the Hanford Site.

5.1.2 Summary of 1996 Land Use

Land use was summarized by broad categories related to crop type as presented in Table 5.1. Some, such as the round center pivot irrigated fields were obvious from the aerial photography and were known to produce field crops although the exact crop was unknown. Center pivots are used for field crops such as potatoes, sweet corn, and alfalfa. They are very seldom used on tree and vine crops in the inland Pacific Northwest although center pivots are used on orchards and vineyards in other areas of the world. Orchards and vineyards could be distinguished from the orthoquads, but whether they were apples or cherries, wine (vinifera) or Concord grapes could not be determined. Field visits were made to verify crops in certain situations. For example, it was necessary to determine whether a vineyard was wine grapes or Concords because of the substantial water use differences (2X) between these crops.

Table 5.1. Summary of Study Area Statistics on 1996 Agricultural Land Use

Category	Acres	Hectares
Center Pivot Irrigated Field Crops	139403	56416
Other Field Crops	148252	59998
Wine Grapes	5632	2279
Orchard	51311	20765
Feedlots	511	207
Concord Grapes	578	234
Towns (Urban)	23271	9418

Field crops are irrigated by center pivots and other sprinkler systems and some are surface irrigated. Orchard and vine crops are typically irrigated by sprinkler and microirrigation methods. Microirrigation and other pressurized water application techniques are more appropriate for vine and tree crops, in fact, the rigorous water management requirements of wine grapes in this region make microirrigation the system of choice of most growers. Figure 5.1 shows current land use on the Hanford Site and surrounding agricultural areas. It is evident that center pivot irrigation is a major water application method.

Analysis of crops based on soil type, aspect, and percent slope shows a consistent pattern of most irrigated production occurring on silt loams, sandy loams, and loamy sands. Because of the regional stratigraphy, the majority of crops are produced on southwest, south, and west sloping lands (a factor that makes the region so suitable for orchard and vineyard crops). In addition, most crops are grown on slopes of less than three percent, although a substantial portion of the orchard crops are on slopes of 10% or less because of cold air drainage concerns. Much of the lands within the Hanford Site have the same characteristics and would be expected to produce similar crops with similar yields to the surrounding lands.

As noted, the majority of irrigated agriculture in the study area is located on loamy sand, sandy loam, fine sandy loams, and silt loam soils. These soil types are common on the Hanford Site (Figure 2.1). Table 5.2 summarizes land use by soils for the study area. Some relatively small areas of cobbles and stoney soils occur on the Hanford Site; however, as seen in Table 5.2, these are seldom farmed because of the very low water holding capacities.

Slope and aspect are important considerations in the long-term production of orchard and vineyards in central Washington. Center pivot irrigation systems are not recommended for use on general slopes exceeding 15%. Figures 5.2 and 5.3 show the slope and aspect characteristics of lands within the study area that includes the Hanford Site. As can be seen, numerous similarities exist between slope and aspect conditions on the Hanford Site and the surrounding agricultural lands. Soil types are also similar.

Figures 5.4 and 5.5 graphically summarizes the percent slope of the study area and the Hanford Site, respectively. While the study area includes the Hanford Site, there is substantially greater area in the study area. The Hanford Site has lower general slopes, which is desirable for irrigated agriculture because it reduces soil erosion and decreases pumping costs.

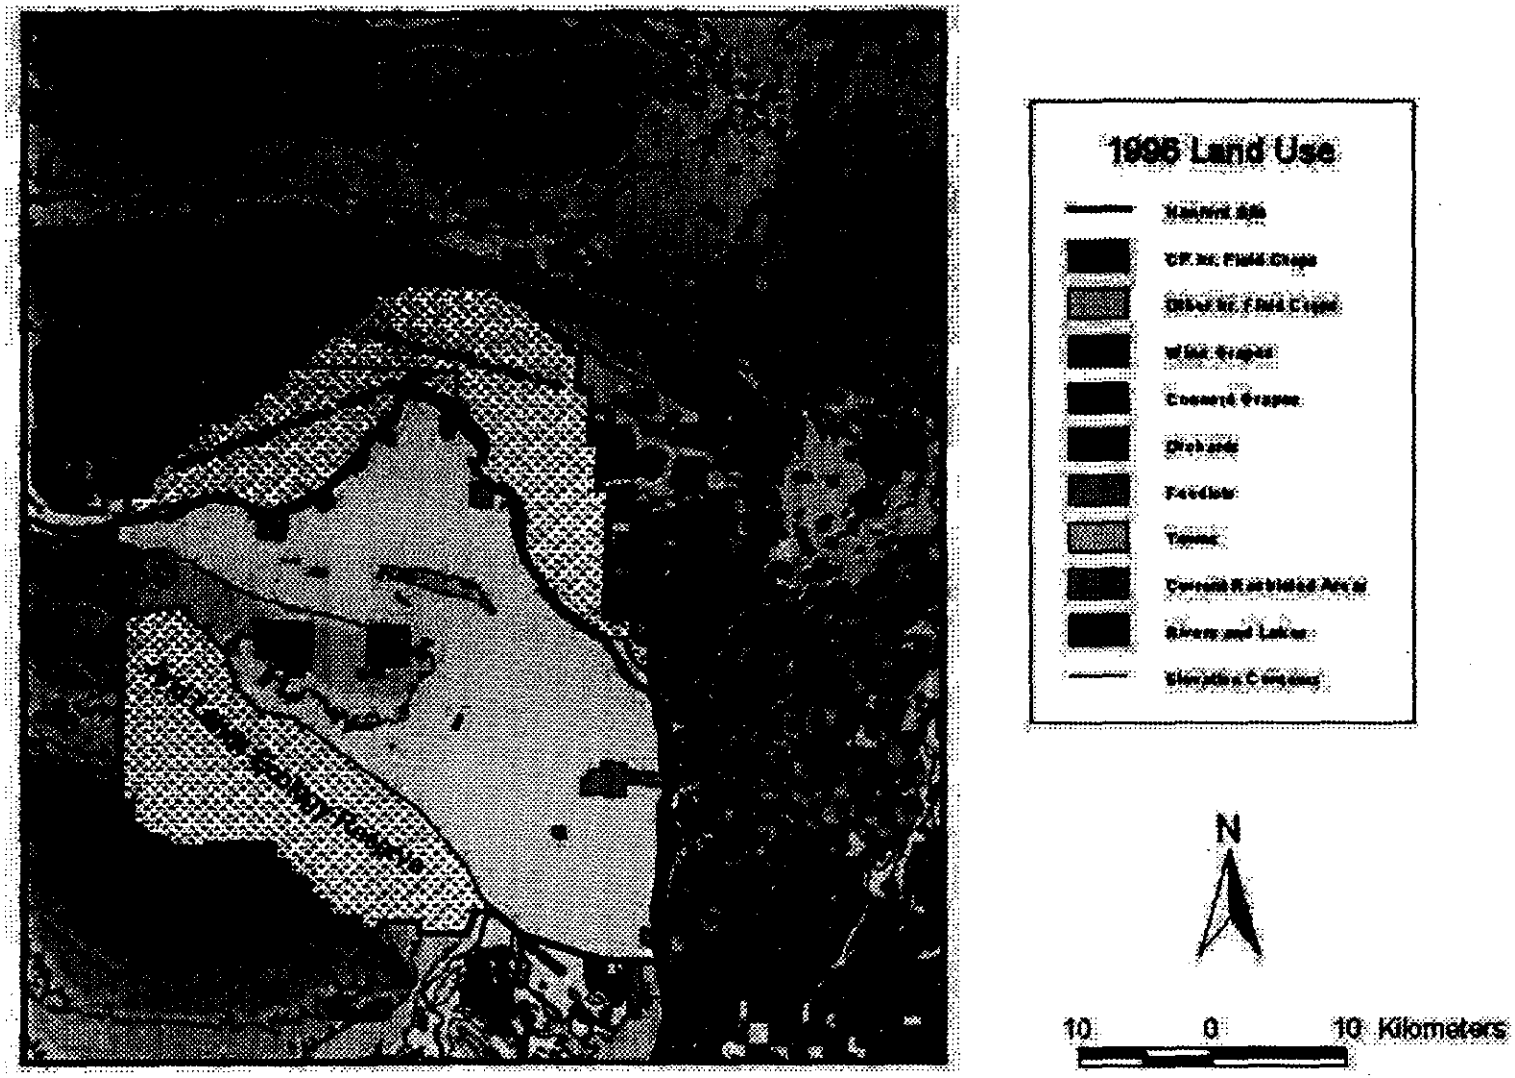

Figure 5.1. Land Use on the Hanford Site and the Surrounding Area in 1996. The white areas are range land in dry land wheat production.

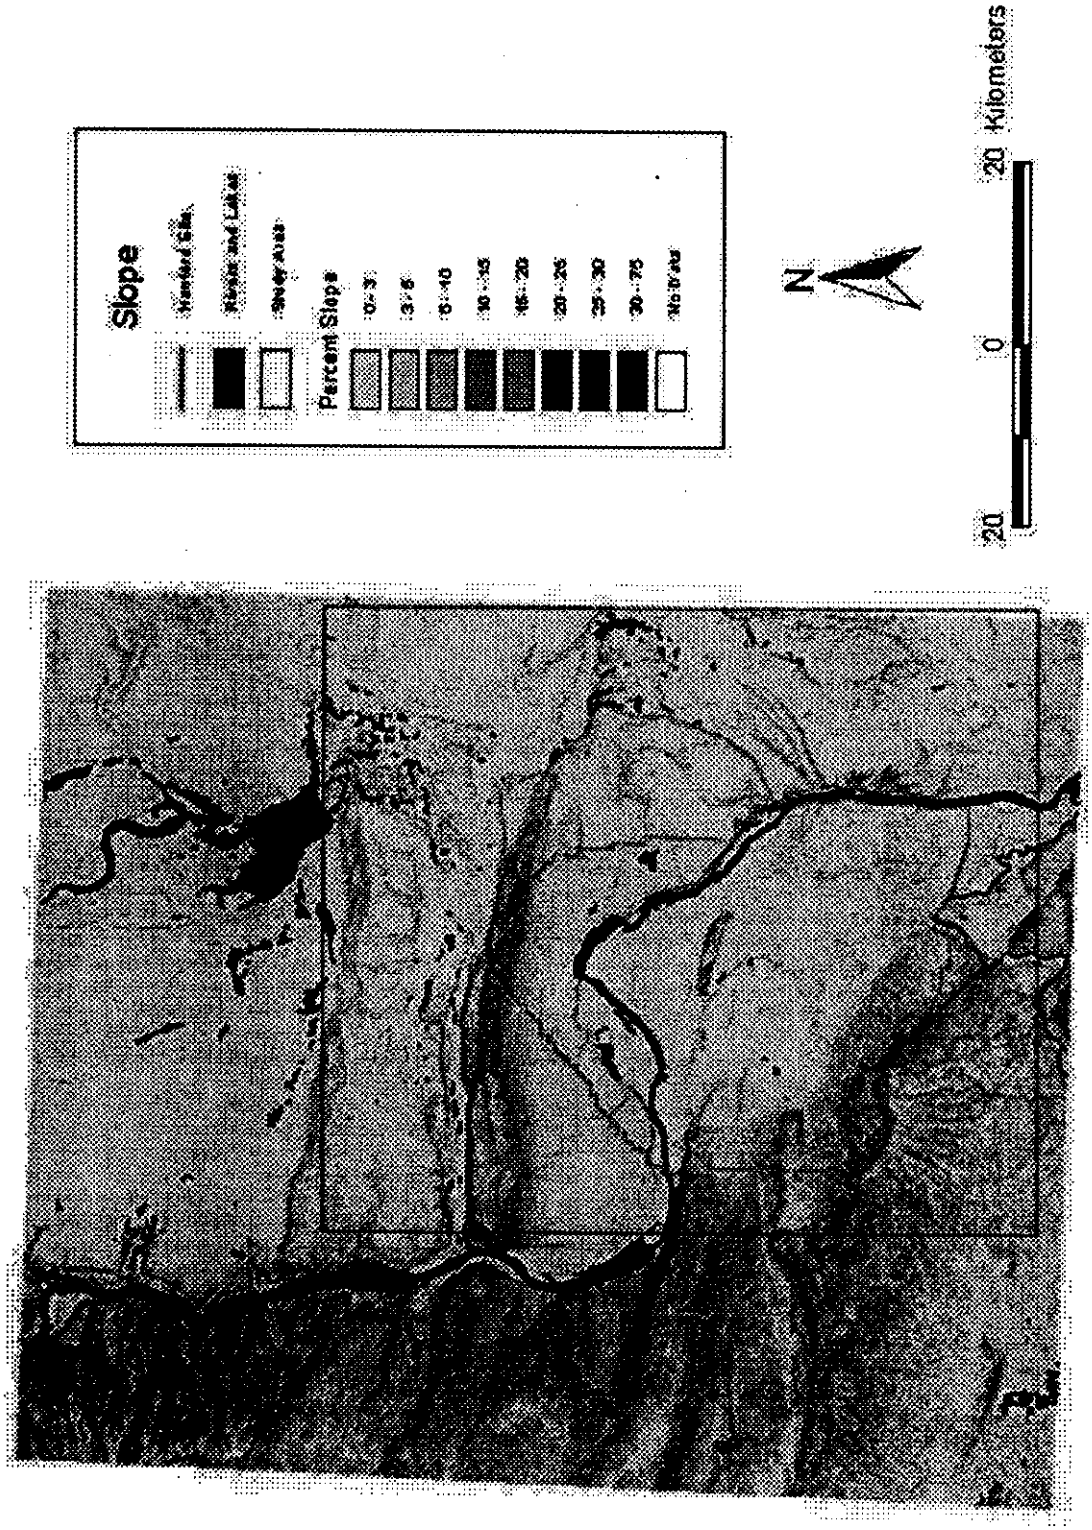

Figure 5.2. Map Showing the Slope Analysis of the Study Area Including the Hanford Site

Table 5.2. Summary of Irrigated Agricultural Land Use in the Surrounding Areas by Soil Types Found Within the Hanford Site

Soils	Hectares				
	Center Pivots	Trees	Wine Grapes	Concord Grapes	Field Crops
Loamy Sand	33403	4588	189	48	6433
Sand	6077	580	8	0	836
Fine Sandy Loams	12486	320	10	0	146
Sandy Loam	28612	6750	342	185	25940
Silt Loam	7953	5530	1048	0	15666
Cobbly Loam	74	15	0	0	3
Cobbly Sandy Loam	619	165	114	0	484
Stony Silt Loam	32	22	0	0	92
Cobbly Silt Loam	103	149	77	0	10
Stony Loam	242	0	0	0	28

Figures 5.6 and 5.7 graphically summarize the aspect characteristics of the study area and the Hanford Site, respectively. When examined in conjunction with Figure 5.3, it is obvious that aspect would not deter future agricultural development of the Hanford Site. For example, the Hanford Site has numerous similarities to the very productive Wahluke Slope area.

5.1.3 Recharge Rates

Under irrigation, recharge to the groundwater depends on the application efficiencies of each irrigation and the uniformity of water applications, which are largely functions of system design, management, and environmental conditions (e.g., wind). Recharge is greatly affected by soil texture and soil chemical properties as well as crop cover and rooting extent. Deep percolation losses (artificial recharge) will vary by crop because of management and ancillary uses of the irrigation systems such as for frost protection or agrichemical applications applied for cultural reasons even though soil water levels may already be high.

Application efficiency is defined as the ratio of the average depth of irrigation water infiltrated and stored in the root zone available for plant use to the average depth of total irrigation water applied, expressed as a percentage. Application efficiencies will change during the irrigation season, and calculated values may even exceed 100% under soil water deficit conditions. Dividing the required depth of water to be applied to refill the root zone by the decimal value of the application efficiency will give the required diversion of water to the field.

Applied water may be lost by surface runoff, deep percolation, and soil evaporation (typically 2-5%). Surface runoff may be as much as 50% of the applied water with poorly designed and managed systems. However, surface runoff from a field often collects in small off-site depressions and drainage ways, and some of the runoff returns to the rivers and streams. Much of it infiltrates the soil and contributes to the

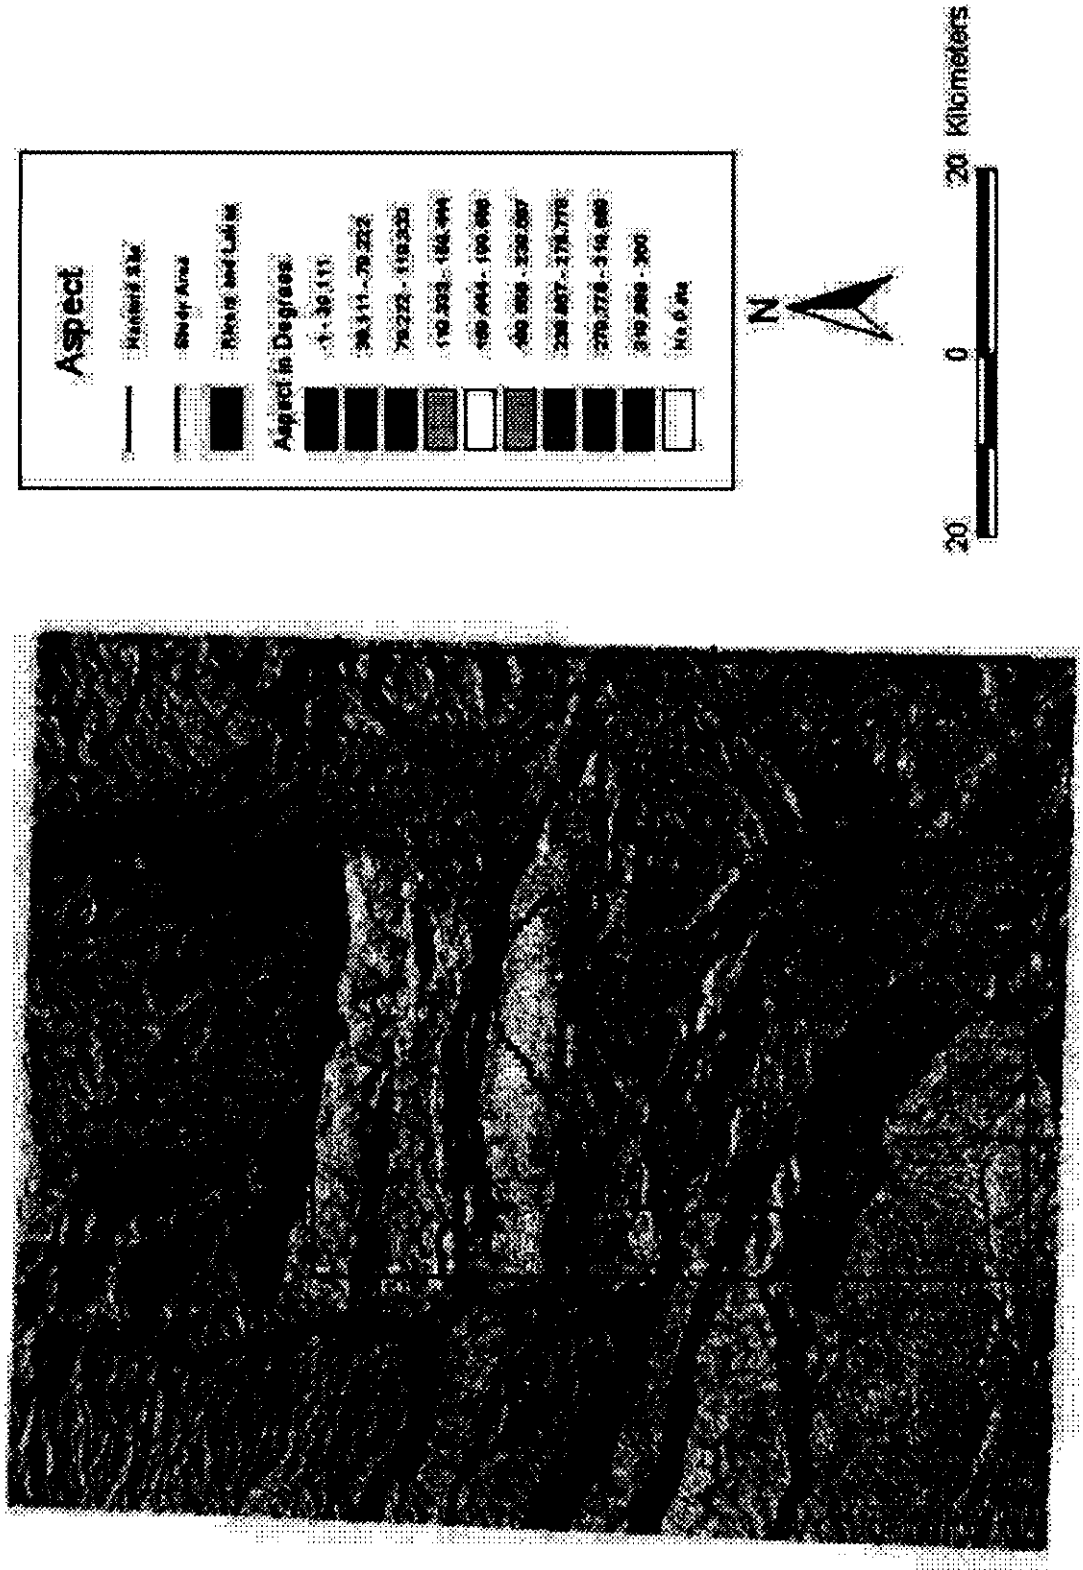

Figure 5.3. Map Showing the Aspect Analysis of the Study Area Including the Hanford Site

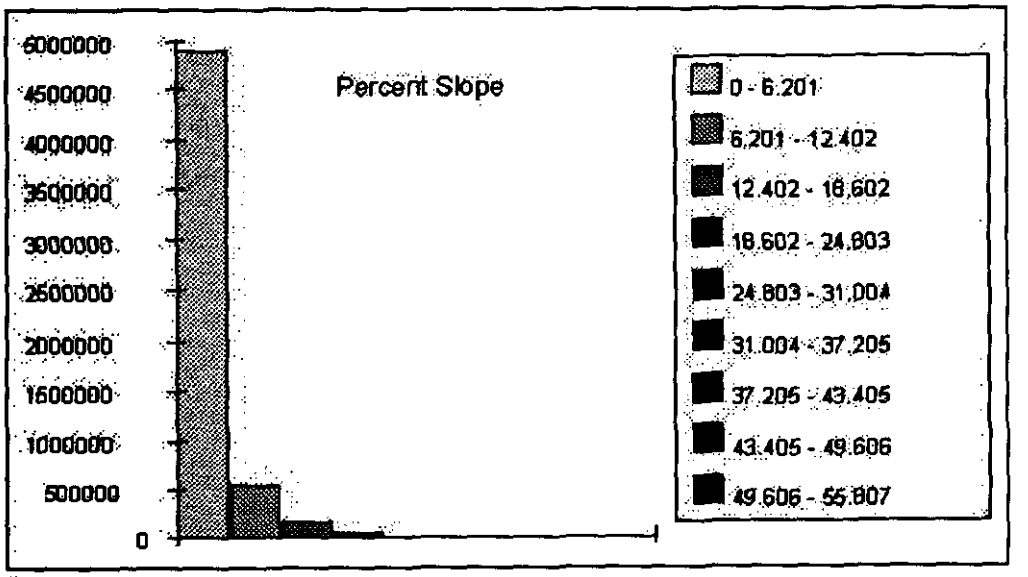

Figure 5.4. Summary of the Slope Characteristics in Percent Slope for the Study Area

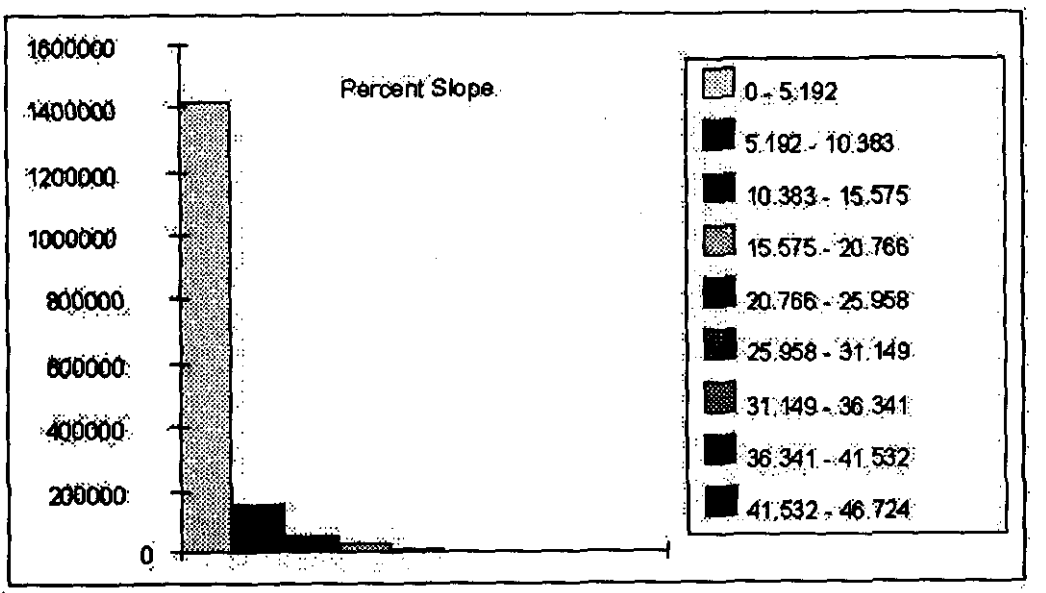

Figure 5.5. Summary of the Slope Characteristics in Percent for the Hanford Site

deep percolation towards the groundwater in the locale. Small wetland areas are often indications of where sustained runoff has percolated towards the water table. Consequently, estimates of deep percolation from irrigation over a broad areas often combine much of the runoff into the recharge calculations (i.e., 80% of losses). Since little surface runoff would be expected to return directly to the river on the light, sandy soils on the Hanford Site, this is a reasonable assumption for irrigated development in that

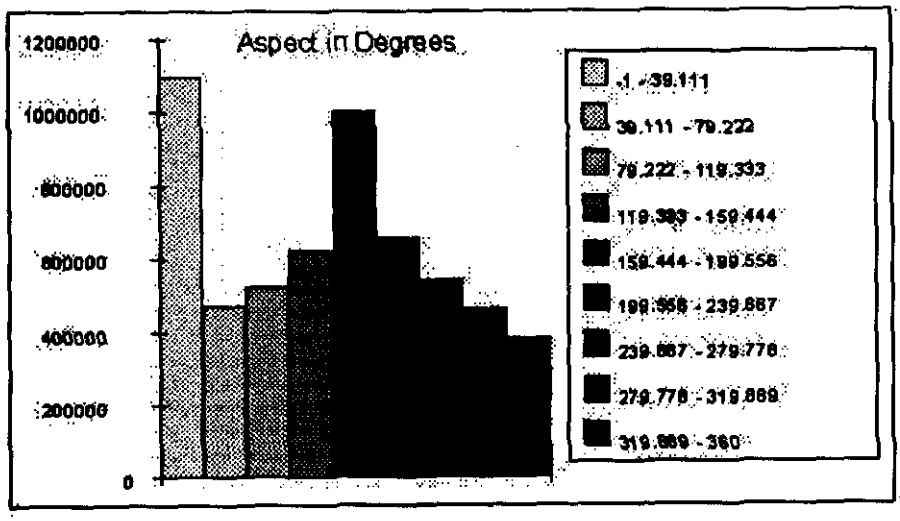

Figure 5.6. Summary of the Aspect Characteristics in Degrees for the Study Area

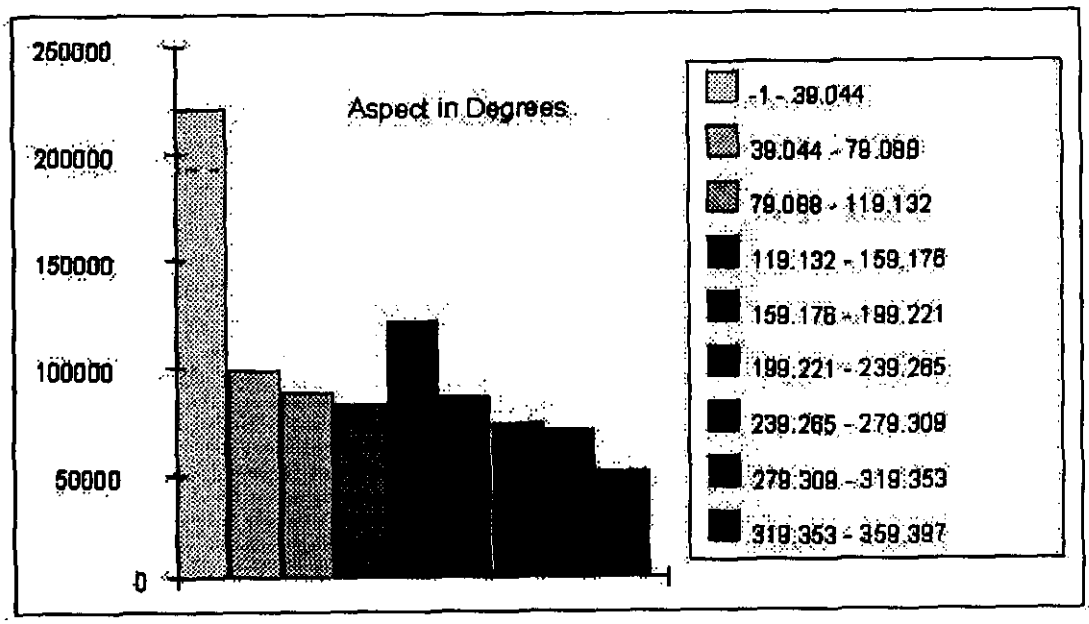

Figure 5.7. Summary of Hanford Site Aspect Characteristics in Degrees from North

area as well. However, estimates of deep percolation losses based on current irrigation practices will probably be higher than what will be the case in 2050 because of growers assumed increased management capability and improved technology.

Some deep percolation is always necessary (generally less than 2% of total annual water application in central Washington) under irrigated conditions to prevent salination of soils (leaching requirement). However, excessive amounts of deep percolation also carry fertilizers and other chemicals towards the groundwater and is a cause for concern.

It is highly probable that any future irrigation development on the Hanford Site would be with pressurized irrigation systems because of the very sandy soils and undulating topography Water supply to fields would be by pressurized pipelines rather than canals or ditches. Thus, any deep drainage losses from the water delivery system would be extremely small and not a major factor except in the infrequent and brief event of a pipeline structural failure.

The average on-farm delivery is about 1.13 ha-m/ha (3.7 acre-feet/ac) to all crops in the CBP. Average annual crop irrigation requirements are estimated at 0.83 ha-m/ha (2.71 af/a) (Montgomery Water Group 1997). This is a difference of about 305 mm (12 in.) in losses, but the percentage of this approximate value that is runoff compared to deep percolation (recharge) is not known since much of the surface runoff is captured and reused.

It is extremely difficult to obtain reasonable values for deep percolation because this is the only value in the water balance that cannot be measured or calculated accurately. Consequently, deep percolation is the term that contains all the errors from the other parameters. Estimates of deep percolation range from less than 25 mm (1 in.) to more than 250 mm (10 in.) per growing season depending on the crop and water management practices. It is known, however, that most of the deep percolation losses occur early and very late in the growing season with very little during peak water use periods in between. Nevertheless, the values for irrigation in Table 5.3 are probably fairly typical for current central Washington conditions during the growing season. These values do not including chemigation, frost protection, crop cooling or other ancillary water applications.

Current estimates of seasonal deep percolation (water lost below the plant's root zone) depend on soils, crop, soil and water salinity, type of irrigation system used, and the level of water management. Deficit irrigation strategies can reduce deep percolation within the growing season whereas using water for frost protection in orchards and vineyards can be a major source of water loss. Properly managed overcrop sprinklers used for crop cooling will have almost no impact on deep percolation; most water is lost by evaporation by design and intent.

Depending on management, center pivot irrigated potatoes tend to have most of their deep percolation occur in the early spring or late fall with very little, if any, during the middle of the summer. Because of the necessary strong emphasis on water management of wine grapes for winter hardiness, wine grapes will have almost no deep percolation (background rates), unless overcrop sprinkling is used for frost protection in the spring and fall.

Table 5.3. Comparative Average Seasonal Application Efficiencies for Various Irrigation Methods and Estimates of a Reasonably Attainable Percent of the Applied Water Resulting as Deep Percolation With Current Technology on Sandy Loam Soils in Washington (assuming irrigation systems are not also used for other purposes)

Method		Application Efficiency		Estimated % of Applied Water as Deep Percolation	
		Range	Average	Range	Attainable[a]
Surface:					
	Furrow (rill)	35 - 60	45	10 - 50	25
	Furrow w/land leveling	50 - 65	60	10 - 40	15
	Furrow w/automation[b]	75 - 80	75	10 - 20	15
	Furrow w/tailwater re-use	75 - 90	85	10 - 20	15
Sprinkle:					
	Hand-move	60 - 70	65	20 - 30	25
	Wheel-move	60 - 70	65	20 - 30	25
	Center pivot/Lateral Move	60 - 85	75	10 - 30	10
	Precision System	80 - 95	90	2 - 10	2
	LEPA	85 - 98	90	2 - 10	5
	Traveling gun	55 - 70	60	20 - 35	20
	Solid set	60 - 80	70	10 - 30	20
Microirrigation:					
	Drip/trickle	80 - 98	90	2 - 20	5
	Micro-sprayers	80 - 90	85	2 -15	8

(a) Percentage of deep percolation attainable under reasonably good current management practices.
(b) Automated surge flow furrow irrigation.

The owners of future suburban-type developments in the Hanford Site would likely insist on irrigation using groundwater sources for at least small portions of their properties. It is highly probable that irrigation efficiencies would still be low. In addition, use of shallow groundwater for domestic purposes, which is typical for such developments, may be difficult because of real or perceived contaminant problems. Water use requirements and distribution are extremely difficult to estimate for this option. If these developments were fully irrigated, recharge rates would be expected to be at least twice that of large-scale agricultural developments.

Deep percolation under furrow (gravity surface) irrigation on the sandy soils and topographic conditions in the Hanford Site will be much larger than presented in Table 5.3. These losses could be reduced somewhat with short runs and surge flow techniques, but these options are not economically competitive with pressurized sprinkler or microirrigation methods.

6.0 Discussion

The current high-value irrigated agricultural production on neighboring lands near Mattawa and east of the Columbia River in Grant and Franklin counties with similar slope, aspect, and soil textures s have clearly demonstrated that a considerable portion of the Hanford Site would likewise be quite valuable for large-scale farming of crops such as potatoes, fruit trees, and wine grapes. Some sloping areas would be especially suitable for orchard and vineyard crops whereas many of the lower elevation areas are appropriate for multi-year rotations of vegetable crops. The high value of these crops (see Table 4.2) would provide the economic ability to adopt advanced technologies and high-level management. Based on current trends and conditions, economics dictate that farm sizes would be large.

It is highly likely that precision agriculture and precision irrigation (center pivots and microirrigation) technologies will be standard operating practices in large-scale agriculture in the future. Portions of these advanced technologies are currently in development but have already demonstrated it is possible to greatly minimize chemical use and deep percolation. However, they will require excellent management, sophisticated control systems, and other resources available in highly capitalized, professional operations. Scientific irrigation scheduling and a supporting network of weather stations must be included.

New advances in microirrigation and self-propelled linear move and center pivot systems will probably have the most promise for future irrigation of field and vegetable crops on new lands like the Hanford site that have light soils and undulating topography. Microirrigation would be most appropriate for tree and vine crops.

The dry climate, long daylight hours, and the ability to control soil water levels throughout the season, make cultivation of specialty crops (e.g., pharmaceuticals, seed crops, herbs, special oil crops) highly likely. The capability to implement exact water and agrichemcial management scenarios to achieve specific quality parameters in a particular crop will allow growers to better respond to economic conditions and produce high-quality crops for niche markets. Pharmaceuticals from bioengineered plants and animals likely will be an important part of the future of agriculture in the region. Likewise, aquaculture may be important considering its intensive nature (small area required), the abundant water supply from the Columbia River, and the potential to apply wastes to nearby agricultural areas economically.

Potential exists to integrate confined livestock feeding and irrigated crop production. With careful management, livestock wastes could be applied to the land as a nutrient source.

Irrigated crops also would be a potential winter food source for migratory water fowl. Other wildlife (e.g., deer and elk) may feed all year on crops and may cause substantial damage to orchard and vine crops. Thus, it may be necessary to compensate growers for some level of damages from wildlife feeding as an incentive for development. Leasing hunting rights to private groups would also help offset crop loss due to wildlife.

Salination of the irrigated soils is not expected to be a problem, but soil erosion could be significant without proper management. Based on a large body of research and experience in the CBP, leveling fields to improve irrigation uniformities is not generally recommended for Hanford Site lands because it would cause long-term soil fertility problems.

Figure 6.1 shows the potentially irrigable lands within the Hanford Site, excluding the wildlife refuges on the north side of the Columbia River, and probable types of crops. Land use is indicated as either most probably field crops or most probably orchard and vineyard based on the land use patterns surrounding the Hanford Site. The areas defined as field crops would probably be irrigated with center pivots and could produce a wide variety of crops. Orchards and vineyards would likely be microirrigated and could be intermixed within the center pivot areas. Likewise, the designated orchard/vineyard areas also could be planted to field crops irrigated with center pivots. The crops produced under center pivots would most likely be part of multi-year potato cropping rotations and not trees and vines.

Analysis of the land use data shows that the total irrigable area (not including buffers) including both the north (wildlife refuge areas) and south side of the river is about 120,380 hectares (297,442 acres). The total (entire site) classified as suitable for field crops is 78,570 hectares (194,143 acres) whereas orchard and vine crops are 14,665 hectares (36,236 acres). Near the northern boundary, 8360 hectares (20,660 acres) is ideally suited for orchard and vine crops. Over the entire site, 27,160 hectares (67,116 acres) was classified as unsuitable for irrigation, not including buffer areas. One kilometer-wide buffers were excluded from all rivers and lakes (20,100 hectares [49,681 acres]) and current restricted areas (16,280 hectares [40,239 acres]). The state and federal wildlife reserves account for 35,740 hectares (88,315 acres).

If the wildlife areas are excluded and just the south side of the Hanford Site is opened for agricultural development (as shown in Figure 6.1), 6300 hectares (15,576 acres) are classified for tree and vine crops and 62,640 hectares (154,775 acres) for field crops. The 25,950 hectares (64116 acres) on the side of Rattlesnake Mountain are classified as unsuitable for irrigation and are totally within the Arid Lands Ecology Reserve (30,910 hectares [76,380 acres]).

6.1 Impacts of Development

A number of unresolved issues will have a large impact on future land use for the Hanford Site. Population growth in the western United States is projected to increase by 30% by 2020 (Western Water Policy Review Advisory Commission 1998). The populations of Washington, Oregon, and Idaho are expected to increase by more than 30% by 2020, which will place additional pressures on the region's water resources for industry, domestic use, agriculture, recreation, and power generation.

A crisis in water demand that continues to worsen has been created by unhealthy trends in aquatic ecosystems and water quality, endangered species regulations, sharp population growth in the region, international and interstate agreements on water allocations, unfilled Native American water claims, and an agricultural economy in transition. Global warming may have a large affect on the availability of future water resources.

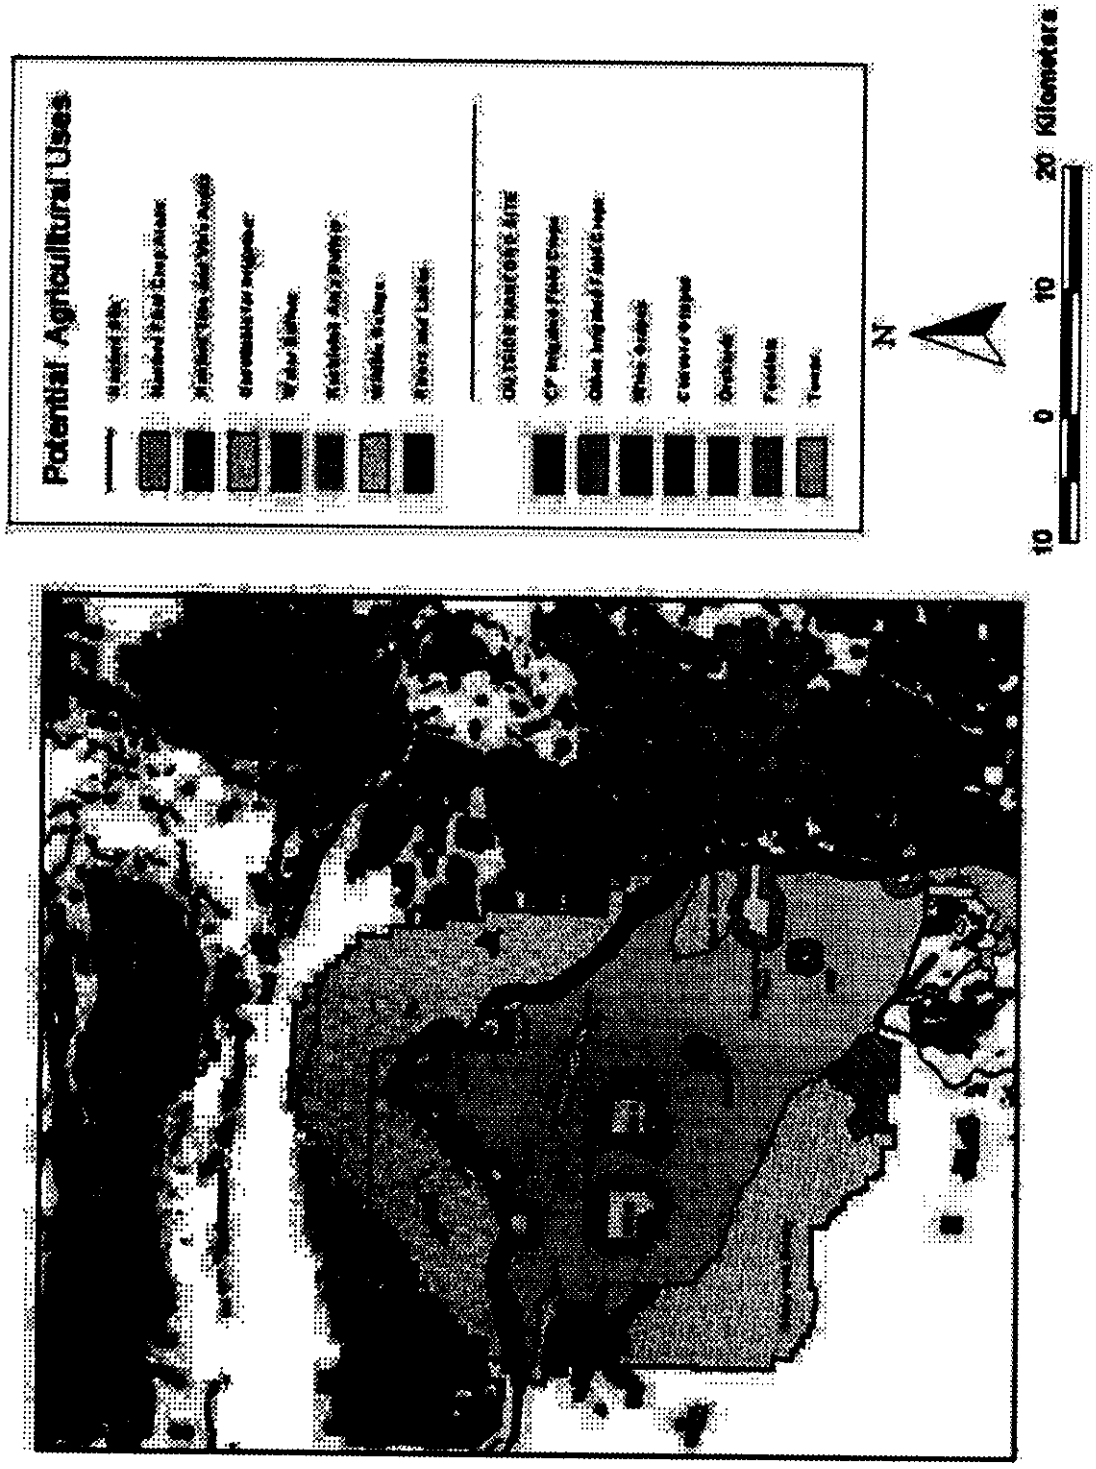

Figure 6.1. Map Showing Potential Agricultural Land Uses on the Hanford Site

Several salmon and steelhead fisheries in the Columbia River system are listed as endangered by the federal government, which will have a huge impact on current and future development of regional water resources. Reduced flows in the river system caused by irrigation withdrawals may have a negative impact on hydropower generation. Any additional future development must consider these and other environmental issues that will arise as well as potential mitigating measures.

Based in the CBP experience, irrigation can increase wetland areas, which would benefit migrating birds and local wildlife. However, increased wetlands would probably not occur under more precise and improved irrigation management. Nevertheless, large-scale agricultural activities would provide a considerable food source and foraging area for migratory and local birds during the fall and winter months.

The Hanford Site is part of the oldest and largest old-growth desert ecology community in eastern Washington. However, the future status of the Arid Lands Ecology Reserve or the wildlife refuge areas were not considered in this study. Ecosystem issues could have a significant impact in which lands might be developed for agricultural uses such as livestock grazing and crops such as wine grapes and orchards.

Migration of deer and elk herds on the Hanford Site will probably not be compatible with irrigated agriculture. They and smaller wild animals and birds would certainly suffer under a small farm/ranchette scenario because of the potential large number of fences as well as abundant dogs and cats, based on the current model. Large-scale agriculture would be more compatible, although it is likely growers would request compensation (under current state laws and regulations) for crop damages caused by the large herds. It is probable that critical areas, defined by county law under the state Growth Management Act as wetlands, areas prone to landslides, and fish and wildlife conservation areas, would be kept as permanent wildlife habitat.

It is assumed groundwater contaminants resulting from past industrial activities on the Hanford Site will still be a problem if and when the site is opened for agricultural or other development in the future. In addition to radioactive materials (i.e., tritium, iodine-129, uranium, technetium-99, strontium-90), significant problems are toxins and other chemicals (heavy metals, trichloroethylene, chloroform, carbon tetrachloride, or any exotic persistent organics such as PCBs, dioxin, etc.) that shouldn't be deposited on agricultural lands. If these contaminants cannot be kept from the applied water, then soil filtration, biological treatment, or other appropriate specific treatment processes may be required before the water is applied to crops. If these industrial contaminants cannot be removed, they must not be applied to any agricultural crop because the perceived implications of unhealthy foods could be transferred to all Northwest crops and result in huge financial consequences. It is entirely likely that water sources would be limited to upgradient unconfined groundwater, the Columbia River, and deep confined aquifers.

6.2 Water Rights

Wallace Stegner (1994) said that "water is the true wealth in a dry land." This is certainly the case in central Washington, with its high-quality, abundant flows of the Columbia River. The control over who gets water at what time for what use is a very emotional issue with huge environmental and economic

impacts. The issue of changing the control paradigm of water in the West is a priority of many environmental and conservation groups and is being bitterly challenged by pro-development and agricultural interests.

Water rights in Washington are a mix of prior appropriation and riparian doctrines depending on location. Arid areas east of the Cascades are primarily prior appropriation. Water rights are determined by the Superior Court and regulated (administered) by WDOE. WDOE is also responsible for developing regulatory programs and enforcing water quality laws and regulations.

However, the issue of water rights and the control of water in Washington is in a state of flux. There is little chance that the existing water rights structure will exist when, or if, the Hanford Site is developed for agriculture. The state government is currently proposing sweeping changes to existing water rights law in Washington. Regional water markets based on the true economic value of water will likely appear in many areas and influence water distribution. The federal government is rethinking its water policies and priorities in the western United States, which Congress will undoubtedly act on in the next decade. Endangered species regulations are accused of abrogating state's authority on water issues. Interstate and international agreements combined with societal needs for flood control, navigation, and electrical power will exert strong influences. The courts, politics, and public opinion will shape the final outcome and determine how we manage our precious water resources. Whatever the result, obtaining a reliable and adequate water supply will be crucial for any future economic development of the Hanford Site, agricultural or otherwise.

6.2.1 Hanford Site Water Rights

Section 4.3.3.1 of the Final Hanford Comprehensive Land-Use Plan Environmental Impact Statement (DOE 1999) provided the following statement on water rights in the Hanford Site:.

"The DOE's past and present water withdrawals at the Hanford Site are based on the "Federal Reserved Water Rights" doctrine. This doctrine, developed as case law from U.S. Supreme Court rulings, holds that the Federal government, when it withdraws public domain lands for the purpose of the creation of a Federal reservation, necessarily withdraws unappropriated water rights sufficient to meet the needs for which the reservation was created. The date of priority of these rights is the date of creation of the reservation. In the case of the Hanford Site, this date is 1943. It is the general rule that Federal reserved water rights cease to exist when the Federal reservation ceases to be used for the purposes for which it was created. The limited exception to the rule is reflected in the U.S. v. Powers, 305 U.S. 527 (1939), wherein the Court allowed that a purchaser of agricultural land on an Indian reservation may be entitled to a portion of Federal reserved water rights where the use of the property did not change.

The Federal government has not established its own water rights regulation. Instead, it uses the regulatory procedures outlined in the State water rights laws to document the extent of its rights. There has been no general adjudication in the State of Washington of the water rights in the Columbia River and, therefore, the reserved water right of the Hanford Site has not

been documented. The quantity of that right, however, would be equal to the maximum amounts used at Hanford during its operation, up to the amount of unappropriated water in the Columbia River as of 1943.

In a report titled, Hanford Land Transfer (Washington Department of Ecology 1993), Ecology indicated that if water rights were attached to privately owned parcels of land acquired in fee by the Federal government for the creation of Hanford in 1943, those water rights may continue to be attached to these parcels of land. Ecology has indicated that it has not taken action to extinguish these rights, although under Washington law appropriative water rights are subject to be extinguished if unused for a period of five years.

Further complications exist regarding non-Federal water rights claims at the Hanford Site. The first is the issue of groundwater contamination at Hanford. The second is that the date for filing a water rights claim in the Hanford sub-basin, for both Columbia River water and groundwater, expired in 1992. No claims for water rights under state law appear to have been filed within the required time period (NPS 1994).

7.0 Conclusions

The area known as the Hanford Site in south central Washington has all of the components that favor successful irrigated farming. Environmentally, it has good soils, a mild climate and abundant high-quality water supplies. Economically, the Hanford Site benefits from the excellent transportation systems (roads, rail, and barge), extensive power systems, and the already well developed agricultural processing, supply and service infrastructure that supports the regions agriculture. Constraints to agricultural development of the Hanford Site are political and social.

In the event that irrigated agricultural land use is permitted, it is anticipated that only parts of the Hanford Site will likely be developed as irrigated agriculture in conjunction with wildlife and ecosystem reserves and the permanently restricted areas. A staged development scenario that integrates all uses may be the best process.

Potential land use and economic scenarios favor intensive large-scale agricultural development growing orchard and vegetable crops. Irrigation technologies would be limited to highly efficient methods such as center pivots and microirrigation. Precision agriculture techniques are likely to be more efficiently applied on large fields under limited ownership/management with resulting ecological benefits. These scenarios produce the fewest environmental problems with groundwater contamination and the flexibility to fit within eventual DOE operational strategies for groundwater management.

If portions of the Hanford Site are ever developed for irrigated agriculture, future development probably would focus on large-scale commercial enterprises that can afford to import clean water and employ high levels of water management to minimize deep drainage. Any suburban or small ranchette developments should be carefully examined in light of water safety concerns (real or imagined) and their generally poor levels of water management.

Numerous future advances in irrigation and resource conservation techniques are anticipated. Improved systems will be the norm in 50 years. Scientific irrigation scheduling and a network of supporting weather stations must be part of the total system for water and pest management of any future agricultural development on the Hanford Site. Because of the light soils and widely variable topography, new advances in microirrigation and self-propelled irrigation (i.e., linear move and center pivot systems) will probably have the most promise for future irrigation of new lands such as the Hanford Site.

A reasonable estimate of deep percolation in 50 years would be the current best achievable levels of the best technology: from 2% to 15% of the applied water not including water applied for frost protection or other non-irrigation uses. However, because of lack of uniformity in water distribution, soil types, topography, and imperfect management decisions, the deep percolation loss (recharge) is almost always larger than the required leaching fraction to prevent soil salination (about 2% of annual water delivery to the farm). Recharge from irrigation would probably range from 50 to 500 mm/yr compared to historical estimated natural recharge rates ranging from 0.1 to 10 mm/yr, even with the expected improved technologies and systems. Wine grapes would have the least recharge while field crops would potentially have the greatest deep percolation losses.

Extreme care must be exercised to avoid even the appearance that crops are irrigated with or otherwise exposed to toxic and radioactive substances, even at very low concentrations scientifically considered safe for humans. Agriculture is a large portion of the economy of Washington and a major source of exports. The delicate national and international trade balances would be easily upset by even unfounded rumors of contamination, resulting in huge economic consequences for agriculture throughout the Pacific Northwest.

The economic and political drivers can be anticipated to expand irrigated crop production in the Pacific Northwest. The most likely areas for future irrigated agriculture expansions are the undeveloped East High areas of the CBP and non-restricted areas within the Hanford Site. If environmental, water supply, and other concerns are met, it is probable based on current trends that both areas would be developed using private funding sources rather than public sources.

Obtaining adequate water rights for any irrigated development will be a major issue. Many of the salmon and steelhead fisheries in the Columbia River system are listed as endangered by the federal government. Thus, ecological consideration will have a significant impact on current and future development of regional water resources.
