All discoveries and changes (i.e., physical modifications, new construction, new procedures, procedure modifications, and tests and experiments) receive an unreviewed safety question (USQ) screening and, if required, a USQ evaluation. Screenings and evaluations are performed in accordance with Section 2.23, "Identification and Resolution of Unreviewed Safety Questions," of the PFP Administration Manual, FSP-PFP-5-8. Section 2.23 of the Administration Manual is used in conjunction with HNF-PRO-062, *Identifying and Resolving Unreviewed Safety Questions*. HNF-PRO-062 is the governing procedure for implementation of an unreviewed safety question process necessary to comply with DOE Order 5480.21, *Unreviewed Safety Questions*.

9.0.1.2.5 Receptor Location for Dose Consequences. The radiological dose consequences resulting from the postulated accident scenarios were calculated at the location of the maximally exposed onsite and offsite receptors as determined using the GXQ code [described in *GXQ Program Users Guide* (Hey 1993a)]. The receptor location was dependent upon the type of release applied to the accident scenario. For the accident scenarios at the PFP, four different types of releases were applied: 1) elevated release (release occurs from the 291-Z-1 stack), 2) ground level release (release occurs from openings in a building), 3) buoyant plume rise release (waste drum fire outside buildings), and 4) point source ground level release (waste drum rupture outside of buildings and collapse of the 232-Z Building in a seismic event). The location of the onsite and offsite receptor was determined to be as follows:

Type of Release	Onsite Receptor Location	Offsite Receptor Location
Elevated	242-S Facility	12.5 km west of PFP
Ground-level	272-WA Facility	12.5 km west of PFP
Buoyant plume rise	U-Plant	17.4 km north-northwest of PFP
Point-source ground-level	272-WA Facility	12.5 km west of PFP

9.0.1.2.6 Chapter Layout. This chapter consists of four more sections and eight appendices. Section 9.1 presents the analysis of events that do not breach containment or confinement. Section 9.2 presents the analysis of events that are generally thought to have a potential for breaching the protection systems. These include natural phenomena hazards, fires, and

explosions. Section 9.3 discusses the methods used to calculate radiation dose, and Section 9.4 presents the risk guidelines and evaluation. Appendix 9A documents the preliminary hazard analysis initially performed for the PFP. Appendix 9B provides a discussion of release fractions for plutonium powders dispersed from a seismically unqualified glovebox. Appendix 9C presents a model for estimating the number of grams of plutonium released from the PFP to the environment. Appendix 9D documents a hazards and operability (HazOp) analysis performed for the plutonium-bearing solution stabilization process. Appendix 9E presents the calculations related to rupture of a compressed gas cylinder. Appendix 9F presents the Preliminary Hazards Analysis performed for the thermal stabilization of "clean" plutonium oxide. Appendix 9G presents the Preliminary Hazards Analysis performed for the thermal stabilization of non-product quality oxide material. The plutonium-bearing solution and plutonium oxide stabilization processes were added to the PFP after the PHA in Appendix 9A was performed. Appendix 9H presents a hazards analysis evaluation of plutonium metal opening and stabilization.

Figure 9-1 provides a flowchart to the various sections of the Chapter. Note that Figure 9-1 has not been updated to reflect reactive plutonium-bearing material thermal stabilization operations or plutonium-bearing solution stabilization using the Laboratory Prototype Calciner.

9.0.2 Preliminary Analysis

9.0.2.1 Discussion. Plant malfunctions are analyzed in two categories, Abnormal Operations and Accidents. The two categories are defined as follows:

1. Abnormal Operations - In this category, events which could result from malfunctions of systems, operating conditions, or operator error are presented. In general, the magnitude of the events discussed in this section would not have a significant consequence beyond the exclusion area.

2. Accidents - This category contains analyses of situations where primary and/or secondary confinement may credibly be breached to the extent of releasing toxic/radioactive materials beyond the exclusion area or a quantity that could seriously endanger personnel within the exclusion and restricted area. Include consideration of industrial type accidents that would not result in a release of radioactivity but could endanger onsite personnel.

There is no clear-cut distinction between the two categories but in actuality there are two distinct types of events. The two can be distinguished by whether or not the building containment or confinement is breached. In general, those events chosen as accidents potentially occur with sufficient energy to both breach the structure and disperse hazardous materials. A number of events, such as a fire, that were originally selected as accidents were later shown via analysis to have low consequences or probability. Even so, the analyses were retained in the accident section from a sense of expectation. This is also true for natural phenomena events (earthquakes, flood, high winds) and for criticality. These are the types of events which are generally thought to have a potential for defeating the protection systems. Thus, they are included as accidents.

The first step in the identification of abnormal operations and accidents is to determine where combinations of energy and hazardous material exist in sufficient quantities to pose a hazard. The second step is to determine if credible mechanisms (e.g., equipment failures, human errors) exist for combining these two parameters to create unacceptable consequences. A Preliminary Hazard Analysis (PHA) was performed to accomplish these two tasks. The PHA helps identify events and also provides a qualitative estimate of risk.

Appendix 9A describes the rigorous hazards-analysis methodology used to identify and qualitatively assess hazards associated with the PFP, and presents the results in tabular format. The hazard analysis systematically:

1. Identifies building processes, systems and subsystems

2. Identifies activities and associated failures that could lead to potentially hazardous conditions

3. Identifies safety systems, preventive and mitigative controls, and administrative procedures that would prevent the failure event from occurring or reduce its consequences

4. Presents a qualitative hazard screening.

5. Identifies the location in Sections 9.1 and 9.2 where representative or bounding quantitative analyses can be found for each of the hazardous conditions.

The hazard analyses presented in Appendix 9A are grouped into the following major PFP buildings:

Appendix 9A.1--234-5Z Building

- 9A.1.1 RMA/RMC Line
- 9A.1.2 PFPAL
- 9A.1.3 PPSL
- 9A.1.4 Radiochemical standards laboratory
- 9A.1.5 Load-in/load-out (LI/LO)
- 9A.1.6 Storage vaults
- 9A.1.7 Miscellaneous areas

Appendix 9A.2--2736-Z Building; Support/Storage Complex

- 9A.2.1 2736-Z Building
- 9A.2.2 2736-ZA Building
- 9A.2.3 2736-ZB Building
- 9A.2.4 2736-ZC Building
- 9A.2.5 2736-ZD Building
- 9A.2.6 2721-Z Building

Appendix 9A.3--236-Z Building; PRF

Appendix 9A.4--241-Z Building; Waste Storage and Treatment Facility

Appendix 9A.5--232-Z Building; Waste Incinerator Facility

Appendix 9A.6--243-Z Building; Low-Level Waste Treatment Facility

Appendix 9A.7--291-Z Building; Exhaust Fan House

Appendix 9A.8--242-Z Building.

Floor plans and oblique aerial photographs of buildings in the PFP complex are presented in Figures 9-2 through 9-6 as an aid in following the systematic search for various possible events. These and other drawings, plus repeated visits to the plant, and consultations with cognizant/plant engineers were used in performing the hazards analysis.

The hazards analyses contained in Appendix 9A do not address severe natural phenomenon and external events. The severe natural phenomenon are known accident initiators and the phenomenon analyzed in Section 9.2 (e.g., earthquake and strong wind) were selected based on known site characteristics. The external event analyzed (e.g., aircraft crash) was selected based on a evaluation of nearby industrial, transportation, and military facilities (see Chapter 3.0, Section 3.2).

9.0.2.1A Preliminary Hazards Analysis of Plutonium-Bearing Solution Stabilization Using the Production VDC Process. The hazards analysis documented in Appendix 9A does not include the process for plutonium-bearing solution stabilization using the Production VDC. This process was added to the PFP after Appendix 9A was completed. Solution stabilization is accomplished using the Production VDC installed in glovebox HC-230C-2, added to the end of the RMC line in room 230C of the 234-5Z Building. In addition to the Production VDC, glovebox HC-230C-2 contains glass vessels for supplying feed and flush solution to the Production VDC, a NaOH scrubber to condense and treat offgases from the VDC, a phase separator tank, spent scrub solution receiver tanks, and various pipes, pumps and valves to transfer liquids and gases through the system. The Production VDC, scrubber, and phase separator tank are connected to the plant vacuum system. Plant compressed air is used to operate pumps and valves associated with the process. Bottled compressed air is used to atomize plutonium nitrate solution fed into the VDC and to blowback filters on the VDC to prevent clogging. The VDC receives plutonium nitrate solutions from PR cans and L-10 bottles. The plutonium nitrate solutions are loaded into tanks in glovebox HC-227S (via hood HC-227T) and then pumped to glovebox HC-230C-2 via an encased transfer line. A more detailed description of the equipment used to stabilize plutonium bearing solutions is contained in Chapter 5.0, Section 5.2.1.2. The solution stabilization process is further described in Chapter 6.0, Section 6.4.1.

A hazards and operability (HazOp) analysis was performed to identify the potential hazards associated with Production VDC operations in glovebox HC-230C-2. The HazOp analysis is documented in Appendix 9.D. As discussed in Appendix 9.D, the scope of the HazOp analysis includes the operations performed within glovebox HC-230C-2 and the systems interfacing with glovebox HC-230C-2. The potential effects of various external natural phenomena on Production VDC operations are also examined. Operations supporting solution stabilization using the Production VDC that are performed outside glovebox HC-

230C-2 (e.g., load-in of Pu nitrate solutions, LOI sampling, and canning) are considered to be adequately covered by the PHA contained in Appendix 9A.

The HazOp in Appendix 9D systematically identifies process deviations that can lead to hazardous conditions (initiating events or sequences) at logical nodes in the Production VDC solution stabilization process by following the flow of material through the stabilization equipment in glovebox HC-230C-2. The HazOp is documented in a tabular format in Table 9D-4. The HazOp qualitatively estimates the consequences and frequencies of each postulated hazardous condition and identifies the engineered and administrative features available to prevent or mitigate the hazardous condition. The rigorous methodology employed in developing the HazOp is discussed in detail in Appendix 9D.

The hazardous conditions identified in the HazOp in Appendix 9D are summarized and binned into logical categories based on the type of initiating event and mitigative barriers challenged in Appendix 9D, Table 9D-3. The hazards bins in Table 9D-3 are identified as abnormal occurrences or accidents based on the likelihood of their occurrence and their potential to breach primary confinement barriers. The abnormal occurrence bins from Table 9D-3 are addressed in detail in Section 9.1 along with the other abnormal occurrences identified prior to installation of the Production VDC process for plutonium-bearing solution stabilization. The accident bins from Table 9D-3 are addressed in detail in Section 9.2 with the other accidents identified prior to installation of the Production VDC process for plutonium-bearing solution stabilization.

9.0.2.1B Preliminary Hazards Analysis of Thermal Stabilization of Plutonium Oxide Process. A Preliminary Hazards Analysis (PHA) was performed that covered the operations performed within the RMC line glove boxes for the thermal stabilization of plutonium oxide (both "clean" and non-product quality) and other non-product quality feed materials, from seal-in of containers of feed material into Glovebox HC-21A to bag-out of the thermally stabilized product oxide from Glovebox HC-18M.

The PHAs in Appendices 9F and 9G systematically identify the potential hazardous conditions associated with the thermal stabilization of reactive plutonium-bearing materials within the RMC line and is broken down into logical sets of operations performed at specific locations. The PHA related to thermal stabilization of "clean" plutonium oxide is documented in a tabular format in Table 9F.2. The PHA related to thermal stabilization of non-product quality feed material is documented in a tabular format in Table 9G.2. The PHAs qualitatively estimate the consequences and frequencies of each postulated hazardous condition and identifies the engineered and administrative features available to prevent or mitigate the hazardous condition. The methodology employed in developing the PHA related to thermal stabilization of "clean" plutonium oxide is discussed in detail in Appendix 9F. The methodology employed in developing the PHA related to thermal stabilization of non-product quality feed material is discussed in detail in Appendix 9G.

The hazardous conditions identified in the PHA in Appendix 9F are summarized and binned into logical categories based on the type of initiating event and mitigative barriers challenged in Appendix 9F, Tables 9F.3 - 9F.20.

Grouping according to event consequence is shown in Tables 9F.21 - 9F.23. The event bins are discussed in Appendix 9F, Section 9F.4.1, including the assignment of Accident Designation categories. The event bins are given Accident Designation categories based on the likelihood of their occurrence and their potential to breach primary confinement barriers. The hazardous conditions identified in the PHA in Appendix 9G are summarized and binned into logical categories based on the type of initiating event and mitigative barriers challenged in Appendix 9G, Tables 9G.3 - 9G.20. The event bins are discussed in Appendix 9G, Section 9G.4.1, including the assignment of Accident Designation categories. The event bins are given Accident Designation categories based on the likelihood of their occurrence and their potential to breach primary confinement barriers. The abnormal occurrence Accident Category event bins are addressed in detail in Section 9.1.11 related to both PHAs discussed above. The Accident Category "Accident" event bins are addressed in Section 9.2.10 related to both PHAs discussed above.

9.0.2.1C Preliminary Hazards Analysis of the Laboratory Prototype Calciner. In addition to plutonium-bearing solution stabilization using the Production VDC, the Laboratory Prototype Calciner in Room 188 of the PPSL is used for solution stabilization operations. The hazards analysis for the Laboratory Prototype Calciner as well as descriptions of the process and equipment are provided in the Laboratory Prototype Calciner addendum to this FSAR.

9.0.2.1D. Thermal Stabilization of Metal. A Hazards Evaluation (HE) was done for the opening of containers of Pu metal, conversion of the metal and corrosion products to plutonium oxide product, and sampling, testing and packaging the product. Hazards evaluation is the analysis of the significance of hazardous situations associated with an activity or process. The HE used the qualitative techniques of Hazard and Operability (HazOp) analysis and What-If analysis to identify those elements of handling and thermal stabilization processing that could lead to accidents. The hazards evaluation is documented in Appendix 9H.

The results of the hazards evaluation determined that the consequences are worker related, i.e., there were no consequences to the onsite individual or the public. The primary causes identified include: 1) superfluous and uncontrolled combustibles ignited by corrosion product reaction sparks from opened cans; and 2) accumulation and subsequent reaction of more than 200 grams of the most reactive corrosion products (hydrides) producing sufficient energy to pressurize a glovebox during can opening (Glovebox 636) or processing (Gloveboxes HC-21A, HC-21C and HC-18M) and breach containment.

No new accident analyses were performed to address these issues. The PFP declared a USQ, which evaluated the concern. The results of the USQ and subsequent process controls are discussed further in Section 9.1.9.

9.0.2.1E. Preliminary Hazards Analysis of Chemical Hazards. Due to the explosion of Tank A109 in the PRF multiple chemical hazards assessments were performed at the PFP. The assessments evaluated damage to the PRF, current chemical operations, and chemical storage and handling areas within the facility, including the laboratories. The analyses are summarized in HNF-6492, *Summary of Chemical Hazards Assessments and Chemical Management*

Programs at the Plutonium Finishing Plant, (Ullah 2000). The results of the analyses determined the following represent the greatest hazards at the PFP:

1. Potential for incompatible chemical mixing
2. "Hold-up" or legacy chemicals
3. Chemical storage and storage container integrity
4. Chemical aging effects
5. Process piping or vessel integrity

It was determined that these areas have the potential to injure facility workers due to fires, explosions, or contact, or expose facility workers, on-site individuals, and the public to airborne chemical releases. Each of these issues have been addressed by the PFP in chemical management programs or completed and planned remedial actions. The following PFP actions and programs were identified in Ullah 2000, as requirements to ensure chemical hazardous or hazardous conditions within the PFP are understood and managed appropriately, thus reducing the potential for adverse impacts to Hanford Site personnel and the public (see Section 10.4.5 for programs descriptions):

- PFP Chemical Management Program (implementation of HNF-PRO-2258)
- PFP Hazardous Material Management Plan (FSP-PFP-5-8, Volume 1, Section 7.1)
- PFP Chemical Hygiene Program (ZAP-000-010)
- Facility or vessel or piping specific operating and surveillance procedures (series ZO)
- For those systems identified as remedial actions the existing PFP controls to manage those systems (e.g., RMC Chem Prep Tanks, Duct Level piping) must be maintained. These systems have been inspected, process data has been reviewed, and, where necessary, residual chemicals have been sampled.

9.0.2.2 Screening Process, Plutonium Releases. The radiological Risk Acceptance Guidelines given in Table 9-49 are not very useful during a screening process because plutonium inventories and release fractions are given in grams. Thus, it is not clear, without further calculation, how much material must be released in order to arrive at the dose figures. During the PHA the dose limits were converted to gram-release-equivalents (Tables 9-51 and 9-52) to give the analyst a more easily-used mental tool for estimating whether or not an event should be forwarded to Sections 9.1 or 9.2. An additional mental calibration tool was provided by translating the stack alarm set point to a gram release by assuming a 1-h duration of release (Section 9.4.4).

From Table 9-52, the most sensitive or lowest amount of release derived from risk criteria is that for a ground-level, offsite organ dose with Class W material where

$$\text{Release} = 0.005 \text{ g}$$

Derivation of this number and other combinations of probability, and type of release, are presented in Section 9.4.3.

A useful benchmark for evaluation is to assume a 1-h release of plutonium at the stack alarm level of 2×10^{-12} Ci/m^3 and a flow rate of 270,000 ft^3/min. Such a release corresponds to 5.7×10^{-7} g/h. A comparison of this alarm limit value with the least allowable stack release of 0.015 g during an accident, at probability 1.0 (Table 9-52), shows a factor of 2.6×10^4 difference.

9.0.2.3 Functions Excluded from Analysis. Analysis of an operating facility cannot be completed in one version of a document. Certain functions of the facility are out of operation at any given time and must undergo procedural or design modifications that are not defined. In order to publish a document a time comes at which the scope must be frozen. The functions listed in Table 9-2 were excluded. As other functions are brought online they will be included as future revisions.

In addition, the activities associated with terminal cleanout operations (TCO) are not addressed in the accident analysis. TCO must be evaluated to determine that they are covered by the facility authorization basis. If the activities directly or indirectly affect the facility authorization basis, then the activity must be reviewed in accordance with the Unreviewed Safety Question (USQ) process specified by DOE Order 5480.21, *Unreviewed Safety Questions*. Changes to the authorization basis will be incorporated into the PFP FSAR during the annual update.

9.1 ABNORMAL OPERATIONS

Section 9.0.2.1 defined abnormal operations and how they differ from accidents. While the upper bound of what constitutes an abnormal operation is fairly well defined, the lower bound has no definition.

Most events identified by the hazards analysis process are those caused by or resulting from deviation from normal or expected operation. Once an abnormal event has been identified, a decision must be made as to whether the event requires additional formal evaluation or will simply remain in the PHA. For this safety analysis the decision as to whether or not an abnormal event was selected for further evaluation was based on probability of occurrence and subjective engineering judgement of possible impact on plant personnel. Events identified as "abnormal" were not selected for further evaluation if two or more independent errors or failures were required to cause the event. Note however, that some abnormal events were forwarded for evaluation in spite of the two-failures rule. The bounding scenarios for the release of plutonium compounds into the buildings require more than two failures, but the scenarios were selected for further evaluation to present bounding cases.

9.1A ABNORMAL OPERATIONS FOR THE PLUTONIUM-BEARING SOLUTION STABILIZATION PROCESS USING THE PRODUCTION VERTICAL DENITRATION CALCINER

Abnormal operations for the plutonium-bearing solution stabilization process using the Production VDC in glovebox HC-230C-2 are defined as those relatively high likelihood process upset conditions with the potential to result in elevated radiological or toxicological releases to the glovebox confinement or plant vacuum systems. The glovebox confinement system is considered to be composed of the glovebox structure and the E-4 ventilation system. Two general types of abnormal operations were identified from the HazOp contained in Appendix 9D: releases of radiological material from solution stabilization equipment to the glovebox HC-230C-2 atmosphere (Bin ID B from Table 9D-3); and releases of process liquids, NO_x, or nitric acid vapor to the plant vacuum system (Bin ID I from Table 9D-3). Both types of events have the potential to increase facility worker doses (either direct shine dose during normal operations or personnel contamination potential during maintenance activities) but do not pose an immediate inhalation hazard to facility workers since airborne particulates and toxic gases remain confined to the E-4 ventilation and plant vacuum systems. Accident scenarios that can result in significant releases of radiological material outside the glovebox or Zone 4 confinement system, which could pose inhalation hazards to facility workers or to individuals outside the PFP exclusion zone, are addressed in Section 9.2.

In addition to performing the HazOp analysis to identify new or unique hazards associated with the plutonium-bearing solution stabilization process, the abnormal operations in Sections 9.1.1 through 9.1.9 were revisited to identify potential impacts from Production VDC operations. Additional analyses or changes to the existing analyses would be required if: 1) a process upset condition within the Production VDC solution stabilization process was identified that was of a similar type to the existing abnormal operation but with postulated consequences that were higher than in the existing analysis, or 2) if the radiological inventory associated with the

Production VDC solution stabilization process required that the release source term in an existing plant abnormal operation analysis be increased significantly. The evaluation of potential impacts posed by the Production VDC process for plutonium-bearing solution stabilization on the original abnormal operations contained in Sections 9.1.1 through 9.1.9 is summarized in Table 9-54. The evaluation examined the effects of potential upset conditions within glovebox HC-230C-2 and potential upset conditions in other areas of PFP associated with the Production VDC solution stabilization process. No significant changes to the original abnormal operation analyses were found to be warranted. In all cases the original analyses were found to be adequately representative of postulated upset conditions in the Production VDC solution stabilization process or to be not relevant to upsets in the solution stabilization process.

Sections 9.1.1 through 9.1.9 contain the abnormal operations developed for the PFP before the Production VDC process for plutonium-bearing solution stabilization was put in place. The two abnormal operations for the Production VDC process for plutonium-bearing solution stabilization, identified from the HazOp analysis, are addressed separately in Section 9.1.10.

9.1B ABNORMAL OPERATIONS FOR THE THERMAL STABILIZATION OF PLUTONIUM OXIDE PROCESS

Abnormal operation categories (bins) identified for the thermal stabilization of "clean" plutonium oxide are summarized in Appendix 9F, Table 9F.22. The abnormal operation categories were screened from the PHA and are discussed in Appendix 9F, Section 9F.4.3.2. Abnormal operation categories (bins) are identified for the thermal stabilization of non-product quality feed material as those operation categories represented by hazards with either an "S0" or an "S1" consequence rank in Appendix 9G, Table 9G.2 The abnormal operation categories were screened from the PHA and are discussed in Appendix 9G, Section 9G.4.1. The abnormal operations categories represent types of events associated with the thermal stabilization operations in Glove Boxes HC-21A, HC-2, HC-21C, HA-21I, HC-18BS, and HC-18M that have a relatively high likelihood of process upset conditions with the potential to result in elevated radiological or toxicological releases to the room atmosphere, glovebox interior, or temporary waste storage area. Ten categories of abnormal operations for the plutonium oxide thermal stabilization process were identified in the PHAs documented in Appendices 9F and 9G. These event categories are: contaminated wound, dispersal of plutonium oxide powder inside a glove box, dispersal of minor amounts of plutonium oxide powder outside a glove box during bagout operations, dropped container outside glovebox, flammable gas deflagration in glovebox, flammable gas deflagration in a waste drum, loss of glovebox confinement due to mechanical breach, loss of glovebox confinement due to ventilation failure, rupture of container in storage vault, and pyrophoric reaction in furnace. Each of the abnormal operations categories from Table 9F.22 and Table 9G.2 are discussed in Section 9.1.11. Each abnormal operations category is compared and evaluated against the original analyses contained in Sections 9.1.1 through 9.1.10.

In addition to performing the PHA analysis to identify new or unique hazards associated with the thermal stabilization of plutonium oxide process,

the abnormal operations in sections 9.1.1 through 9.1.10 were revisited to identify potential impacts from the process. Additional analyses or changes to the existing analyses would be required if: 1) a process upset condition within the thermal stabilization process was identified that was of a similar type to the existing abnormal operation but with postulated consequences that were higher than in the existing analysis, or 2) if the radiological inventory associated with the thermal stabilization process required that the release source term in an existing plant abnormal operation analysis be increased significantly. No significant changes to the original abnormal operation analyses were found to be warranted. In all cases the original analyses were found to be adequately representative of postulated upset conditions in the thermal stabilization process or to not be relevant to upsets in the thermal stabilization process.

9.1C ABNORMAL OPERATIONS FOR THE LABORATORY PROTOTYPE CALCINER

Abnormal operations identified and evaluated for operation of the Laboratory Prototype Calciner are discussed in the Laboratory Prototype Calciner addendum to this FSAR. It is noted that operation of the laboratory calciner is not currently authorized.

9.1D ABNORMAL OPERATIONS FOR THE MAGNESIUM HYDROXIDE PRECIPITATION PROCESS

Abnormal operations identified and evaluated for operation of the Magnesium Hydroxide Precipitation Process are discussed in the related addendum (Carson 2000) to this FSAR.

9.1E ABNORMAL OPERATIONS FOR THE BAGLESS TRANSFER SYSTEM (BTS)

Abnormal operations identified and evaluated for operation of the BTS are discussed in the calculation notes (FH 2000) for the BTS.

9.1F SYNOPSIS OF ABNORMAL OPERATIONS

Table 9-3 presents a synopsis of each of the abnormal operations considered in the following subsections.

9.1.1 Radioisotope-Bearing Liquid Spills

Three different types of containers, each having a volume of 10 L, are used to store $Pu(NO_3)_4$ solution. The three containers are designated: L-10, 10-L, and the FL-10. These containers are all stored within the 234-5Z Building. There are no plans for moving these containers to other buildings of the PFP complex. The containers are transported within the building by hand trucks. Even if plans should change and the containers were moved to the 2736-Z Building for storage, the probability of a spill is considered incredible. The L-10 and FL-10 containers are built to withstand the forces involved in a public highway accident without loss of containment. In such accidents, the outer container may lose integrity but show no evidence

of inner containment vessel leakage. (The actual innermost vessel is a plastic bottle but, given the embrittlement caused by radiation, it is assumed that even in a low energy accident such as tipover the bottle would leak.) The containment vessel consists of type 304-L stainless steel, 5-in.-dia, schedule-40 pipe, 53.5 in. long, with type 304-L stainless steel 300-lb slip-on flange. A blind flange is fastened to this with 8 3/4-in. steel bolts. The blind flange is gasketed to the vessel and equipped with a protected vent valve (Genoni 1984, p. 29). Thus, loss of liquid to the environment from a simple tip-over accident during hand transport is assumed to be incredible. In contrast, the 10-L container is equipped with a clamp-on closure for the containment vessel. Even though they do not meet U.S. Department of Transportation requirements and are not approved for cross-country highway use they are not expected to leak from both the inner and outer containers as a result of a simple tipover event.

9.1.1.1 Postulated Cause of the Event.

9.1.1.1.1 Starting Conditions and Assumptions. Plutonium-containing liquid spills have occurred during past PFP operations and may be expected to occur in the future due to common human errors. Factors such as psychological stress, the quality of training and supervision, differences in attention to human factors details, design and maintenance are all variables which affect the probability that a spill will occur. In the past, spills have been caused by the misrouting of glovebox connections, accidental discharge of sprinkler systems in contaminated areas, failed seals, leaking valves, overfilling of vessels, check valves failing in the open position and allowing unanticipated backflows, operators turning the wrong valve, management error, and corrosion of a protective barrier.

The composition of a potential liquid spill can run from slightly contaminated waste water to liquids containing significant amounts of radionuclides. A liquid spill can produce contaminated aerosols, which are then dispersed as a function of the available air currents. Aerosols are classified as either condensation or dispersion, depending on the mechanism of their deposition. Liquid spills can produce both condensation-type aerosols from offgasing or gas-phase reactions and dispersion-type aerosols from liquid shear during a spill.

Virtually any liquid handled at the PFP has some probability of being spilled. These spills can occur anywhere within the facility that the liquids are handled. However, PFP design, equipment, systems, training, management, and operations, reduce the likelihood of large spills with concentrated material. The likelihood for inconsequential spills is greater. The greatest likelihood of a spill occurs during routine handling of small plutonium-bearing laboratory samples. If the samples are spilled, the consequences would be minimal and are, in fact, anticipated events.

9.1.1.1.2 Engineered Safety Features and Protective Systems. All radionuclide-bearing liquids handled in the PFP are confined within systems such that a single failure will not result in the release to the environment. In most cases, several failures would be required to result in an environmental release. Contaminated liquids are normally handled within enclosed gloveboxes or hoods that have preferential airflow away from operational personnel. Liquids are not brought out into a room until they

have been enclosed in several protective layers which include containers, canisters, and sealed plastic bags.

Laboratory sample-size radionuclide-bearing liquids may be handled in open-faced fume hoods, which are standard laboratory equipment, and exhausted via the ventilation system serving the particular room. Airflow is maintained into the hoods at aerosol capture velocity and there are capture ledges to prevent spilled liquids from running out. The high efficiency particulate air (HEPA) filters are not normally installed at the point of fume hood exhaust. The rooms containing fume hoods are provided with continuous air monitors (CAMs) and air samplers. Shielding is not normally provided. For high dose rate samples, extension tools or smaller sample sizes are used to reduce exposure. Each workstation is normally provided with a trouble alarm.

In the event a spill occurs, the first line of personnel defense is operator training, which teaches the correct responses to a spill. In addition, the processing rooms are equipped with CAMs that alert personnel to the presence of respirable airborne contaminants. Either due to actions of trained operators and/or the warning by CAMs, response to upsets has historically resulted in evacuation of the immediate area before operators have inhaled significant amounts of any airborne contaminants. The CAMs are an aid to warn personnel of airborne contamination; however, the first and best detection/warning is the operator on the scene.

The construction of the facility and systems, training, operation, maintenance, and management are designed to include appropriate redundancy and diversity of safety features to minimize the possibility of concurrent common-mode failures. The PFP confinement systems include the confinement barriers and the associated ventilation systems. Multiple barriers and redundancy in systems are provided in the unlikely event that any barrier or component of a particular confinement system fails.

The PFP has at least three redundant confinement systems that protect against an inadvertent release of radionuclides.

- **Primary Confinement System**--Consists of the process enclosures and their associated ventilation system, which maintain a negative pressure drop from the room into the process enclosures or gloveboxes. The primary system can also be considered to be the process vessels within the enclosures or the cans and containers that products are handled and stored in.

- **Secondary Confinement System**--Consists of the barriers that enclose the areas (rooms) that house the primary confinement system and the system that ventilates those areas. Those areas may be referred to as operating areas or operating area compartments.

- **Tertiary Confinement System**--Consists of the building structure and its ventilation system.

Ventilation systems within each of the confinement systems maintain a controlled, continuous airflow pattern from the environment into the confinement building, then from uncontaminated areas of the building (zone 1) to potentially contaminated areas (zone 3), and then to normally contaminated

areas (zone 4). Thus, the airflow is toward areas of higher radioactive or hazardous material contamination. Note that ventilation zone designations are reversed in the 2736-Z Complex; Zone 1 is the most contaminated, Zone 4 is uncontaminated. The three confinement systems are balanced so as to ensure that the individual system air pressures in zones 3 and 4 are normally negative with respect to the outside atmosphere to prevent movement of airborne material out of the building.

The confinement systems are instrumented and monitored to display/record system status and to alert operations and response personnel in the event of upset conditions or loss-of-confinement capability. The ventilation systems are instrumented so that an alarm will sound in the power control room following loss of negative pressure from one confinement system into the next, except from zone 3 to zone 4. The CAMs are provided to detect airborne radioactive material resulting from a liquid spill into zone 3.

9.1.1.2 Detection of Event. A liquid spill may be detected by a variety of established passive or active methods.

9.1.1.2.1 Methods or Means of Detection. An operator or other individual may simply observe a spill; a Radiological Control Technician (RCT) performing a surveillance could find evidence of a spill; CAMs may detect the radioactive aerosols produced from a spill; personnel in the course of self-monitoring may detect evidence of a spill; or, as a last recourse, surveys done at building or protected-area exits may detect spill spread contamination.

Air monitoring and warning systems are installed in work areas where dispersible radioactive materials are handled in order to detect airborne contamination. Air sampling heads are located to provide a representative sample of potential airborne radioactive materials being breathed. Depending on the volatility or energization of the potentially spilled radionuclides, air monitors may or may not be able to discover a spill. The CAMs are set to detect and alarm at prescribed airborne radioactivity levels, but, if the components of a spill do not become airborne in sufficient concentration then detection may not occur by this method.

Spills are also detected by RCTs performing routine area or equipment surveillances or preinspection of a radiation work area.

9.1.1.2.2 Response Time Assessment. Since the most likely component of a liquid spill in the PFP is potentially airborne radionuclides, the immediate evacuation of the spill area is required. Respiratory protection must be used if room access is necessary. However, unless the extent of the spill is large or the liquid falls from a significant height, automatic detection may not be affected due to the small amount of material that becomes airborne. In that case there may be significant lag time between the event and detection. First detection may come about through self-monitoring of shoecovers at exits by personnel who walk through a contaminated area. Detection of spills in remote areas may take some time until found by a RCT making a periodic check of the area. An experienced operator or laboratory technician is often aware of a spill as soon as it occurs, because they recognize their own error. Process or laboratory personnel can, with the aid of RCTs, assess the extent of the spill. Often this can be accomplished from the door to an adjoining room or

corridor. Personnel safety is assured through a combination of airflow and respiratory protection devices.

9.1.1.3 Analysis of Effects and Consequences. For the purpose of this analysis it was assumed that the entire contents of a 10-L polyethylene or steel bottle containing plutonium nitrate solution spilled from a height of 3 m within the facility and onto the floor outside a glovebox. This is considered to be very conservative since 10-L polyethylene bottles at one time were hoisted up and out of the container to be emptied. This required that the bottles be lifted ≈1.5 m in hood HC-227T, but this method of unloading has been discontinued. The product receiver (PR) cans are still lifted up and out of their containers to be unloaded; however, they are considerably stronger than the polyethylene 10-L bottles; PR cans are constructed of steel. It was also assumed that all other protective systems were operating normally before the spill.

Spill energy is an important factor in determining the magnitude of release. Spill height determines the amount of gravitational energy available to break up and rebound particles on impact. Height also influences the amount of time source material is exposed to shear forces during the fall. These forces work to break off particles from a falling stream. Some plutonium may be resuspended from a spill surface but this amount is estimated to be insignificant to the spilling process and is time dependent.

As the result of a spill from a height of 3 m, it is estimated that 0.002% by weight of the plutonium nitrate solution as droplets will become airborne (NRC 1981). For a 10-L bottle of plutonium nitrate solution with a 1.64 g/cm^3 density, a total of 0.33 g of plutonium nitrate solution (0.16 g of plutonium) may become airborne. This amount can vary depending on the presence of air currents, the relative humidity, and the temperature; however, these factors are considered small contributors to total airborne mass. A single stage of HEPA filtration reduces the quantity of plutonium released to approximately 1×10^{-4} g. This is significantly below the quantity of plutonium necessary to be released to exceed the allowable dose for an event with probability 1.0 (Table 9-51).

9.1.1.4 Corrective Actions. If a liquid spill occurs outside a glovebox, the corrective actions necessary can be summarized into evacuation, exclusion, investigation, confinement, cleanup, and restoration/inspection. The first step would be to establish and post the area as an Airborne Radioactivity Area following the evacuation of personnel. Reporting the event through required channels would ensure that additional help would be made available. Evacuation would then restrict or exclude access to all but those individuals authorized to monitor and clean up the spill. The next step would be to determine the nature and extent of the spill and to prevent it from moving or being moved from its known location using established procedures designed to ensure that any contamination is fixed in-place. Cleanup begins only after trained operators have donned prescribed protective equipment. Care is taken that recovery efforts do not expand the event beyond its present confines or cause contamination of operators. It might be necessary to erect a greenhouse at the entry to the adjacent room or corridor to confine the spread of contaminants while cleanup proceeds. Cleanup would involve removing and stabilizing the spilled material until the results are satisfactory to Radiological Control and management personnel. Once the area has been

restored to the prespill condition, any further inspections and administrative functions necessary would be applied to release the area to a normal operational status.

9.1.2 Radioisotope-Bearing Pressurized Liquid Container

Containers of plutonium-bearing solutions, all of which have some small potential to become pressurized, are stored in the PFP in a variety of locations, quantities, and concentrations. Due to physical and procedural controls, potential for significant discharge of a pressurized container into an occupied area is low. Discharge within a glovebox would be contained. The discharge of a pressurized container of plutonium-bearing liquid outside of a process enclosure was reviewed and the consequences were found to be marginal within the PFP. Plutonium nitrate liquid is stored in 10-L containers, which represents the largest total quantity and most concentrated solution that is routinely handled outside a process enclosure in proximity to the plant staff. Laboratory sample-size containers and dilute quantities from cleanup operations are also routinely handled outside of process enclosures and are more numerous; however, they involve smaller quantities of materials. This section discusses both types of pressurized liquid containers.

A variety of liquid containers handled within the PFP have the potential to become pressurized to the point that, when opened, part of the contents could be rapidly discharged. The manner in which the pressurization of the containers could occur, and the resultant relieving of the pressure buildup in general, is of concern. The Fire Hazard Analysis (McKinnis 1998) identified a potential hydrogen deflagration resulting from a pressurized release from a Product Receiver (PR) drum. The hydrogen flammability concerns for all containers are briefly discussed in this section and are detailed for PR drums in Section 9.1.2A.

9.1.2.1 Postulated Cause of the Event. Liquid containers can either be passively or actively (i.e., due to application of an outside agent) pressurized. Passive causes can be attributed to the chemical decomposition of the contained liquids, nuclear degradation of the container material, chemical corrosion of the container material, or radiolytic gas buildup. Active pressurization agents could be attributed to the application of heat; mishandling, resulting in physical crushing; or a chemical reaction within the vessel.

9.1.2.1.1 Starting Conditions and Assumptions. It is assumed for this analysis that liquid containers are handled in a normal manner. The primary containers are located within secondary vessels or containers designed for that usage. They are handled with devices provided for that usage. In addition, it is assumed that experience recorded in event reports and their corrective actions exists and personnel training includes this information. The PR cans and L-10 containers (overpacks) are opened in open-faced hoods with the operators wearing supplied-air respirators in the event of an inadvertent release that could be inhaled. All venting and lid removals are performed in these hoods.

Pressurization of a liquid container does not constitute a problem until it causes the failure of its primary container or causes an event when an

attempt is made to transfer the liquid. The result of primary container failure would, in most cases, be mitigated by the secondary container or overpack. Should the primary container fail during transfer of the primary container to a hood or glovebox, the result could be personnel injury and contamination spread. To a lesser degree, there could be spread of contamination during the venting steps of a piped liquid transfer.

The major portions of plutonium solutions are typically kept in either FL-10 or L-10 shipping containers and PR cans and 10-L storage containers. Liquid solutions containing plutonium nitrate require unloading for processing. Plutonium solutions are currently stored in the PFP and delivered to the room 227 load-in/load-out (LI/LO) hood as needed. Due to a prohibition against shipping radioactive solutions offsite, it is anticipated that the PFP will not receive any additional offsite plutonium solutions. Shipping containers for liquids have a special provision for venting internal pressure, while storage containers have vents built in or installed that allow continual venting of the interior. Normally, a shipping container will be in a vented condition while being stored, and the vent will be closed or removed by an operator before transport to the 234-5Z Building to minimize the possibility of a leak during shipment.

In addition to the large containers of liquid products that are routinely handled outside gloveboxes, small bottles of samples for analysis are routinely handled that also have the potential to become pressurized. The PFPAL receives sample bottles of liquids from PFP operations, the PPSL, and other Hanford Site and offsite customers. Sampling or nondestructive assay NDA is made of materials entering or leaving various points in the process. Measurements of material are used in process control, criticality control, and in the control and accountability of plutonium as part of the overall safeguards program.

9.1.2.1.2 Sequence of Events. There are essentially two points in the processing of liquid containers where the overpressurization of the container can become an abnormal event. The first occurs when, upon opening an overpack, the operator observes that the primary container has failed due to overpressurization. The contents must now be emptied from the overpack into a new container and the ruptured container must be removed and discarded. The overpack must be decontaminated before reuse, or simply discarded.

The second case arises when the pressure has not been relieved from the liquid container either through plugging of the vent valve or the improper application of the venting procedure before opening the pressure vessel (PV). Most liquid containers and overpacks have vents constructed into them to prevent an overpressure condition. The L-10 and 10-L bottles are closed with a vented cap and placed into an overpack that has a vent valve constructed into the lid. Before opening the overpack, a discharge line is connected to the vent valve and the valve is opened to allow any excess pressure to be safely discharged. In a past event, venting of the overpack was overlooked with the result that excess gas volume was discharged and the gas ignited. The resulting deflagration singed the operator's eyebrows and lashes.

During storage PR cans are closed with a vented stopper held in place with an attachment clamp, and the outer PR container is equipped with vent clips or a filtered vented lid. During shipping the vent clips are removed

from the outer drum and the ring tightened to a specified value with a torque wrench. After receipt of a full PR container/can, the outer container is vented and vent clips applied within a specified period of time. Due to the low gas buildup rate, lack of venting the container itself would represent a minimal hazard. A potentially significant hazard would exist if the vented polyethylene stopper in the PR can were to become plugged; the gas buildup rate is significant within the smaller volume of the can and the eventual discharge of the pressure could distribute a fraction of the PR can contents. However, since the PR can is normally enclosed in the PR container, discharge into its bigger volume would not be a serious problem. It is only if the outer PR container is open during unloading that a pressure discharge would pose a significant hazard. The venting device resembles an inverted hat set into the neck of the PR can, with a vent hole in the crown and the hat filled with glass wool. The brim of the "hat" acts as a gasket which, along with a softer gasket, is held in place by a bolted-down steel lid. Pressure could blow out the gasket or collapse the "hat" upward and break it. With the PR can upright for loadout not much solution would come out. Workers handling the PR cans are garbed to handle releases. Failure to vent the outer container could lead to H_2 enrichment and pressurization of the outer container, which is described in Section 9.1.2A.

As required, liquid containers are transported by a hand operated dolly to room 227. A 10-L bottle/overpack or PR can/container is placed in the lower section of the LI/LO hood, 227-T. The containers are surveyed for contamination and radiation levels before opening. The outer container or jacket is then electrically grounded to prevent sparking that could ignite any enclosed hydrogen, and the lid removed. The open top of the FL-10 or L-10 shipping container, PR cans, and 10-L storage containers would then be enclosed into the PR hood and a greenhouse placed around the container. The interior of the container is surveyed and decontaminated as necessary. The inner container is then grounded. If the container is an FL-10 or L-10, the vent valve outlet is connected to the building's 26-in. vacuum system, the vent is opened, and the container is vented. The container lid would then be unbolted using nonsparking tools and the lid removed. If the venting procedure was less than adequate, the rapid discharge of collected gases and possibly some liquids would occur. A load-out head is then used to vacuum-transfer the solution to a glass tank in glovebox 227-S.

If a PR can vent port was to become plugged, pressure could build up in the can and, upon loosening the PR can lid, a rapid discharge of gases and some liquids could occur. Hydrogen flammability issues are described in Section 9.1.2A. The lid of a 10-L bottle is similar in configuration to the lid of a PR can and is subject to vent blockage in the same fashion as a PR can lid. In all cases the discharge of gas with contained liquid due to excessive pressure would occur from the periphery of the lid or cap, and probably be directed in a flat spray from one side of the container. This would spread contamination within the hood but would not expose the operators, since during unloading the operators are required to wear respiratory protection, acid suits, and heavy Viton[1] gloves.

[1]Viton is a trademark of E.I. DuPont de Nemours and Company, Wilmington, Delaware.

Experience indicates that a small number of the polyethylene bottles can be expected to leak within the overpack. The leak usually occurs along a seam. If the bottle vent is plugged, the pressure of radiolytic gas may force liquid out of the bottle, causing a level lower in the bottle than that in the surrounding PV. In this situation the contaminated bottle would rise out of the vessel as the lid is removed. In either case, the liquid is vacuum-transferred out of the bottle and the PV if necessary. If the bottle is contained in a 10-L storage container, the bottle and vessel are rinsed with acid, sprayed with fixant, the lid is clamped in place on the overpack, and the entire storage container is disposed of as waste. If the bottle is contained in a shipping container, the bottle is normally bagged and disposed of, and the container decontaminated for reuse.

Small bottles of laboratory samples can become pressurized due to the chemical decomposition or radiolysis of the contained materials. The samples are taken to ascertain the characteristics of the product or recoverable materials stream at various points in the process. One of the characteristics is the ability to cause offgasing, which will build up pressure in a closed container. The offgasing process is time dependent and, if the sampling or NDA is performed quickly, there is little hazard. However, over a period of time overpressurization of the sample bottle can result. Bottles that must be kept for some time are either vented on a scheduled basis or are equipped with a vented cap.

There have been several examples of pressurized PFPAL sample containers failing. Some years ago a glass bottle exploded in a closed cupboard, leaving glass shards stuck into surrounding objects. In another instance the contents of a 30-mL plastic bottle of plutonium-product solution were found spread over a considerable area of laboratory floor, after the bottle pressure was relieved through a small hole blown out of the bottom of the bottle, where the plastic entered the mold during manufacture. The bottle rose out of its container and, as it was propelled to the back of the hood, the liquid squirted out into the room. These events did not lead to release to the environment or result in exposure to plant personnel due to the training, controls, and barriers at the PFP.

9.1.2.1.3 Operator Actions. Operator actions other than normal handling routines, need not be required at the time of the occurrence. Incorrect actions of others set up the situation, as when a PR container that had the vent clips removed for shipping had not had the clips replaced in the required time specified by procedure. Effort is made to learn from past events to preclude the reoccurrence and any similar events and continued declines in event occurrence rates indicate success. There is little likelihood that any operator actions would increase the consequences, other than the gross violation of procedures (e.g., opening a pressurized container in an occupied area). Although in the past, procedural steps have been missed and hold points sometimes bypassed, the probability of that occurring to a bottle that had a venting failure or blockage of a vent is not likely.

9.1.2.1.4 Engineered and Administrative Safety Features and Protective Systems. The uncontrolled spread of airborne contamination outside of the facility is prevented by a combination of physical barriers and the building ventilation system. The probability of contamination release to the environs is minimized by maintaining progressively decreasing pressures from

noncontaminated, or "cold" zones, to the highly contaminated gloveboxes, and by pulling the exhaust air from these areas through HEPA filters. Integrity of the filters is ensured by the specified periodic aerosol penetrant challenge tests (Section 5.4.1.2.2) and are monitored continuously for signs of failure by the stack-sampling program.

To eliminate pressurization, containers must be properly vented while in storage and sample bottles must be emptied or vented. If it is determined that the containers are not vented or sample bottles have not been emptied, immediate corrective action must be taken to protect personnel.

9.1.2.2 Detection of Event.

9.1.2.2.1 Methods or Means of Detection. Detection of a liquid container that has not been properly vented is most likely to occur through direct observation by the operator or technician. For bulk process solutions this is likely to happen when the operator removes the L-10-type PV lid or the PR can lid. This will result in the rapid discharge of the excess pressure into the greenhouse around the FL-10 or L-10 containers. The PR cans would discharge the excess pressure into the 227-T hood, having been raised out of the container before lid removal. The enclosure constructed around the bottom of the container would contain any discharged contaminants and prevent operator exposure, unless the greenhouse was defective. In that event, CAMs and other protective measures would detect the loss of confinement, warning the operator and management of the event.

Small plastic bottles are likely to be swollen. The most hazardous are the glass bottles, which show no visible signs of pressurization, but could explode while in a worker's gloved hand.

9.1.2.3 Analysis of Effects and Consequences. For the purpose of this analysis it was assumed that 5 L of the contents of a 10-L polyethylene bottle containing plutonium nitrate solution were ejected and dropped from a height of 3 m, within the facility and onto the floor outside a glovebox. This highly improbable scenario was chosen from the various sequences in Section 9.1.2.1.2 as a bounding case. This is considered to be a highly conservative estimate, since the top of the tallest container assembly is less than 2 m and, for the most part, only gaseous products would be released from the top of the container, since the most likely source of pressure relief would occur during improper container opening. Unlike a pressurized leak from a line under pump pressure, the pressure here would decrease with time. It was also assumed that all other protective systems were operating normally before the pressure relief. Pressure and height are the most important factors in determining the magnitude of the release. The liquid must fall onto the floor outside the hood and the spill height determines the amount of gravitational energy available to break up and rebound particles on impact. Height also influences the amount of time source material is exposed to shear forces during the fall. These forces work to break off particles from a falling stream. Some plutonium may be resuspended from a spill surface, but that amount is estimated to be insignificant compared to suspension from the spilling process, and is time dependent.

As the result of a spill from a height of 3 m, it is estimated that 0.002% by weight of the plutonium nitrate solution as droplets will become

airborne (NRC 1981). For a 5-L spill from a 10-L bottle of plutonium nitrate solution with a 1.64-g/cm^3 density, a total of 0.16 g of plutonium nitrate solution (0.08 g of plutonium) may become airborne. This total number can vary depending on the presence of air currents, the relative humidity, and temperature; however, these factors are considered small contributors to total airborne mass. A single stage of HEPA filtration reduces the quantity of plutonium released to approximately 1 x 10^{-4} g. This is less than the quantity of plutonium necessary to be released to exceed the allowable dose for an anticipated event (see Table 9-51).

Contaminated liquids are normally handled within enclosed gloveboxes or hoods that have preferential airflow away from operational personnel, and they are not brought out into a room until they have been enclosed in a number of different layers of protective containers and canisters. An exception to this is laboratory sample-size amounts and laboratory waste bottles; however, in contrast to a postulated 5-L release, the amount is insignificant. Either due to actions of trained operators and/or the warning by CAMs, response to upsets has historically resulted in area evacuations before operators have ingested significant amounts of any airborne contaminants. The CAMs are an aide to warn personnel of airborne contamination, but the first and best detection/warning is the operator on the scene.

9.1.2.4 Corrective Actions. The PFP has trained plant personnel, administrative procedures, and equipment available to recover from any potential spill. Regardless, emphasis is placed on prevention of spills, which is based on information of past spills and postulated spills. However, if the sudden release of an overpressurized liquid container occurs, such as to spray liquid out of the load-out hood or a sample bottle breaks outside a glovebox, the necessary corrective actions can be summarized as evacuation, exclusion, confinement, cleanup, and restoration/inspection. The first step would be to establish the area as an Airborne Radioactivity Area after the alarms have sounded and the personnel were evacuated. This would restrict or exclude access to all but those authorized individuals needed to monitor and clean up the spray. The next step would be to determine the nature and extent of the spill and prevent the liquid from moving or being moved from its known location. Cleanup would involve removing and stabilizing the spilled material until the results are satisfactory to monitoring and management personnel. Once the area had been restored to the pre-event condition, any further inspections and administrative functions necessary would be applied to release the area to normal operational status.

9.1.2A Hydrogen Flammability Conditions of Product Receiver Drums

Containers of plutonium-bearing solutions all have the potential to pressurize. Some of the radiolytic gas generated is hydrogen, which is flammable at concentrations above 4%. This section examines the hydrogen flammability potential in PR drums (overpacks) and in Room 236, which stores a maximum of 378 PR drums, at the PFP. The Fire Hazard Analysis (McKinnis 1998) indicates that there is no hydrogen flammability concern (with a large safety margin of more than 5 orders of magnitude) in Room 236 under normal ventilation conditions (6800 ft^3/min).

9.1.2A.1 Postulated Cause of the Event. Radiolysis takes place in all radioisotope-bearing pressurized liquid containers and generates gases. Hydrogen is one of the radiolytic gases generated. The radiolytic gas generation rates depend upon the types of radiation particles, their integrated energies, the chemical composition of the solutions, and the chemical composition of the containers. It has been shown in HNF-2061, *Plutonium Finishing Plant Project: Gas Generation from Plastics during Vault Storage via Radiolysis Reactions* (HNF 1999c), that alpha radiation from plutonium dominates the production of radiolytic gases from hydrogenous substrates. The main substrate with hydrogen in the bottles stored in the PR drums is plutonium nitrate ($PuHNO_3$), and the radiolytic gases are hydrogen, oxygen, nitrogen, and nitric oxide, with hydrogen making up about 62% (mole number percentage) of the generated gas (Cooper 2000, *Gas Generation in Product Receiver Can Drums*).

With hydrogen being generated in the bottles stored in the PR drums, flammability conditions can be reached as soon as 3000 hours (Cooper 2000, Figure 2) for a worst-case drum, and in 20,000 hours (< 2.5 years)for an average drum, if the PR drums are leak tight (i.e., with only hydrogen diffusion through gasket occuring) and are not vented. Furthermore, hydrogen flammability conditions can be reached in a worst-case PR drum with a small vent, but not in an average PR drum (Cooper 2000). With flammable conditions expected in the PR drums (assuming that the interior bottles leak under pressure) with no vent or a plugged vent, and in a worst-case drum with a small vent, opening the PR drums could ignite the hydrogen and cause a hydrogen deflagration.

In regards to flammability conditions in the storage room (Room 236), the Fire Hazard Analysis (McKinnis 1998) conservatively used a maximum hydrogen generation rate of 0.82 L/week per drum (based on the higher, more conservative, radiolytic G-value of water instead of plutonium-nitric acid solutions), for a total generation rate of 44.3 L/day for 378 drums in Room 236. More realistic calculations result in a maximum hydrogen generation rate of about 0.63 L/week (Cooper 2000) per worst-case PR drum, for a total generation rate of 33.9 L/day for Room 236, assuming each of 378 drums is the worst-case drum. With a room ventilation rate of 193 m^3/min ($2.78 \times 10^{+8}$ L/day), the maximum hydrogen generation rate of 44.3 L/day is only 0.000016% of the total ventilation rate. Hence, flammability conditions (hydrogen concentration of 4%) cannot be reached in the storage room if the ventilation system is functioning since the conservative maximum hydrogen concentration is only 0.000016%. Even if the ventilation system is not functioning, the analysis in 15F00-00-42 (Cooper 2000) indicates that flammability conditions are not expected in Room 236 based on just barometric pressure changes and resulting leakage and dilution.

Hence, the only concern with hydrogen flammability conditions is inside a PR drum, which is leak tight and not vented or plugged, or the worst-case PR drum with small vent (Cooper 2000).

9.1.2A.1.1 Starting Conditions and Assumptions. The small bottles in the PR drums are assumed to leak under pressure or vent into the PR drums by design. The accidental PR drum is assumed to have no vent or a plugged vent, or the drum is a worst-case drum (in regards to hydrogen generation rate) with a small vent.

9.1.2A.1.2 Sequence of Events. In order for a hydrogen deflagration to occur when a PR drum is opened, improper application of the venting procedure must have been followed on a problem drum (not vented or worst-case vented drum).

9.1.2A.1.3 Operator Actions. Based on the results of the analysis there will be the potential for hydrogen gas at or above the LFL within unvented (e.g., no vent clip) or non-venting drums (e.g. plugged vent orifice). This is based on the analysis of a worst case configuration (i.e., low molarity and high plutonium concentration and activity). The solutions contained in a product receiver poly-bottle or other vessel were generated during processing and can be segregated by batch.

The first required action, operations will identify and segregate PR drums by batch and identify the worst case drum (i.e., low molarity and high plutonium concentration and activity) based on the existing solution sample analysis results. An analysis will be made to determine if there is potential for the gas in the drum to exceed 25% of the LFL for hydrogen (or 1% hydrogen). If the modeling or analytical results determine that the gas within the drum is less than 25% of the LFL, the drum can be opened without punching.

If the modeling or analytical results determine that the gas within the drum is equal to or greater than 25% of the LFL (equal to or greater than 1% hydrogen) the worst case drum will be punched and sampled. If the modeling or analytical results are validated, then all drums within the batch must be punched. If the modeling results cannot be validated, that is, the sample results do not agree with the modeling results, a representative sample of the batch must be punched and sampled. If any gas sample indicates that the gas within the drum exceeds 25% of the LFL all drums in the batch must punched. If all sample results indicate that the gas within the drum is less than 25% of the LFL, the drum can be opened without punching.

9.1.2A.1.4 Engineered and Administrative Safety Features and Protective Systems. Before opening or moving, the PR drums are grounded (grounding clips, drum webs and transportation carts) to prevent sparks, and only non-sparking tools are used to open the PR drum. There is also a remote drum opener for drums without vents (BWHC 1999b). In the storage room, the ventilation system prevents flammability conditions by a large margin, and passive ventilation due to barometric pressure changes and leakage would be sufficient to prevent flammability conditions.

9.1.2A.2 Detection of Event. Detection of a PR drum that has no vent clip is by direct observation by the operator. However, detection of a drum with a plugged passive vent is not directly observed; hence, all drums are treated as if they have flammable conditions.

9.1.2A.3 Analysis of Effects and Consequences. The main consequence of a hydrogen deflagration is injury to the operator. The gas volume is relatively small, such that the deflagration will be very localized.

9.1.2A.4 Corrective Actions. The PFP has trained plant personnel, administrative procedures, and equipment available to prevent a hydrogen deflagration upon opening a PR drum with flammable conditions inside. The

emphasis is placed on prevention by following normal venting procedures and using proper equipment.

9.1.3 Radioisotope-Bearing Powder Spills

Plutonium-bearing powders are generated and stored in the PFP in a variety of locations, quantities, and concentrations. The handling of containers of plutonium-bearing powders both within and outside of the process enclosures was reviewed for the potential to cause an abnormal condition or spill in the PFP and a subsequent release into an occupied area. It is more likely that a container of powder could be spilled within a glovebox or process cell, but any material released would be completely confined. A plutonium-bearing powder container is less likely to be spilled, due to overpacks and a plastic bag, but if released in transit or while in a storage vault, the spill could cause an exposure to personnel. The PuO_2 powder is placed in metal slip-lid cans capable of holding a mass of 2.5 kg. The slip-lid is taped and then removed from a glovebox in a heat-sealed 8-mil-thick bag. Tests have shown that slip-lid cans can withstand drops of 3 meters without loss of contents (Reichmuth 1988). The slip-lid can and bag are then mechanically sealed into two successively larger food-pack cans. Smaller quantities, principally laboratory sample-size containers and cans of scrap from cleanup operations, are also stored but represent an insignificant risk of release compared to the 2.5-kg cans.

Plutonium oxide is assumed for this discussion rather than plutonium tetrafluoride for three reasons. Plutonium fluoride powders are handled less often in slip-lid cans. Plutonium fluoride powders contain a lower fraction of respirable powder than plutonium oxide. Plutonium fluoride is not produced at the PFP anymore. However, it may still be stored in the PFP.

9.1.3.1 Postulated Cause of the Event.

9.1.3.1.1 Starting Conditions and Assumptions. Powder spills and subsequent airborne contamination (aerosols) have occurred in the past due to improper handling, inadequate training, less-than-adequate design of containers, etc. Aerosols are classified as condensation and dispersion aerosols. Powder (or dust) spills produce dispersion-type aerosols from the resuspension of the powder by air currents or vibration.

The composition of a potential powder spill can vary from laboratory sample-size containers containing barely detectable quantities of radionuclides, to an oxide form of plutonium. Virtually any powder that will be handled within the facility has some remote probability of being spilled. However, PFP design, equipment, systems, training, management, operations, and review make the relative likelihood for spills inversely proportional to the hazard presented. For instance, production quantities of PuO_2 are containerized in metal slip-lid cans and the joint taped. Before any material or laboratory samples are transported within the PFP, the container is sealed out of a glovebox using plastic bags, which maintains contamination control of the can from the room.

In order for a spill to occur, the overbag on the bagged and sealed slip-lid can would have to rupture and the slip-lid can would have to open up

and spill its contents. The penetration of an overbag could result from an exposure to any sharp object, but the accidental opening of a slip-lid is unlikely. Drop tests were performed on slip-lid cans containing a variety of materials, and in 25 drop tests from heights up to 14 ft, not one can failed to maintain integrity (Reichmuth 1988). Integrity was maintained despite the fact that the tape seal normally placed over the can/lid joint was purposely left off during the drop tests.

The outer surface of cans is routinely contaminated, however. Therefore, cans must be kept in overbags to prevent the spread of smearable contamination. Overbags also offer additional protection from a potential accidental spill.

The release of plutonium from a spill during seal-out is comparable to the scenario of the oxides spill in *Z Plant Plutonium Handling Operations Safety Analysis Report*, RHO-CD-1224, Rev. 1, Vogt (1983). Plutonium metal buttons, slag and crucible (S&C) fragments, and scrap materials are sealed out occasionally if repackaging is necessary. Buttons and S&C fragments are mechanically sealed in food pack cans in contrast to the taped slip-lid cans described as the single can (Vogt 1983, Section 9.2.1). Dry powders from the vacuum cleaner are sealed out in slip-lid cans with taped lids. Wet or damp scrap is loaded out in wide-mouthed, screw-capped plastic jars (polyjars). Thus, the probability of a single drop resulting in a complete spill is much less than 1.0 due to the nature of the seal-out procedure and equipment used. The probability of such an accident is quite low, as evidenced by the absence of such an incident reported in the accident history (Roemer 1987).

The can and portion of bag being sealed are placed on a special table, which is either portable with adjustable height or is attached to the glovebox. The two layers of bag are heat-sealed and then the end section, in which the can is located, is cut off and the exposed edges reinforced with tape. In addition, the lid on the slip-lid can is normally taped in place as required by procedure. Thus, to have the contents of a can spill out into the room a series of errors, rather than a single error, must occur. There would have to be no tape on the can lid or the can would have to fall in a manner not yet observed or conceived to cause the taped lid to pop off.

9.1.3.1.2 Engineered Safety Features and Protective Systems. All radionuclide-bearing powders handled in the PFP are confined at all times within safety systems such that, at a minimum, a single failure will not result in the release to the environment. In most cases several failures would have to occur. The construction of the facility and systems, training, operation, maintenance, and management are designed to include appropriate redundancy and diversity of safety features to minimize the possibility of concurrent common-mode failures of redundant items.

The PFP confinement systems are composed of the confinement barriers and the associated ventilation systems. Multiple barriers and redundancy in systems is provided in the unlikely event of the failure of any barrier or component of a particular confinement system.

Plutonium-bearing powders are transported between buildings of the PFP and from hand trucks in the three basic types of containers. Powders are stored and transported within and between buildings in steel cans of the type

used in the food industry. All units are at least double contained in metal food pack cans, with the cans mechanically sealed as in the food industry. These cans are then placed in another device for handling. Individual cans are sometimes placed in a 50-lb slip-lid can known as a "lard-can" that is either carried by hand or in a specially designed wagon, depending on the radiation dose rate. When more than two units are transported, they are placed in a fixed-array wagon that is covered by a cage to hold the cans in place should the wagon tip over.

Roadway transport between the PFP and other facilities is done by trucks that are loaded at a dock. The possibility exists for an ≈4-ft drop during loading or unloading. However, the cans of plutonium powder are within U.S. Department of Transportation (DOT)-approved cross-country shipping containers. These containers, usually DOT-6M, are built to withstand the much higher forces of a public highway accident.

There is no credible way to get a release of plutonium-bearing powder into the environment from dropping or overturning a DOT-approved transport device at a loading dock.

9.1.3.2 Detection of Event. A powder spill may be detected by a variety of either passive or active established methods.

9.1.3.2.1 Methods or Means of Detection. The most likely method of detection would be by operational personnel in the immediate area of a spill. A RCT performing a routine surveillance could also find evidence of a spill, personnel in the course of self-monitoring may detect evidence of a spill, or CAMs located within the facility would detect aerosols released from a powder spill.

Air monitoring and warning systems are installed in work areas where radioactive material is handled in order to detect airborne contamination. The air monitors are highly sensitive and, in some cases, will detect evidence of contamination not otherwise detectable by an unaided human. If plutonium is released into the PFP atmosphere, then alarms will be actuated when the CAM alarm setpoint is reached. Upon actuation, facility workers are trained to promptly evacuate the affected air space. These actions in combination serve to reduce the potential plutonium inhalation dose received by the affected facility workers, thereby mitigating some potential facility worker hazards at PFP.

The PFP ventilation systems are sized to exchange room air volume six times every hour so there is adequate air passage from all areas of any room past the air monitors. Air sampling heads are located to provide a representative sample of potential airborne radioactive materials being breathed. Depending on the volatility or energization of the potentially spilled radionuclides, air monitors may or may not be able to discover a spill. The CAMs are set to detect and alarm at prescribed airborne radioactivity levels; if the components of a spill do not become airborne or quickly drop to the floor then detection is not possible by this method.

Throughout the facility provisions have been made for personnel monitoring devices.

Spills are also detected by RCTs performing routine area or equipment surveillances or pre-inspection of a radiation work area.

9.1.3.2.2 Response Time Assessment. Since the most likely component of a powder spill in the PFP is potentially airborne radionuclides, the immediate evacuation of the spill area is required. Respiratory protection for re-entry is also required. With the aid of RCT personnel, an assessment of the spill and its composition can be made by authorized personnel and mitigative action taken. Upon detection, assessment, mitigation, and decontamination, the isolated/confined area can then be prepared for investigation of the cause of a spill and for maintenance and repair purposes.

9.1.3.3 Analysis of Effects and Consequences. For the purpose of this analysis it was assumed that the entire contents of a 2.5-kg slip-lid can containing PuO_2 spilled from a height of 3 m onto the floor outside a glovebox. The 2.5-kg mass and slip-lid can are conservative choices since 2.5-kg masses are normally mechanically sealed into three successively larger containers and most plutonium powder handling is done in 400-g amounts. It was also assumed that all other systems were operating normally before the spill. As stated in Section 9.1.1, spill energy is an important factor in determining the magnitude of airborne releases. Spill height determines the amount of gravitational energy available to break up, shear, and rebound particles on impact. Height also influences the amount of time source material is exposed to shear forces during the fall. These forces work to break off particles from a falling stream. Some plutonium may be resuspended from a deposit pile due to air currents, but this is estimated to be insignificant compared to the spilling process and is also time dependent.

As the result of a free-fall spill from a height of 3 m, it is estimated that 0.12% by weight of the PuO_2 will become airborne (NRC 1981) or, for a 2.5-kg slip-lid can, 0.0030 kg (3.0 g) will become airborne immediately. This number is an upper-bound case from spill tests of free-falling powders, a condition not likely to occur in the PFP. The locations with the highest probabilities for powder spills within the PFP are the glovebox seal-out stations, which are 1 m off of the floor. From the same free fall spill tests identified previously, the observed maximum average weight percent airborne for a 1-m free fall spill was stated as 0.034%. The 0.12% represents a maximum observation from a series of tests where spill height, spill weight, and chemical composition were varied for a free-falling powder. Additionally, the amount of material airborne will vary depending on the size of the powder particles, presence of air currents, the relative humidity, and duration of release.

All PuO_2 powder is handled within enclosed gloveboxes. In case of a breach of confinement these gloveboxes have preferential airflow from operational personnel to the glovebox to reduce potential personnel exposure. The PuO_2 powder is only brought out of a glovebox once the powder has been enclosed in several overpacks and in an outer can. In the unlikely event of a spill occurring, the processing rooms are equipped with CAMs that would alert operators to the presence of respirable airborne contaminants even if the actual spill was not observed. Additionally, operators are required to wear respiratory protection (masks) rated at 99% efficiency during glovebox seal-outs. Seal-outs are anticipated to be the locations for the highest probability of contamination and powder spills.

The most extensive treatment given offgases in the 234-5Z Building is the particulate removal from the ventilation system exhaust. This includes exhaust from contaminated hoods, gloveboxes, process vessels (E-4 exhaust system), and potentially contaminated rooms around the gloveboxes (E-3 exhaust system). The Zone 3 rooms discharge into the E-3 system. The E-3 system air is filtered through a single stage of roughing filter at the exhaust point from the room and then through a single stage of HEPA filtration. The HEPA filter has an efficiency of greater than 99.95% (transmission fraction of 1 - 0.9995 = 0.0005). Given the 3.0 g of plutonium powder potentially spilled in this section and the HEPA filter rating, only 3.0 g x 0.0005 = 0.0015 g plutonium would reach the PFP stack. This is below the 0.02 g acceptance criteria for a stack release of Class Y material (Table 9-51) given a probability of 1.0.

9.1.3.4 Corrective Actions. The PFP has trained plant personnel, administrative procedures, and equipment available to recover from any potential spill. Regardless, emphasis is placed on prevention of spills, which is based on information of past spills and postulated spills. If a powder spill were to occur outside a glovebox, the necessary corrective actions can be summarized into evacuation, exclusion, stabilization, confinement, cleanup, and restoration/inspection. The first step would be to establish the area as an Airborne Radioactivity Area after the alarms had sounded and the personnel were evacuated. This would restrict or exclude access to all but those individuals needed to monitor and clean up the spill. The next step would be to stabilize the spill to prevent it from moving or being moved from its known location. Then it would be necessary to erect a greenhouse with a ventilation system to confine the spread of contaminants while cleanup proceeds. Cleanup would include removing and stabilizing the spilled material until the results are satisfactory to monitoring and management personnel. Once the area has been restored to the pre-spill condition, any further inspections and administrative functions necessary would be applied to release the area to normal operational status.

9.1.4 Radioisotope-Bearing Pressurized Powder Container

Potentially pressurized powder containers may include those containers containing PuO_2 powder, PuF_4 powder, plutonium metal buttons, and recoverable materials (containing reportable amounts of plutonium metal or compounds). Plutonium-bearing powders are generated and stored in the PFP in a variety of locations, quantities, and concentrations. The handling of containers of plutonium-bearing powders, both within and outside of the process enclosures, was reviewed for the potential to cause an abnormal condition or release in the PFP and a subsequent release into an occupied area due to a potential pressurized release.

Plutonium-bearing materials stored in closed containers can pressurize those containers due to the effects of radiolysis, chemical reactions, or internal thermal energy. Plutonium-bearing material forms that may be stored or handled include plutonium metal, dry powders (e.g., PuO_2), and plutonium-bearing recoverable material items.

Plutonium-bearing materials principally are seen as oxides or fluorides but may be combined with organic compounds. The probability of container

failure and the magnitude of any resultant contamination spread is increased by container pressurization. Personnel exposures may be incurred if pressurized containers rupture during handling or rupture occurs outside of confinement and is not detected in a timely manner.

Plutonium-bearing recoverable materials are divided into three categories: (1) unstabilized recoverable material [i.e., recoverable material that is known to be capable of gas generation sufficient to pressurize a container to 34 lbf/in^2 (gauge) during storage]; (2) stable/shippable recoverable material (i.e., material that has well-defined characteristics and is safe for shipment); and (3) potentially unstable recoverable material (i.e., material for which insufficient information is on hand to readily categorize).

Recoverable materials come from processing activities and are obtained from glovebox sweepings meant to control the loss of plutonium-bearing materials and to keep operator exposures As Low As Reasonably Achievable (ALARA). The types of plutonium-bearing recoverable material that may be stored or handled include, but are not limited to, PuF_4 sweepings, PuF_4 for recycle, incinerator ash, polystyrene cubes, Pu-U mixtures, S&C fragments, unirradiated fuel rods, plutonium-beryllium sources, and unique plutonium-bearing solutions.

9.1.4.1 Postulated Cause of the Event.

9.1.4.1.1 Starting Conditions and Assumptions. The PuO_2 powder is contained in metal slip-lid cans capable of holding a mass of 2.5 kg. Smaller quantities, principally laboratory sample-size containers and cans of recoverable materials from cleanup operations, are also stored but represent an insignificant risk of release compared to the 2.5-kg cans. Plutonium powders are stored in a series of successively larger cans, which provide the assurance of a can-within-a-can protection against both inward and outward leakage. The innermost container is typically a 2.5 kg capacity steel can with a lid commonly known as a slip-lid can. The second container, or overpack, is a standard food industry size container commonly used to pack tomatoes, and the outer 7-in. can is the kind commonly used for fruit juices. The successively larger cans provide head space to accommodate expansion; the void space between cans is not filled with any solid materials.

Plutonium metal ingots or "buttons" are stored and overpacked in steel cans of the type used in the food industry. The inner can is the type of small can commonly used to pack tuna fish while, the overpack or "tomato" can size is large enough to accommodate any compound formed from the reaction of the metal with any oxygen or nitrogen contained in the overpack, or with oxygen or nitrogen that might leak through a defective can seam. However, plutonium metal buttons have been known to oxidize in a manner in which the resulting oxide powder did not act as a fluid as it expanded. Rather than rise and expand laterally with approximately equal pressures, the lateral force predominated to rupture the side of the containing can. The use of overpack cans provides additional environmental protection, reducing the probability of an in-leakage of gas, thereby reducing the probability of a rupture due to expansion. Improved canning methods since the mid-1970's have reduced compound formation significantly.

Can pressurization also occurs as a result of radiolysis of hydrogenous material or chemical reaction products. Recoverable materials suspected of containing such materials are heated to temperatures on the order of 600 °C and then tested against Loss-On-Ignition (LOI) criteria. The LOI test is conducted by heating a sample amount of product for a specified amount of time and then measuring the weight loss. No attempt is made to determine the chemical species present. It is assumed that the gaseous products are composed of principally CO, CO_2, air, small amounts of hydrogen/oxygen radicals, and an insignificant amount of water. An LOI of less than 1 wt% is used as one criterion in evaluation of scrap destined for vault storage. The entire history of the material is considered because, as is shown in *Gas Generation in Stored Packed Plutonium*, ARH-CO-433 (Crawley 1975), as little as 0.1 wt% of water in 1,000-g plutonium powder would form ≈2.1 L of gas. Gas production of 2.1 L at atmospheric pressure in a closed 1-L container will produce pressures in excess of 30 lbf/in^2 (absolute).

After LOI samples have been taken, the material is placed in a sealed container before possibly being exposed to a high-moisture environment. As indicated in *Hygroscopicity of Plutonium Dioxide*, RFP-1056 (Stakebake and Dringman 1968), PuO_2 can adsorb water up to 9 mg/g PuO_2 at a temperature of 27 °C. The water seems to be involved in a chemisorption process that is essentially nonreversible at temperatures less than 100 to 200 °C. Loss of moisture control can therefore not be compensated for by simply placing the powder in a dry atmosphere for a comparable period of time.

Current plutonium-handling operations in the storage vaults and storage gloveboxes at the PFP are directed toward shipping and receiving stable/shippable materials, and maintaining the inventory of reactive and potentially unstable recoverable material items in a safe configuration until they can be stabilized. Stable material is that material for which sufficient information is available to ensure that shipment or retrievable storage of the item may occur without incurring undue hazard.

Unstabilized recoverable material is stored in specified gloveboxes in the 234-5Z Building. Items received from off plant that violate the LOI criterion (per acceptance testing), or bulging containers, are categorized as unstabilized recoverable material.

The recoverable material is placed in vented 0.5-L polypropylene or polyethylene jars (polyjars) or in slip-lid cans, which serve as primary containers. The containers are then placed in gloveboxes. The quantity of recoverable material in each container and position in the gloveboxes are controlled by fixed pedestal positions and administrative controls to provide critically safe arrays.

In the past, due to the common usage of unvented 55-gal drums for transuranic (TRU) and non-TRU waste disposal, it was necessary to recover from situations where the drum became a hazard (i.e., pressurized or contaminated). While rare, pressurized drums are generally identified by bulging of the top and bottom. However, not all internally pressurized drums are visibly bulged. There have been several reports, in publication by the DOE Office of Nuclear Safety, of drums burping (i.e., the lids popped off, apparently due to chemical reaction of the contents). These incidents have occurred at various facilities throughout the DOE complex. The internal pressure is caused by

chemical reactions taking place inside the drum, giving off various gases as a byproduct. One example is the nitration of cellulose in acid-soaked rags. Procedures require washing and neutralization of acid-soaked rags. If not so treated, a degree of nitration may result. Various reactions are possible in these drums, due to the varied nature and condition of their contents. Reactions may also take place that evolve hydrogen gas. Since 1978, procedures have specified fitting all drums with vent clips before sealing them, to allow gradual venting of any internal pressure, and with catalyst packets, to eliminate any hydrogen that may evolve during storage. Drums so equipped are assumed not to be pressurized and are opened without the precautions used for bulged drums and drums without vent clips.

9.1.4.1.2 Sequence of Events. Plutonium metal buttons may be transferred to a dry air glovebox for inspection and repackaging. When finished, each button is mechanically sealed into cans. Cans are purged with argon and sealed, and the quality of the seal is inspected to prevent even a minute hole in a can from leading to oxidation of the plutonium metal. The can is then labeled for seal-out. The can is worked to the end of a polyethylene sleeve and placed on a special table where an electronically heated bar seals a section, which is then removed. After securing the sealed edges with tape and the appropriate survey for contamination, the bagged tuna fish can is sealed into a larger can and finally into a 7-in.-dia. food pack can of the type typically used for fruit juices. This can is then surveyed, tamper-indicating seal/labels are applied, the can is weighed and sent to Building 2736-ZB for NDA, and then to storage in Building 2736-Z. If a leakage path is overlooked by the above procedures, oxidization could occur and cause can failure.

Failure to evaluate and control moisture in packaged plutonium metal can lead to container pressurization and possible container rupture. In past instances, container failure resulted from the direct pressure of PuO_2 formation. As the plutonium metal with a density of approximately 19.6 g/cm^3 oxidized to a powder of density approximately 3 g/cm^3, the pressure developed slowly. The release of pressure was not very dramatic. Pressure released following gas generation causes more of a problem. In one instance a can was found off of its pedestal and the contents spread on the floor after it apparently relieved its internal pressure. In another instance a seal ruptured as personnel were picking up the container, causing considerable personnel contamination.

Three mechanisms would likely be responsible for spread of material throughout the affected room. In an instance where a slow growth of oxide took place, the powder would tend to slowly work its way out of the can and fall at a slow rate to the objects and floor below. The airborne release would come about during the fall and by resuspension after it fell. In those instances where gas pressure was responsible, the primary suspension would come about from the violent ejection of powder. Resuspension of the ejected material is a function of the escape gas velocity and would probably take place in proportion to the air velocity.

9.1.4.1.3 Engineered Safety Features and Protective Systems. Plutonium-bearing recoverable material known to be capable of gas generation that could cause pressurization in a sealed container during storage is stored in a vented configuration, which maintains contamination control. The use of

nested cans to contain plutonium provides multiple barrier confinement. In addition, the cans are stored in facilities with at least one stage of HEPA filtration.

In the event that a drum was closed without a vent clip, as required by procedure, and the drum became pressurized, it would be opened under controlled conditions. The drums would be remotely opened using a drum punch assembly. Protective shielding would mitigate the effects of a rapid discharge of gases. Venting of any internal pressure would be done into the E-4 exhaust system. The interior would then be flooded with argon to displace and dilute any residual explosive gases.

For drums not exhibiting bulging, the puncturing device would be fixed just above the drum lid to act as a restraining device, and the lid vented manually. Manual venting would be accomplished by loosening the drum ring and prying up the lid to break the seal and vent the interior.

9.1.4.2 Detection of Event.

9.1.4.2.1 Methods or Means of Detection. Containers are inspected periodically for pressurization as indicated by bulging of the container. Containers are inspected for corrosion, dents, penetrations, and faulty seams or seals before being placed into storage in Building 2736-Z. In addition, electronically operated detectors in the storage positions can sense bulged cans. Any container pressurization revealed by these methods results in the container being taken to a glovebox and repackaged. Following an actual release in storage, the event would most likely be detected by the room CAMs and later by personnel inspection.

Chapter 8.0 of this FSAR details radiation detection. A brief summary follows.

Ambient air sampling and monitoring systems are placed in strategic locations to detect and evaluate potential airborne contamination at work locations. Air sampling equipment is used in occupied areas where, under normal operating conditions, a person is likely to receive an annual intake of 2% or more of the specified Annual Limit of Intake (ALI) values (40 Derived Air Concentration (DAC) hours). Locations of fixed head samplers (FHS) and CAMs are determined, documented, and periodically reviewed using the guidance of *Criteria for Westinghouse Hanford Company Work Place Air Sampling Program*, WHC-SD-GN-TA-30001, Rev. 0 (Ruben 1994), which was the guidance document for air sampling at WHC facilities. Air sampling and monitoring equipment and techniques used can be divided into four general categories: (1) breathing zone or room air samples, (2) CAM devices, (3) stack effluent samplers and monitoring systems, and (4) portable air samplers. Breathing zone or room air samplers are used to establish average breathing zone air concentrations or to quantify chronic low-level airborne exposures. The CAMs are used in areas where dispersible radioactive material is handled and/or the potential for airborne radioactive release is high.

The CAMs provide an annunciation of a changing workplace environment. Continuous air monitoring equipment is in occupied areas where a person without respiratory protection is likely to be exposed to a concentration of radioactivity in air exceeding 1 DAC or where there is a need to alert

potentially exposed workers to unexpected increases in the airborne radioactivity levels. Continuous air monitors are capable of measuring 1 DAC when averaged over 8 hours (8 DAC-hours) under laboratory conditions. Facility exhaust stacks are monitored by CAMs to provide rapid indication of a detectable release of airborne radioactivity. Portable air samplers are used for special or supplemental air sampling (grab sampling) when a CAM indicates an increase in radioactivity, for special evaluations of radiological conditions, or for specific tasks.

In addition to providing detection of the event, CAMs and their associated alarm function mitigate some potential facility worker hazards at PFP. Upon actuation, facility workers are trained to promptly evacuate the affected air space. These actions in combination serve to reduce the potential plutonium inhalation dose received by the affected facility workers. The public and onsite workers are not significantly affected by these potential releases inside PFP because the exhaust air flow is filtered by the applicable exhaust ventilation system prior to release outside of PFP.

9.1.4.2.2 Response Time Assessment. The discharge of gases from a pressurized powder container in the PFP could contain airborne radionuclides. Therefore, if a discharge occurs, the immediate evacuation of the area is required and can be affected in several seconds upon alarm notification. Unless the extent of the spill is large, automatic detection may not occur due to the small amount of material that becomes airborne. In that case there may be a significant lag time between the event and detection. Small quantities of radionuclides may be detected by self-surveying of personnel who come in contact with the material. In general, the smaller the quantity of uncontained radionuclides, the longer the response time will be due to detection lag. A significant release of a radionuclide can be expected to be detected immediately by a variety of means. Primary reliance is on using only trained personnel, and in prompt evacuation of the work area if a problem occurs.

9.1.4.3 Analysis of Effects and Consequences. The handling of containers of plutonium-bearing powders that become pressurized both within and outside of the process enclosures was reviewed for the potential to cause an abnormal condition or release in the PFP and a subsequent release into an occupied area. It is most probable that a container of powder would be discharged within a glovebox or storage vault, and any material released would be completely contained with the enclosure and the associated ventilation/confinement system. A pressurized plutonium-bearing powder container would be more likely to cause a release than handling an unpressurized container, but, due to the low incidence of pressurization, the risk to personnel is expected to be similar.

The effects of a can rupture can be modeled from data on pressurized releases (Sutter 1983), from free fall powder spill experiments (Sutter et al. 1981) and from various sources of resuspension data. The pressurized container information must be used with care when applied to the case of multi-packed containers. The free fall powder spill experiments involved spills of 100-g to 1,000-g quantities of UO_2 powder that caused interaction between particles and produced localized air currents as the material fell. The slow dribble of material to a floor might not produce as much disruptive energy per particle. Resuspension by the slow-moving air in a storage cubicle

is less than that reported in the literature. Upper-bound figures are not likely to be more than a few grams. While this would be sufficient to cause a significant in-plant event, it would not seriously challenge even a single stage of HEPA filtration.

The concentrations of airborne radioactive material expected during off-normal occurrences were based on historical data from 1986 through 1988 that was collected from 90 out-of-tolerance reports (see Chapter 8.0). This information shows that the concentrations of airborne radioactive material that exceeded the operational plant limit of 2×10^{-12} μCi/mL (^{239}Pu) has averaged 9.2×10^{-12} μCi/mL. Only two incidents occurred where concentrations were in the 10^{-10} range. The worst case reported was 2.52×10^{-10} μCi/mL.

Typical processing rooms are ventilated at rates of 300 ft^3/min to 1,000 ft^3/min and the stack discharges at ≈225,000 ft^3/min. Thus, even without any filters the release concentrations would be factors of 300/225,000 to 1,000/225,000 lower. The E-3 filter would lower this by another factor of 2,000 and the various other air clearing forces by some undeterminable amount. Thus, a release into a room at a level of 2.5×10^{-10} μCi/mL would result in an increase at the stack of between 5.6×10^{-16} μCi/mL and 1.7×10^{-16} μCi/mL both of which are well below the minimum detection level of 5×10^{-15} μCi/mL (Chapter 8.0, Section 8.6.1.1.1). This is in contrast to normal stack emissions in the range of 4×10^{-14} μCi/ml and an alarm limit of 2×10^{-12} μCi/mL. Such a room contamination would be undetectable at the stack, and if it was detectable, it would be orders of magnitude below a significant amount (Section 9.0.2.2).

Personnel involved with plant or process operations that may result in airborne radioactivity are routinely required, by procedure, to wear respiratory protection during these operations. The effectiveness of this requirement is demonstrated by the low incidence of recorded body burdens of personnel.

9.1.4.4 Corrective Actions. In the event that radioactive material that does not meet the LOI specifications is identified to be in pedestal, cubicle, or cabinet storage, management is alerted and the material is removed from storage within one working day and dispositioned per an approved work plan.

As a result of past container pressurization experiences, numerous corrective actions were taken to prevent recurrence. The range of lessons learned from container overpressurizations and the corrective actions that resolved the situation are summarized in Vogt (1983, Table 4).

9.1.5 Stack Release Resulting from Filter Changes

The secondary HEPA filters are the last barrier between contamination and the stack; if this barrier is in some way circumvented, then a release to the atmosphere is possible. Great care and judgment must be used in the changing out of these filters to avoid release of plutonium to the stack.

HEPA filters have proven to be the most effective, reliable, and economical device for removing low concentrations of sub-micron particles at extremely high collection efficiency. A HEPA filter is a throwaway,

extended-media dry-type filter with a rigid casing enclosing the full depth of the pleats. HEPA filters exhibit a minimum efficiency of 99.97% when tested with an aerosol of essentially monodispersed 0.3 micrometer particles. The type used in the 236-Z Building are cubes, 2 ft on a side. A plate with a nipple in the center is used for the front and back faces of the cube, the remaining sides are made of plywood. Those used in the filter rooms in the 234-5Z Building are only 11 3/4 in. deep and have open faces instead of the plate with a nipple. Other filters in the building are cylindrical with a metal housing. All cylindrical filters are in locations where there are other filters downstream, so that any material that might get loose would be caught on the downstream filter. The cylindrical filters will not be considered further.

9.1.5A Dropped Filter, Filter Room 309 or 310

The filter rooms within the 234-5Z Building use all plywood-cased HEPA filters that are either nailed or screwed together. The filter pack consists of a continuous sheet of glass fiber mat, pleated back and forth over itself so that it has a large surface area, is self-supporting, and is permanently bonded to the integral frame. The banks of filters in these rooms constitute the secondary or final stage of filtration before air is discharged from the 200-ft-tall stack.

9.1.5A.1 Postulated Cause of the Event. It is postulated that during a routine filter change in room 310 in the 234-5Z Building, a HEPA filter is dropped ≈8 ft onto a concrete floor. This results in the release of contaminated dust into the filter room. Because the louvered outlet dampers for these rooms do not close completely, the plutonium laden dust would be drawn to the exhaust plenum and directly to the stack, setting off the stack CAM.

9.1.5A.1.1 Starting Conditions and Assumptions. A filter change is in progress in either E-4 filter room 309 or 310. The louvered dampers have been closed to isolate the room from the stack plenum, but they leak and no plastic is placed over them as required by procedure (to prevent flow up the stack). To estimate the amount of plutonium present on the E-4 HEPA filters, reference is made to recent NDAs performed following a HEPA filter change-out of room 310 *Measurement Results of HEPA Filters* (Fazzari 1994). The measured plutonium loading of over 100 individual filters ranged from a low of 5.0×10^{-4} g to a high of 3.7×10^{-3} g, with a mean of 1.2×10^{-3} g. For this analysis, the measured high value of 3.7×10^{-3} g is used in conjunction with a safety factor of 2, which yields an inventory at risk of 7.4×10^{-3} g. The safety factor of 2 is applied to account for potential increases in future filter loadings and is judged to be appropriately conservative given that (a) the measured high value is used, and (b) the NDA results are for filters that were in place for 14 years, with major PFP processes operating during 7 years (e.g., the RMC Line and its support operations). In contrast, current plant operations are conducted on a much smaller scale (e.g., operation of glovebox HC-21C versus operation of the entire RMC Line) such that filter loadings are expected to be lower. Note that Fazzari (1994) and a safety factor of 2 are also used to assess the consequences associated with seismic-induced failures in the filter rooms (see Section 9.2.4.6.3.1.X.a).

9.1.5A.1.2 Sequence of Events. The normal complement for entry into the filter room includes two millwrights for removing and installing filters, two operators to assist in packaging and removal of filters from the filter room, two more operators outside of the filter room for final packaging of the filters, two RCTs for contamination surveys outside of the filter room, and vent and balance personnel for adjusting the airflow of the room. While the top filter on the south corner of the east bank is being removed, the millwright drops it to the floor. The filter lands on a corner of the frame, violating the integrity of the case, but the filter retains its original shape and dimension. The filter media is retained. Some contaminated dust from the filter is released. The airborne dust is exhausted from the room into the plenum and released from the 291-Z stack. Although the flowrate through leaking dampers would be low, respirable particles stay in the air for some minutes. As is shown in Section 9.2.4.7, a 4-μm particle falls at a rate of 0.32 ft/min and smaller particles at a slower rate. On notification of the stack alarm, the job would be terminated.

9.1.5A.1.3 Action Taken. In this scenario the personnel involved with the filter change do not recognize the problem associated with dropping the filter, and continue with the changeout. When the stack CAM exceeds its set point, it activates an alarm panel in MICON control room 714. The power operator immediately notifies the Shift Manager/Building Emergency Director in Room 104. Upon determining that it is a stack alarm for the 291-Z stack, a RCT is sent to pull a sample, count it, and determine if it is necessary to send the sample for laboratory analysis. (If the initial count by the RCT is high, then the CAM alarm is considered to be real until official results are received from the laboratory.) Operations Managers are notified, and the filter change is shut down.

9.1.5A.2 Detection of Events.

9.1.5A.2.1 Methods or Means of Detection. The first detection of the problem would most likely come from the changeout crew itself. However, because they would not know if they had created a stack release or how large it might have been, the assumption is that the work continues.

The airflow out of the building is monitored by a CAM that will annunciate an alarm when pre-established set points are exceeded. The stack CAM is also connected to the annunciator board in room 714 (MICON™ power control room) within the 234-5ZA Building. The room 714 board is monitored by power and operations personnel.

9.1.5A.2.2 Response Time Assessment. The time it takes from first notification of a stack alarm to initial assessment of release levels is assumed to be ≈1/2 h. Within this time frame the filter change is terminated and necessary notifications are made.

9.1.5A.2.3 Engineered Safety Features and Protective Systems. The dampers controlling the airflow into and out of the filter rooms do not provide a positive closure, allowing a minimum amount of airflow to exist, unless plastic sheeting is placed over dampers. This condition is allowed as it provides a negative atmosphere to the room while work is being performed within. Directly outside of the filter rooms on the outlet plenum is an

inline air sampler that is used to confirm any release and determine the level of particles released from the filter room.

There are no inline CAMs downstream of the filter rooms other than the stack CAM itself.

The filters are the final barrier between contamination and the 291-Z-1 stack. Based on the stack release shown in the previous section, it seems probable that the release would not exceed the guidelines for significant release even for an event with a probability equal to 1.0.

9.1.5A.3 Analysis of Effects and Consequences. A number of studies lead to a conservative estimate that 1% of the inventory on a dropped HEPA filter would be released as respirable particles. This figure is used in a study of the Westinghouse Cheswick Site, in which a strong wind was postulated to dislodge plywood cased HEPA filters from their housings. In the initial drop, 1% of the filter inventory was estimated to be released (Mishima et al. 1979a, p. 46). A number of the studies cited in *Waste Encapsulation and Storage Facility, K-3 Filter Drop-Inventory Release Fraction*, WHC-SD-WM-TI-171 (Wodrich 1984) indicate that the 1% figure is appropriately conservative. Thus

$$0.01 \text{ respirable powder released} \times 0.0074 \text{ g per filter} = 7.4 \times 10^{-5} \text{ g respirable powder released}$$

As is shown in Table 9-51, this amount of plutonium is below the release limit for a stack release event having an annual probability of one. It would be well above the amount needed to trip the stack alarm as is shown in Section 9.4.4.

9.1.5A.4 Corrective Actions. Corrective actions would be limited to cleanup of the filter room as the event would be over in seconds and there is no way to stop the airflow after the fact.

9.1.5B Filter Room 26, 236-Z Building

The 236-Z Building ventilation is exhausted through four banks of filters. Three of the banks are used to exhaust E-3 air and the other one is used to exhaust the E-4 air. There are HEPA filters in each bank. The E-4 exhaust can be switched over to one of the E-3 banks when the E-4 bank filters are changed out.

The filters used in the 236-Z filter room are 24-in. by 24-in. by 24-in. nipple-connected filters with a plywood casing. The casing completely encloses the filter except for two metal nipple connectors, one on each end of the filter.

The filters are held in place with metal hangers, with the nipple connectors facing one up and the other down. When the filters are removed,

the connectors are immediately covered with a cardboard or Lucite™[1] cover to prevent any contamination from being released from the filter media. Due to the ability to cap the nipples, there is little chance for noticeable stack release.

Radionuclides present in the PRF canyon and gloveboxes were deposited in the form of residues and sludges associated with wet processes and are not easily resuspended. In addition, PRF is an inactive facility, thus, significant amounts of contamination are not being disturbed and released to the ventilation system.

It is reasonable to assume that the release from 236-Z to the 291-Z-1 stack would be considerably less than the 7.4×10^{-5} g respirable released from a dropped filter in filter rooms 309 or 310.

9.1.6 Overpressure of Remote Mechanical C Line Pressure Vessel

Since plutonium metal is no longer produced at PFP, Section 9.1.6 is not required. The RMC Line pressure vessel is no longer used at the PFP. If future use of the vessel is required, Section 9.1.6 will be analyzed and incorporated.

9.1.7 Ventilation System Upsets

In no case was a ventilation upset in itself found to be the cause of a loss of plutonium control, but was shown to be a significant contributor to spread of contamination if it was already loose or to an external release if confinement was breached. The analysis examines a variety of upset conditions on a building-by-building basis which is reflected in the organization of this section. The sections associated with each building are designated by letters in the paragraph numbering system. The most plausible upset conditions found were for inadvertent pressurizations due to supply system malfunctions. The supply system for the 234-5Z, 242-Z, and 236-Z Buildings are served by a common source. Upsets in these buildings could come about through failures of one or more of the five Zone 3 subsystems.

Flowing air is the primary vector for the spread of radioactive materials within a building following events that cause their release from containment. An air pressure upset becomes significant because airflows that have been established for protection may become reversed. Events regarding airflow reversals are detailed in Sections 9.1.7, 9.1.8, and 9.2.4.

9.1.7A Excessive Building Pressurization--234-5Z

This analysis examines the mechanism for pressurizing the rooms in the 234-5Z Building housing sources of radioactive materials. If the pressure level is greater than the surrounding atmospheric pressure, any loose

---

[1]Lucite is a trademark of E. I. Du Pont de Nemours and Company, Wilmington, Delaware.

radioactive materials will tend to be forced out of the building to the environment.

9.1.7A.1 Postulated Cause of the Event.

9.1.7A.1.1 Starting Conditions and Assumptions. Eight electric motor-driven supply fans and seven electric motor-driven exhaust fans provide the bulk of the ventilation for the 234-5Z Building. The ventilation provides contamination control as well as normal ventilation functions.

The supply fans furnish outside air to a supply plenum in Building 234-5Z. The fans are divided into two groups on the second floor of the 234-5Z Building. Three of the fans use continuously variable dampers for modulating the airflow and operate together under a single control system to maintain fine control of the plenum pressure (+2 in. w.g. with respect to an atmospheric reference point). The five remaining fans operate with full-open or full-closed dampers to provide large step sources of pressurized air. Each fan is on a separate on/off switch. None of the fans are on emergency power.

The exhaust fans are located both in the 291-Z Building and the 234-5Z Building. These fans remove air from the various rooms within the 234-5Z Building and discharge it to the outside. The exhaust fans are divided into two groups. Group one, in the 291-Z Building, discharges highly filtered air that ventilates the production part of the building. Group two, housed in the 234-5Z Building, discharges air that ventilates that part of the building used for office personnel (Zone 1).

Group one consists of seven exhaust fans. The controls and functioning are similar to the supply fans with two of the fans having modulating dampers while three of the remaining fans use full-open or full-closed dampers. The last two fans use manually adjustable dampers. Two of the group 1 electric motor-driven fans are on backup power. Group two consists of two main exhaust fans and other lesser exhaust fans dumping to atmosphere.

The ventilation air establishes four levels of pressure for rooms within Building 234-5Z to maintain contamination control. The rooms and areas housing radioactive materials are maintained at the lowest pressure, below the surrounding atmospheric pressure. The levels are labeled as in Table 9-4.

The ventilation is controlled by 5 dampers in the various airstreams. Continuously variable dampers controlled by closed loop pneumatic (instrument air pressure-driven) systems are used in the discharge of the supply plenums, on three of the supply fans, and on two of the exhaust fans in the 291-Z Building.

Office areas, designated as Zone 1 for being free of radioactive materials, are maintained at the highest pressure, above the surrounding atmospheric pressure. There are rigid barriers between Zone 1 and the other zones. Personnel must use an airlock to pass between the areas. Zone 3A is at a slightly higher pressure than Zone 3 but is still negative with respect to atmospheric pressure. Zone 3B is in the old inspection area (rooms 192 through 197). Zone 3B is at a negative pressure higher than either Zone 3* (serviced by damper B alone), 3 (serviced by damper C alone), and 3A.

Normal operation would find the system operating with all zones at pressures as shown in Table 9-4. Flowrates into the various areas are discussed in Chapter 5.0.

In all instances the amount of additional flow was found to be insufficient to load the filter to the overpressure resistance rating as stated in *Hanford Specifications for Fire- and Moisture-Resistant Nuclear Grade HEPA Filters*, HPS-157-M, Rev. 1, paragraph 6.2.5 (Price 1991).

An impact on the E-4 system (Zone 4) was not evaluated. Gloveboxes draw air from the rooms or from the building dry air system. Hoods draw air from the rooms. By drawing air from the rooms the gloveboxes and hoods follow the movement in the room pressure level and maintain the same DP with the room. Those gloveboxes ventilated with the dry air system are equipped with a large gas diaphragm-operated valve (DOV) designed to shut off the supply of dry air if the glovebox starts to pressurize with respect to the room. This would have no effect if the room overpressurizes; the glovebox would be at a negative pressure with respect to the room. However, if the room drops in pressure (see Section 9.1.7F), the valve would close--shutting off the source of dry air and allowing the glovebox to remain negative with respect to the room.

9.1.7A.1.2 Sequence of Events. A hypothesized scenario is that the building might be partially pressurized by the opening of one of the supply dampers attached to the supply plenum controlling the discharge of the air from the supply plenum to the various zones. It was hypothesized that an inadvertent opening would occur through the loss of control air caused by someone inadvertently opening (or closing) a valve on the pneumatic control lines. There are numerous small valves associated with the system both in back of the panelboard in the control room and at the dampers.

The postulated single event would be the opening of the single valve at any of the dampers. The control pressure would be lost and the damper would fail open, as this is its normal failure mode. The airflow to the system controlled by the individual supply damper would increase (to some level) and then stabilize. The drop in pressure in the supply plenum would be compensated for by the remainder of the supply system. There are normally five fans, each rated at 76,100 ft^3/min at 5 in. w.g., in service to pressurize the supply plenum. On the discharge side, the filter plenum pressure would likely rise a small amount. The sensor in the filter plenum would adjust the modulating damper to the one exhaust fan using such a damper, and the filter plenum pressure would return to its preset level.

The failure of damper A is not discussed. Zone 1, supplied through damper A, is maintained at a positive pressure with respect to atmosphere and all the other zones. A failure of the damper would drive the zone additionally positive, which would have no effect on contamination control. The amount of additional pressurization would be small.

9.1.7A.1.2.1 The Failure of Damper C. The S-3 ventilation supply, controlled by damper C, was the first situation examined. The production area is ventilated with this system and the failure could occur without tripping any alarms. The S-3 system supplies ventilation for those rooms in the building that contain most of the gloveboxes and hoods (Zone 3).

A failure of damper C (the damper opens) would have the following effects on a normally operating system.

- The filter plenum and exhaust plenum pressurize. The dampers have not had an opportunity to adjust. All pressures, except the supply plenum, rise.

- The pressure sensor in the supply plenum senses a drop in supply plenum pressure. It then signals the automatic controller for the supply plenum supply system to adjust the damper on the modulated supply fans to open. This increases flow to the supply plenum until supply plenum pressure is reestablished.

- The timer on the Zone 1 to Zone 3 pressure reversal alarm starts. If the reversed condition has not corrected itself within 5 s, an alarm sounds and the system shuts off the electrically driven supply and exhaust fans.

- The sensor in room 235-C signals the automatic controller for the supply plenum discharge system to adjust both damper B and C, since they are tied to a common control line, to decrease flow to both Zone 3* (serviced by damper B alone) and Zone 3 to reestablish zone pressure. However, this postulation has stated that damper C has failed and cannot respond. Damper B remains operative and does respond to the point where room 235 is returned to the preset pressure (room 235 receives ventilation air from both damper B and damper C controlled systems).

- Those Zone 3* rooms that are supplied solely from damper B will experience a drop in pressure.

- The sensor in the filter plenum signals the automatic controller for the exhaust system to adjust the damper on the modulated exhaust fans to increase flow from the filter plenum to reestablish filter plenum pressure.

- In the previous step, if the modulating damper on exhaust fans 3 or 4 adjusts to full-open, an alarm will sound.

Zone 3* serviced by damper B alone, Zone 3 serviced dually by duct work from dampers B and C, and Zone 3A serviced by duct work from damper D can all be pressurized with the same failure mechanism. These will be addressed later.

Scoping calculations for the damper C failure scenario show that an opening of damper C would briefly change the ventilation pressure for those rooms throughout Zone 3 receiving air solely from the S-3 ventilation supply. Pressure would increase from the normal range of -0.14 to -0.17 in. w.g. to 0.9 in. w.g. The exhaust damper adjusting and the supply plenum adjusting have no effect. Room 235 and certain others with a dual supply from both the damper B and damper C controlled ventilation supplies will return to near the preset pressure.

Those Zone 3 rooms serviced solely from damper B will experience a drop in pressure. Room 235 houses the pressure sensor for a feedback loop to correct the control of both damper B (Zone 3*) and damper C (Zone 3) and receives air from both supply ducts. In this scenario damper C has failed and is thus inoperative, but damper B remains active and will be responsive to the control loop throttling supply air to correct room 235 back to the original preset pressure. This throttling of damper B could drive air from the dually supplied rooms back into the damper B system to supply those rooms served solely by damper B. Predicting the resultant pressure level in these rooms is nearly impossible as all pneumatic resistances from the supply plenums to the rooms change. A scoping calculation predicts that the room will depressurize to as much as -2.5 in. w.g. The fact that other sources will feed into rooms 210, 211, and 212 to raise the pressure in the rooms is not considered. Zone 1 supplies air to the "clean side" of rooms 210, 211, and 212.

Failure of damper C would not trip the low pressure alarm for the supply plenum. The instantaneous loss of pressure would be ≈0.11 in. w.g. The system requires a loss of 1 1/2 in. w.g. before tripping. Lacking an alarm the system would reestablish the supply plenum pressure to a 2 in. w.g. without further incident.

A failure of damper C would likely fail to trip the pressure level reversal alarm between Zone 1 and Zone 3. A reversal between building ventilation Zone 1 and Zone 3 will occur but would likely clear within the 5 s count delay for sounding the alarm. A worse case is to assume that damper B would compensate to bring the pressure in room 235-C back to the preset pressure level. If the compensation occurs within the 5 s alarm time delay, the automatic shutdown system will not complete its cycle and the ventilation will continue operation. The system would not be sensing a pressure reversal between Zones 1 and 3 because none would exist at the respective sensing points.

Damper C opening would likely fail to trip the position alarms on the exhaust modulating dampers D-95 and D-97. The magnitude of the total building flow change due to the upset is too small.

Damper C opening would also likely fail to trip the pressure level alarm in the main exhaust plenum.

The failure of damper C would result in a pressure reversal between the operating (viewing) galleries (rooms 229 and 233) and the process areas (rooms 228 and 235-A) (Figure 9-3). A similar reversal would exist between process rooms 235 and 232. Note that room 235-A-1 may, at times, be maintained as an Airborne Radioactivity Area, while room 232 is normally maintained as a Surface Contamination Area.

In conclusion, damper C opening would pressurize rooms 146, 148, and 308; however, any release due to this pressurization is considered of low probability since so many events must occur simultaneously. Although these rooms house a variety of containers, including gloveboxes, open-faced hoods, filterboxes, or the equipment that provides the 26-in. Hg vacuum system a substantial quantity of suspendable contamination from them must be present in the room free of the containers. As discussed in Sections 9.1.1

through 9.1.4, free materials, even if completely released, would not exceed the Risk Acceptance Guidelines.

A pressurization of Zone 3 (damper C supply) cannot transfer radioactive materials from Zone 3 to Zone 1. That part of Zone 3 that is supplied from damper C lacks a direct interface with Zone 1. The other zones will buffer any influence from this zone into Zone 1.

9.1.7A.1.2.2 The Failure of Damper B. The control rooms for the RMA and RMC Lines, the radiation zone side of rooms 210, 211, 212, and the 225 (vault) are the only areas serviced solely by the damper B controlled S-3 system. Other rooms have a mix of S-3 air from both the damper B and damper C duct work, as listed in Table 9-5. As with the damper C failure, a failure could occur without tripping any alarms. A failure of damper B (the damper opens) would have the same effects as those of damper C, except the roles of dampers B and C are reversed.

Scoping calculations for the damper B failure scenario show that an opening of damper B would change the ventilation pressure, for those rooms throughout Zone 3 receiving air solely from the duct work serviced by damper B ventilation supply, from the normal range of -0.14 to -0.17 in. w.g. to 1.0 in. w.g. Again, room 235 and certain others with a dual supply from the S-3 (both dampers) ventilation supply will return to near the preset pressure.

In this scenario, damper B has failed open and is thus inoperative, but damper C remains active and will be responsive to the control system. The control loop will throttle supply air to correct room 235 back to the original preset pressure. This throttling or shutting down of damper C will drive those rooms supplied by only the S-3 (damper C) system to a -0.9 in. w.g. pressure. Those rooms serviced dually by the S-3 (both dampers) supply air systems will behave similarly to room 235 and will return to close at the preset negative pressure. The actual pressure will depend upon the original mix of S-3 supply from both dampers.

Damper B's failure would not trip the pressure level alarm for the supply plenum. The instantaneous loss of pressure in the supply plenum would be less than 0.07 in. w.g.

A failure of damper B would likely fail to maintain a trip of the pressure level reversal alarm between Zone 1 and Zone 3. A reversal between building ventilation Zone 1 and Zone 3 would occur and trip the timer on the alarm. However, the upset condition between the sensors in corridor 14 (Zone 1) and room 235 (Zone 3) will clear; the timer would reset within the 5-s count delay for sounding the alarm, and the alarm would not sound.

Damper B opening would likely fail to trip the position alarms on the exhaust modulating dampers D-95 and D-97. The magnitude of the total building flow change due to the upset would be too small to trip the pressure level alarm in the main exhaust plenum.

A pressurization of Zone 3* (damper B supply) cannot transfer reasonable quantities of radioactive materials from Zone 3 to Zone 1. Room 211 is supplied from damper B and lies wholly within Zone 1. A pressurization

would sweep Zone 3 air into Zone 1. This should not result in spread of contamination to Zone 1 since the room is free of contamination. The other interface of Zone 3 with Zone 1 exists between room 233 and corridors 2 and 13. Door 305 connects room 233 and corridor 2. Door 306 connects room 233 and corridor 13. Room 233 is the control room for the RMA Line. There are no radioactive materials stored in this room.

9.1.7A.1.2.3 The Simultaneous Failure of Damper B and Damper C. There are numerous valves on the control lines to these dampers, and it could be postulated that the control air is inadvertently shut off to both dampers. The possibility of damage has been recognized.

The S-3 ventilation supply, controlled by dampers B and C, presents a condition that would be immediately recognized in the control room due to the alarms that sound. The nature of the areas serviced with these systems has been noted previously.

A failure of dampers B and C (the dampers open) together would have the following cascade of effects (in a rough order of occurrence).

- The filter plenum and exhaust plenum pressurize to a point where the exhaust fans cannot handle the increased flow. The dampers have not had an opportunity to adjust. All pressures, except the supply plenum, rise.

- The pressure sensor in the supply plenum senses a drop in supply plenum pressure. It then signals the automatic controller for the supply plenum supply system to adjust the damper on the modulated supply fans to open. This increases flow to the supply plenum until supply plenum pressure is reestablished.

- The timer on the Zone 1 to Zone 3 pressure reversal alarm starts. After 5 s, it sounds an alarm.

- The sensor in the filter plenum signals the automatic controller for the exhaust system to adjust the damper on the modulated exhaust fans to increase flow from the filter plenum to reestablish filter plenum pressure.

- If, in the previous step, the modulating damper on exhaust fan 3 or 4 adjusts to full-open the alarm will sound.

- A minor effect would be the driving of Zones 3A and 3B to above atmospheric pressure as in the first listed response above. The sensors in room 270 for Zone 3B and corridor 5 for Zone 3A would signal the control system for both zones to return the zones to the preset pressure. Their pressure excursion above atmospheric would be brief.

Scoping calculations for this dual damper failure scenario show that all the rooms serviced by either the S-3 from damper C or a mix of each ventilation system will change from the normal range of -0.14 to -0.17 in. w.g. to a positive 0.9 in. w.g. Thus, failure of dampers B and C would not trip the pressure level alarm for the supply plenum. The instantaneous loss

of pressure would be less than 0.2 in. w.g. The system requires a loss of 1 1/2 in. w.g. prior to tripping. Lacking an alarm, the system would reestablish the supply plenum pressure to a 2 in. w.g. without further incident.

A failure of these dampers will trip the pressure level reversal alarm between the Zone 1 and Zone 3.

A failure of these dampers will trip the position alarms on the exhaust modulating dampers D-95 and D-97.

A failure of these dampers will fail to trip the pressure level alarm in the main exhaust plenum.

In conclusion, a failure of these dampers will have the same effect to the outside environment as a failure of the individual dampers. This would mean a problem will exist with potential releases to the atmosphere from corridor 4C (door 122), room 169 (door 123), room 171 (door 125), and room 179 (door 126) as with the failure of damper C. As with the failure of damper B, the radiation zone side of the RMA and RMC Line area will be pressurized, dumping air into Zone 1.

A pressurization of Zone 3 (damper B and damper C supply) could transfer radioactive materials from Zone 3 to Zone 1. That part of Zone 3 supplied by both dampers B and C interfaces with Zone 1 at room 221-B (door 280), at room 233 (doors 305 and 306), at room 235-B (door 308), at room 264 (door 363), at corridor 34 (door 440), at room 308 (door 405), and at room 235-D (door 651). These doors all are latched security doors. The doors are either sealed with tape or are close fitting. There are no materials stored in room 221-B and only drums stored in room 235-D. Room 235-B does have materials contained in gloveboxes housed within the room. A simultaneous pressurization and existence of materials outside (an accident situation) would stress the interface barriers. The barrier would then have to experience a breach.

9.1.7A.1.2.4 The Failure of Damper D. A fail open occurrence of the S-3A ventilation supply, controlled by damper D, will pressurize almost the entire south wall of the 234-5Z Building and will pressurize the 242-Z Building. The S-3A system supplies ventilation for the remainder of the rooms in the building that contain gloveboxes and hoods (see Table 9-6).

A failure of damper D (the damper opens) would have the following cascade of effects (in a rough order of occurrence).

- The filter plenum and exhaust plenum pressurize to a point where the exhaust fans can handle the increased flow. The dampers have not had an opportunity to adjust. All pressures, except the supply plenum, rise.

- The pressure sensor in the supply plenum senses a drop in supply plenum pressure. It then signals the automatic controller for the supply plenum supply system to adjust the damper on the modulated supply fans to open. This increases flow to the supply plenum until supply plenum pressure is reestablished.

- The sensor in the filter plenum signals the automatic controller for the exhaust system to adjust the dampers on the modulated exhaust fans to increase flow from the filter plenum to reestablish filter plenum pressure.

- If, in the previous step, the modulating damper on exhaust fan 3 or 4 adjusts to full-open, the alarm will sound.

Scoping calculations for the damper D failure scenario show that an opening of damper D would change the ventilation pressure for those rooms throughout Zone 3 receiving air solely from the S-3A ventilation supply from the normal range of -0.11 to -0.14 in. w.g. to 0.8 in. w.g.

There are two other rooms that are also driven positive. These are supplied from both S-3 and S-3A ventilation supply systems through dampers and so should be at a higher positive pressure, somewhere between the S-3 pressure and the supply plenum pressure, than those rooms supplied by the S-3 system solely.

Failure of damper D would not trip the pressure level alarm for the supply plenum. The instantaneous loss of pressure would be less than 0.13 in. w.g. The system requires a loss of 1 1/2 in. w.g. before tripping. Lacking an alarm, the system would reestablish the supply plenum pressure to a 2 in. w.g. without further incident.

A failure of damper D would likely fail to trip the pressure level reversal alarm between Zone 1 and Zone 3 as it is a separate system.

Damper D opening would likely fail to trip the position alarms on the exhaust modulating dampers D-95 and D-97.

Damper D opening would likely fail to trip the pressure level alarm in the main exhaust plenum.

In conclusion, damper D opening could cause a problem with releases to the atmosphere from rooms 131, 146 (from corridor 4B), 152, 153, 155, 169, and 170. These rooms have an outside wall of standard PFP construction and house a variety of confinement structures consisting of gloveboxes and open-faced hoods. There has to be contamination in the room free of the confinement structures. The gloveboxes and hoods, which set their own pressure based on the room pressure, would have to be breached sufficiently so that control through maintenance of a DP would not be adequate. And, finally, the building has to be breached along the outside walls of these rooms. Recent mathematical studies and actual testing (Giller 1989b, pp. 8 and A-23) demonstrate that the walls have structural capacity beyond that imposed by the pressure exerted by these upset conditions.

A pressurization of Zone 3A (damper D supply) could transfer radioactive materials from Zone 3 to Zone 1. Room 308 interfaces with Zone 1 at the airlock bounded by doors 404 and 405, at the abandoned office area comprised of rooms 341 through 350, at the airlock bounded by doors 440 and 439, at

door 452 into the Maintenance Shop area (room 325), and at the airlock bounded by doors 425 and 426. Room 308 houses filterboxes and the motive system for the building 26-in.-Hg vacuum system. This system services contaminated gloveboxes and process vessels. If a simultaneous release of the contamination within a filterbox or the 26-in. Hg vacuum system were to occur with a pressurization, stress would be placed on the barriers between the two zones.

9.1.7A.1.2.5 The Failure of Damper E. The failure of damper E was not evaluated in detail as there are no unsealed sources of radioactive materials. In addition, the rooms would not be pressurized as the damper fails closed, unlike all the other major dampers emanating from the supply plenum that fail open. Damper E could conceivably cause a decompression of that part of the building, but is frequently outfitted with blocks to limit travel. This would preclude the possibility of shutting off all air to the rooms serviced by this damper.

In conclusion, the upsets shown above would likely be short lived because of the effect on the people working within the facility. Very strong drafts would be felt upon the opening of interconnecting doors. There would be the physical effect of ear popping and possibly earaches. Unlatched doors may spring open.

9.1.7A.1.3 Operator Actions for Situations 9.1.7A.1.2.1 Through 9.1.7A.1.2.5 Upon being alerted to these upset conditions, the Power Operations personnel verify that a problem exists per operational procedures. Upon verification, they would follow their procedures to deactivate the supply fans and the Zone 1 exhaust fans.

9.1.7A.2 Detection of Event (234-5Z Building Pressurization).

9.1.7A.2.1 Methods or Means of Detection. Means of detection consist of a pressure level alarm for the supply plenum, a pressure level reversal alarm between Zone 1 and Zone 3, position alarms on the exhaust modulating dampers D-95 and D-97, and a pressure level alarm in the main exhaust plenum. The supply plenum alarm will sound if the supply plenum pressure is not within the bounds of 0.5 and 2.4 in. w.g. The Zone 1 and Zone 3 reversal alarm will sound if the pressure in the Zone 3 system sensor (room 235) is higher than that in the Zone 1 system sensor (corridor 14). The position alarms on the exhaust modulating dampers D-95 and D-97 will sound when either damper travels to a full-open position. These dampers service the exhaust fans EM-3 and EM-4. The pressure level alarm will sound if the pressure level in the main exhaust plenum rises above -3.5 in. w.g. This exhaust plenum pressure level alarm system appears to be more directed toward a failure of the exhaust fans than a pressurization of the building.

These means of detection incorporate protective systems that respond with alarms. The alarm for the supply plenum acts alone except for a required operator response. The reversal alarm between Zone 1 and Zone 3 does include a subsequent automatic shutdown protective system. When position alarms on the exhaust modulating dampers D-95 and D-97 indicate a problem, an operator response is required to bring the system under control in three minutes, or operations are halted. The pressure level alarm in the main exhaust plenum includes a subsequent automatic shutdown protective system.

The protective system between Zone 1 and Zone 3 will shut down the EM-11 and EM-12 fans that exhaust the Zone 1 air if the upset exceeds 5 s. The 5-s period was designed into the system to avoid shutdown due to transitory events. Shutdown of these fans pressurizes Zone 1 to re-reverse pressure levels between Zone 1 and Zone 3 and maintains contamination control. The EM-11 and EM-12 fans will remain shut down due to action of the seal-in contact relay MA. Closure of the reversal alarm switch DPS-1A-25A will cause, after a 5-s delay, an opening of contacts K-3 (1) and K-3 (2) in the EM-11 and EM-12 exhaust fan circuits deenergizing the fans. However, this will only occur if control switches are in the "auto" position, which is the normal operating position.

The protective system, acting in conjunction with the pressure level alarm in the main exhaust plenum, can shut down the supply fans and the exhaust fans EM-11 and EM-12.

9.1.7A.2.2 Response Time Assessment. The response time would vary with the type of event. If only a single damper (such as damper C) failed, it has been postulated above that no alarms would sound. The power operators may notice that their printing recorders and gauges have jumped or that the bank of Magnehelics[1] are indicating less than zero (needles pinned).

A period of 2 min can be expected to pass before the people in the affected zones call the power operators. An additional 3-min period is allowed for the power operators to correct the condition before deactivating the electric power for the supply fans. On shutting down the supply fans to the building, all but the emergency exhaust fans are interlocked to shutdown. Although this clears the condition, it is only a backup. Upon shutdown of the building ventilation supply system, personnel in all the Zone 3 areas will quickly be evacuated. Generally, evacuation is complete in 5 min, although personnel who must perform shutdown duties don full face respirators and leave later.

9.1.7A.2.3 Engineered Safety Features and Protective Systems. The PFP ventilation system depends upon deactivating the electric-driven supply fans and shutting down all but the emergency electric-motor driven exhaust fan(s) to stabilize the building ventilation to maintain contamination control. This system does not have the capacity to provide the number of changes per hour for proper ventilation.

The above feature is generally manually tripped. A failure to sustain a preset level of vacuum in the exhaust plenum can also cause the trip.

9.1.7A.3 Analysis of Effects and Consequences.

9.1.7A.3.1 Methods, Assumptions, and Conditions. Calculation of room pressures resulting from failure of supply plenum discharge dampers assumes the following conditions:

---

[1]Magnehelic is a trademark of Dwyer Instruments, Inc., Michigan City, Indiana.

- The supply and exhaust fans with fixed dampers are operating at rated conditions: 76,100 ft^3/min at 5 in. w.g. for the supply fans, and 72,500 ft^3/min at 11 in. w.g. for the exhaust fans.

- To simplify the calculation, the Bernoulli flow equation was linearized. This approach yields somewhat smaller values of head drop than those resulting from the use of the straight Bernoulli flow equation. The friction factor used for the calculation for the damper open will compensate for this reduction.

- The friction factor used for the duct work leading from the supply plenum to the rooms when the damper is full-open is deduced by treating the duct outlet from the supply plenum as an orifice of the same area as the duct outlet. This number is probably lower than the actual but is satisfactory because the linearization of the Bernoulli equation compensates for this lower approximation of the friction factor.

- All doors are closed and remain closed. There is no crossflow from zone to zone.

- The fans operate along their rated fan curves.

- The flowrates are those discussed in Chapter 5.0.

- The supply fan dampers and the exhaust fan dampers operate precisely. Unless driven to their stops, they return the system to 2 in. w.g. in the supply plenum and -3.2 in. w.g. in the filter plenum.

- The air washers and filters between the outside and the supply fan inlets provide a fixed pneumatic resistance that obeys Bernoulli's theorem. The same is true of the passage from the filter plenum to the exhaust fans and from the exhaust fans to the stack discharge.

- The 236-Z system does not change flowrates during upsets in Building 234-5Z.

- The flows into Zone 1 are constant.

Procedure for Calculation. The principal heating, ventilation, and air-conditioning (HVAC) system components are discussed in Chapter 5.0.

Purpose. Determine the room air pressures of representative rooms that can be expected in the various ventilation zones of the 234-5Z Building if a failure of one of the outlet dampers attached to the supply plenum occurs. These dampers control the air to the various zones throughout the building. The dampers will fail open, except for the E damper, which fails closed.

The method of analysis was based on *Electrical and Mechanical Networks*, "An Introduction to Their Analysis" (Harman and Lytle 1962). The method uses Kirchoff's law and D'Alembert's principle to set up, in a matrix, a system of differential equations to describe a mechanical or electrical system. The method then provides a means for solving for the desired performances.

The matrix could be addressed as a mathematical model of the system. In this instance the technique has been extended to a pneumatic system. Note that pressure drop through an element does vary as the square of the velocity through the element. However, for small changes the pressure drop can be taken as linear. This would appear to be acceptable within the simplifications used to allow the calculation to be made. It will be used for examining the phases of the system performance and finally solving the model for room pressures after the upset. Although the text gives the technique for solving differential equations, simple equations were used by noting that masses and dampers (mechanical springs) are not involved. The system consists solely of flows and pressure drops.

The pneumatic system servicing the 234-5Z Building consists of six branches. Although the branches do intermingle, for this analysis it is considered of insignificant consequence. One branch services the "front" side of the building. This uses a separate exhaust system and so, for simplicity, is considered to behave independently of the other branches and can be ignored. Another branch provides air to the 236-Z Building and is analyzed in a separate section. On the remaining branches there are supply dampers feeding the branches and connected to the common supply plenum. These dampers are varied by controllers receiving signals from a single room for each branch, except for two of the dampers, which are controlled by a single room; coincidentally, this room receives air from both dampers.

A mathematical model of the system was developed using simultaneous linear equations to describe the various parts of the system (see Figures 9-8 and 9-9). These equations were then entered into a matrix that could be solved to yield system responses. The values of the elements were calculated from existing system operating parameters. The procedure is to change any one of these element values and recalculate the matrix. The element values chosen in this study are those of the supply dampers.

Following an upset of a supply plenum damper, system performance (or response) will vary with time. There will be two phases. The first will be that occurring prior to the controllers responding and the second will be after the controllers have responded. This latter response will be one of two possibilities: (1) the controllers have corrected the dampers to their control points (except where the supply plenum damper has experienced failure) or (2) the controllers have pushed the control dampers to their stops and full return of the control points to normal cannot be achieved without special manual assistance, which will not be discussed here.

Mathematical Model. The following mathematical model was developed from the simplified system description shown in Figure 9-8. The mechanical system shown at the top of the figure was represented by the equivalent pneumatic network in the middle of the figure in which resistors represented pressure loss (energy) components such as air washers, ductwork, dampers, and filters. This network is further developed into the lumped pneumatic network shown at the bottom of the figure. This allows system description with linear equations as required to solve matrices. The supply fans are designated H_S, which is a lumped equivalent source (or pneumatic head) consisting of the supply fans and the system, including duct work, dampers, and air washers, from the outside of the building through the supply plenum. The exhaust fans, with the exception of the Zone 1 fans, are designated H_E, which is a lumped

equivalent source consisting of the exhaust fans and the system, including duct work, dampers, and filter room filters, from the filter plenum to the discharge of the stack. Although H_S and H_E are not linear, they are sufficiently linear in the range of operation to allow use of an equivalent linear equation. The performance of the rooms and system from the supply plenum to the filter plenum also is not linear but is sufficiently linear in the range of operation to allow the use of equivalent linear equations.

The lumped pneumatic network is shown on Figure 9-9. Note that both H_S and H_E take or give air to the atmosphere and thus can have a common base (atmospheric air is at atmospheric pressure).

Setting up loop equations for this Building 234-5Z performance, where the summation of head losses equals zero for each loop arbitrarily drawn and identified as Q (flow) subnumber, results in the following:

$$Q_1(R_B + R_1) + (Q_1 - Q_2)(R_C + R_2) = 0$$

$$(Q_2 - Q_1)(R_C + R_2) + (Q_2 - Q_3)(R_D + R_3) = 0$$

$$(Q_3 - Q_2)(R_D + R_3) + (Q_3 - Q_4)(R_E + R_4) = 0$$

$$(Q_4 - Q_3)(R_E + R_4) = H_S - H_E$$

where: H_S = Lumped equivalent source for the supply side head in inches water gauge

H_E = Lumped equivalent source for the exhaust side head in inches water gauge.

This is based on the flow equation for the rooms (etc.) being linearized to:

Head loss(H) + Flow (Q) * Pneumatic Resistance (R)

These two lumped equivalent sources are represented by a straight line curve of the flow versus pressure into the plenum:

$$H_s = M_S * Q_4 + B_S$$

where: M_S = the slope of the supply system straight line curve and B_S is the intercept of the straight line curve. This is based on fan performance only. The supply fan damper is taken to remain stationary.

$$H_E = M_E * Q_4 + B_S$$

where: M_E = the slope of the exhaust system straight line curve and B_E is the intercept of the straight line curve. This is based on fan performance only. The exhaust fan damper is taken to remain stationary.

Rewriting the fourth line in the loop equations for this Building 234-5Z performance:

$$(Q_4 - Q_3)(R_E + R_4) = H_S - H_E \text{ becomes}$$

$$(Q_4 - Q_3)(R_E + R_4) = M_S * Q_4 + B_S - M_E * Q_4 - B_E$$

Rearranging terms in the loop equations for this Building 234-5Z performance:

$$Q_1(R_B + R_1 + R_C + R_2) + Q_2(-R_C - R_2) = 0$$

$$Q_1(-R_C - R_2) + Q_2(R_C + R_2 + R_D + R_3) + Q_3(-R_D - R_3) = 0$$

$$Q_2(-R_D - R_3) + Q_3(R_D + R_3 + R_E + R_4) + Q_4(-R_E - R_4) = 0$$

$$Q_3(-R_E - R_4) + Q_4(R_E + R_4 - M_S + M_E) = B_S - B_E$$

Setting the values in the loop equations into a 4*4 matrix:

$$\begin{bmatrix} A_1 & B_1 & C_1 & D_1 \\ A_2 & B_2 & C_2 & D_2 \\ A_3 & B_3 & C_3 & D_3 \\ A_4 & B_4 & C_4 & D_4 \end{bmatrix} * \begin{bmatrix} Q_1 \\ Q_2 \\ Q_3 \\ Q_4 \end{bmatrix} = \begin{bmatrix} E_1 \\ E_2 \\ E_3 \\ E_4 \end{bmatrix}$$

where: $A_1 = (R_B + R_1 + R_C + R_2)$

$A_2 = (-R_C - R_2)$

$A_3 = 0$

$A_4 = 0$

$B_1 = (-R_C - R_2)$

$B_2 = (R_C + R_2 + R_D + R_3)$

$B_3 = (-R_D - R_3)$

$B_4 = 0$

$C_1 = 0$

$C_2 = (-R_D - R_3$

$C_3 = (R_D + R_3 + R_E + R_4)$

$C_4 = (-R_E - R_4)$

$D_1 = 0$

$D_2 = 0$

$D_3 = (-R_E - R_4)$

$D_4 = (R_E + R_4 - M_S + M_E)$

$E_1 = 0$

$E_2 = 0$

$E_3 = 0$

$E_4 = B_S - B_E$.

The values of Q1 through Q4 are to be determined.

The values of flow through the rooms are then calculated, noting that the flow through damper B is Q1, through damper C is (Q2-Q1), through damper D is (Q3-Q2), through damper E is (Q3-Q4), and the flow into all the rooms is Q4. These values are absolute.

The resultant mathematical system is solved for the values of flow (i.e., Q_1). To accomplish this, the matrix was programmed on a spreadsheet. The mathematical procedure was that set forth in *Higher Mathematics for Engineers and Physicists*, p. 110, (Sokolnikoff and Sokolnikoff 1941).

The system is checked by comparing the calculated performance against the actual performance of the ventilation system at a known condition, usually normal performance.

As stated, H_S and H_E are straight line equations of the flow through the plenums. To find these equations the actual curve of the performance must be determined. This curve has to be determined from the fan performance

curve and the connecting system. Graphically, the system is shown on Figure 9-9 as that portion of the path, for H_S, from the outside building into fan inlet through the supply plenum and, for H_E, from the filter plenum (the exhaust plenum can be used but will be addressed when used) to the stack exit.

The first step in finding values for the lumped equivalent sources was to address the fans. A quadratic equation ($Jx^2 + Kx + L = y$) that fit the fan curve for the supply and exhaust fans had to be determined. These fan curves were produced from actual test data taken from testing the fans. These data are available in Certified Vendor Information (CVI). To start the curve-fit process, three points on the fan curve are used to set up three simultaneous quadratic equations that can form a 3*3 matrix:

$$\begin{bmatrix} A1 & B1 & C1 \\ A2 & B2 & C2 \\ A3 & B3 & C3 \end{bmatrix} * \begin{bmatrix} D1 \\ D2 \\ D3 \end{bmatrix} = \begin{bmatrix} E1 \\ E2 \\ E3 \end{bmatrix}$$

where: $A1 = X_1^2$

$A2 = X_2^2$

$A3 = X_3^2$

$B1 = X_1$

$B2 = X_2$

$B3 = X_3$

$C1 = 1$

$C2 = 1$

$C3 = 1$

$E1 = Y_1$

$E2 = Y_2$

$E3 = Y_3$.

The values of D1 (J from the quadratic equation), D2 (K), and D3 (L) were determined from the programmed spreadsheet. The resultant equation was then checked by plotting it over the values taken from the fan curve (additional to the three chosen).

The next step in the determination was to integrate the curve fit equation into the performance of the system (e.g., H_S) (see Figure 9-10). Repeating the portion under discussion of Figure 9-9.

The normal conditions and assumptions are:

- The outside is the baseline
- The flow is the total fan flow
- The supply plenum is at 2 in. w.g.
- The fans are operating at their rated capacity
- The pressure drop across each individual air washer will be the same at the same flow through the air washers.

Note that, at the normal conditions, the pressure profile as air passes through the building will look as shown on Figure 9-7. The portion under discussion is reproduced below (Figure 9-11).

The portion of the performance from the outside of the building to point A (across the air washers and ducting) can be deduced by noting that the supply fans are rated at 5 in. w.g. Thus, point A is the supply plenum pressure (2 in. w.g.) minus the head gain from the fans operating at rated conditions (5 in. w.g.) (i.e., -3 in. w.g.). The loss across these air washers and others at other flows can be calculated from Bernoulli's equation for compressible flow. This equation states that flow (Q) is proportional to the square root of head loss across a restriction:

$$Q_f = Q_i * \{[(\text{differential head}_f)/(\text{differential head}_i)]^{1/2}\}$$

where: f = final condition
i = initial condition.

The contribution of the fans represents the remaining portion of the performance. The fan operation can be calculated by noting what each part of the sketch represents. That portion from point A to the supply plenum is the head gain of an unfettered fan (no control damper). That portion from point A to B is the head loss across the supply fan damper, and that portion from point B to the supply plenum is the performance of the fettered fan (with the supply fan damper). Note that the flow from point A to B and from point B to the supply plenum is the same.

At normal conditions the assumption has been made that the unfettered supply fans are operating at rated conditions. The total flow consists of the input from the fettered and unfettered fans. Thus, the flow from the fettered fans is the difference between the total flow and the number of unfettered fans operating times their rated flow each. The head gain from the fettered fans is obtained from the fan curve at that flow. Therefore, the head loss across the supply fan dampers (point A to B) is the difference between the head gain of the fettered and unfettered supply fans:

$$Q_{total} = Q_{fettered} + Q_{unfettered}$$

$$\text{Head loss (A to B)} = \text{Head gain}_{\text{fettered fan}} - \text{Head gain}_{\text{unfettered fan}}$$

Pressure gains necessary to achieve other flows can be determined by reversing this procedure: (1) increment the fettered fan flow, (2) determine the new pressure gain from the fan curve to achieve that flow, and (3) determine the new pressure drop across the supply fan dampers (use the Bernoulli equation). The difference is again the pressure gain across the unfettered fans. The flow from the unfettered fans is determined from the fan curve. The total flow is again the summation of the fan flows. Repeating this several times will yield a loci of points describing the performance of this system. In the area of interest a linear equation can be written. In actual practice this linear curve was a very close fit to the actual curve shape.

The determination of the exhaust system performance was similar to the scheme for determining the supply system performance. It was deducible by viewing the analogous system and the pressure profile. The baseline was the discharge of the stack, which is considered atmospheric or 0 lb/in^2 (gauge). The portion of the system to be discussed is shown in Figures 9-12 and 9-13.

The calculation procedure is identical to that used for the supply side. The only exception is that the performance curve matched or fitted was that of the electrically driven exhaust fans instead of the supply fans.

Part 2, linearizing the room performance, consisted of simply finding resistance numbers for the part of the room system from the supply plenum to the room and for the part of the room system from the room to the filter plenum. These evolved from the simple equation:

$$R = \frac{\text{Head loss}}{\text{Flow}}$$

To offset the minor error introduced by this linearizing, an assumption was made for determining a new resistance for the performance of the ducting to the rooms from the supply plenum after the damper fully opened (the "upset" condition). The new resistance for the supply plenum to room must be estimated. The least resistance the new system could be is if the duct work separated from the supply plenum and only the annulus remained. The resistance for this annulus can be determined from the Bernoulli equation:

Flow (Q) = The cross-sectional area of the annulus times a flow loss coefficient times the square root of two times the gravitational constant "g" times the head loss in feet (of the media being passed)

$$= A*C*(2*g*H)^{1/2}$$

To determine an equivalent pneumatic resistance of the form

$$\text{Flow (Q)} = \frac{\text{Head loss (H)}}{\text{Pneumatic resistance (R)}}$$

or

$$R = H/Q$$

Bernoulli's equation can be roughly linearized by noting the range of H. If H varies in a narrow range of about 2, then $(H)^{1/2}$ is roughly the same as $[(2)^{1/2}*H/2]$. Thus, the Bernoulli equation can be rewritten as:

$$Q = \frac{A*C*H[(2)^{1/2}]*[(2*G)^{1/2}]}{2}$$

Dividing the Bernoulli equation by the pneumatic resistance equation yields:

$$1 = \frac{Q}{Q} = \frac{A*C*H*[(2)^{1/2}]*[(2*g)^{1/2}]}{H*2}*R$$

or

$$R = \frac{2}{A*C*[(2)^{1/2}]*[(2*g)^{1/2}]}$$

where: A = Area of annulus at each supply damper
C = 0.5 for rough annulus
g = 32.2 ft/s^2.

Thus, the fact that the new resistance is smaller than that probably seen will offset the assumption of linearity.

The phases of the system performance are as stated at the beginning of this section (i.e., the first phase will be that occurring prior to the controllers responding and the final phase will be after the controllers have responded).

The first phase can be determined by using the linear values of H_S and H_E found as shown previously. The final phase can take one of two forms:

- Both the supply and filter plenums have returned to the original settings of pressure. The modulating dampers in both fettered fans have adjusted to accomplish this.

- The filter plenum and or the supply plenum is incapable of returning to the preset pressure. The modulating damper on the fettered fan is fully open and the fans are operating at a new position on the fan curve to handle the full flow and/or the supply fan damper is fully open and the fans are operating at a new position on the fan curve to handle the full flow. However, the original straight line equation for H_E is no longer valid. A new equation must be developed, assuming that there are no fettered fans in the exhaust system and all operating fans are operating as unfettered fans.

Condition one of the final phase again uses the simultaneous equations:

$$Q_1(R_B + R_1) + (Q_1 - Q_2)(R_C + R_2) = 0$$

$$(Q_2 - Q_1)(R_C + R_2) + (Q_2 - Q_3)(R_D + R_3) = 0$$

$$(Q_3 - Q_2)(R_D + R_3) + (Q_3 - Q_4)(R_E + R_4) = 0$$

$$(Q_4 - Q_3)(R_E + R_4) = H_S - H_E$$

where: $H_S = 2$
$H_E = -3.2$.

Condition two of the final phase can be evaluated by noting that $H_S = 2$. H_E is again the straight line function $H_E = M_E*Q_4 + B_S$; however, M_E and B_S have new values. These values have been determined based on all exhaust fans operating in the unfettered mode. This final phase condition must be calculated. If the filter plenum pressure is found to be less than -3.2, then this calculation is invalid, as this would indicate that the exhaust damper has not opened fully, which is not the condition indicated by the new H_E.

9.1.7A.3.2 Source Term. Not applicable.

9.1.7A.3.3 Margin of Protection. Several events must occur for a discharge to the atmosphere to occur. A damper supplying ventilation air to an area housing confinement vessels must have failed; there must be loose materials in the glovebox or hood; there must be a breach of the glovebox or hood; the breach must be large enough so that the confinement structure ventilation cannot maintain an adequate DP across the breach to maintain contamination control; and, finally, the flow path to the existing exhaust system must be incapable of sweeping all the materials into the exhaust duct such as would occur if the wall to the outside had opened a large hole. The

wall structure, however, has been determined to have sufficient structural capacity at this pressure to prevent such a hole from occurring. Without detailed examination it is clear that such a series of independent events has a very low probability. When combined with the low onsite/offsite consequences of plutonium spills into rooms postulated in Sections 9.1.1 through 9.1.4, this event will not be considered further.

9.1.7B Excessive Pressurization of 236-Z Building

This analysis examines the mechanism for creating a pressurization of the areas in the 236-Z Building housing sources of radioactive materials.

9.1.7B.1 Postulated Cause of the Event.

9.1.7B.1.1 Starting Conditions and Assumptions. The ventilation air for the 236-Z Building is taken from the ventilation system for the 234-5Z Building. A damper (damper F) is attached to the supply plenum within the 234-5Z Building. The ventilation air is routed in a long outside duct over the roof of the 234-5Z Building to the 236-Z Building.

A cascading system of air usage is used for contamination control. Air is introduced into corridors 20 and 30. From there, a portion of the air is HEPA filtered, more to guard against a reversal than for normal flow, and passed progressively into the canyon, the glove-boxes, a two-stage filter housing, and finally into the main building filtration system (room 26 in the 236-Z Building). The air exits from there into the discharge duct, emptying into the exhaust plenum within the 291-Z Building. At each successive point the air pressure is less than at the previous location (greater negative pressure or vacuum).

Parallel systems for ventilating the office areas, maintenance areas, room 19, miscellaneous treatment (MT) area in room 41, and solvent extraction and S&C gloveboxes (no longer in use) in room 43 parallel the canyon flow system. The gloveboxes in rooms 27, 41, and 43 draw air from the rooms and thus will not be driven to a positive pressure relative to the rooms.

The pressure levels set in the rooms are:

- -0.3 in. w.g. rooms 10, 11, 14, 19 to 21, 25, 30, 31, and 33
- -0.15 in. w.g. rooms 15 to 18, 26, 27, 34 to 38, 40 to 48, 50, 60, and stairs 1 and 2
- The pressure level in room 12 is not controlled.

The pressure is controlled by damper F within the 234-5Z Building. The individual levels (noted above) are preset with manual dampers.

There is a controller on the ducts emanating from the canyon gloveboxes. This has circular chart paper, marked with a range that varies from 0.0 to 1.0, on a chart recorder. There is a marker on a gauge that reads, "Operating Range 0.5 to 2.0 in. w.g." This controller powers a DOV that establishes filterbox and glovebox negative pressure.

Prior to the postulated upset, the rooms are all at the pressures set above. There is no gauge on the canyon, so the pressure within is unknown, except that it lies in a range whose upper limit is less than the pressure existing in room 20 or 30 as these rooms are the sole source of air for the canyon. There is a gauge on the canyon gloveboxes. The controller downstream of the canyon gloveboxes uses a sensor that taps into the canyon glovebox. Each of the four gloveboxes has an individual system. As of July 17, 1989, the controllers on the discharge duct from the canyon gloveboxes were reading from 0.69 to 0.74 on the chart paper. The chart paper is calibrated such that 100% is -1 in. w.g. Normal glovebox pressures are from -0.6 to -0.7 in. w.g. This sets the lower limit to the range of pressures the canyon and gloveboxes can be experiencing.

The canyon and canyon gloveboxes could be at pressures at opposite extremes of the range specified. Air for the gloveboxes passes through the plug holes in the canyon wall separating the canyon and canyon gloveboxes. These plug holes are part of the fastening device that mounts the tanks and dunnage maintained in the canyon to the canyon wall. If sufficient plugs are in use to severely limit the amount of remaining plug holes, a substantial DP would exist across the canyon wall. This would also severely limit the amount of flow passing through the canyon and canyon gloveboxes.

9.1.7B.1.2 Sequence of Events. The entire 236-Z Building, including the production area, can be pressurized above its individual normal operating range by the opening of damper F. Such an inadvertent opening could occur through human error during the semiannual changeout of the damper motor. Such an error may well be as simple as a craftsperson, or other who has a reason to handle the linkage, releasing the damper shaft before securing it to the alternate damper motor or securing the opposite damper motor rod to the wrong end of the damper shaft.

The postulated result of this single event would be the opening of the damper either by being driven open or by being blown open. The air pressure in the 236-Z Building (those rooms normally at -0.15 in. w.g.) would increase to 0.3 in. w.g. and then stabilize. The drop in pressure in the supply plenum would be compensated for by the modulation system on the supply fans. The air that discharges from the 236-Z Building would drive the 291-Z exhaust plenum to an increased pressure (from -6 in. w.g. to -5.9 in. w.g.), allowing the 291-Z exhaust fans to handle the flow. A system instability should then occur as two independent systems both try to correct. The sensor in the 234-5Z Building filter plenum would adjust the damper, throttling an exhaust fan to return the 234-5Z Building filter plenum to its preset pressure, and the 234-5Z Building room sensors would adjust their respective supply dampers to reduce the flow and return the rooms to their preset pressures.

Failure of Damper F. A failure of damper F (the damper opens) would have the following effects (in a rough order of occurrence).

- The 236-Z Building pressurizes.
- The 291-Z exhaust plenum pressurizes until the exhaust adjusts to handle the increased flow. The dampers have not had an opportunity to adjust. All pressures, except the supply plenum, rise.

- The pressure sensor in the supply plenum senses a drop in supply plenum pressure. It then signals the automatic controller for the supply plenum supply system to adjust the damper on the modulated supply fans to open. This increases flow to the supply plenum until supply plenum pressure is reestablished.

- The room pressure sensors in the 234-5Z Building signal the automatic controller for the supply plenum discharge system to adjust dampers to decrease flow to the 234-5Z Building rooms to reestablish zone pressure.

- The sensor in the filter plenum signals the automatic controller for the exhaust system to adjust the damper on the modulated exhaust fans to increase flow from the filter plenum to reestablish filter plenum pressure.

- In the previous step, an alarm will sound if the modulating damper on exhaust fan 3 or 4 adjusts to full-open.

Scoping calculations for the damper F failure scenario show that an opening of damper F would briefly change the ventilation pressure for those rooms normally at -0.15 in. w.g. to 0.35 in. w.g. Those rooms normally at -0.3 in. w.g. would change from their normal range to 0.20 in. w.g.

Failure of damper F would not trip the low pressure alarm for the supply plenum. The instantaneous loss of pressure would be 0.04 in. w.g. The system requires a loss of 1.5 in. w.g. to trip. Lacking a trip of the alarm, the system would reestablish the supply plenum pressure to a positive 2.0 in. w.g. without further incident.

Failure of damper F would probably not trip the position alarms on the exhaust modulating dampers D-95 and D-97 because the magnitude of the total building flow change due to the upset is too small. Failure of damper F would probably not trip the pressure level alarm in the main exhaust plenum.

9.1.7B.1.3 Conclusion. Failure of damper F to full open would not cause a problem with potential releases to the atmosphere, except possibly through the large airlock located at the south end of the 236-Z Building. The canyon could be driven positive with respect to atmosphere. There are no gauges monitoring canyon pressure, so its present status is unknown. The airlock is occasionally found to have spots of contamination. Operating personnel speculate that the contamination seeps from around the canyon door into the airlock. If pressurization were to occur, the change would not be noticeable as the remainder of the building would be similarly pressurized. The outside wall has sufficient structural capability to resist this pressurization. The airlock is sealed against the outside of the building and surrounds the door. A HEPA filter is mounted through the door so that air will flow through the airlock toward the canyon when the outer doors are opened. Other HEPA filters are mounted throughout the airlock. A pressurization of the canyon would cause a backflow through these filters to the airlock. A DP gauge is mounted on the airlock entry door, which could alert someone of the pressurized condition. A portable CAM located in the airlock would sound if canyon pressure caused airborne contamination in the airlock; however, the facility is not continuously manned, and the noise could go unnoticed.

There may be no notification in the power control room (by alarms) that an upset has occurred. The power operators action is to deactivate supply fans to reduce overpressurization. Exhaust fans may be tripped off to keep the balance of the plant from going too negative while bringing the 236-Z Building differential pressure within operating range. If exhaust fans are tripped off to prevent too high a negative in other zone 3 ventilation areas, the zone 3 areas are evacuated. The various DP gauges will show a new setting.

9.1.7B.1.4 Operator Actions. Unless alerted with alarms, the first notification of the problem may be through phone calls from plant operating personnel to the power operators. Upon being alerted to these upset conditions, the power operations personnel check the recorders on the 236-Z Building controller in the power control room (321-A) to verify that a problem exists per operational procedures. Upon verification, they would follow their procedures to deactivate the supply fans and the Zone 1 exhaust fans.

9.1.7B.2 Detection of Event.

9.1.7B.2.1 Methods or Means of Detection. The final differential pressures determined by calculation demonstrate that the impact of damper F failure on the 234-5Z Building is insufficient to trip any of the detection systems. These consist of a pressure level alarm for the supply plenum, position alarms on the exhaust modulating dampers D-95 and D-97, and a pressure level alarm in the main exhaust plenum. The supply plenum alarm will sound if the supply plenum pressure is not within the bounds of 0.5 and 2.4 in. w.g. The position alarms on the exhaust modulating dampers D-95 and D-97 will sound when either damper travels to a fully-open position. These dampers service exhaust fans EM-3 and EM-4. The pressure level alarm in the main exhaust plenum will sound if the pressure level rises above -3.5 in. w.g. This exhaust plenum pressure level alarm system appears to be more directed toward a failure of the exhaust fans than a pressurization of the building.

These means of detection incorporate protective systems that respond with the alarms. The alarm for the supply plenum acts alone, except for a required operator response. When position alarms on the exhaust modulating dampers D-95 and D-97 indicate a problem, an operator response is required to bring the system under control in three minutes, or operations are halted. The pressure level alarm in the main exhaust plenum includes a subsequent automatic shutdown protective system.

The protective system, acting in conjunction with the pressure level alarm in the main exhaust plenum, can shut down the supply fans and the exhaust fans EM-11 and EM-12.

9.1.7B.2.2 Response Time Assessment. The response time would have to include the time for notification of the problem. Without any alarms sounding, the operating personnel phoning the Power Control room inquiring about the ventilation may be the first indication of a problem, unless the power operators notice that their chart recorders are indicating that a jump in pressure occurred.

A period of 2 min is expected to pass before the people in the affected zones call the power operators. An additional 3-min period is allowed for the

power operators to correct the condition before deactivating the electric power to the supply fans and all but the emergency exhaust fans. Although this clears the condition, it is only a backup. If the stabilization effort requires the exhaust fans to be taken out of service, ventilation zone 3 areas are evacuated.

9.1.7B.2.3 Engineered Safety Features and Protective Systems. Ventilation system upset conditions are controlled through automatic or manual shutdown of the supply fans. Control of the PFP ventilation system upsets depend upon deactivating the electric-driven supply fans and all but the electric-driven emergency exhaust fan(s) to stabilize the building ventilation to maintain contamination control. This system does not have the capacity to provide normal flow rates but can maintain negative pressure in most gloveboxes throughout the facility and proper direction of flow. If stabilization activities require shutdown of the exhaust fans, ventilation zone 3 areas are evacuated and power operators are placed on mask.

9.1.7B.3 Analysis of Effects and Consequences.

9.1.7B.3.1 Methods, Assumptions, and Conditions. Calculating room pressures resulting from failure of supply plenum discharge dampers assumes the following conditions:

- Under normal operation, the supply and exhaust fans are operating at rated conditions: 76,100 ft^3/min at 5 in. w.g. for supply fans and 72,500 ft^3/min at 11 in. w.g. for exhaust fans.

- To simplify calculation, the Bernoulli flow equation was linearized. This will yield somewhat smaller values of head drop than those resulting from the use of the straight Bernoulli flow equation. The friction factor used for the calculation for the damper open will compensate for this reduction.

- The friction factor used for the ductwork leading from the supply plenum to the rooms when the damper is full-open is deduced by treating the duct outlet from the supply plenum as an orifice of the same area as the duct outlet. This number is probably lower than the actual butis satisfactory because the linearization of the Bernoulli equation compensates for the lower approximation of the friction factor.

- All doors are closed and remain closed. There is no crossflow from zone to zone.

- The fans operate along their rated fan curves.

- The flowrates are those discussed in Chapter 5.0.

- The supply fan dampers and the exhaust fan dampers operate precisely. Unless driven to their stops, they return the system to 2 in. w.g. in the supply plenum and -3.2 in. w.g. in the filter plenum.

- The air washers and filters between the outside and the supply fan inlets provide a fixed pneumatic resistance that obeys Bernoulli's theorem. The same is true of the passage from the filter plenum to the exhaust fans and from the exhaust fans to the stack discharge.

- The flows from Zone 1 are constant.

Procedure for Calculation. The system is essentially as shown in Figure 9-14. The following procedure was used to calculate the room pressures.

Purpose. Determine the room air pressures of representative rooms that can be expected in the ventilation zone of the 236-Z Building if a failure of outlet damper F attached to the supply plenum occurs. This damper controls the air to the various areas throughout the building. The damper will fail open.

The method of analysis will be based Harman and Lytle (1962). The method uses Kirchoff's law and D'Alembert's principle to set up, in a matrix, a system of differential equations to describe a mechanical or electrical system. The method then provides a means for solving for the desired performances.

The matrix could be addressed as a mathematical model of the system. In this instance the technique has been extended to a pneumatic system. Note that pressure drop through an element does vary as the square of the velocity through the element. However, for small changes the pressure drop can be taken as linear. This would appear to be acceptable within the simplifications used to allow the calculation to be made. It will be used for examining the phases of the system performance and finally solving the model for room pressures after the upset. Although the text gives the technique for solving differential equations, simple equations were used by noting that masses and dampers (mechanical springs) are not involved. The system consists solely of flows and pressure drops.

The pneumatic system servicing the 234-5Z Building consists of six branches. The branch that provides air to the 236-Z Building is covered in this section.

Mathematical Model. To generate a mathematical model of the system, simultaneous linear equations were developed to describe the various parts of the system. These equations were then fit into a matrix that can be solved to yield system responses. The values of the elements are calculated from existing system performance. The procedure is to change any one of these element values and recalculate the matrix. The element values chosen in this study are those of the supply damper F.

Calculation of system performance after a failure of damper F is similar to the procedure used for the 234-5Z Building (see Section 9.1.7A.3.1).

The system description is shown in Figure 9-14. The mathematical model is drawn from that description (see Figure 9-15). The 234-5Z Building model has been lumped into a single resistor. That is justified as the action of the 234-5Z Building is only of interest in this evaluation as it interacts

with the 236-Z Building. The lumped pneumatic network is redrawn below (Figure 9-15).

Setting up loop equations for this Building 236-Z performance is simplified from the 234-5Z Building effort as only two loops are involved (Figure 9-16). The straight line equations are:

$$Q_1(R_1) + (Q_1 - Q_2)(R_F + R_2) = 0$$

$$(Q_2 - Q_1)(R_F + R_2) = H_S - H_E$$

The values of H_S and H_E are the same as for the 234-5Z Building and are again the lumped equivalent sources for the supply and exhaust systems. Again, taking $H_S = M_S*Q_4 + B_S$ and $H_E = M_E + B_E$, these equations change to:

$$Q_1(R_1 + R_F + R_2) + Q_2(-R_F - R_2) = 0$$

$$Q_1(-R_F - R_2) + Q_2(R_F + R_2 - M_S + M_E) = B_S - B_E$$

Setting the values of the loop equations into a 2*2 matrix:

$$\begin{bmatrix} A_1 & B_1 \\ A_2 & B_2 \end{bmatrix} * \begin{bmatrix} Q_1 \\ Q_2 \end{bmatrix} = \begin{bmatrix} E_1 \\ E_2 \end{bmatrix}$$

where: $A_1 = (R_1 + R_F + R_2)$

$B_1 = (-R_F - R_2)$

$A_2 = (-R_F - R_2)$

$B_2 = (R_F + R_2 - M_S + M_3)$

$E_1 = 0$

$E_2 = (B_S - B_E)$

The values of Q_1 and Q_2 are to be determined.

These values are used to determine the system flows, $Q_{234\text{-}5Z}$ and $Q_{236\text{-}Z}$, where the value of flow through the 234-5Z Building is Q_1, and the value through the 236-Z Building is Q_2-Q_1. To perform the actual calculations, the matrix was programmed on a spreadsheet. The mathematical procedure was that set forth in Sokolnikoff and Sokolnikoff (1941, p. 110). The programming was according to the instructions for operating the spreadsheet.

A new R value for damper F after the damper has failed open is determined as for the 234-5Z calculations. The Bernoulli equation is solved to determine flow through an orifice of the same size as the duct supporting the F damper. The assumed head is 2 in. w.g. These values are then used in the linear equation to determine the R value.

The system is checked by comparing the calculated performance against the actual performance of the ventilation system at a known condition, which is usually normal performance.

As with the 234-5Z Building, the system will need to be checked with values of H_E that are derived from assuming all the exhaust fans operate unfettered. If this results in the exhaust plenum pressure being less than -6 in. w.g., the run is invalid. This result would indicate that the modulating damper opened to decrease the pressure to this point. In fact, the damper would have stopped at the set point and thus would not be fully open. The exhaust plenum at -6 in. w.g. is used as a set point instead of the filter plenum (within Building 234-5Z) pressure; which is set by sensor and control equipment that adjusts the exhaust modulating damper on one of the exhaust fans to reset the filter plenum pressure to the set point -3.2 in. w.g. Because there has been no physical change in the 234-5Z Building, the pressure drop between the filter plenum and the exhaust plenum will return to the initial value. The pressure relationship between the filter plenum and the exhaust plenum will remain intact and -3.2 in. w.g. at the filter plenum corresponds to -6.0 in. w.g. at the exhaust plenum.

Once all the flows are known the system pressures can be determined. The differential heads across the resistances can be determined from the linear equation used to set up the matrix:

$$\text{Head loss (H)} = \text{Flow (Q)} * \text{Pneumatic Resistance (R)}$$

The actual head at the typical room within the 236-Z Building is then:

$$\text{Room pressure} = \text{Atmospheric pressure (zero)}$$

$$- H_E - (-\text{head loss across } R_2)$$

Following an upset of a supply plenum damper, system performance (or response) will vary with time. There will be two phases: phase 1 will occur before the supply plenum and filter plenum controllers respond and phase 2 will occur after the controllers have responded. This latter response will be one of two possibilities; either the controllers have corrected their control points to the initial settings (except where the supply plenum damper has experienced failure) or the controllers have pushed the control dampers to their stops and full return of the control points to normal cannot be achieved without special manual assistance, which will not be discussed here.

9.1.7B.3.2 Margin of Protection. Several events must occur for a discharge to the atmosphere. A damper supplying ventilation air to an area

housing confinement structures must have failed; potentially loose materials must be available in the glovebox or hood; the glovebox or hood must be breached; the breach must be large enough so that the internal confinement structure ventilation cannot maintain a usable DP across the breach; and, finally, the flow path to the existing exhaust system must be incapable of sweeping all the materials into the exhaust duct. The 236-Z Building is an all concrete structure fully capable of withstanding the small pressurization postulated herein. The only possible bleed to the outside is through the airlock attached to the south wall of the 236-Z canyon. A single stage of HEPA filtration protects this path. Extrapolation of the suspension discussions in Section 9.1.1, involved with a spill of 8 L of concentrated solution to the wet material on the floor of the process cell indicates that the factor of 2,000 provided by the filter is enough. Together, these postulations regarding probability and consequence represent such a low risk of radioactive release that the event will not be discussed further.

9.1.7C Excessive Building Pressurization, 2736-ZB Building

This analysis examines a mechanism for pressurizing areas in the 2736-ZB Building housing sources of radioactive materials. If the pressure level is greater than the surrounding atmospheric pressure, any loose radioactive materials could be forced to the outside environment.

9.1.7C.1 Postulated Cause of the Event.

9.1.7C.1.1 Starting Conditions and Assumptions. The 2736-ZB Building ventilation system is self-contained and independent of other ventilation systems serving the PFP.

The system for the 2736-ZB Building is much newer than the systems serving the other PFP buildings. The instrumentation is considerably more extensive, more sophisticated and uses a distributed control system computer to monitor and control system operation. Two separate systems, which are essentially independent except for sharing an exhaust stack, comprise the system. System one pumps air into the building and into an air duct, which then separates into two streams. Air for the Zone 4 office areas is branched off the main duct circuit and recirculated (except for restrooms, where the air is discharged to the outside) back to the supply fan inlet. The alternate stream is split again prior to recombining in the repackaging room to ventilate that area. This duality provides redundancy for each branch. Part of the split flow is first routed to the east side of the building before entering the repackaging room while the remainder is directly routed to the repackaging room. The total system one flow, now recombined, is dumped into the extensive filtering system and pumped to the stack for discharge. System two also pumps air into the building and into an air duct. Here, however, the air sweeps through the NDA room and then to a separate filtering system. From this section, the air is pumped to the same stack as system one.

The pressure is controlled by variable dampers on both the supply side and exhaust side. On system one these dampers are used on the discharge of the supply dampers (four units total, two units in series off each of the two parallel supply fans) and the discharge of the exhaust fans (two total, one

per each of two parallel exhaust fans). Controllable dampers with motors are also provided on the inlets of the supply fans, the exhaust fans, and the recirculating fans.

The following are the pressure levels set in the zones.

Zone	Reference point	Pressure
1	Repackaging room	-1.0 in. w.g. (glovebox) -0.5 in. w.g. (airlock)
2	Atmosphere	-0.20 to -0.30 in. w.g.
3	Atmosphere	-0.10 in. w.g. (mech. room)
4	Atmosphere	+0.05 in. w.g.

9.1.7C.1.2 Sequence of Events. The ventilation system in Building 2736-ZB includes instrumentation to preclude pressurization.

One of three scenarios is usually responsible when a building is accidentally pressurized. The supply control damper has failed open or been driven open, the exhaust fan has failed, or the exhaust control damper has failed closed or been driven closed.

Failure of the supply discharge damper in this instance seems rather remote. The dampers are designed to close upon loss of pneumatic pressure (fail close). An open condition is required for a malfunction. A general failure of electrical power or instrument air would not cause the dampers to be driven open.

The configuration of the exhaust fans offers the possibility of malfunction. An abnormal event would be if one fan was temporarily out of service for repairs and the other fan failed. A further complication would be that the supply fans are on manual control. In this scenario the system could pressurize the repackaging room, which would be signaled on the annunciator in the control room.

The exhaust dampers are all fail-close units. This includes the dampers on the exhaust fan inlets. Thus, a loss of control air would allow these units to close. Again, if the supply fans were on manual control, the supply fans could not respond to the shutdown signal generated from flow switch FS-5 or FS-6. The repackaging room and most of the east side of the building would pressurize.

Two differential pressure switches, DPS-610-1 and DPS-610-2, sense changes in exhaust fan plenum pressure and NDA Laboratory recirculation fan plenum pressure. Either switch will shut down all Building 2736-ZB fans if a pressure abnormality is detected. These switches are hard wired into the circuitry that disconnects power to the Building 2736-ZB fans. In addition the PFP DCS system that monitors and controls 2736-ZB Building HVAC will, if control is in automatic mode, safeguard against a pressurization upset.

Consequences of a Pressurization. The area could not conceivably be pressurized much above atmospheric pressure. The supply plenum would probably be maintained at 2 in. w.g. as the dampers for the supply fans do not appear to be affected by switching the fans into the manual mode. The repackaging room and the NDA room share a common section of duct beyond the mechanical equipment room. The repackaging room would likely discharge air backwards to the NDA exhaust. This path should be near atmospheric, although no calculations were performed to demonstrate this.

The building should be capable of withstanding such an internal pressure loading. The building was designed to withstand a tornado (Giller 1990, p. 12). Although the interaction of wind with a building is a complex phenomena, a much simplified generalization can be made that high velocity external wind will have the same effect on the roof of the building as a pressurization within the building. The wind will create a reduction in the pressure on the exterior roof of the building with respect to the interior. The effect would be identical to a pressurization of the interior of the building (ASHRAE 1985, p. 146).

The repackaging glovebox, the only normal source of loose contamination within the building, will be affected by this upset but not to the point where radioactive materials could be released. The glovebox is supplied from an independent air source and only becomes common with the room supply on the exhaust side of the glovebox. However, by this postulation, the exhaust pressure, being blocked except by leakage from the room, will rise and the glovebox pressure will rise with it. The automatic controls will prevent the glovebox from exceeding the room pressure because supply to the glovebox will be shut off. The limited amount of flow backwards through the mechanical equipment room into system two should allow the glovebox to remain below the repackaging room pressure.

9.1.7C.1.3 Operator Actions. The upset would be signaled immediately by alarms in the MICON™ power control room (room 714 in the 234-5ZA Building). CRT displays show a description of the alarm and an audio alert sounds. Appropriate action to the trouble indication is taken following investigation of the reason for upset.

9.1.7C.2 Detection of Event.

9.1.7C.2.1 Methods or Means of Detection. Functional explanations and definitions are found on Figure 9-17 (Sheets 1 and 2) and in *Z-Plant HVAC Ladder Diagram*, WHC-SD-RE-SDR-002 (White 1987). Figure 9-17 (Sheets 3, 4, and 5) shows the HVAC airflow and control diagrams. Alarms in the MICON™ power control room (room 714 in the 234-5ZA Building) would alert operators to excess zone pressure.

9.1.7C.2.2 Response Time Assessment. The response time should be 1 to 3 min as the Building 234-5ZA MICON™ power control room (room 714) is continuously manned.

9.1.7C.2.3 Engineered Safety Features and Protective Systems. The main safety features associated with the system are alarms. There are alarms for the supply fans (low flow/fan fail), for the exhaust fans (low flow/fan fail), for the repackaging glovebox pressure (low differential pressure), and for the

2736-ZB Building instrument air. Alarms detected are transmitted to operators consoles in the MICON™ power control room (room 714 in the 234-5ZA Building) and the supervisors console in room 712. The MICON™ system has the capability to run the HVAC system both automatically or in manual mode requiring operator actions in response to changes in field conditions. Power operations personnel are trained in proper responses to system inputs when operating in manual mode.

9.1.7C.3 Analysis of Effects and Consequences.

9.1.7C.3.1 Methods, Assumptions, and Conditions. This scenario requires no calculations. The postulated upset is caused by an additional input to an existing upset condition (i.e., one exhaust blower is out of service).

9.1.7C.3.2 Margin of Protection. The possibility of building pressurization through this scenario is remote. Several factors would have to occur simultaneously: one of the two exhaust fans has to be out of service, the other fan has to fail, and the supply fans have to be on manual.

The majority of work performed in this building is with material sealed for storage or transport. The discussions in Sections 9.1.1 through 9.1.4 show that any slight contamination spread, as experienced infrequently, would not have significant onsite/offsite consequences.

9.1.7D Excessive Building Pressurization, 2736-Z Building

The facility has a hard interlock (fail closed) and a soft interlock (computer). If the supply fan dampers close, the fans are also closed. When supply fans are shut down so are the exhaust fans. This action will not allow pressurization of the facility; however, this scenario is left in as a postulated event.

This analysis examines the mechanism for creating a pressurization of the areas in the 2736-Z Building housing sources of radioactive materials. If the pressure level achieved is greater than the surrounding atmospheric pressure, any loose radioactive materials will be forced to the outside environment.

9.1.7D.1 Postulated Cause of the Event.

9.1.7D.1.1 Starting Conditions and Assumptions. Supply air for ventilation of the 2736-Z Building is provided by the 2736-ZB supply fans via a stainless steel duct. Air from 2736-Z is HEPA filtered and discharged to the environment by exhaust fans located in Building 2736-ZA.

The system for the 2736-Z Building combines two systems: the original ventilation system and the new system incorporated with the 2736-ZB Building installation. The existing system, at least the essential parts for this discussion, had a pair of exhaust fans with diesel generators for standby power located in the 2721-Z Building. The 2736-ZB Building addition provided a supply air system and controls for tying the exhausters into the total ventilation control system for the 2736-Z Building. The system uses LCU-6/DCS to monitor and control system operating parameters.

The pressure level set in the 2736-Z Building is -0.28 to -0.32 in. w.g.

The pressure is controlled through the use of variable dampers on both the supply and exhaust sides. These dampers are used on both sides of the supply dampers (four units total, two units in series off each of the two parallel supply fans) and the inlet of the exhaust fans (two total, one per each of two parallel exhaust fans).

9.1.7D.1.2 Sequence of Events. The sophisticated ventilation system in Building 2736-Z includes considerable instrumentation to preclude pressurization. However, the fan control portion of the system is deactivated and has been since the building went into service.

One of three scenarios is usually responsible when a building is accidentally pressurized. The supply control damper has failed open or been driven open, the exhaust fan has failed, or the exhaust control damper has failed closed or been driven closed.

Failure of the supply discharge damper in this instance seems rather remote. The dampers are designed to close upon loss of pneumatic pressure (fail close). An open condition is required for a malfunction. A general failure of electrical power or instrument air would not cause the dampers to be driven open.

The configuration of the exhaust fans tempers the effect of a malfunction. The two fans are in parallel, which allows one to take over the function of the other in case of malfunction. A trouble scenario would be if one fan was temporarily out of service for repairs and the other fan failed (the inlet damper is a fail closed device). A flow would decrease and pressure would rise, pressurizing the 2736-Z Building. Flow sensors on this line would send an alarm to the control room that flow was dropping. The supply system would receive a signal that flow was dropping. However, beyond these signals there is no automatic relief.

Consequences of a Pressurization. The 2736-Z Building could conceivably be pressurized close to the full 2-in. w.g. available in the supply plenum.

The building should be capable of withstanding such a loading, as this is equivalent to a 65-mi/h wind. The building was evaluated and subsequently upgraded for a 175-mi/h tornado (Giller 1990).

The consequences of this action would not be severe as there is no loose material stored in the facility.

9.1.7D.1.3 Operator Actions. The upset would be signalled immediately by alarms on the operator console displays. The Power Operators would change to a manual mode and have three minutes to correct the zone pressure or initiate facility shutdown.

9.1.7D.2 Detection of Event.

9.1.7D.2.1 Methods of Means of Detection. The schematic flow diagram of the heating and ventilating system in the 2736-Z Building is shown on Figure 9-18. The description of system operation is shown on Figure 9-17

(Sheets 1 and 2). There are flow alarms for the supply fans and for the exhaust fans in the control room and a pressure alarm for the 2736-Z Building. These alarms are signalled on the operator CRT displays and sound on the operator console speaker systems in rooms 712 and 714 of the 234-5ZA Building. The pressure alarm is identified as "7-6 loss of negative pressure 2736-Z."

9.1.7D.2.2 Response Time Assessment. The response time should be quite short as the 234-5ZA control room is continuously manned.

9.1.7D.2.3 Engineered Safety Features and Protective Systems. The use of a computer allows the ventilation system to shut down automatically if the exhaust fans are lost. The computer senses a loss of flow from the exhaust fan or an open exhaust fan contactor and shuts down the supply fans with an automatic interlock. This is a redundancy of the system since the fans can also be shutdown manually. The computers limitation is that it can not transfer the operation between the two supply fans or the two exhaust fans.

9.1.7D.3 Analysis of Effects and Consequences.

9.1.7D.3.1 Methods, Assumptions, and Conditions. No calculations were involved in this analysis. It was assumed that, as the supply plenum is pressurized to 2 in. w.g., any downstream blockage could raise to a maximum of 2 in. w.g. in intervening ductwork, rooms, etc.

9.1.7D.3.2 Margin of Protection. The possibility of building pressurization through this scenario is remote. Several events would have to occur simultaneously: one of the two exhaust fans would have to be out of service, the other fan would have to fail, and the supply fans would have to be on manual.

The possibility of the release of radioactive materials to the environment is even more remote as loose materials would have to be available. As the materials stored in the rooms are packaged elsewhere, there should be no loose materials. An upset of this magnitude would not cause the packaging to rupture. Release of plutonium from containers is discussed in Sections 9.1.1 through 9.1.4. The conclusions drawn in these sections concerning consequences and probability when combined with the small probability of a ventilation upset makes it clear that the risk is acceptable.

9.1.7E Excessive Building Pressurization, 241-Z Building

This analysis examines the consequences of the building ventilation system creating a pressurization of the areas in the 241-Z Building containing radioactive materials. If the pressure level achieved is greater than the surrounding atmospheric pressure, any loose radioactive materials will be forced to the outside environment.

9.1.7E.1 Postulated Cause of the Event.

9.1.7E.1.1 Starting Conditions and Assumptions. Unlike the other facilities examined, the 241-Z Building ventilation does not use a supply system. The air for the ventilation of the 241-Z Building is drawn from the environment through infiltration into the building. In turn, this air is

drawn into the covered vaults. (These vaults are below ground, concrete-lined cavities housing tanks used for temporary storage of contaminated liquids. The vaults are contaminated with smearable surface contamination.) The air is drawn from the vaults through HEPA filtration with two exhaust fans that discharge through the 296-Z-3 stack to the atmosphere.

9.1.7E.1.2 Sequence of Events. Ventilation upsets that could be caused by a ventilation abnormality, a break in a service line, and a chemical reaction in a tank within a vault were examined.

Ventilation upsets caused by some malfunction of the ventilation equipment were found to be an incredible event. There is no published standard for setting the vault pressure, so the only standard to be satisfied is that the vault be at some pressure less than the overhead room.

Two service lines could be pressurized: a 3/4-in. steam line rated at 40 lbf/in^2, used in a steam jet for fluid transfers, and a 1/2-in. air line at 60 lbf/in^2 (gauge), used to supply a small, diaphragm-operated pump used for sampling in cell 8. Both lines, however, are pressurized by valving or other switching devices from outside of the vault confines. Thus, a break would have to occur when the lines are energized; and such a break should be noticed fairly quickly as a weight factor (WF) device in the tank is monitored during the transfer. The WF device would show that there was no diminishment of waste occurring. A break in the airline would be noticed as line pressure is monitored during sampling. A break at any other time would not discharge pressurized gas (air or steam) as these services are deenergized.

As stated in *Waste Gassing Mechanisms at 241-Z*, (Barrington 1989), adding $NaNO_2$ to the D-5 tank of the 241-Z system may lead to outgasing if the tank contents reach a pH of five or less. He bases his statement on observations made when a process tank was used to prepare subsequent solutions of $Fe(NO_3)_3$ and $NaNO_2$. The potential for outgasing was evaluated in *Test Results of Gas Evolution and Foaming When $NaNO_2$ is added to Dilute HNO_3 and $Fe(NO_3)_3$ Solutions* (Barney 1990). Barney reported that under strong acid conditions, $NaNO_2$ forms HNO_2, which decomposes to NO(g) and NO_2(g). At HNO_3 concentrations of 1% or less, solutions of $NaNO_2$ in HNO_3 are stable; however, when small amounts of $Fe(NO_3)_3$ are added, the decomposition reaction proceeds at a rapid rate.

Under worst case conditions a gas flow of 36 ft^3/min is anticipated for 6.6 min or a total gas generation of 237.6 ft^3 of NO_x. The exhaust system for the 241-Z facility is capable of exhausting 1,000 ft^3 of air per minute. This condition thus presents no potential for pressurization of the facility or spread of contamination.

9.1.7E.1.3 Operator Actions. There were no upsets of adequate consequence identified to require operator response.

9.1.7E.1.4 Methods or Means of Detection. Five gauges are available to measure exhaust vault DP with respect to the building (DPI-D4-241Z, D5-241Z, D6-241Z, D7-241Z and D8-241Z).

9.1.7E.1.5 Engineered Safety Features and Protective Systems. There are no engineered safety features or protective systems other than the presence of the ventilation fan.

9.1.7E.1.6 Methods, Assumptions, and Conditions. These were not required, as no substantial upset could be identified.

9.1.7F Building Depressurization--All Plutonium Finishing Plant Operating Buildings

9.1.7F.1 234-5Z Building.

9.1.7F.1.1 Postulated Cause of the Event. Two possible events are considered as possible mechanisms for depressurization: valve adjustment errors and the humidifier pads on the supply unit air washers icing over. Depressurization of portions of the building caused by an inadvertent adjustment of the valves on the control lines leading to damper B or C could cause localized dumping of the control air, in turn causing the damper to fail to its safe position (i.e., open). Because of the common sensor for the control of the two dampers, the common controller would attempt to correct the resultant overpressurization. The working damper would respond and close down. The nonworking damper would remain nonworking. In those rooms serviced by the functioning damper depressurization would occur. The second event concerns icing over of the inlet pads to the supply unit air washers. If the pads ice over, the supply plenum will depressurize, which in turn causes a depressurization of the rooms. The effect would likely be minimal as there are two large automatic dampers, or vacuum breakers, to provide air to the supply plenum if the plenum starts to depressurize below atmospheric pressure.

9.1.7F.1.2 Starting Conditions and Assumptions. The 234-5Z Building is serviced with ventilation air from a supply plenum. This supply plenum is in turn fed with air from four supply fans (eight fans are available). The air for these fans first passes over steam heaters and moisturizing pads to condition the air. The building is exhausted by exhaust fans located in the 291-Z Building. The supply plenum is maintained at 2 in. w.g. Inside the building there is an exhaust air filter plenum that is maintained at -3.2 in. w.g. These plenum settings are maintained by dampers on the supply fans and by a damper on an exhaust fan. The controls on these dampers are automatic.

The pressure levels within the building are set slightly below atmospheric for the processing areas and slightly above atmospheric for the office areas.

9.1.7F.1.3 Sequence of Events. The first scenario for depressurization occurs because of failure of either the B or C supply plenum discharge dampers. However, only certain parts of the building would be affected because the two dampers are tied to the same controller with a single sensor in a room fed from both dampers (see Section 9.1.7A.1.2.1). A failure of one damper will overpressurize the room housing the sensor. The controller will signal the pair of dampers to compensate. Only the functioning damper can respond and will close. Such a closure will starve those rooms served solely by that damper and these rooms will experience a drop in pressure. In general, intervening doors with adjoining rooms will open and air from these rooms will flow into the rooms in an attempt to reestablish the pressure.

The second scenario, depressurization of the building through a failure to sustain the supply air system, would have only a minimal effect. The two vacuum breakers (held closed by weights) on the supply plenum would limit the effect of the occurrence. These vacuum breakers are maintained and tested yearly. The scenario would occur as follows:

- The fan inlets are preheated with steam.
- If the steam failed, the weather was cold enough, and the event happened too quickly to turn off the water, the water impinging on the spray pads would freeze, shutting off the inlet to the fans.
- The modulating dampers on those fans so equipped would open, slowing down the effect but not preventing it.
- As the supply plenum pressure dropped below the 0.5 in. w.g. setting, an alarm would signal in the control room.
- As the supply plenum dropped below atmospheric pressure the vacuum breakers would open, dumping outside air into the supply plenum.
- Downstream, the supply dampers from the supply plenum would open fully.
- The filter plenum would send a signal to the exhaust damper (on exhaust fan EM-3 or EM-4) to reduce the exhaust flow by closing down the modulating damper on the exhaust fan.

9.1.7F.1.4 Consequences of a Depressurization. Depressurization of certain rooms by the failure of dampers B or C could expose certain of these rooms to potential airborne radioactivity from other rooms. If doors are not securely latched, there would be a rush of air from those rooms to the newly created low pressure rooms.

A depressurization of the building through freezing of the supply unit air washer humidifier pads would have a different effect. There would be no severe DPs between the rooms of the backside such as described previously. There may be, however, a reversal between Zone 1 (frontside) and Zone 3 (backside). The reversal would be brief as there is automatic circuitry to shut down the exhaust fans servicing the frontside if an incipient reversal occurs. A pressure reversal occurs because the pressure in the filter plenum on the backside is controlled while there is no exhaust side pressure control for Zone 1. Both sides have dampers emanating from the supply plenum. These would both open fully to attempt to compensate for the falling supply plenum pressure. In Zone 3, the control system for the filter plenum would close down the modulating damper of the exhaust fan. This would effectively remove one of the four exhaust fans from service. There is no similar compensation for Zone 1.

The E-4 system would be impacted as follows. Gloveboxes draw air from the rooms or from the building dry air system; hoods draw air from the rooms. By drawing air from the rooms, the gloveboxes and hoods follow the movement in the room pressure level and maintain the same DP with the room. Those glove-boxes ventilated with the dry air system are equipped with a large, diaphragm-

operated gas valve designed to close if the glovebox starts to pressurize with respect to the room. This would have no effect if the room overpressurizes; the glovebox would be at a negative pressure with respect to the room. However, if the room drops in pressure, the valve would close, shutting off the source of dry air and allowing the glovebox to remain negative with respect to the room.

9.1.7F.1.5 Operator Actions. The Power Operator's response to a depressurization caused by a failure of damper B or C is identical to that for a pressurization (see Section 9.1.7A.2.2). In the event of a depressurization of the building through freezing of the humidifier pads, an alarm will sound as the supply plenum drops below its trigger positive setting. Upon receiving an alarm from the supply plenum, the operator would have three minutes to bring the ventilation system into control or shut down operations and reduce exhaust ventilation to flow through a single exhaust fan. The lack of steam pressure, presented as a factor in the upset scenario, may cause freezing of plumbing lines in the building. A recovery action would be developed, with the circumstances of the shutdown determining the response.

9.1.7F.2 236-Z Building. This analysis examines the building ventilation system for a mechanism for creating a depressurization of the 236-Z Building.

9.1.7F.2.1 Postulated Cause of the Event. There are two possible contributors to a depressurization of the building: collapse of the supply air duct or reversal of the control linkage. In the event of a depressurization of the 234-5Z Building through loss of supply air, the 236-Z Building would also experience depressurization. Building supply air is ported over to the 236-Z Building through a long outside duct, which is fed from damper F on the supply plenum located in the 234-5Z Building. The long duct is exposed and could be damaged (e.g., by a falling crane). Damper F is driven by a linkage system that is mirror-image duplicated on the opposite side of the discharge duct on the supply plenum. These mechanisms are used alternately, each for 1 yr. It has been postulated that during routine switchover the linkage could be accidentally connected backwards. The control system would then drive the damper full-open or full-closed, depending upon the sensing point pressure at the time of putting the damper controls into service. For this scenario, it is assumed that damper F is driven closed. The building could depressurize to the full -6 in. w.g. set in the exhaust plenum.

9.1.7F.2.2 Starting Conditions and Assumptions. The building is serviced by the same supply plenum and exhaust system that supports the 234-5Z Building.

9.1.7F.2.3 Consequences of a Depressurization. Physiological consequences to the people working within the facility at the time of the upset are likely. The sudden drop in pressure may cause earaches and other discomforts. The concrete building would likely suffer no consequences. An air pressure differential of 6 in. w.g. level would be similar to the snow loading for which the roof was designed. The interior of the building should experience no reversals of pressure as the exhaust system controls and fixed damper positions maintain Zone 4 pressures lower relative to Zone 3.

The canyon and, hence, all the gloveboxes use air drawn from the rooms. In a depressurization their internal pressure would follow the room pressure.

9.1.7F.2.4 Operator Actions. There are no specific low level alarms to alert the power operators in the 234-5Z Building control room. Their instrumentation would indicate the nature of the upset, however. The pressure indicating device, a chart recorder, would show a sharp change in pressure. Their first awareness of a problem may well be from personnel telephoning to report the atmospheric change. Again, the power operators response would be to shutdown the PFP ventilation supply system and operate the exhaust system solely with the emergency electric-driven exhaust fans until the problem can be identified and corrected. Ventilation zone 3 areas would be evacuated.

9.1.7F.3 2736-ZB Building. This analysis examines the building ventilation system for a mechanism for creating a depressurization of the areas in the 2736-ZB Building housing sources of radioactive materials. A depressurization would have to be of such a magnitude to cause a rupture of the building and subsequent release of any loose radioactive materials to the outside environment when the depressurization was corrected.

9.1.7F.3.1 Postulated Cause of the Event. There was no credible event that could be postulated to achieve a depressurization of the building.

9.1.7F.3.2 Starting Conditions and Assumptions. The building is serviced with ventilation air from the atmosphere directly. There is a dual system to supply this air to independent parts of the building. The air is ducted through the 2736-ZB Building into each set of parallel supply fans. Here the air is pressurized for distribution throughout the building. Before entering the parallel alternating supply fans, the air is passed through reheat steam coils, steam heat coils, and two stages of HEPA filtration. The system does not use an air washer. The system is controlled by the MICON™ system (LCU-6/DCS).

The pressure levels within the building are slightly below atmospheric for the processing areas and slightly above atmospheric for the office areas.

9.1.7F.3.3 Sequence of Events. Depressurization of the building through a failure to sustain the supply air system would not be credible. Depressurization classically occurs when (a) all supply air dampers are closed, or (b) all supply fans shut off while exhaust fan(s) continues to operate. There are only the filters in the supply system. These would not be expected to sustain a quick change in resistance so that the point where shutoff occurs should not be achieved with any kind of a maintenance program. The automatic control program will sense for flow; failing to find it, the program will shut down the supply fans.

9.1.7F.3.4 Identification of All Protective Systems. The protective systems are built into the LCU-6/DCS computer program that controls the ventilation system. The system, described in Chapter 5, Section 5.4.1.2.1, is defined on engineering drawings and in White (1987).

9.1.7F.3.5 Operator Actions. None are required.

9.1.7F.4 2736-Z Building. This analysis examines the building ventilation system for a mechanism for creating a depressurization of the areas in the 2736-Z Building housing sources of radioactive materials. A depressurization would have to be of such magnitude as to cause a rupture of the building and subsequent release of any loose radioactive materials to the outside environment when the depressurization was corrected.

9.1.7F.4.1 Postulated Cause of the Event. Depressurization can come about from a failure of the automatic controls, human error, or a combination of the two. One such depressurization has been reported. The control system was off to perform maintenance on an exhaust fan. The supply fans were disabled prior to the exhaust fans being shut off, which apparently caused a depressurization to -3 in. w.g. No damage occurred.

9.1.7F.4.2 Starting Conditions and Assumptions. The building is serviced with ventilation air from the atmosphere directly. Air is drawn from the outside, through preheaters and filters, and into parallel supply fans. These fans force the air into the 2736-Z Building. A pair of parallel exhaust fans take the air from the 2736-Z Building and discharge it to the atmosphere through a stack. This system is computer controlled.

9.1.7F.4.3 Consequences. There would be no radiation-related consequences as materials in this building are sealed in containers or equipped with HEPA-filtered vents. A pressure differential of a few inches of water would not cause leakage of the containers. However, if people were in the building, the doors would be pressed shut so that they could not get out.

9.1.7F.4.4 Identification of all Protective Systems. The protective systems are built into the computer program that controls the ventilation system. The system, described in Chapter 5, Section 5.4.1.2.1, is defined on engineering drawings and in White (1987).

9.1.7F.4.5 Operator Actions. During the reported depressurization, the exhaust fans would be deenergized.

9.1.7F.5 241-Z Building.

9.1.7F.5.1 Postulated Cause of the Event. The simplicity and low flowrate of the system precludes any means to significantly depressurize the building. See Figure 9-20 as discussed below.

9.1.7F.5.2 Starting Conditions and Assumptions. The ventilation system consists solely of a pair of parallel exhaust fans drawing infiltration air into the building and forcing it out a stack. The infiltration air is drawn into the building, through multiple locations as the building is a simple, metal shell intended as a weather cover. Air is drawn into the vaults by infiltration paths around the cover blocks, and then into piping through filters, and then into the fan.

9.1.8 Loss of Ventilation

A loss of ventilation would occur if both supply and exhaust fans were to lose power simultaneously. Air in a facility would become essentially

stagnant, except for the very slight movement caused by convection or by the DPs resulting from weather changes. All facilities would have similar effects on loss of all powered ventilation, but only the buildings serviced by the 291-Z-1 stack are analyzed mathematically. This event is initiated when all normal electrical power is lost to the supply and exhaust fans, rendering both systems inoperable. Standby power from the diesel-generators in the 2721-Z Building would also have to fail to maintain emergency fan EM-1 or EM-2 on line. During such an event, the only airflow in the building would be from natural circulation. Except for the two very specialized conditions described below, there would be a flow of air up the 200-ft-high stack. In all but very hot weather, convection can provide significant draft, as can the suction caused by wind blowing across the lip of the stack. The following situations could provide motive force for a slight reverse flow. Reverse flow down the 291-Z stack could occur as a result of (1) summer heat-induced convection or (2) winter weather induced DP from a passing storm front.

9.1.8.1 Postulated Cause of the Event, 234-5Z, 236-Z, and 242-Z Buildings.

9.1.8.1.1 Starting Conditions and Assumptions. A complete loss of ventilation occurs due to a simultaneous loss of electricity and standby power from the diesel-generators. Electrical loss could be local to the 291-Z Building or site wide. Loss of standby power could occur due to failure of the diesel-generators, switchgear or control systems. Such an occurrence would involve three simultaneous, unlikely events (i.e., loss of two electrical circuits and standby power from the diesel-generators).

9.1.8.1.2 Sequence of Events. Upon failure of normal and standby electrical power to the 291-Z Building, the following events would take place.

1. The supply fan dampers would open, and supply fans would stop due to deactivation of electric switch ES-9 by the rise in exhaust plenum pressure.

2. Simultaneously, zone dampers B through E open to their designed fail positions and dampers A and F close to their fail positions, isolating Zones 1 and 3B from the rest of the system. Also, Zone 1 electrically powered exhaust fans EM-11 and EM-12 shut down.

3. Dampers to the EM-3 through EM-7 exhaust fans fail closed.

4. Dampers to the EM-1 and EM-2 exhaust fans fail open.

This sequence of events leaves an open path from the supply louvers through all Zone 3 rooms. Also, an air path is opened through all room ventilated gloveboxes. The supply dampers for the dry air system gloveboxes close, preventing flow through the dry gloveboxes.

9.1.8.1.3 Operator Actions. There would be no operator action possible to correct the problem. An announcement would be made by power operations on the building paging system to evacuate Zone 3. All personnel, except those needed for orderly shutdown, would evacuate to Zone 1. The shutdown personnel would don respiratory protection and evacuate to Zone 1 when the shutdown was complete.

9.1.8.2 Detection of Event.

9.1.8.2.1 Methods or Means of Detection. The loss of ventilation will be immediately detected by an alarm system in room 321. Simultaneously, the building will become much quieter. Filter media from the E-3 exhaust air grilles will fall off, as they are normally held on by suction. Emergency lighting would be supplied by a series of facility emergency lights. Lighting would be very dim. All strip chart recorders indicating pressures within Zone 3 would stop.

9.1.8.2.2 Response Time Assessment. The immediate response for a loss of ventilation would be an announcement via the Private Automatic Exchange (PAX) system that normal ventilation has failed and all Zone 3 areas are to be evacuated. The evacuation could be expected to be complete in 5 to 10 min.

9.1.8.2.3 Engineered Safety Features and Protective System. The safety features and protective systems for such an event are inherent within the ventilation system. In this event, it is possible that air can flow down through the 291-Z stack and into the 234-5Z Building. A comparison of duct areas in the airflow path indicates that there is more area in the E-3 system than the E-4 system. In addition, the air that flows in the E-3 system will encounter three parallel banks of 112 HEPA filters each. It is expected that the pressure drop across these filters will be very small and that the airflow rate will not be greatly reduced. In addition, the E-3 system has only one stage of HEPA filtration, versus four or five stages in the E-4 system. (Counting the filter rooms, the two in-series filters in filterboxes that are tested as one stage, the nontestable filter at the outlet of gloveboxes and glovebox inlet filter.)

Any airflow through the E-4 system will be even further reduced due to the change in areas of the duct geometries, bends in the duct routing, and filter banks. There is much more resistance to airflow in this system than in the E-3. For these reasons the flow to rooms will be higher than to the gloveboxes.

9.1.8.3 Analysis of Effects and Consequences.

9.1.8.3.1 Flow Reversal, Hot Day.

9.1.8.3.1A Flow Reversal, Hot Day, Methods, Assumptions, and Conditions. The following conditions are assumed for this event: (1) it is a hot summer day with an outside temperature of 110 °F and an inside temperature of 80 °F in Buildings 234-5Z and 236-Z and (2) it is windless. Wind would produce a low pressure due to Bernoulli effect at the top of the stack; air within the building would continue to be drawn up the stack. Therefore, to get the effect of airflow down the stack, there could not be any wind. To obtain the condition of the air flowing down the stack, the air in the building must backflow through the ducting into the supply plenum and up into the supply fans. From the fans, the air would backflow through both the wet and dry filters to exit from the fan inlet grilles.

The maximum backflow rate would be about 15,000-ft^3/min, as compared to a normal forward flow of about 225,000-ft^3/min. The upward and downward flow patterns (with time) that might be expected are shown in

Figures 9-21 and 9-22. Note that the downward graph cuts off at about 220 second (plus 3 minute). At this time the stack has emptied of cool air and warm outside air is postulated to flow horizontally through the building duct work. This voided the mathematical model and no further calculations could be made.

If all ventilation goes down at once, the flow through the building would not stop instantaneously. The momentum in about 252,000 lb of air would coast to a stop after about 42 second, as shown in Figure 9-21.

The following calculation was made to determine the rate of ventilation flow decay through the building. The solution is to solve the second law of motion:

$$\text{Force (F)} = \text{Mass (M)} \times \text{Acceleration (A)}$$

where: F = Friction force encountered by airflow passing through building (pounds)

M = Mass of air in buildings

= W/g, where W equals the weight of air and g is the gravitational constant 32.2 ft/s^2

A = Acceleration.

This equation yields an acceleration number that, when integrated over a small span of time, yields a change of velocity. This change of velocity is subtracted from the original velocity. The friction factor is then recalculated at the reduced flowrate and a new acceleration number is achieved. This procedure can be repeated until flow stops.

The whole procedure can be represented by the differential equation:

$$F = M(dv/dt) + D(v)$$

where: M = Mass
D = Friction (damper)
v = Velocity
t = Time.

However, the friction D, is not linear with velocity, v, as indicated. This makes solving the equation much more difficult. The friction, D, varies in pneumatics as the square of the velocity, v. Thus, the solution would be iterative by allowing only small changes in time, t, so as to keep the relationship between v and D nearly linear. The brute force solution makes the iterative process more understandable. A crucial assumption in this calculation is that the shape of the air mass is cylindrical, with diameter equal to the stack diameter. This yields an average velocity fairly representative of the velocity of air in the ducts. The head loss at full flow, in inches water gauge, is assumed to act against this cross-sectional area.

The equation is solved using known data. The mass, initial velocity, and head drop (or friction force) are taken from known operating conditions.

Acceleration is calculated from the second law of motion. A change in velocity is calculated from integrating acceleration over the small space of time. The new velocity is the old velocity minus the change on velocity.

The new head drop (or friction force) is calculated from the fact that the head varies on the ratio of new and old velocity squared.

For the record iteration, the process is repeated: (1) calculate acceleration, (2) integrate acceleration, (3) calculate velocity, and (4) determine new head drop. This procedure is repeated as required until the airflow through the building stops or approaches zero.

The results of the iteration are shown graphically on Figure 9-21, which shows that on a hot day workers would have time to leave the immediate work area. The Vent and Balance personnel working dampers with crews involved in jobs such as panel changes would have time to react. In addition, reversal does not build to half flow until about 50 s have passed (Figure 9-22).

The calculation to determine the acceleration of backflow in the ventilation stack follows the same iterative procedure as for the flow decay rate. The only difference is that a driving force, consisting of the block of cool air existing in the stack above the inlet grille for the building supply fans, is now part of the equations. The same assumption regarding the shape of the air mass is made.

The results of the iterations are shown in Figure 9-22.

9.1.8.3.1B Flow Reversal, Cold Day, Methods, Assumptions, and Conditions. The starting condition of this event is a sudden change of atmospheric pressure while the building ventilation system is inoperable. For this event to occur the building would have had to be without heat for a considerable time because the forces of convection up the stack on a cool day are considerable. Studying the forces involved with the backflow shows that cool day velocities would build to a considerable rate. The drop in backflow rate was due to the fact that the small volume of the stack filled with warm air that then was below the point of pneumatic balance and only dropped as far as it did on the basis of inertia. Flow in the upward direction would continue to build until friction stopped the acceleration. After the reservoir of heat stored in the building structure and equipment cooled convection would cease. This event is being presented primarily for completeness of the reversal scenario and not because it is credible as an abnormal operation.

The Hanford Site weather data collected for 50 years show that an atmospheric condition of this type would only occur during the winter months on the approach of a high pressure front. The worst frontal system recorded by the Hanford meteorological station (HMS) was on November 3, 1958 (Stone et al. 1983, p. VIII-1). The pressure fall averaged 0.082-in.Hg/h over a 6-h period (0.492-in. Hg total). The maximum hourly fall was 0.160-in. Hg.

The method used to calculate the airflow through the 234-5Z, 236-Z, and 242-Z Buildings that could cause a "breathing" effect is very conservative. The calculation assumes no loss of airflow through the ducting or filter banks. A pressure drop of 0.492-in. Hg is used to calculate the airflow.

The approximate volumes of the 234-5Z, 242-Z, and 236-Z Buildings are listed below:

Building	Volume (ft^3)
234-5Z	3,128,000
236-Z	377,000
242-Z	49,000
Total Volume	3,554,000

Standard atmospheric pressure at the Hanford Site, which is 733 ft above sea level, is 29.21-in. Hg. The maximum pressure drop experienced over a 1-h period was 0.160, which lowered the atmospheric pressure to 29.05 in.-Hg.

The ideal gas law is used to determine the volume change of the building air at the maximum hourly pressure decrease, (0.160-in. Hg). Assuming the pressure and volume change occurs at constant temperature, the following calculation is made (Baumeister et al. 1967):

$$V_2 - V_1 = (P_1/P_2) \times V_1 - V_1$$

$$V_2 - V_1 = [(P_1/P_2) - 1] \times V_1$$

$$V_2 - V_1 = [(29.21/29.06) - 1] \times 3.6 \times 10^6 \text{ ft}^3$$

$$V_2 - V_1 = 1.8 \times 10^4 \text{ ft}^3$$

Assuming this volume change equillibrates during the hour that the pressure is changing, the flow rate will be:

$$Q = 1.8 \times 10^4 \text{ ft}^3/60 \text{ minutes} = 310 \text{ ft}^3/\text{min}.$$

9.1.8.3.2 Source Term Convection Scenario (A). The convection scenario is calculated as it is the least unlikely of the two. Since the flow rate for the weather front scenario is only 4 times as great, the consequences for neither scenario are of significance. There is no significant source term or even significant internal-to-building contamination following either the convection or the weather induced flow. This is due to the presence of HEPA filters and building integrity and the lack of a driving force to push plutonium out of the primary confinements. There is a possibility for removal of material normally downstream of open-faced hoods. This is expected to be low level as the airflows would be low.

The velocity of air flowing in reverse through the media of a typical first-stage filter serving an open-faced hood is very low. For example, typically a single filterbox serves four hoods. The filterbox is equipped by a single 24-in. by 24-in. by 12-in. HEPA filter. The hoods are typically equipped with an armported face with a total area of ≈3 ft^2. The face velocity is typically set at 125 ft/min so each hood is drawing ≈375 ft^3/min. The four hoods are then drawing about 1,500 ft^3/min. A normal stack flow is assumed to be 225,000 ft^3/min. Thus, a reverse flow of ≈15,000 ft^3/min is 15,000/225,000 = 0.066 the normal flow. This figure is conservative as most of the airflow would go the path of least resistance through the E-3 system and into the rooms. Thus, it is conservative to assume that the reverse flow out of the four hoods will be 0.066 x 1,500 ft^3/min = 100 ft^3/min. The HEPA filter has a total surface area of ≈216 ft^2 (Gunn and McDonough 1981). Thus, the velocity that would thrust particles back off the filter would be 100 ft^3/min/216 ft^2 or 0.46 ft/min. This is only 0.46 ft/min/88 ft/min/mi/h = 0.0052 mi/h, which is not enough to loosen significant amounts of impacted and electrostatically adhered particles.

Backflow from gloveboxes in an opened condition (e.g., during a panel change) would involve yet another low probability coincidence. In addition, before such work begins the gloveboxes are wiped of much loose material. Flowrates of only 0.066 normal would suspend very little material.

9.1.8.3.3 Margin of Protection. The margin of protection for these abnormal operations is within the ventilation system itself. The ducting is of varied geometric shapes and sizes routed throughout the building by many bends. Also included in the ventilation system are several banks of HEPA filters. These features offer resistance to any backflow of air that may occur. Assuming the airflow would take the path of least resistance, this flow would be directed to the E-3 system, which would go to the rooms. The E-4 system includes several stages of filterboxes with HEPA filters as compared with the one stage of the E-3 system. The dry air system contains a valve upstream of the normal inlet that would close on a loss of air signal.

The margin of protection to the environment between any minor contamination that might result from open-faced hoods would be very high. This is deduced from highest values of historical room contamination incidents which are about 2.5 x 10^{-10} μCi/mL. From the discussions in Sections 9.0.2.2 and 9.1.4.3 it is apparent that a release into even several laboratory rooms would produce an effect many orders of magnitude below the lowest acceptable release for an event having an annual probability of one.

9.1.8.4 Hydrogen Accumulation. The primary and secondary containment barriers for materials in vaults and the steel food pack cans might be breached by pressurization. Pressurization of these materials might come about as a result of heat generation following ventilation loss.

Tanks containing plutonium solutions are constantly evolving hydrogen gas as a result of radiolysis. The vessel vent systems direct this and other gases to the gloveboxes and then to the E-4 vent system. Loss of ventilation would mean that some increase in hydrogen levels would occur within gloveboxes. The two gloveboxes examined in this section previously contained significant quantities of concentrated plutonium nitrate solution and are considered to be worst cases. They were used to receive product solutions

from PUREX and PRF or are used for RMC Line feed storage. The calculations which follow show that, even assuming worst case conditions with no air movement, it would take nearly 4 weeks to accumulate enough hydrogen to result in a structure-threatening detonation. Glovebox HC-227S is located within the concrete walled portion of the RMC Line and glovebox HC-4 is located in vault room 166, so a simple deflagration is not expected to breach the outer building walls.

9.1.8.4.1 Starting Conditions and Assumptions. The conditions and assumptions used in this analysis are presented below with a discussion of any conservatism associated with them.

- **Plutonium Concentration = 450 g/L**--This concentration is the upper limit from the criticality prevention specification (CPS). The nominal concentration of these solutions is 255 g/L as given in the RMC Line flowsheet. This provides a factor of 1.8 conservatism.

- **Acid (H+) Concentration = 1.3M**--This concentration is the lower limit from the CPS. It gives a significant degree of conservatism for hydrogen evolution. The hydrogen evolution rate at 1.3M is 7.3 times as great as that from the 7M acid normally used (Sheppard 1968, Figure 2).

- **Hydrogen Evolution Rate (G_H) = 0.22 molecules/100-eV** (Sheppard 1968).

- **Ventilation = None**--The gloveboxes are assumed to be essentially nothing more than closed bottles with only a capillary vent which reduces any loss of hydrogen by diffusion. In reality, both gloveboxes are ventilated by pulling room air through an 8-in. by 8-in. HEPA filter. Hydrogen generated at a low rate would leave and be diluted by diffusion both ways through this and the exhaust filter. In addition, over the weeks that would be required for buildup, atmospheric effects as discussed above would provide dilution.

- **Detonable Concentration = 14%**--The lowest detonable concentration reported by *Light Water Reactor Hydrogen Manual*, NUREG/CR-2726, p.2-51 (Camp et al. 1983) is 14%. This is lower than predicted by shock-tube experiments. In larger enclosures containing equipment the flame front can become perturbed to the point that deflagration proceeds to detonation.

- **Ignition = Present**--The presence of an ignition source when the ventilation system has been down for an extended period is a conservatism. Procedures call for shut down of processes and evacuation of Zone 3 in the event of even a partial ventilation failure. Equipment within the gloveboxes would not be activated until some time after ventilation had been restored.

- **Free Volume of Gloveboxes**--Glovebox HC-227S = 275 ft^3, glovebox HC-4 = 178 ft^3.

- **Volume of Solution in Each Glovebox**--Glovebox HC-227S = 132 L, glovebox HC-4 = 120 L.

9.1.8.4.2 Calculations. The rate of energy released into the solution in each tank is given by the following expression:

$$E/T = v \times c \times 3.7 \times 10^{10} \times \sum_{i} a_i \times f_i \times e_i$$

where: E/T = Rate of energy production (MeV/s)

v = Volume of plutonium solution in all tanks

c = Concentration of plutonium (g/L)

Ci = Curie = 3.7×10^{10} dis/s/Ci

dis = Disintegration

a_i = Activity of each nuclide (Ci/g)

f_i = Fraction of each nuclide in solution

e_i = Energy evolved with each disintegration (MeV).

The characteristics of the plutonium mixture are presented in Table 9-7 with the summation term of the equation given above. The isotopic distribution in Table 9-7 is based on the greater than 19% ^{240}Pu data in Table-43.

Thus, for the two gloveboxes the rates of energy production are as follows:

HC-227S:

$$E/T = 132L \times 450g/L \times 3.7 \times 10^{10}\text{-dis/s-Ci} \times 1.6\text{-Ci-MeV/g-dis}$$

$$= 3.5 \times 10^{15}\text{-MeV/s}$$

$$3.5 \times 10^{15}\text{-MeV/s} \times 10^{6}\text{-eV/MeV} = 3.5 \times 10^{21}\text{-eV/s}$$

HC-4:

$$E/T = 120L \times 450g/L \times 3.7 \times 10^{10}\text{-dis/s-Ci} \times 1.6\text{-Ci-MeV/g-dis}$$

$$= 3.2 \times 10^{15}\text{-MeV/s}$$

$$3.2 \times 10^{15}\text{-MeV/s} \times 10^{6}\text{-eV/MeV} = 3.2 \times 10^{21}\text{-eV/s}$$

The rate of hydrogen gas generation as taken from *Alpha Radiolysis of Plutonium IV - Nitric Acid Solutions* (Sheppard 1968) is 0.22 molecules (mol) per 100-eV or 2.2×10^{-3}-mol/eV (see above). Thus, for HC-227S:

$$3.5 \times 10^{21}\text{-eV/s} \times 2.2\text{x}10^{-3}\text{-}H_2\text{/eV} = 7.7 \times 10^{18}\text{-}H_2\text{/s}$$

Assume that the glovebox temperature is 25 °C, so a mole of gas occupies 24.3 L.

$$1.3\text{x}10^{-5}\text{-mol/s} \times 24.3\ \text{L/mol} \times 1/28.3\ \text{L/ft}^3 = 1.1 \times 10^{-5}\ \text{ft}^3\text{/s}$$

The free glovebox volume is 275 ft^3. Thus, 14% of this is 38.5 ft^3.

The time required to generate this much hydrogen gas is:

$$38.5\ \text{ft}^3 \times 1/1.1 \times 10^{-5}\ \text{ft}^3\text{/s} = 3.5 \times 10^{6}\ \text{s}$$

$$3.5 \times 10^{6}\ \text{s} \times 1/8.64 \times 10^{4}\ \text{s/d} = 40\ \text{d}$$

For glovebox HC-4, calculated in the same way, the time is 29 d.

As stated above, these figures are based on the assumption that no diffusion and no mixing takes place during this entire period. When the conservatism (see Section 9.1.8.4.1) in concentration of plutonium and acid are excluded and nominal values used, the time is 13 times as great or 373 d for glovebox HC-4.

This event will not be further developed as there is very little probability that the building would be left with no ventilation for a period of 1 month with solution in the tanks.

9.1.8.5 Entrain Downstream Powder. The ductwork downstream of the final filters that lead to the 291-Z-1 Stack is contaminated with an estimated 10 g of plutonium (Schilling 1989). This estimate was based on analysis of surveys of surfaces in the filter room and internal ducting downstream of final filters. Analysis of these samples indicates all were nominally 6% ^{240}Pu material and tightly adhering to surfaces. Historical ventilation transients caused by switching operating fans and switchovers to one and two backup steam-driven exhausters (now deactivated) did not result in abnormal stack releases. This supports the observations that the material is tightly adhered to surfaces. Resuspension due to ventilation transients is not expected.

9.1.8.6 Vault Temperature Rise. The effect of a loss of ventilation to the containers of plutonium in the vaults would be minimal. The calculations in Section 9.2.4.6 show temperatures of about 280 °F and pressure of 20 lb/in^2. The storage cans would not burst under these conditions.

9.1.8.7 2736-Z and 2736-ZB Buildings. Loss of ventilation for the 2736-Z and 2736-ZB Buildings would have similar results as in the 234-5Z complex as presented in Section 9.1.8.1.

9.1.9 Glovebox Glove Breach

Any pressurization of primary confinement relative to a room can be expected to result in a spread of radioactive material. Pressurizations less than required for actual failure of gloves, bags, or sphincter seals should not result in a spread of contamination but, as a practical matter, might do so in some locations due to small holes normally not noticed due to inward airflow. Such spreads are not expected to be great in themselves, but, if a glovebox is even slightly pressurized at the same time as a major breach, an amount of radioactive material could be released into the room which would be significant in terms of occupational exposure.

Penetration of a glovebox glove may result in the release of plutonium-bearing materials to areas occupied by personnel. Plutonium-bearing materials are handled in the PFP in a variety of gloveboxes during many different processing stages, quantities, and concentrations subject to criticality considerations. The handling and maintenance of glovebox gloves and the associated hand tools were reviewed for the potential to breach a glove and cause an abnormal condition or breach of primary confinement, and potential subsequent release into an occupied area. Factors that could lead to glove failure have been identified as hot surfaces, sharp objects, and deteriorated glove material. A breached glove would be a violation of primary confinement but would not necessarily result in the release of a plutonium-bearing material. This section analyzes the conditions and scenarios that could result both in the violation of primary confinement and the release of a plutonium-bearing material into an occupied zone.

9.1.9.1 Postulated Cause of the Event.

9.1.9.1.1 Starting Conditions and Assumptions. This scenario assumes that sources such as a hot surface, a sharp object, or deteriorated glove material will lead to the failure of a glove. A glove breach would cause the violation of a confinement barrier between operational personnel and a contaminated area. For a release to occur as a result of a glove breach, the action involved in penetrating the glove must also spew out contaminants; or during the time of an event that breaches a glove (e.g., incorrectly set ventilation system), the normal negative DP must be missing or reversed, or the event itself must create a reverse pressure pulse.

In addition to the breach of a glovebox glove several other sources could cause the loss of the contamination barrier that the gloveboxes and gloves define. Any object of significant mass and velocity (e.g., a falling maintenance ladder or a missile generated by an explosion or rapid release of gas pressure) could potentially penetrate a glovebox. Slight

overpressurizations (e.g., due to material handling or plutonium hydride reactions) can also fail deteriorated or defective gloves resulting in a release to the room (see Appendix 9H). However, it is expected that these types of events are less likely to occur and the expected consequences no worse than a glove breach.

9.1.9.1.2 Sequence of Events. One sequence of events that could lead to a breached glovebox glove is an operator reacting to a supposed fire situation and attempting to extinguish the fire. Fire extinguishers with wands sharpened to resemble large hypodermic needles capable of penetrating glovebox gloves are provided for control of small glovebox fires. The wands are connected to the extinguishers with quick disconnects so that they can be left in the glove when an extinguisher is emptied. However, if the glove is deteriorated or defective, forcing the wand through the material could rip out a much larger hole than is necessary to insert the probe, thereby violating primary confinement.

Contact with hot surfaces during any operation could produce burns and lead to the potential release of radionuclides should a glove burn through. Normally, prior to the operation of a heating element or furnace in a glovebox the gloves are to be withdrawn to a stowed position, usually tied up to prevent the glove from being drawn into the glovebox by the prevailing DP. A glovebox furnace may radiate heat through joints between lagging blocks and possibly ignite that portion of a glove left in close proximity to the high-temperature portions of the furnace. The opening in the glove then is a direct path which could allow any contamination present to leak into a worker occupied area.

Moving equipment such as the HC-1 conveyor, sweep arms, and rams may contact and cause a hood glove breach which could potentially lead to a contamination release. Normally, prior to the operation of glovebox mechanisms the gloves are to be withdrawn to stowed positions. If a sweep arm were to snag a glove, or a conveyor belt were to pinch a glove, the glove could be breached and primary confinement would be violated.

9.1.9.1.3 Operator Actions. An operator may, through an inadvertent action, cause the breach of a glove. A possible action that could lead to breaching a glove would be the mishandling of a sharp object within the glovebox. The operator's field of view is restricted within many gloveboxes due to the presence of radiation shielding intended to reduce the operator's radiation dose. Also, the area just beyond and below the gloveport is normally a visually obscured area due to the presence of the glove itself and optical limitations of the glovebox windows. An operator's sense of touch is restricted when using a set of gloves and he may not realize that he has grasped a sharp object until the object has penetrated the glove and possibly his hand.

9.1.9.1.4 Engineered Safety Features, Protective Systems, and Administrative Controls. The principal method of preventing breached gloves, aside from reducing the number of operations requiring the use of gloves, is adherence to a good housekeeping program. Gloves are replaced on a routine preventive basis in accordance with established procedures. Glovebox windows must be kept clean and corrodible tools and other objects which could cause punctures must be replaced regularly. Management is responsible for ensuring

that a glove control program is implemented and maintained. Essentially, it is through the exercise of due caution and diligence that the relatively small number of breached glove incidences can remain insignificant.

The DPs are maintained in the ventilation exhaust systems so that airflows are always toward more highly contaminated or potentially contaminated areas up to filtration. Safety considerations and controls on the ventilation systems provide dampers and valves for regulation/isolation, measurement of DP across the filters, continuous radioactive particulate monitoring, exhaust air sampling, and continuous measurement of exhaust airflow.

The fans for maintaining the correct airflow are configured in a redundant parallel system and are used in the number required to maintain the exhausted quantity of air under stable control or the designed flowrate. These fans have dampers that control airflow through the fan as required to maintain a specified DP. They are supplemented by manually operated dampers on several other fans.

On the RMA Line, RMC Line, and certain laboratory locations, gloveboxes are equipped with ventilation control valves. Pressure sensors monitor glovebox pressure and control valves maintain DP in gloveboxes within a specified range and are able to operate from full-open to full-closed within 3 s. As glovebox DP increases above the allowed setting, the valve closes, thus avoiding loss of negative pressure, overpressurization, or discharge of air through an open port. A DP switch connected to an annunciator in the power control room monitors the pressure in the RMC Line gloveboxes and alarms if pressure exceeds the DP set point.

Two similar valves regulate exhaust on an emergency basis. Each parallel valve exhausts to a common duct. The valves are normally closed tight for any upstream pressures within the allowable range. They are set to start opening when the negative DP rises toward zero and to be opened fully before upstream pressure becomes positive.

All glovebox negative pressures and exhaust filter pressure drops are to be verified to meet safety standards before entry into any gloveboxes for testing or maintenance.

Actions taken to minimize the probability of internal deposition include:

- Use of leather gloves over the rubber gloves when handling miscellaneous plutonium-bearing materials
- Training personnel to use special care when handling material that could have sharp edges or working in the vicinity of equipment having sharp edges
- Careful inspection of containers for bulging or other indication of internal pressure buildup
- Use of full-face respirators with HEPA filter cartridges when handling containers suspected of holding reactive material or having internal pressure.

In the past, upon identification of potential hazards which could lead to the breach of a glove, changes have been requested and made to equipment, facilities, tools, and procedures. A conveyor "key switch" shutdown system was installed to lock out the HC-1 or HC-2 conveyors when it was necessary to work in the hood gloves near the belts. The addition of the key switch allows the operator to prevent the inadvertent startup of the conveyors should they find it necessary to use a gloveport near the conveyor while the system is energized.

To prevent glovebox overpressurization due to potential plutonium hydride reaction when opening cans containing brushings or sweeps from plutonium metal, limits on the amount of corrosion products that can be accumulated in containers or exposed to the glovebox atmosphere have been established. These limits are based on USQ evaluation 99-017 "Pu Metal Reaction Upon Opening Item with Paneled Inner Container" and Appendix 9H "Hazards Evaluation of Plutonium Metal Opening and Stabilization". The limits are as follows:

- No more than 150 grams of corrosion products accumulated from multiple metal items in a single container
- No more than 200 grams of corrosion products exposed to glovebox atmosphere at one time.

The impacts associated with a slight glovebox overpressurization are bounded by the glovebox glove breach in Section 9.1.9. Additional analyses addressing plutonium metal stabilization are provided in Section 9.2.10.

9.1.9.2 Detection of Event.

9.1.9.2.1 Methods or Means of Detection. A breach in a glove may be detected in a variety of ways. They range from an operator observing a defective glove or a defect found during the routine inspection of a glove installation to instrumented methods, such as the loss of glovebox/room DP or detection of contamination released out through the breach. Gloves are routinely surveyed. After leaving gloves, operators are required to make self surveys to detect leaks at an early stage.

An operator generally knows when a glove has just been penetrated with a sharp object and will shout for help. This type of penetration would probably not spread contamination over a wide area but might internally deposit radionuclides into the operator. In addition to operator feedback, glove breaches may be identified when ventilation anomalies are investigated and the opening discovered. A breached glove may also be detected through routine inspections of the glovebox exteriors, either by operators or RCTs.

9.1.9.3 Analysis of Effects and Consequences. The event having the most significant consequence would likely be a puncture wound where the penetrating object carries radioactive materials into the tissues. This and other events may lead to contamination within operator occupied areas. Although procedures require operators to survey each time they leave a glove, it is postulated that some contamination is missed and thus, may be spread by contact. This latter type of spread, if the airborne concentrations were significant, would be detectable by room air monitors and be contained by the ventilation system. These events can be expected several times per year and while considered to have a potential for exposure to individuals, the mitigating efforts taken by

RC personnel result in minimal health effect to the people involved (see Chapter 8.0, Sections 8.4, 8.5.2.9, and 8.5.2.8).

9.1.9.4 Corrective Actions. Upon discovery of a breached glove, the immediate action is to keep the worker's hand in the ruptured glove while another worker or RCT wearing a respirator puts a respirator on the worker. The work area is placed on airborne radioactivity status, and the worker is carefully removed from the glove in a manner to reduce contamination spread. After operators secure contamination, the worker is taken to the decontamination facility (Section 8.5.2.9). The worker is evaluated for external and internal contamination and given appropriate treatment.

Once permission is obtained as required by procedure, personnel don appropriate protective gear, move into the area with the breached glove, set up controls for glove replacement, change out the glove, clean up any contamination, and restore the area for normal operations.

9.1.10 Plutonium-Bearing Solution Stabilization Process Using the Production Vertical Denitration Calciner

Two categories of abnormal operations for the plutonium-bearing solution stabilization process using the Production VDC were identified in the HAZOP contained in Appendix 9D. The first category of abnormal operations includes those process upsets that can result in elevated radiological releases inside glovebox HC-230C-2 (See Table 9D-3, Bin ID B). Postulated events that can result in elevated releases of radiological material to the glovebox atmosphere include vessel or pipe leaks within the glovebox, overflows of vessels, toppling of slip lid cans or product collection jars, leaks from the transfer line between gloveboxes HC-227S and HC-230C-2 that drain back via the transfer line encasement to glovebox HC-230C-2, and various upset conditions that result in the Production VDC pressurizing causing a release of PuO_2 powder through the calciner relief cap to the glovebox atmosphere. Of the postulated upset conditions, overpressurization of the calciner presents the bounding case because that mechanism can produce the largest airborne concentrations of dispersible and respirable sized plutonium-containing particulates within the glovebox and hence the greatest challenge to the E-4 ventilation system and filters. The analysis of a pressurized Production VDC is presented in Section 9.1.10.1

The second category of abnormal operations identified from the HAZOP includes those upset conditions that can result in the release of process liquids or elevated quantities of NO_x to the process vacuum system (Table 9D-3, Bin ID I). Scrubber solution containing small amounts of Pu could overflow into the plant vacuum system due to failures of the phase separator and vacuum trap level controllers. Elevated NO_x releases to the process vacuum system could occur due to various hardware and controller failures that result in insufficient scrubbing of the NO_x offgases within the Production VDC scrubber. The specific failure modes that can cause releases of contaminated caustic solution or elevated releases of NO_x gases to the plant vacuum system are identified in the HAZOP Table in Appendix 9D (Table 9D-4).

Liquid contamination of the process vacuum system is possible in other areas and processes within the PFP where the vacuum system is used to transfer

radioactive solutions. The potential for liquid contamination of the vacuum system is not unique to Production VDC operations and is considered to be adequately covered by the plant radiological protection programs. Portions of the process vacuum system are not considered to be criticality safe. Because of the ceramic filters on the calciner, the transfer of significant quantities of Pu to the vacuum system due to overflow of the phase separator tank is very unlikely. The consequences of a criticality in the process vacuum system are bounded by the accident analysis presented in Section 9.2.3. An interlock is provided in the process vacuum system to shut down the vacuum system pumps on detection of liquid in the vacuum system. This interlock is identified as a safety class item in Chapter 4.0 (Table 4-7), to prevent a criticality in the process vacuum system HEPA filters.

Elevated NO_x releases to the process vacuum system could result in accelerated corrosion of vacuum system components (resulting from the production of nitric acid in wet parts of the system such as seal loops). This presents primarily an ALARA issue for plant maintenance personnel. Credible NO_x releases from the Production VDC will be diluted enough by the rest of the E-4 ventilation flowrate that significant degradation of the E-4 filter room HEPA filters would not be expected (the process vacuum system cascades into the E-4 ventilation system). The NO_x production rate of the Production VDC is not high enough to cause significant exposures outside the plant if released unscrubbed through the 291-Z-1 exhaust stack. Elevated releases of NO_x to the process vacuum system from Production VDC operations are therefore not considered further in this section.

9.1.10.1 Pressurized Production Vertical Denitration Calciner. The water vapor, nitric acid vapor and NO_x offgases produced in the calciner are exhausted along with the air fed to the calciner through the plant 26-in.-Hg vacuum system. The vacuum system is relied on to keep the calciner under negative pressure with respect to the glovebox. The Production VDC can pressurize during processing of plutonium nitrate solutions due to a number of causes, including: shutdown or valving out of the plant 26-in.-Hg vacuum system, plugging of the calciner ceramic filters, oversupply of feed solution to the calciner, oversupply of air to the feed injection nozzle, or loss of pressure control on the calciner filter back-pulse system. During prototype testing, the Laboratory Prototype Calciner pressurized when feed solution backed up into the air supply line. A slug of liquid was introduced into the very hot calciner when the pluggage broke free due to the working of the nozzle cleanout needle. The slug vaporized very quickly overwhelming the calciner vacuum system.

The calciner is equipped with a pressure relief cap which is sized to lift when the pressure in the calciner exceeds 1.3 psig. Should the calciner overpressurize due to any of the above discussed causes, PuO_2 particulate from inside the calciner vessel, steam, nitric acid vapor, and NO_x would be relieved through the calciner pressure relief cap into glovebox HC-230C-2. Such a release would be confined to the glovebox and the E-4 ventilation system. The following analysis quantifies the potential release through the 291-Z-1 exhaust stack and compares the release to the screening limits discussed in Section 9.0.2.2.

9.1.10.1.1 Postulated Cause of Event. A rotameter and check valve have been installed in the Production VDC air supply line to minimize the

likelihood of a pressurization event similar to that experienced in the Laboratory Prototype Calciner. For this analysis, therefore, the cause of the pressurized calciner is assumed to be a failure in the vacuum system which results in no vacuum flow from the calciner. Loss of vacuum flow through the calciner could be caused by failure of the plant vacuum pump or the inadvertent closing of a valve in the vacuum system. Equally, loss of vacuum flow can be postulated to occur due to plugging of the calciner ceramic filters.

The Production VDC and supporting systems are well instrumented to detect and respond to loss of vacuum in the calciner vessel. Differential pressure is measured between the calciner vessel and the glovebox. Also differential pressure across the calciner ceramic filters is measured. Through software interlocks, a low vacuum reading in the calciner or a high DP reading across the ceramic filters (indicative of filter plugging) will result in the instantaneous shut down of liquid feed pump (P-230-A), the closing of a solenoid valve on the atomizing air supply, and the closing of a solenoid valve on the filter blowback air supply. These shutdown interlocks limit the severity and duration of the pressurization event and limit the driving mechanisms that can expel PuO_2 particulate through the pressure relief port.

For the purposes of this analysis, the software interlock system is assumed to not respond to loss of calciner vacuum due to hardware failures or a software programming error. This scenario is unlikely but produces conservative results. Software interlock failure on loss of vacuum results in the calciner being continuously fed plutonium nitrate solution, atomizing air, and filter backflow air until the process can be manually shut down by operators. Operators are assumed to shut off the solution feed supply, atomizing air supply, and filter backflow air 30 minutes after the calciner relief cap is forced off. This response period is conservative as operators are required to verify the calciner is under vacuum every 15 minutes. During the 30 minute event time frame, flashing of vapor through the PuO_2 bed in the calciner, sparging of the PuO_2 bed with atomizing air, backflow of pressurized air through the ceramic filters, and the stirring action of the calciner agitator causes significant quantities of PuO_2 particulate to be released through the calciner relief port into the glovebox, contaminating the glovebox air and causing and elevated PuO_2 powder release to the E-4 ventilation system.

9.1.10.1.2 Detection of Event. Operators periodically (every 15 minutes) monitor the calcination process to verify the calciner is under vacuum. Pressure indicators monitor vacuum in the vacuum trap and in the phase separator tank. Operators can detect loss of plant vacuum flow at either one of these indicators. As mentioned in the previous section differential pressure (DP) across the calciner ceramic filters and between the calciner and glovebox are monitored via software. The computer display screen and local panel recorders and indicator lights provide for manual detection of calciner pressurization. Finally, the operator can detect overpressurization events that result in the ejection of the calciner relief cap by observing that the cap has fallen off; by observing steam and brown NO_x gases in the glovebox atmosphere, or by observing dust in the glovebox atmosphere. Prior to the calciner relieving through the pressure relief cap, pressurization of the calciner is also indicated by the presence of water vapor in the glass product collection jar.

9.1.10.1.3 Analysis of Effects and Consequences. The atmosphere in the calciner vessel is expected to contain a fairly high concentration of PuO_2 particulate during normal calciner operations due to the flashing of water vapor within the bed of the calciner, sparging of the PuO_2 bed from the atomizing air, back pulsing of the ceramic filters with pressurized air, and the action of agitator. The Production VDC produces PuO_2 powder that is highly dispersible. The amount of PuO_2 powder in the respirable size range (<4 μm) is expected to range between four and 20 weight percent.

On loss of vacuum, the PuO_2 release to the glovebox through the calciner pressure relief port is the product of the particulate concentration in the calciner vessel atmosphere and the expected vapor/gas flowrate through the relief port. The concentration and particle size distribution of PuO_2 particles within the vapor space of the calciner have not been measured directly. The PuO_2 release to the glovebox atmosphere during a calciner pressurization event is therefore estimated based on particulate concentrations measured in rotated canisters containing UO_2 powder and on general airborne particulate loading measurements from available literature.

Schwendiman (1977) measured the concentration of UO_2 powders inside canisters that had been rotated several times. UO_2 powders have a similar particle size distribution and density to PuO_2 powders. The experiments involved a mass of UO_2 (4.5 Kg) similar to that used in the bed of the calciner. Schwendiman found that the concentration of particles inside the canisters rapidly fell from values as high as 10 g/m^3 immediately after rotating to around 1 g/m^3 5 s later. Based on a curve fit of data from several experiments, Schwendiman estimates an average particulate concentration of 100 mg/m^3 100 s after rotating. The concentration levels off around 50 mg/m^3 1400 s after rotating the canisters. After 100 s, 100% of the particles in the canister were found to be less than 2 microns in diameter. Particles this small are considered to be respirable.

A few other values from Sutter (1982) provide some perspective. This reference reports airborne particulate concentrations ranging from 500 mg/m^3 to 10 g/m^3 for dust storms, 50 mg/m^3 to 500 mg/m^3 for mine air, 10 mg/m^3 for nuisance dust in the atmosphere, and 5 mg/m^3 for a cigarette smoke filled room. The dust storm values are comparable to Schwendiman's measurements a few seconds after rotating the canisters. The mine air values are comparable to the longer term concentrations measured by Schwendiman.

Dust storm concentrations and Schwendiman's measurements a few seconds after rotating the canisters are not representative of the steady-state particulate loading inside the calciner. Those measurements are for conditions that are more severe than the particulate lofting mechanisms inside the calciner. Those measurements also include larger particles that rapidly settle and are not dispersible. The data in the literature indicate an upper quasi-stable loading limit for small (respirable) particles in the 100 mg/m^3 range. The 100 mg/m^3 value represents the inflection point in Schwendiman's curve fit where UO_2 particles larger than 2 um (individual particle densities of 10 g/cm^3) can be expected to settle out by gravity. The particulate concentration inside the calciner, however, can be expected to be higher than nuisance dust in the atmosphere.

Based on the above discussion, the concentration of PuO_2 in the vapor/gas stream coming out of the calciner is assumed to be 100 mg/m^3. The material balance for the Production VDC predicts the following molar flows in the normal calciner offgas stream: HNO_3 -- 16.53 M/h, $H_2O(v)$ -- 84.13 M/h, N_2 -- 38.01 M/h, O_2 -- 13.37 M/h, NO_2 -- 8.53 M/h, NO -- 1.51 M/h. This gives a total molar flowrate of 162 gmoles/h. With calciner vacuum shut down, 100% of this flow can be expected to be expelled through the calciner pressure relief port. The expected temperature of the offgas stream, based on the material/energy balance for the calciner, is 300 °C. Using the ideal gas law, the volumetric flowrate of gas and vapor through the pressure relief port at 300 °C and atmospheric pressure is 7.62 m^3/h, or 0.127 m^3/min.

Over the assumed 30 minute duration of the accident, the PuO_2 release to the glovebox atmosphere is:

$$R = (0.127\ m^3/min)(30\ min)(100\ mg/m^3)$$

$$= 381\ mg.$$

This release is considered to be 100% respirable. It is assumed the operator shuts down the calciner agitator along with the liquid feed, atomizing air feed, and filter blowback air supply at 30 minutes. The residual release of respirable sized particles from the calciner will be small in comparison to the release over the first 30 minutes and is ignored.

The release of hot vapors, gases, and PuO_2 is confined to the HC-230C-2 glovebox. The volume of gas and vapors and the heat released is not high enough to overwhelm the glovebox exhaust system (flowrate through the HC-230C-2 glovebox is 100 cfm). Operators in room 230C are therefore not at significant risk. The E-4 system contains 2 stages of testable HEPA filters (E-4 filter boxes and the E-4 filter rooms). Testable HEPA filters have a minimum collection efficiency of 99.95%. For two stages of HEPA filtration the transmission factor is $(1-0.9995)^2 = 2.5 \times 10^{-7}$. The total release through the 291-Z-1 exhaust stack is $(0.381\ g)(2.5 \times 10^{-7}) = 9.5 \times 10^{-8}$ g. This is orders of magnitude below the 0.015 g release limit to meet the offsite dose acceptance criteria for a stack release of Class Y material (Table 9-51) given a probability of 1.

9.1.10.1.4 Corrective Actions. The PFP has trained plant personnel, administrative procedures, and equipment available to recover from potential calciner pressurization events. Recovery from this event would involve sweeping up the visible PuO_2 contamination in the glovebox, restoring vacuum system flow, and repairing any problems in the calciner low vacuum shutdown interlock system. Working on equipment in the glovebox may require that the calciner bed be drained, that PuO_2 containers be moved out of the glovebox, and that the feed receipt tank and feed pump tank contents be pumped back to glovebox HC-227S receipt or batch tanks to reduce worker exposures. The process could then be restarted in the usual manner. The recovered PuO_2 would be tested for water content, restabilized if necessary in one of the thermal stabilization furnaces, and canned with other PuO_2 for storage.

9.1.11 Reactive Material Thermal Stabilization Process

Ten categories of abnormal operations for the plutonium oxide thermal stabilization process inside Gloveboxes HC-21A, HC-2, HC-21C, HC-18BS, and HC-18M were identified in either the PHA documented in Appendix 9F or in the PHA documented in Appendix 9G. Metals stabilization are addressed in a PHA documented in Appendix 9H. These same categories also apply to seal-in/seal-out operations in glovebox HC-13MD and thermal stabilization operations in gloveboxes HA-28 and HA-22B. These same categories of abnormal operations for reactive plutonium-bearing material thermal stabilization apply to thermal stabilization inside Glovebox HA-21I (excluding thermal stabilization of PRF sludges). This exclusion is due to the absence of capability to provide the required cover gas for sludge processing in Glovebox HA-21I. These event categories are: contaminated wound, dispersal of plutonium oxide powder inside a glove box, dispersal of minor amounts of plutonium oxide powder outside a glove box during bagout operations, dropped container outside glovebox, flammable gas deflagration in glovebox, flammable gas deflagration in a waste drum, loss of glovebox confinement due to mechanical breach, loss of glovebox confinement due to ventilation failure, rupture of container in storage vault, and pyrophoric reaction in furnace. Because most of the abnormal operations that have been identified are not considered unique to the plutonium thermal stabilization process, additional analysis is required for only the flammable gas deflagration in Glovebox HC-21A. Discussion of the ten categories of abnormal operations for the plutonium oxide thermal stabilization process follow.

Postulated events that can result in dispersal of plutonium oxide powder inside a glove box include particulate release from can opening activities and spilling material during filling or moving furnace boats. This type of event is not unique to the plutonium thermal stabilization process and is considered to be adequately covered by plant radiation protection programs. Postulated events involving dispersal of plutonium outside a glove box occur as a result of bagout activities or sample handling. This type of event also is not unique to the plutonium oxide thermal stabilization process and is considered to be adequately covered by plant radiation protection programs.

The potential for dropping a container in an operating area exists whenever containers are handled outside of gloveboxes. The principal mitigative controls are packaging and CAMs. This event is not unique to thermal stabilization operations and is adequately addressed by the analysis of a plutonium powder spill outside of a glovebox presented in Chapter 9, Section 9.1.3.

Flammable gas deflagration in a waste drum was postulated as a potential event resulting from various waste disposal activities related to thermal stabilization of plutonium. This event may occur as a result of radiolytically generated hydrogen from the presence of plutonium oxide in a waste drum being ignited during movement of the drum. The activity of handling and disposing of contaminated material is not unique to the thermal stabilization process. The quantity of material produced during this activity is a small percentage of the total waste being processed at PFP. This event is considered to be adequately covered by considerations of waste drum handling already contained in Chapter 9.

Many causes of loss of glove box confinement due to mechanical breach were postulated in the plutonium thermal stabilization PHA (Appendix 9F and 9H). Included in the causes were operational errors producing holes or tears in gloves and, improper bag-in or bag-out. This type of event is not unique to the plutonium oxide thermal stabilization process and is considered to be adequately covered by requirements specified for the operation of the E-4 ventilation exhaust system and filters.

The loss of glovebox confinement due to ventilation failure could result in a spread of contamination from a glovebox. The E-4 ventilation system maintains a negative pressure differential between gloveboxes and the surrounding operational areas. Either a loss of both supply and exhaust ventilation resulting in stagnant conditions, or a loss of only exhaust ventilation resulting in a pressurized glovebox, could result in a spread of contamination from the gloveboxes. This hazard is not unique to thermal stabilization operations and is considered to be adequately addressed by the analysis of a loss of ventilation in Section 9.1.8 and the analysis of a glovebox breach in Section 9.1.9. In Gloveboxes HC-21C and HA-21I the ventilation system also serves to remove heat generated by furnace operation. Loss of the E-4 system could result in overheating of the gloveboxes leading to a breach of confinement. This hazard is also considered to be adequately addressed by Sections 9.1.8 and 9.1.9. Even though there are total glovebox and boat inventory differences between Gloveboxes HC-21C and HA-21I, these inventories are not involved in the abnormal operations evaluations or do not affect the evaluation conclusions.

The rupture of a container in the storage vault could result in a release of product oxide into the vault atmosphere. The PHA in Appendix 9G identified numerous process upsets and failures that could result in inadequately stabilized plutonium oxide. If this condition was not detected before the oxide was packaged, the container could rupture in storage due to internal pressurization. Should a container rupture while being handled in the 234-5Z Building, any airborne plutonium would be filtered by the E-3 ventilation exhaust system prior to release. In Building 2736-Z, many storage vault pedestals are instrumented to detect bulging cans. Those without this instrumentation are visually inspected monthly. A release from a ruptured can would be confined and filtered by the vault ventilation system. Section 9.1.4 analyzes the rupture of a pressurized plutonium powder container outside of a glovebox.

Pyrophoric reactions in the thermal stabilization furnace located in Glovebox HC-21C were identified as having abnormal operations implications in the plutonium oxide thermal stabilization PHA (Appendix 9F). The processing of unstabilized plutonium oxide may involve the presence of small quantities of pyrophoric material that have been created as a result of the conditions in the storage containers or inadequate reaction of metallic plutonium before the material was placed in storage. If the pyrophoric materials are placed in the thermal stabilization furnace there is the potential for release of small amounts of hydrogen and a minor flammable gas burn in the furnace. There is no significant potential for severe operator injury from the reactive plutonium-bearing oxides to be processed through the stabilization furnaces. The E-4 ventilation exhaust system and glovebox structure would ensure confinement of any material dispersed from the furnace. Previous Loss-on-Ignition (LOI) testing on the material to be thermally stabilized provides

confidence that significant quantities of pyrophoric materials are not present. Plant radiological protection programs are considered adequate to address cleanup and recovery from such an event.

The abnormal operation of a hydrogen deflagration in glovebox HC-21A is discussed in the following paragraphs.

Flammable gases, primarily hydrogen, may be present in multiple overpack containers due to the thermal and radiolytic decomposition of plastic packaging materials and moisture. Only mechanically sealed cans have the potential to hold significant pressure. As shown in the following analysis, the release and subsequent ignition of the hydrogen potentially present in multiple overpack containers does not result in a breach of Glovebox HC-21A.

Scenario

Plutonium oxide and MOX transferred to HC-21A from vault storage are contained in multiple overpack containers comprised of standard food-pack cans. The material may be contained in two, three, or four nested containers. In all cases, the outer container is a crimp-sealed 7-Inch Can.

Pressurization criteria have been developed that correlate storage can deformation to internal can pressure. Based on the degree of deformation, cans are designated as A, B, C, or D. The corresponding pressure ranges are:

- A 0 to 5 psig
- B 5 - 15 psig
- C 15 - 20 psig
- D 20 - 40 psig.

The generation of hydrogen can result in pressurized containers. Pressurization criteria have been developed that correlate storage can deformation to internal can pressure, as shown in Figure 9-37. For the non-product quality plutonium thermal stabilization operations described in this document, it is postulated that only Type A through D cans will be processed, and therefore, opened in Glovebox HC-21A.

For the purposes of this analysis, it is assumed that a Type D can be pressurized to 30 psig is sealed into Glovebox HC-21A and opened. A value of 30 psig was chosen for analysis because containers may vent at their seams beginning at a pressure of 30 psig.

Given a pressure of 30 psig, the quantity of gas in a container can be calculated using the Ideal Gas Law:

$$PV = nRT$$

where: P = pressure, atm
V = volume, L
T = absolute temperature, K
n = number of moles
R = universal gas constant, 0.0825 atm liter/mol K

The volume of a 7-inch Can is 1.5 L. Some fraction of this volume will be filled by the plutonium oxide or MOX, inner can or cans, and packaging materials. After accounting for these items, it is estimated that the free volume within the 7-inch Can is 1.25 L.

Given a free volume of 1.25 L and assuming a temperature of 300 K, the number of moles of gas present at a pressure of 30 psig is:

$$n = [(44.7 \text{ psia})(1 \text{ atm}/14.7 \text{ psia})](1.25 \text{ L})/(0.0825 \text{ atm-L/mol-k})(300 \text{ K})$$

$$n = 0.15 \text{ moles}$$

The 0.15 moles of gas in the 7-Inch Can at 30 psig is comprised of the hydrogen generated by thermal and radiolytic decomposition of plastic packaging materials and moisture and the air initially present in the container. Applying the Ideal Gas Law, the quantity of air in the can before pressurization is 0.05 moles. Therefore, the 7-Inch can contains 0.05 moles of air and 0.10 moles of hydrogen at the time it is opened.

Mechanically sealed storage containers are opened in Glovebox HC-21A by use of an electric can opener. Per procedure, D cans are vented with a puncturing tool prior to being opened. Regardless of method, once the 7-inch can is punctured, a flammable mixture of hydrogen and air will be released. Because of its low ignition energy, nominally small heat producing sources (e.g., friction and static generation) can result in the prompt ignition of hydrogen. Should this occur, the hydrogen would burn as a jet or flare. This short duration, unconfined burn would not pressurize the glovebox.

If the hydrogen does not burn as it exits the 7-Inch Can, it will, given its high diffusivity, rapidly mix with the glovebox atmosphere. Glovebox HC-21A, with dimensions of 10 ft 8 in. by 3 ft 6 in. by 3 ft, has a volume of 3,170 L. Subtracting the 680 L volume of the Inert Atmosphere Confinement portion of the glovebox yields a volume of 2,490 L. Applying the Ideal Gas Law, this volume can contain 101 moles of gas at 300 K and I atmosphere. If the 0.10 moles of hydrogen released from the 7-Inch Can were to mix uniformly within the volume of the glovebox, the resultant concentration would be 0.10 %, which is significantly below the lower flammability limit of 4 %. Accordingly, the hydrogen would not burn but would be swept from the glovebox via the E-4 ventilation system and further diluted.

As the hydrogen is released from the 7-Inch Can and mixes with the glovebox atmosphere, localized concentrations within the flammability range could exist for a short period. If all of the hydrogen is released as a puff and is ignited before mixing below the lower flammability limit, the instantaneous energy release would be:

$$Q = (240 \text{ kJ/g-mole})(0.10 \text{ moles}) = 24 \text{ kJ}$$

where: Q = heat generated
kJ/g-mole = heat of combustion of hydrogen.

Conservatively assuming 100% of the heat from the hydrogen burn is transferred to the air in the glovebox, the increase in temperature can be calculated by:

$$\Delta T = Q/mC_p$$

where: ΔT = change in temperature (K)
Q = heat generated (kJ)
m = mass of air in glovebox (kg)
C_p = specific heat of air (kJ/kg-K).

The mass of air in Glovebox HC-21A is equal to the volume of air multiplied by its density:

$$m = (\text{volume})(\text{density}) = (2.47\ m^3)(1.16\ kg/m^3) = 2.86\ kg$$

Solving for ΔT yields a temperature increase of:

$$\Delta T = 24\ kJ/(2.86\ kg)(1.007\ kJ/kg\text{-}K) = 8.33\ K$$

Applying the Ideal Gas Law and assuming the glovebox is a perfectly sealed space, the pressure in the glovebox given a temperature rise of 8.33 K is calculated as follows:

$$(P_{final}/P_{initial}) = (T_{final}/T_{initial})$$

$$P_{final} = (14.7\ psia)(300\ K + 8.33\ K)/(300\ K) = 15.1\ psia$$

Therefore, the theoretical maximum increase in pressure is 0.4 psig.

A pressure increase of 0.4 psi is not expected to fail the glovebox gloves. Walden (1980) suggests gloves fail at an overpressure of 0.6 psi. A pressure increase of 0.4 psig could breach the glovebox via failed seal-in ports. Although a pressure increase of 0.4 psig can be conservatively calculated, such an increase would not be realized for three principal reasons. First, 100% of the hydrogen released in a puff would not burn as assumed. A stoichiometric mixture of 0.10 moles of hydrogen and air has a volume of 8.4 L, which would fill approximately 0.4% of the glovebox. Accordingly, the hydrogen would burn as an unconfined cloud, the efficiency of which can be significantly less than 100%. As stated in Evaluation of Unconfined Vapor Cloud Explosion Hazards (Pugh 1987), when small, unconfined vapor clouds are ignited, the vapors usually burn without pressure effects and with a low flame speed. Second, 100% of the heat from the hydrogen burn would not be transferred to the air as assumed above, i.e., the system is not adiabatic. Third, Glovebox HC-21A is not a sealed vessel. A 3-ft. by 17-in. opening in the north end of Glovebox HC-21A provides access to conveyor Glovebox HC-2. Qualitatively considering these factors, it is concluded that

the release and subsequent ignition of hydrogen from a pressurized Type D can would likely not breach Glovebox HC-21A since there would be little or no pressure increase. This conclusion is consistent with operating experience at PFP and throughout the DOE complex.

Consequence Analysis

The analyzed scenario does not result in a significant breach of the glovebox. The quantity of plutonium potentially suspended inside Glovebox HC-21A by burning hydrogen is judged to be small relative to that suspended by normal operations (e.g., pouring oxide through a sieve, use of mortar and pestle). The quantity of material potentially released outside the glovebox given the breach of a seal-in or sphincter port, should it occur, is bounded by the release of plutonium from a pressurized powder container analyzed in Section 9.1.4 and by the spill of 2.5 kg of plutonium outside of a glovebox analyzed in Section 9.1.3.

The impact of the thermal stabilization of non-product quality oxide feed materials on the existing FSAR analysis has been discussed above.

9.1.12 Laboratory Prototype Calciner

Abnormal operations associated with the Laboratory Prototype Calciner are identified and evaluated in the Laboratory Prototype Calciner addendum to this FSAR. It is noted that the laboratory calciner is not currently authorized for operation.

9.1.13. Loss of Filtration.

Two buildings were evaluated to determine the potential consequences associated with a loss of filtration. The buildings evaluated are the 232-Z building and the 241-Z building. Both evaluations assume that filtration is lost due to catastrophic breach in the HEPA filters or that a significant leak in the seals occur and the ventilation fans continue operating. Both exhaust systems are aerosol penetrant tested annually and releases from the individual exhaust stacks are continuously monitored. Section 9.1.13.1 describes the accident scenario and consequence calculations associated with an unfiltered release from 232-Z and Section 9.1.13.2 describes the accident scenario and calculated consequences associated with an unfiltered release from 241-Z.

9.1.13.1. Loss of Filtration, Building 232-Z. Building 232-Z originally contained a series of process enclosures housing equipment used for the recovery of plutonium from various waste substrates. The facility has been deactivated and current activities within the facility are limited to routine surveillance and monitoring.

The facility has a maximum total holdup of 661 grams Pu based on NDA measurements performed following equipment removal and cleanout. The majority of this material (i.e., 405 grams) is located in the incinerator in the form of thick slag coatings on the combustion chamber walls; however, it is possible that ash exists outside the combustion chamber but inside the glovebox. The cyclone separator contains 102 grams, which is assumed to be

fixed, and the scrubber cell contains 77g. The remaining 77 grams are located in miscellaneous glovebox ventilation ducting; however, much of this material is fixed to the piping and ductwork. The quantity of material available for resuspension, i.e., ash in the multisection glovebox and piping or ductwork has not been determined. Therefore, assuming no activities are occurring in the gloveboxes, for this analysis it is assumed that 50 grams Pu (ash plus material in the piping and ductwork) is available for resuspension by the ventilation system.

In DOE-HDBK-3010-94 ARF and RF values of 4E-05/hr and 1.0, respectively are recommended for resuspension of loose particulate by the ventilation system. These values are for materials exposed to normal process ventilation flow rates or less. However, it is noted that no applicable data to model aerodynamic entrainment and resuspension, were identified. Applying these values to the quantity of material available for resuspension (i.e., 50 grams Pu) and assuming the filters are not available, it is estimated that a maximum of 2.0E-03 respirable grams Pu/hr can potentially be released to the atmosphere or up to 17.5 grams annually.

The average annual filtered release (January 1996 to July 1999) from the building 232-Z stack is 1.8E-06 Ci total alpha. Assuming the filters are unavailable or failed the calculated average annual unfiltered (assuming the HEPA DF at 5E-04) release is approximately 3.7E-03 Ci total alpha or 7.6E-02 grams Pu (Pu-238, Pu-239/240, Pu-241).

Comparing the calculated annual releases, i.e., releases based on the DOE HDBK-3010-94 and empirical data adjusted for HEPA DF, it can be assumed that, although there is 50 grams of unconfined Pu in the facility, the majority of the material is not available for resuspension by the ventilation system. However, this material can be resuspended and available for release due to activities within the glovebox or in the ductwork. Thus a control requiring an evaluation for the HEPA filters and stack CAM is required prior to performing any activities in the glovebox or the ductwork with the potential to resuspend Pu particulate.

Operator Actions. This analysis assumes that no activities, except for routine surveillance outside of the glovebox or ductwork, are being performed inside the glovebox and ductwork. If activities are being performed inside of these structures, the quantity of material potentially released to the atmosphere, based on the activity, may be substantially increased. Therefore, it can be concluded that the HEPA filters and subsequently the stack CAMs are not required during surveillance activities. If other activities (e.g., glovebox or ductwork cleanout or other waste disturbing activity) are undertaken, the need for HEPA filtration will be reanalyed. If appropriate, based on the reanalysis, the HEPA filters may be reclassified.

Methods or Means of Detection. In accordance with LCO 3.2.1.1 HEPA filters are aerosol penetrant tested annually.

Engineered Safety Feature and Protective Systems. There are no engineered safety feature and protective systems other than the annual DOP test required.

Methods, Assumptions, and Conditions. It was assumed no activities, other than routine surveillance, are performed in the gloveboxes.

9.1.13.2. Loss of Filtration, Building 241-Z. As described in Section 5.2.4 the 241-Z building contains storage tanks ranging from 16,400 L (Tanks D-4 and D-5) to 17,900 L (Tanks D-7 and D-8) and a 700 L overflow tank, that typically contain Pu bearing solutions. With the exception of the overflow tank, each tank is limited to 400 grams Pu. All tanks and tank cells are exhausted through a two-stage testable HEPA filter, and discharged to the atmosphere via stack 296-Z-3. This analysis assumes that the two-stage HEPA filter is unavailable, e.g. catastrophically failed and that the exhaust fans continue operating. There is no supplied air to the tanks or tank cells. Air to the cell and tanks is provided by in-leakage.

This analysis assumes the fans continue operating. The exhaust system is capable of exhausting 1000 cfm (see Section 9.1.7E.1.2) from the cells and tanks combined. For this analysis it is assumed that any residual or fixed contamination in the cells will contribute negligibly to the total release from the facility. That is, any radioactive materials released to the atmosphere will be from the liquid waste stored in the tanks.

Because the exhaust fans continue to operate the release from the surface of the tank waste is modeled based on the resuspension flux from a small pool corresponding to sea spray releases in winds up to 6.6 ft/s (2 m/s). Each tank is 3 ft (0.91 m) in diameter and has a cross sectional area of approximately 0.65 m2 or 3.3 m2 for all 5 tanks. Using a conservative resuspension flux of 1.4E-10 L/m2-s (WHC-SD-WM-CN-049) the release rate from the waste in the 5 tanks is approximately 4.6E-10 L/s (resupension flux times tank cross sectional area). Typically transfers to 241-Z have very low plutonium concentrations (approximately 0.033 g Pu/L). Therefore, the potential airborne release is approximately 1.5E-11 grams Pu/s or 5.5E-08 grams Pu/hr (approximately 5.0E-4 grams Pu annually).

Operator Actions. The quantity of Pu released from this abnormal accident is compared to the annual release from stack 291-Z to determine if additional controls or operator actions are required beyond those currently in effect. Based on the comparison, the potential unfiltered release from 241-Z is less than or equivalent to the annual filtered release from 291-Z. Therefore, no new or additional operator actions are required.

Methods or Means of Detection. In accordance with LCO 3.2.1.1 HEPA filters are aerosol penetrant tested annually.

Engineered Safety Feature and Protective Systems. There are no engineered safety feature and protective systems other than the annual aerosol penetrant test required.

Methods, Assumptions, and Conditions. These were not required as no substantial upset could be identified.

9.1.14 Magnesium Hydroxide Precipitation Process

Abnormal operations associated with the Magnesium Hydroxide Precipitation Process are identified and evaluated in the related addendum (Carson 2000) to this FSAR.

9.1.15 Bagless Transfer System (BTS)

Abnormal operations associated with the BTS are identified and evaluated in the related calculation notes (FH 2000).

9.2 ACCIDENTS

Events discovered in the PHA that appear to have enough energy or other parameters to result in unacceptable onsite or offsite consequences are analyzed in sections 9.2.1 through 9.2.8. During the analysis, all of the events were found to have either probabilities of occurrence less than 1 x 10^{-6} or consequences below the Risk Acceptance Guidelines presented in Section 9.4. The events are maintained in the Accident section because they are considered classical accident events or because they were treated as real events with significant consequences in former SARs.

9.2A PLUTONIUM-BEARING SOLUTION STABILIZATION USING THE PRODUCTION VERTICAL DENITRATION CALCINER

9.2A.1 Accidents Postulated for the Plutonium-Bearing Solution Stabilization Process

Accident categories (bins) identified for the plutonium-bearing solution stabilization process using the Production VDC are summarized in Appendix 9D, Table 9D-3. The accident categories were screened from the HazOp analysis contained in Table 9D-4, as discussed in Section 9.0.2.1A. The accident categories represent types of events associated with the Production VDC operations in glovebox HC-230C-2 that have the potential to breach confinement barriers, resulting in significant spread of radiological or toxicological contamination to Zone 3 or Zone 4 areas within Building 234-5Z and the potential to cause a significant release of radiological or toxicological material from the building to the atmosphere. Each of the accident categories from Table 9D-3 are discussed in Section 9.2.9. Each accident category is compared and evaluated against the original accident analyses contained in Sections 9.2.1 through 9.2.8. For accident categories not bounded or adequately represented by the preexisting accident analyses in Sections 9.2.1 through 9.2.8, new detailed accident analyses are provided in Section 9.2.9.

9.2A.2 Assessment of Plutonium-Bearing Solution Stabilization Process Impacts on Original Accident Analyses

For completeness, the accident analyses contained in Sections 9.2.1 through 9.2.8 were individually evaluated for potential impacts posed by the plutonium-bearing solution stabilization process using the Production VDC. This evaluation was performed to determine if any of the original analyses required changes because Production VDC operations added potential source term to those accidents, made those types of accidents significantly more likely, or posed an accident similar to the original accident but with consequences that were not bounded by the original accident. The results of this evaluation are summarized in Table 9-54. Production VDC operations were found to not impact any of the original analyses with the exception of the RMC line fire and seismic events. The additional release and dose consequences of the postulated RMC line fire spreading to glovebox HC-230C-2 are addressed in Section 9.2.9.2. The additional release and dose consequences in the postulated seismic event from Production VDC operations are addressed in Section 9.2.9.4.

9.2B REACTIVE PLUTONIUM-BEARING MATERIAL STABILIZATION

9.2B.1 Accidents Postulated for the Thermal Stabilization of Plutonium Oxide Process

Accident categories (bins) identified for the thermal stabilization of "clean" plutonium oxide are summarized in Appendix 9F, Table 9F.23. The accident categories were screened from the PHA shown in Table 9F.23 and are discussed in Appendix 9F, Section 9F.4.3.3. Accident categories (bins) are identified for the thermal stabilization of non-product quality feed material as those accident categories represented by hazards with either an "S1*" or an "S2" consequence rank in Appendix 9G, Table 9G.2 The accident categories were screened from the PHA and are discussed in Appendix 9G, Section 9G.4.2. The accident categories represent types of events associated with the thermal stabilization operations in Glove Boxes HC-21A, HC-2, HC-21C, HA-21I, HC-18BS, and HC-18M that have the potential to breach confinement barriers, resulting in significant spread of radiological or toxicological material from the building to the atmosphere. The same catgories also apply to seal-in/seal-out operations in glovebox HC-13MD and thermal stabilization operations in gloveboxes HA-28 and HA-22B. Each of the accident categories from Table 9F.23 and Table 9G.2 are discussed in Section 9.2.10. Each accident category is compared and evaluated against the original accident analyses contained in Sections 9.2.1 through 9.2.9. The accident categories not bounded or adequately represented by the preexisting accident analyses in Sections 9.2.1 through 9.2.9 detailed accident analyses are provided in Section 9.2.10.

9.2B.2 Assessment of Thermal Stabilization of Plutonium Oxide Process Impacts on Original Accident Analyses

For completeness, the accident analyses contained in Sections 9.2.1 through 9.2.9 were individually evaluated for potential impacts posed by the thermal stabilization of plutonium oxide process. This evaluation was performed to determine if any of the original analyses required changes because plutonium oxide thermal stabilization operations added potential source term to those accidents, made those types of accidents significantly more likely, or posed an accident similar to the original accident but with consequences that were not bounded by the original accident. Thermal stabilization of Plutonium Oxide operations were found to not impact any of the original analyses with the exceptions of Glove Box Deflagration, Seismically Induced Deflagration, Fire in Glove Box, and Seismically Induced Glove Box Fire. The additional release and dose consequences of these accidents are presented in Sections 9.2.10.1 - 9.2.10.6. The effect of additional source term potential from inventories in the thermal stabilization gloveboxes has been considered and where applicable has been factored into the appropriate sections.

9.2C LABORATORY PROTOTYPE CALCINER

Accidents postulated for operation of the Laboratory Prototype Calciner and an assessment of the impacts of laboratory calciner operations on the original accident analysis performed prior to calciner operations are provided

in the *Laboratory Prototype Calciner* addendum to this FSAR. It is noted that operation of the laboratory calciner is not currently authorized.

9.2D MAGNESIUM HYDROXIDE PRECIPITATION PROCESS

Accidents postulated for operation of the Magnesium Hydroxide Precipitation Process and an assessment of the impacts of those operations on the original accident analysis performed prior to operation of this process are provided in the Magnesium Hydroxide Precipitation Process addendum (Carson 2000) to this FSAR.

9.2E BAGLESS TRANSFER SYSTEM (BTS)

Accidents postulated for operation of the BTS and an assessment of the impacts of BTS operations on the original accident analysis performed prior to BTS operations are provided in the calculation notes (FH 2000) for the BTS.

9.2F SUMMARY OF ACCIDENT ANALYSES

Table 9-1 provides a summary of the accidents analyzed in this section. The new accidents for the plutonium-bearing solution stabilization process using the Production VDC are included. Provided in the table are the estimated annual probabilities and dose consequences for each accident. The last column gives doses at Highway 240 for information purposes only (see Section 9.3.7 for added information).

9.2.1 Explosions

The accidents discussed in this section are events identified in the PHA which have the potential to result in an explosion with enough energy to disperse plutonium to onsite or offsite people.

9.2.1.1 Summary. Two types of explosions ("red oil" and bottled gas) are described in this section. The term explosion is used to identify any event which the general public believes is an explosion. This includes detonation, deflagrations, or overpressurization due to gas generation. A "red oil" explosion results in either (a) an overpressurization of the vessel due to rapid decomposition of an unstable tri-butyl phosphate (TBP) compound or (b) an explosion of flammable gas generated by the decomposition of TBP. The term "red oil" explosion will be dropped in favor of a more exact description, i.e., the rapid decomposition of heavy metal nitrate-TBP complexes. Section 9.2.1.2 presents a further discussion of the decomposition of heavy metal nitrate-TBP complexes. Such complexes were generated by former PFP operations (e.g. the filtrate evaporator), and decomposition events have been historically analyzed. Current operations do not generate new complexes, nor do they process existing complexes. Because future stabilization activities may process material containing heavy metal nitrate-TBP complexes, the following discussion has been retained for information purposes. The bottled gas explosion is described in Section 9.2.1F, "Flammable Gas Explosion."

9.2.1.2 Decomposition of Heavy Metal Nitrate-TBP Complexes. At elevated temperatures, heavy metal nitrate-TBP complexes decompose exothermically. If the rate of reaction is such that heat is generated faster than it can be removed, the reaction becomes autocatalytic. The accompanying rapid evolution of gases may lead to an explosion. Three such reactions have occurred at DOE facilities--two with explosive consequences. However, none of these were plutonium systems.

The study that has involved TBP-plutonium nitrate complexes is found in *Notes Pertaining to Recuplex Product Evaporation*, HW-32100 (Pugh 1954). The diluent used was CCl_4. With a "TBP-to-plutonium nitrate weight ratio of 0.15 or higher, violent reactions were initiated when evaporations where carried out to pot temperatures over 150 °C." The "heat of reaction was sufficient to raise the pot contents to a red heat in a matter of seconds" (Pugh 1954, pg. 5).

Based on this information, operations conducted within the PFP were reviewed for the potential of elevating TBP-plutonium nitrate solutions to temperatures greater than 135 °C. The 135 °C value is based on the recommendation of *The "Red Oil" Problem and its Impact on PUREX Safety*, ORNL/TM-10798 (Campbell and Mailen 1988). Campbell and Mailen state in Section 5, "Recommendations," that the limit of 135 °C could be raised to 150 °C if operations at 150 °C were verified to be safe. However, in the Abstract they state that "an increase in the maximum permissible temperature has not been recommended." For the TBP-CCl_4-plutonium nitrate solutions typical of PFP operations, this temperature may be conservative by as much as 15 °C, based on Pugh (1954). However, the relationship of Pugh (1954) to present day operations is difficult to determine due to insufficient information regarding experimental design (Pugh's work involves the use of Pyrex™ containers in a laboratory setting) and scaling factors to full-scale process equipment.

Former operations within the PRF, where energetic reactions between TBP and plutonium nitrate are conceivable, is within three inactive process vessels: the filtrate evaporator , the product concentrator, and glovebox MT-5. A postulated accident involving the filtrate evaporator has been previously analyzed in two separate documents. In the *Plutonium Finishing Plant Safety Analysis Report*, WHC-SD-HS-SAR-007 (Roemer 1987), a postulated explosion involving 5 L of nitrated TBP was assumed to occur and severely damage the south wall of the process cell, resulting in a direct release of 1.9 g of plutonium to the environment. The event was assigned a nonprocess-specific, nonfacility-specific probability of 1×10^{-3}. In *Safety and Risk Assessment Technical Information to Support PFP Restart*, WHC-SD-SQA-TI-013, Rev. 2 (Marusich 1988a), a postulated explosion involving nitrated TBP was assumed. The calculated pressure within the cell was somewhat higher than in *TRUEX Pilot Plant Safety Assessment* (Marusich 1987), 0.5 lbf/in^2 versus 0.41 lbf/in^2, but because of modifications to the south wall, it was concluded that the south wall would not be breached. The plutonium release, following HEPA filtration, was calculated to be 1.4×10^{-4} g, and the annual probability was estimated to be 5×10^{-6} given a combination of human error and the failure of a PRV.

Analyses of the product concentrator were not performed as the filtrate evaporator was judged to be the limiting case, particularly as related to probability of occurrence.

In addition to the two PRF evaporators, an energetic reaction involving nitrated TBP is conceivable within the PFPAL waste concentrator, but this system is also out of service. Although mentioned in *Plutonium Finishing Plant Laboratory Safety Analysis Report*, WHC-SD-HS-SAR-011 (Jones 1983), no analysis (neither qualitative nor quantitative), is presented.

Present operations within the PFP that may involve a deflagration are conducted in gloveboxes HC-21C and HA-21I. The bounding accident for thermal stabilization of plutonium-bearing oxides is a flammable gas deflagration in glovebox HC-21C that is generated by the pyrolysis of potential plastic contaminant in the oxide. This accident is discussed in Section 9.2.10.2.

9.2.1A Product Concentrator

The product concentrator is not currently authorized for operation by DOE. If future use of the product concentrator is required in PFP, Section 9.2.1A will be analyzed, incorporated into this SAR, and approved by DOE.

9.2.1B Filtrate Evaporator

The filtrate evaporator is not currently authorized for operation by DOE. If future use of the filtrate evaporator is required in PFP, Section 9.2.1B will be analyzed, incorporated into this SAR, and approved by DOE.

9.2.1C Not Used

9.2.1D Laboratory Waste Concentrator

The Laboratory Waste Concentrator is not currently authorized for operation by DOE. If future use of the concentrator is required, Section 9.2.1D will be analyzed, incorporated into this SAR, and approved by DOE.

9.2.1E Explosion, Hydrogen in Fluorinator

Since plutonium metal is no longer produced at PFP, Section 9.2.1E is not required. The fluorinator is not currently authorized for operation by DOE. If future use of HF is required, Section 9.2.1E will be analyzed, incorporated into this SAR, and approved by DOE.

9.2.1F Flammable Gas Explosion

The types and quantities of flammable gases used at the PFP were reviewed and nominal 465-g (16.4-oz) containers of liquid propane gas (LPG) were found to present the greatest risk. Propane is used on an as-needed basis at the

PFP for a variety of activities which require relatively high temperatures. Examples of applications requiring propane include: soldering, brazing, and small welding jobs as required when making repairs to the HVAC system.

Liquid propane gas containers used in the PFP are restricted to small, commercially available cylinders of 465-g (16.4-oz) capacity which meet requirements established by the DOT and the Compressed Gas Association (CGA). Federal requirements are found in 49 CFR 173, *Shippers General Requirements for Shippments and Packaging*, Section 173, 34(d) (49 CFR 173) and 49 CFR 178 *Shipping Container Specification*, Section 178.65 (49 CFR 178). Applicable national consensus standards are found in *Pressure Relief Device Standards Part I--Cylinders for Compressed Gases*, CGA Standard S1.1-89 (CGA 1989).

The former propane supply line in Building 234-5Z is no longer in service and has been disconnected from a propane supply. The former supply header has been cut into segments, flushed, and capped. The line segments have been sampled and found not to contain explosive concentrations of propane (BWHC 1998). The segments of the former propane supply header will have vents installed in them to ensure propane concentrations in this header stay below the explosive limit (BWHC 1998a). Accordingly, deflagrations associated with the former propane header in Building 234-5Z have not been analyzed.

Testing of propane cylinders by Underwriter's Laboratory (UL), in accordance with *Nonrefillable (Disposal) Type Fuel Gas Cylinder Assemblies*, UL 147A (UL 1992), provides added assurance that the cylinders meet or exceed applicable DOT and CGA requirements. All of the propane cylinders at the PFP are UL listed. Some of the UL 147A requirements are listed below:

- The pressure vessels are constructed in accordance with Specification 39 of 49 CFR 178.65.
- The pressure relief device(s) meets the requirements of 49 CFR 173.34(d) and the UL 147A (UL 1992).
- The cylinders are provided with an integral shutoff valve that closes automatically when the cylinder is disconnected from the gas-consuming equipment.
- Cylinders incorporate a Type CGA No. 600 threaded connection in accordance with *Standard for Compressed Gas Cylinder Valve Outlet and Inlet Connections*, CGA V-1 (CGA 1987).
- The gas-confining parts have a minimum solid temperature of at least 510 °C (910 °F) and a tensile strength of at least 68.9 MPa (10,000 psi) at 204 °C (400 °F). Exceptions: A valve disc, soft seat, seal ring, diaphragm, or gasket need not comply with this requirement.
- The brazing material used for joining parts of a cylinder assembly has a minimum melting temperature of 538 °C (1,000 °F).
- A hydrostatic pressure strength test is performed to demonstrate the strength and design failure point of the cylinders. The pressure strength test is performed at four times the marked service pressure

for one minute. Then the pressure is increased at the rate of 690 kPa/min (100 psig/min) until the tested cylinder ruptures. The manner of failure must be in the side wall of the cylinder parallel with its longitudinal axis.

- Pressure relief valves are tested to assure that the start-to-discharge pressure is not less than 120 percent of the marked test pressure [2,480 - 3,307 kPa (360 - 480 psig)] nor more than 80 percent of two times the marked test pressure [1,970 kPa (286 psig)].

- Fire testing of the relief device, to assure that it operates to reduce the risk of rupture or propulsion, is performed over a charcoal bed 610 by 457 by 152-mm (24 by 18 by 6-in.) in a three sided concrete enclosure. The cylinder is placed horizontally on a wire screen above the charcoal. The test temperature is between 537 and 649 °F).

9.2.1F.1 Propane Release Scenarios. A Preliminary Hazards Analysis (PHA), *Safety Assessment of Flammable Gas Explosion at the Plutonium Finishing Plant*, WHC-SD-CP-SAD-003, Rev. 0 (WHC 1994a) was prepared to identify possible hazards associated with the use of small, 465-g (16.4-oz), LPG cylinders within the PFP (for convenience these cylinders will be referred to a "DOT 39 cylinders" in the remainder of this discussion). The hazards were identified based on assumptions of no more than six DOT 39 cylinders being in the PFP process areas and no more than two DOT 39 cylinders simultaneously located in any single room within the PFP (see 9.2.1F.2). Identified hazards associated with the use of propane are fires, leaks, mechanical failures, and boiling liquid expanding vapor explosions (BLEVEs). The use of propane torches for maintenance activities such as soldering could result in ignition of combustible materials and fire in the PFP. Ignition of fires, including those from the use of propane, is analyzed in Section 9.2.2 of this document and the analysis shows that the risk from fire is acceptable.

Hazards associated with use of LPG in DOT 39 cylinders are divided into two general areas: slow leaks (i.e., releases through the normal discharge orifices) and catastrophic container failures. The release scenarios were chosen to show the consequences of a release over a broad range of release possibilities.

9.2.1F.1.1 Slow Propane Releases. DOT 39 cylinders are constructed of two cylindrical sections of cold-drawn, malleable sheet steel having a minimum thickness of 0.0635 cm (0.025 in.). The two halves are welded together, and the entire cylinder is completely annealed. The working orifice and its allied valve are recessed into the top of the cylinder for protection, and any accessories are screwed to a Type CGA No. 600 threaded connection. Gas-consuming tips which attach to the connection are available with valves having two orifice diameters:

1. 0.11-mm, which at the maximum flow rate will discharge an initially full cylinder in 20 hours (WHC 1994a)

2. 0.23-mm, which at the maximum flow rate will discharge an initially full cylinder in 6 hours (WHC 1994a).

The gas-consuming equipment is designed to fail downstream of the valve in the event of an accident.

An uncontrolled leak from either the 0.11-mm or the 0.23-mm orifices may be encountered, for example, if the gas-consuming equipment were to break off the cylinder while the valve was in the "open" position and the flame extinguished or if the valve was inadvertently open.

The maximum cylinder design pressure is 6.9 MPa (1,000 psig). At a normal temperature 30 °C (80 °F) the internal pressure is 1,035 kPa (159 psig). All DOT 39 cylinders are equipped with a safety relief valve (SRV), 2.2 mm in diameter, which opens if the internal pressure exceeds 2,480 - 3,307 kPa (360 - 480 psig), and closes if the pressure falls below that range. If the SRV remains open, a full cylinder will discharge in less than 20 seconds.

As was shown in WHC 1994a, the discharge of propane through the three orifices (0.11-mm, 0.23-mm, and 2.2-mm diameters) does not result in an explosion. The discharges mix with room air and could potentially result in deflagration under the worst discharge condition. This worst condition of discharge is an uncontrolled discharge of propane from the 2.2-mm orifice (WHC 1994a). A deflagration under these conditions into an unventilated 30 m^3 room, which is considerably smaller than any PFP process room, produces a peak pressure of 0.34 lbf/in^2. *PFP 234-5Z Building Wall Panel Testing*, WHC-SD-CP-TRP-035, Rev. 0 (WHC 1989b) shows that simulated PFP wall panels survive a pressure of 0.49 lbf/in^2. Simultaneous discharge of two DOT 39 cylinders and deflagration of the gas in a 65-m^3 room, which is still smaller than, but much more consistent with, the size of PFP process rooms, also results in an acceptable overpressure, less than 0.35 lbf/in^2 (WHC 1994a).

Thus, it logically follows that, even if the frequency for this event is assumed to be 1.0, the risk associated with an accident such as this is clearly acceptable.

9.2.1F.1.2 Catastrophic Cylinder Failure. A catastrophic cylinder failure is defined as a rupture in which virtually all of the LPG escapes instantaneously. Mechanisms that might cause a catastrophic failure of a DOT 39 cylinder include dropping a full cylinder, crushing a full cylinder, or exposure of a full cylinder to a fire with simultaneous failure of the SRV.

Ceiling areas containing building services such as piping, electrical wiring, and ventilation ducts are the only locations where catastrophic failure of a DOT 39 cylinder by dropping is postulated to occur. The maximum potential height of such areas in the PFP is 4.6 m (15 ft). A propane cylinder dropped from that height onto a hard surface such as concrete might be dented but will not fail because the head space above the LPG will collapse slightly to absorb the energy of impact (WHC 1994a). If the internal pressure from denting exceeding 2,480 - 3,307 kPa (360 - 480 psig), the SRV would relieve the excess pressure and then reseat when the pressure fell below that range. The SRV is designed to survive such impacts and is located in a particularly sturdy part of the cylinder.

One could postulate an event in which the container was dropped from a height of 4.6 m (15 ft) onto a sharp object and punctured. The internal

pressure of the propane on the cylinder might then cause a crack to develop and propagate, ultimately causing a catastrophic cylinder failure. As shown in the cylinder perforation analysis contained in WHC 1994a, because of the materials used in the construction of DOT 39 cylinders, the construction methods employed, and the relatively low pressure in the cylinder, this failure mode is not credible. Thus, for the postulated puncture event, the only wound to the cylinder would be the puncture itself. The consequences of a puncture and subsequent deflagration would be similar to those of a discharge through the SRV.

The potential for crushing-type accidents was also investigated in WHC 1994a; no credible case was identified. Mobile heavy equipment, such as forklifts, which might run over a cylinder, is not used in the plant. Even so, the propane cylinders are engineered to withstand such accidents. A case might be also be made for a heavy object falling onto a cylinder as a consequence of a seismic event. Event trees were constructed in WHC 1994a to determine the probability of a seismic event causing equipment to topple onto a DOT 39 cylinder with sufficient energy to cause catastrophic failure. The frequency for such events was determined to be 1.0×10^{-7}/yr. This event is, therefore, considered to be incredible.

WHC 1994a also investigated the probability of a fire in the PFP involving two DOT 39 cylinders to determine if it was credible to have a simultaneous SRV failure result in rupture of the cylinders with subsequent deflagration of the propane gas. The frequency for an accident of this type was determined to be 4.14×10^{-7}/yr and is, therefore, considered to be incredible.

9.2.1F.2 Controls. The analysis and acceptability of risks associated with the use of flammable gases in the PFP are based on the implementation of specific controls on their purchase, storage, and use. Key elements of the control program are as follows:

1. The use of LPG cylinders is limited to those that meet the requirements of DOT Standard 39 and CGA Standard S1.1 containing not more than 465 g (16.4 oz) of LPG, and the former propane supply header in Building 234-5Z remains out of service and disconnected from a propane supply.

2. The inventory of propane cylinders within the portions of the PFP Building used for storing or containing an inventory of transuranic materials is limited to a total of six. No more than two propane cylinders may be simultaneously located within a single room. Introduction of propane cylinders into gloveboxes is prohibited.

3. There are no restrictions on simultaneous use of propane cylinders within the PFP as long as the restrictions in control No. 2, above, are followed.

4. The acetylene supply manifold from 2734-ZK to the 234-5Z Building, Room 199, is out of service and will remain so through the physical disconnection of supply bottles and by the permanent capping and, thus, physical disconnection of the manifold.

5. Measures are in place, FSP-PFP-5-8, *PFP Administration*, to prevent inadvertent introduction of flammable gas cylinders that have not been analyzed and demonstrated to be acceptable.

6. Use of other flammable gas cylinders requires evaluation in accordance with *Identification and Resolution of Unreviewed Safety Questions*, HNF-PRO-062.

The PFP program for limiting and controlling flammable gases within the plant is defined in FSP-PFP-5-8.

9.2.1G Explosion, Slag and Crucible System Deentrainer

Since plutonium metal is no longer produced at PFP, Section 9.2.1G is not required. The S&C process is no longer used at the PFP. If future use of the S&C process is required, Section 9.2.1G will be analyzed and incorporated.

9.2.2 Fire

Fire hazards at PFP have been evaluated from both a fire protection engineering and a safety analysis perspective. A fire hazards analysis (FHA) for PFP has been performed (McKinnis 1998). The objectives of the FHA were to determine: (1) the fire hazards that expose the PFP facilities, or that are inherent in facility operations, (2) the adequacy of fire safety features, and (3) the degree of compliance with specific fire safety provisions in DOE Orders, related engineering codes, and standards. Safety analyses performed for PFP have historically evaluated the probability and consequences of potential fires. The objective of these analyses was to demonstrate acceptable risk. Because of their differing objectives, FHAs and safety analyses typically employ differing analytical methods yet share many common initial conditions and assumptions.

The FHA identified a fire involving the Analytical Laboratory and spreading to adjacent office spaces as the Maximum Possible Fire Loss (MPFL) fire for the first floor of Building 234-5Z based on the replacement cost of laboratory equipment. This FSAR does not analyze a fire in these areas as the associated onsite and offsite radiological consequences were qualitatively evaluated to be bounded by the worst case glovebox process area fire based on (1) the allowed plutonium inventory, and (2) the FHA determination that the MPFL does not breach containment.

The worst case glovebox process area fire analyzed in the FHA is a fire where the maximum area of fire involvement includes the RMC-Line and RMA-Line glove boxes and several adjoining areas. This area includes the RMC-Line (Rooms 227; 228A, B, and C; and 230A, B, and C), the RMA-Line (Rooms 235A-1, 2, and 3; and 235B and C), and adjacent rooms. The fire area is bounded to the south and north by concrete walls. To the west, the fire area boundary is established by plaster on metal lath walls, which are attributed with at least a 1-hour rating by the FHA, and the absence of combustibles in Rooms 245 and 235C. Plaster on metal lath walls and the absence of combustibles in Rooms 224 and 232 limit the fire spread to the east. The fire could occur in any of

the rooms and spread to the entire fire spread area. The RMC Line was determined to represent the greatest fire risk due to the highest combustible loading and the smallest distance between the plaster ceiling and unprotected structural elements in the ceiling assembly. A fire in the glovebox process area (i.e., RMC and RMA Lines) is analyzed in Section 9.2.2A.

Some similarities exist between the RMC and RMA Lines and the glovebox/conveyor system used at the DOE Rocky Flats Plant (RFP) in Colorado. An extensive fire that occurred at the RFP in 1969 was fueled by plastic windows, gloves, trash, and by significant quantities of PMMA and Benelex shielding inside the gloveboxes. It was propagated by airflow along an extensive system of conveyer gloveboxes and drawn into processing gloveboxes by the glovebox exhaust systems. The Rocky Flats gloveboxes and rooms were not equipped with automatic fire suppression systems as are the PFP rooms and gloveboxes. In addition each glovebox at PFP has an exhaust duct. Propagation down the glovebox line via the conveyors is more difficult at PFP as the air velocity is smaller than that at Rocky Flats. However, at PFP, where gloveboxes are close to one another (less than 10 ft separation distance according to the FHA), the fire can propagate due to radiant heating from the burning glovebox. A similar situation is possible, on a much smaller scale, at the RMC Line except that internal fuel from shielding is not present and significant quantities of trash would only be present as the result of a serious breakdown of housekeeping practices.

The fire analysis concluded that fire propagation through a glovebox process line is a possibility based on the Rocky Flats glovebox fire (Patterson 1970). The fire at Rocky Flats originated in a glovebox having plastic window panels. Once the windows ignited, the fire quickly spread to the connected conveyor box. Since the conveyor was also lined with plastic windows, the fire was able to rapidly spread throughout the process line to other gloveboxes. With no fire suppression or fire separations, a fire in one of the RMC or RMA Line gloveboxes could potentially spread throughout the process lines, similar to the Rocky Flats fire, and potentially involve other globeboxes in close proximity.

The FHA also identified a hydraulic oil fire in Room 321 as the MPFL for the second floor of Building 234-5Z. In the absence of mitigation, this fire could potentially result in collapse of the building roof. Section 9.2.2B summarizes the FHA analysis and discusses mitigative design features.

In addition, the FHA identified an exterior TRU drum storage fire as resulting in the highest level of environmental contamination. Section 9.2.2.D analyzes the consequences of a fire involving a minimum of 200 TRU waste drums stored within the fenced security area outside the PFP buildings.

The potential radiological consequences of all other FHA fire scenarios (e.g., small electrical fire in Building 2736-ZB, trash fire in Building 243-Z) were qualitatively evaluated and determined to be bounded by the above identified FSAR fire analyses.

9.2.2A RMC/RMA Lines Fire

The RMC and RMA Lines were originally designed and operated to produce plutonium metal from plutonium nitrate solutions. Currently, portions of the RMC Line and RMA Line are used in support of plutonium stabilization operations. Chapter 6, Section 6.4.1, provides a description of current and former processes.

The PFP FHA identified an RMC Line fire initiated in Rooms 228A, 228B, and 228C as the worst case scenario for process area fires (McKinnis 1998). The 228A, B, C rooms house a total of 13 process gloveboxes and a conveyor glovebox. One glovebox, HC-7, is a stand alone glovebox; the remaining 12 are interconnected via the conveyor glovebox, HC-1 (Figure 9-3). The majority of the gloveboxes are inactive. Active gloveboxes include HC-7, HC-9B, HC-11, HC-13MD, HC-18M, HC-18BS, and Conveyor Glovebox HC-1. Of the active gloveboxes, HC-18M, HC-18BS, and Conveyor Glovebox HC-1 support thermal stabilization operations. Specifically, Glovebox HC-18M is used for the sampling and packaging of product plutonium oxide, Glovebox HC-18BS is used for plutonium metal and oxide storage, and Conveyor Glovebox HC-1 is used for interglovebox material transfers.

Glovebox HC-18BS in Room 228C is connected to a second conveyor glovebox, HC-2, that extends into Rooms 230A and B. Spread of the RMC Line fire through HC-2 could involve Gloveboxes HC-21A and HC-21C and spread the fire to Conveyor Glovebox HC-3, via an airlock, and into Room 230C.

Room 230C, containing the magnesium hydroxide precipitation process glovebox, is located at the West end of the RMC Line. The FHA postulates that the RMC Line fire spreads to Room 230C by consuming the plastic panels in the HC-2 and HC-3 conveyor gloveboxes. Room 227 is located at the East end of the RMC Line area. This room houses the plutonium solutions load-in/load-out glovebox, HC-227S, and hood, HC-227T. The FHA postulates that the RMC Line fire spreads to Room 227. Fire spread to Room 227 is difficult to achieve since the fire must propagate through a wall separating Rooms 228 and 227. While the fire loading in Rooms 228A, B and C is large, it is comprised almost entirely of plastic glovebox panels (per Appendix J of the FHA) which are not near Room 227. However, since the details of fire propagation for the RMC/RMA Line fire are not known and the fire can spread by means of hot gases flowing through openings between rooms, it is conservatively assumed that Glovebox HC-227S and Hood HC-227T are ignited.

The RMA Line in Rooms 235A, 235B and 235C is connected to Conveyor Gloveboxes HC-2 and HC-3 by connecting Conveyor Gloveboxes HC-4, HC-5 and HC-10.

The RMC and RMA Line gloveboxes are constructed of stainless steel frames and floors and clear polycarbonate and polymthylmethacralate (PMMA) safety sheets, or panels, on the sides and top. The walls and tops of the gloveboxes are constructed of approximately 0.5-in. thick clear plastic panels penetrated by numerous gloveports, bag-in/bag-out ports, sphincter ports, solution transfer lines, and instrument and electrical connectors. The plastic panels are of two types, PMMA and polycarbonate. The PMMA burns readily whereas polycarbonate is self-extinguishing, i.e., the polycarbonate panels will burn if flame or heat impinges on them but the fire will go out if the heat is

removed. Approximately 52% (by area) of those RMC Line panels connected by conveyors are constructed of polycarbonate and the rest of PMMA. This same value (52%) is assumed for the RMA Line even though the majority of the panels are likely PMMA. This is conservative since polycarbonate has higher ash loading for evaluation of filter clogging. The plastic panels comprise the majority of the fuel loading in the glovebox process area.

The maximum area of fire involvement is shown in Figure 6-15 of the FHA. This area includes the RMC-Line (Rooms 227; 228A, B, and C; and 230A, B, and C), the RMA-Line (Rooms 235A-1, 2, and 3; and 235B), and adjacent rooms. For the current revision to the FHA, the rooms and areas comprising the glovebox process area fire were walked down and an inventory of combustible material was recorded. The heat potential for various materials was determined by multiplying the quantity of material by its heat of combustion. The combustible loadings for the rooms in the RMC and RMA Lines are approximately 8,000 lb of wood (fuel equivalent; total for both RMC and RMA Lines) (Table 2 of Appendix J of the FHA). The analysis in subsequent sections quantifies the probability and consequences of a fire limited in area to these rooms.

9.2.2A.1 Scenario. Fire initiation is assumed to occur as a result of maintenance or retrofitting activities which have a higher likelihood of resulting in a fire than equipment or processing failures. Such activities are often conducted by personnel who are less familiar with the facility and operations than are the process operators. To reduce the likelihood of accidents, PFP process operators are assigned to work closely with maintenance personnel to keep them from getting hurt or causing harm.

Maintenance and retrofitting activities typically result in the generation of rags, paper, plastic, rubber, and other combustible materials that are not normally present in significant quantities during routine operations. It is assumed that maintenance and operations personnel fail to prevent such materials from accumulating within the gloveboxes and rooms.

Maintenance and retrofitting activities also typically introduce ignition sources (e.g., welding equipment, power tools) that are not normally present. It is assumed that such a source ignites accumulated combustible materials without being noticed by personnel present or, if noticed, that appropriate corrective actions are taken. After personnel exit the area, the fire is assumed to grow sufficiently large to burn or melt a substantial hole in a glovebox glove. The associated inrush of air fans the fire resulting in further growth and ignition of the glovebox windows.

Section 9.2.10.4 discusses the fire scenario based on failures during operation of the muffle furnaces in Gloveboxes HC-21C or HA-21I. The result of the initiation of a fire either due to maintenance or retrofitting or due to failures during processing are similar and are described below.

Following the RFP fire, the PFP installed a wet-pipe sprinkler system in the RMC Line rooms, and, in 1986, a Halon fire suppression system was installed inside the gloveboxes. When glovebox panels must be replaced, self-extinguishing polycarbonate is used instead of the original PMMA. Although these fire protection features exist at the PFP, for this analysis these features are not relied upon to prevent or mitigate the fire.

The burning plastic windows and panels would generate copious amounts of heat and plutonium-laden smoke that would be exhausted via a combination of the E-4 and E-3 exhaust systems. Appendix J to the PFP FHA revised the HEPA clogging analysis of the original FHA. Because the majority of the heat and smoke generated by even a glovebox fire would be expected to be released into the rooms, which are served by E-3 exhaust system, the E-4 exhaust system was not considered in the filter plugging analysis for conservatism. Clogging criteria in Appendix J uses the Ballinger correlation, which is based on data from large-scale experiments and establishes a relationship between the differential pressure across the filter and the amount of soot on the filter. Appendix J also uses revised combustible loading values and soot yield values rather than heat potential values for determining filter clogging. This is because the ratio of soot yield (gram of soot from material as it burns to gram of soot from burning wood) exceeds the ratio of heat yield. Appendix J also assumes that only 4 of the 7 E-3 filter banks are on-line. This is the normal operating configuration of the E-3 system. The revised analysis of filter plugging include both conservatisms and non-conservatisms. Conservative assumptions include 1) all combustibles are involved in the fire, 2) all soot depletion mechanisms are ignored, 3) the E-4 filters are not included in the analysis, 4) the E-3 filters have an initial differential pressure of 2-in. w.g.; normal operating pressure is about 0.5-in. w.g., and 5) 52% of the panels in the RMA Line gloveboxes are assumed to be polycarbonate, which is about 3.5 times more sooty than PMMA, even though it is considered very likely that most panels are PMMA. Non-conservative assumptions include 1) where a range of soot yield values were available, the smaller values were used, and 2) the soot yield values are derived from cleaner burning (producing less soot) well-ventilated fires that cannot be assumed for the glovebox area fire. It is judged that the non-conservatisms do not override the conservatisms.

Applying the soot yield values and the revised combustible loading, a total fuel loading of approximately 49,500 pounds of wood (soot equivalent) equivalent was calculated. Using the Ballinger correlation, a value of 50,775 pounds of wood equivalent is required to plug the on-line E-3 filters. Based on the revised analysis, it is concluded that the filters would not fail as a result of clogging due to soot from the fire.

The effect of hot gases on the E-4 system filters was also considered. A significant amount of heat would be lost as the air flowed through the E-4 system ductwork (Figures 9-24 and 9-26). Additionally, the hot gases would be significantly diluted by ambient temperature air from non-process line enclosures. The total flow through an in-service E-4 system filter room is approximately 35,000 ft^3/min. Airflow through the RMC Line gloveboxes is at a volumetric flow rate of 340 ft^3/min which is less than 1% of the total. Accordingly, it is concluded that the E-4 system filters would not be affected by hot gases.

As is the case for the E-4 exhaust system, hot gases in the E-3 exhaust system would be effectively diluted by ambient temperature air from other areas exhausted by the E-3 system. The typical air flow through Rooms 228A, B, and C is 3,500 ft^3/min, which is less than 2% of the total E-3 flow of 190,000 ft^3/min.

For this scenario, the percentage of air exhausted via the E-3 versus the E-4 system is not relevant to the analysis since both flowpaths result in a filtered release through the stack because the filters in the filter rooms do not plug sufficiently to fail.

The area comprised of Room 228A, B, and C contains the largest quantity of combustible material. The total combustible loading (from Appendix J) is approximately 36,400,000 Btu (38,400,000 kJ) which exceeds the 38,000,000 kJ value analyzed in the original FHA prior to the current revision. Calculations in Appendix J of the current FHA revision result in an additional 17 seconds of fire duration for column exposure and an additional 8 seconds of duration for joist exposure.

Extrapolation of the additional burn time on Figures 6-8 and 6-14 of the FHA results in temperatures that still remained below the failure criteria for columns (649 °C single point and 537 °C average) and joists (704 °C single point and 593 °C average). No structural failure is expected from the additional combustibles identified in Rooms 228A, B, and C.

Fuel loading (lb of fuel per ft^2 of floor area) is the parameter used for comparison of the areas of other rooms to the area of Rooms 228A, B, and C. In Appendix J of the FHA, a fuel loading of approximately 2.67 lb/ft^2 is calculated. The fuel loading in Rooms 227 and 234 exceeds the value in the original FHA but is less than the fuel loading in Rooms 228A, B and C. The combustible loading density in Rooms 245, 235C, 232, and 224 that are at the east and west boundaries of the fire area remain low.

As discussed above, the combustible loading in Rooms 228A, B, and C did not result in structural failure. The increased fuel loading in Rooms 227 and 234 was determined to not result in structural failure since the loading is less than Rooms 228A, B and C which would not experience structural failure.

The analysis of the probability and effects of a fire in the RMC Line, RMA Line and adjacent areas is presented in the subsequent sections. The analysis follows the approach used in the FHA which is based on the following:

- The E-3 and E-4 Exhaust System filters do not plug or fail as a result of the fire
- The fire would not result in a direct release out of the building
- The fire burns to completion without intervention by the Hanford Fire Department
- No fire suppression is credited for the room sprinklers or glovebox Halon systems
- The fire encompasses the RMC Line, RMA Line and adjacent rooms.

9.2.2A.2 Probability. The annual probability of the postulated RMC/RMA Lines fire without regard for the fire protection features is 1.0×10^{-2} which is in the anticipated category. It is noted that the analyzed fire is not mitigated by any fire protection features but is mitigated by the building structure and

by filtration from the exhaust systems. However, Administrative Control 5.20 (BWHC 1999a) requires:

- maintenance and testing of the fire systems
- minimization of combustibles
- administrative control (e.g., fire watch) when the fire protection systems are impaired.

Considering these controls, the annual probability of the analyzed fire is in the range of 10^{-4} to 10^{-6}.

9.2.2A.3 Accident Analysis. The plutonium inventories evaluated are based on the CPS limits provided in Table 9-25. To estimate the inventory involved in the fire, it is assumed that the active gloveboxes are loaded with plutonium to their CPS limit. The inventory within the gloveboxes that comprise the Magnesium Hydroxide Precipitation Process and the Bagless Transfer System (BTS) are not included in Table 9-25 nor are they included in the list below. The inventory is described in Carson (2000) and FH (2000), respectively. The effect of the fire on these gloveboxes is described in separate paragraphs below.

The following is a listing of the inventories used in this analysis along with other relevant information.

Room	Glovebox/Hood	CPS Limit	Material Type
227	HC-227S	20,000 g Pu	(solution)
227	HC-227T	4,500 g Pu	(solution)
228A	HC-7	3,000 g Pu	(oxide powder)
228A	HC-9B	32,700 g Pu	(oxide powder)
228A	HC-11	30,000 g Pu	(oxide powder)
228B	HC-13MD	2,500 g Pu	(oxide powder)
228C	HC-18BS	50,000 g Pu	(metal)
228C	HC-18M	10,000 g Pu	(oxide powder)
230A	HC-21C	5,000 g Pu	(oxide powder)
230B	HC-21A	7,100 g Pu	(oxide powder)
235A-1, A-2, A-3, "A" Button Line	All	8,000 g Pu-holdup	(oxide powder)
235B	HA-19	2,500 g Pu	(polystyrene cubes)
235B	HA-20MB	10,000 g Pu	(oxide powder)
235B	HA-21I	8,000 g Pu	(oxide powder)
235B	HA-23S	44,000 g Pu	(oxide powder)
235B	HA-22B	2,500 g Pu	(oxide powder)
235C	235-B-2	2,500 g Pu	(oxide powder)

Totals: (not including Magnesium Hydroxide Precipitation Process or BTS)

Total Solution	24,500 g Pu
Total Oxide Powder	165,300 g Pu
Total Metal	50,000 g Pu
Total Polystyrene	2,500 g Pu

Table 9-25 does not provide the material types. These are shown in the above list. Glovebox HC-227S and Hood HC-227T are the plutonium nitrate solution load-in and load-out facilities. Therefore, all the inventory is assumed to exist in solution form. This is conservative since the respirable release fraction, as shown later, from boiling solutions as a result of the fire is much higher than from plutonium powders and plutonium metal is not processed in this glovebox. It is noted that Table 9-26 limits the inventory in Glovebox HC-227S and Hood HC-227T to 5,000 g. However, for purposes of this fire analysis, the higher CPS limits shown in Table 9-25 are used for conservatism. Glovebox HC-18BS is the plutonium button storage glovebox. However, other materials, such as plutonium oxide, may also be stored in the glovebox. It is conservatively assumed that all the material in Glovebox HC-18BS is plutonium metal since burning metal has a higher respirable release fraction than most other materials. Solutions are not processed through this glovebox. However, damp precipitate from the Magnesium Hydroxide Precipitation Process can be transferred through this glovebox. The remainder of the gloveboxes, except Glovebox HA-19 which has polystyrene cubes, are considered to contain plutonium oxide powder. These other gloveboxes may also contain metal and other plutonium compounds but the predominant material being processed is oxide. In addition, assuming Glovebox HC-18BS contains only plutonium metal, even though it also contains plutonium oxide powder and damp precipitate, is judged to account for metal that may be periodically located in the other gloveboxes. Therefore, no attempt was made to vary the inventory in the other gloveboxes between metal and oxide forms. The inventory shown for the gloveboxes in the "A" button line in Rooms 235A-1, A-2 and A-3 does not come from Table 9-25. The button line is inactive and the majority of the gloveboxes were cleaned out many years ago. The inventory shown is based on estimates of residual plutonium, primarily oxide, remaining in the gloveboxes which were obtained from discussions with various PFP personnel.

The CPS limits for the inactive gloveboxes are not included since the inactive designation stipulates that only residual quantities of plutonium are allowed and that no plutonium containers may be introduced. As an example of "residual quantities," glovebox HC-10 has a CPS limit of 2,500 g Pu whereas the best estimate of the inventory is 31 g Pu based on NDA data. Therefore, the inactive gloveboxes are judged not to significantly contribute to the inventory at risk relative to the active gloveboxes. In addition, the potential contribution from filterboxes 14, 20, 21, and 22, which are upstream of the E-4 system filter rooms and are assumed to fail due to fire loading, are similarly judged to be insignificant relative to the active gloveboxes.

Two new processes have been started up, recently. They are the Magnesium Hydroxide Process and the Bagless Transfer System. They are also affected by the RMC/RMA Line fire. The inventory from these process gloveboxes is presented below.

The Magnesium Hydroxide Process is performed in Gloveboxes HC-230C-3 and HC-230C-4 in Room 230-C. Glovebox HC-230C-3 contains plutonium nitrate solutions in precipitation tanks, and precipitate containing plutonium hydroxide, water, magnesium nitrate and magnesium hydroxide in varying states of dryness. Glovebox HC-230C-4 contains solution similar in composition to that in the precipitation tanks but with very much less plutonium.

The total quantity of plutonium in glovebox HC-230C-3 is:

- 11,500 g plutonium hydroxide of varying dryness
- 2,500 g plutonium nitrate solution

The total quantity of plutonium in Glovebox HC-230C-4 is very much smaller than that in Glovebox HC-230C-3 as the solution is filtrate from the process. Therefore, the releases in the fire are also very much less.

The Bagless Transfer System (BTS) is located in Room 235B. The BTS occupies a new glovebox at the end of conveyor HA-28. The BTS contains plutonium oxide that has been stabilized or plutonium metal, both of which are placed in bagless transfer convenience cans. The inventory is 5,000 g as oxide or 4,400 g as metal.

Based on the above discussion, the estimated inventory at risk in the form of powder, excluding the Magnesium Hydroxide Process and BTS is 165,300 g Pu. This inventory is assumed to be present as plutonium oxide.

In addition, it can be seen from the above table, that there is the potential for a total of 50,000 g plutonium in metallic form (Glovebox HC-18BS), and 24,500 g plutonium in nitric acid solution (Glovebox HC-227S and Hood HC-227T). In addition, 2,500 g of Pu are contained in polystyrene cubes (Glovebox HA-19).

For a given inventory, the amount of plutonium aerosolized by a fire is dependent upon many variables such as the chemical and physical form of the plutonium, the matrix in which it is held, and the direction and velocity of entraining gases. The calculation to follow uses the inventory from the list of gloveboxes, at the start of this section. The release from the Magnesium Hydroxide process gloveboxes and BTS are shown later.

Considering the plutonium oxide powder, recommended airborne release fractions (ARF) and respirable fractions (RF) for various materials are documented in the DOE handbook for airborne release of materials (DOE 1994). For non-reactive solid compounds, such as plutonium dioxide, the handbook recommends an ARF of 6×10^{-3} and an RF of 1×10^{-2}. Application of the recommended ARF and RF values is judged appropriate in that the sampling period (one hour) for the tests upon which the value is based is of the same order as the estimated duration of the postulated fire.

The recommended values are based on tests in which small quantities of plutonium powders are placed in a depression in a stainless steel planchet that is about 7 cm in diameter. Air was drawn up along the sides of the planchet and into a chimney. Combinations of airflow rates of 0.1 m/s and 1.17 m/s and air temperature of ambient and 800 °C to 900 °C were used. The

respirable airborne fraction varied from 2.5×10^{-6} to 5.6×10^{-5} for plutonium oxide at an air velocity of 1.17 m/s. The DOE Handbook recommended value was based on ambient temperatures. It will next be shown that a more realistic value is smaller.

Section 4.4.4.1 of the DOE Handbook (DOE 1994) discusses the results of air entrainment of powders from a variety of surfaces under ambient conditions. The recommended value for respirable particulate entrainment rate is 4×10^{-5}/hr. Using an assumed duration of 1 hr, this value is very close to the respirable airborne fraction for the resuspension of heated plutonium oxide by ambient air. Section 4.4.4.1 also states that the respirable release is an order of magnitude less for conditions where the powder bed is shielded by structural debris. This implies that respirable release of heated plutonium oxide that is shielded will also be less.

In all cases considered (except for Gloveboxes HC-11, HC-21A, HC-21C, HA-23S, RMA Button Line holdup and HA-21I), the oxide powder is assumed to be enclosed either within a piece of equipment or within a can. The action of the fire may cause the can to fail, but the failed can will still provide some shielding. In many cases, the powder is located near the panel that is burning. The air over the oxide is therefore hot. The respirable release of heated oxide by air at 800 to 900 °C is 5% of that assuming air at ambient conditions. As a result the respirable release fraction for oxide initially contained in cans involved in the RMC/RMA Line fire should be one-tenth that recommended by the handbook. The handbook value is based on ambient air flow over unprotected heated powder. With the exception of oxide in furnace boats or powder pans, a reduction factor of 0.1 is taken. This is because the air is likely heated at the location of the powder or the powder is shielded by the can or both occur.

A fire could result in the pressurization of the cans with some release if they fail. The recommended values of the respirable release fraction are somewhat greater than those used here. However, those values are based on quantities of oxide that are much smaller and whose respirable fraction is very much larger. Applying reduction factors to make the test results more applicable to the conditions in PFP cans results in a similar respirable release factor as used here.

From the glovebox plutonium loadings given in Section 9.2.2A.3, the total plutonium in powder pans, furnace boats or otherwise unprotected (found in gloveboxes HC-11, HC-21A, RMA Button Line holdup, HC-21C, and HA-21I) is 58,100 g. Plutonium enclosed in equipment or within a can is the remainder of the 165,300 g total, or 107,200 g Pu. Of the 107,200 g, 44,000 g are stored in Glovebox HA-23S. This oxide is stored in polyjars which are similar to the polycubes. The release from Glovebox HA-23S is discussed later.

Applying these values, the quantity of respirable plutonium made airborne by the RMC/RMA Line fire is:

$$58{,}100 \text{ g} \times 0.006 \times 0.01 = 3.5 \text{ g}$$
$$63{,}200 \text{ g} \times 0.006 \times 0.01 \times 0.1 = 0.4 \text{ g}$$

$$\text{Total} = 3.9 \text{ g}$$

With respect to the plutonium metal, the recommended ARF and RF for thermal stress of solid reactive plutonium are documented in an NRC accident analysis handbook (NRC 1998). For thermal stress of undisturbed, reactive, plutonium metal, at or above ignition temperature, the NRC handbook recommends an ARF of 5×10^{-4} and an RF of 0.5.

The recommended value came from a set of experiments in which large specimens of plutonium metal were ignited. The airborne release fraction (ARF) ranged from 4×10^{-6} to 5×10^{-4} with most of the data being greater than 3×10^{-5}. In the experiment, the specimen was placed in a ring and set upon insulating material. The Handbook stated that if the specimen of plutonium metal rested on a heat conducting surface, it would not sustain ignition due to heat transfer to the conducting surface. In the experiment, the metal could only be ignited by direct contact of the flame from a heliarc torch for 60 s.

In the condition that exists in Glovebox HC-18BS, the plutonium metal is packaged within a can. It is not bare metal. The glovebox is 8 ft. long and almost 7 ft. wide. The can is placed on a metal storage location, which is on a metal conveyor belt that snakes through the glovebox. The belt essentially results in storage along 4 rows within the glovebox. Two of the rows are close (about 8 in.) to the exterior walls of the glovebox. However the other two rows are each about 2 ft. from the exterior walls.

The storage condition given a fire scenario differs from the experiment in that:

- The plutonium metal is stored on a conducting surface, not on an insulating surface, however due to the fire, this surface is hot. This minimizes heat conduction and makes the situation closer to that of the experiment.
- The metal is in a can. The oxide formed by ignition is at least partially shielded from the airflow from the flame
- Half of the metal is far from the flame

As a result, the ARF will be reduced by a factor of 10 consisting of a factor of 5 for partial shielding and a factor of 2 for the half of the cans that are far from the fire. This yields a value of ARF times RF of 2.5×10^{-5}. As a check, it is noted that the DOE Handbook shows that other data for self oxidation of bare plutonium metal has a mean of 7×10^{-6} and a 95th percentile value of 10^{-4}. The value of 2.5×10^{-5} is in between these two values. As a result, the reduction of the recommended valued by a factor of 10 due to protection, and distance from the fire is justified.

Applying these values, the quantity of respirable plutonium made airborne due to the RMC/RMA Line fire is:

$$50{,}000 \text{ g} \times 2.5 \times 10^{-5} = 1.3 \text{ g}.$$

The bounding ARF and RF applicable to the plutonium in the polystyrene cubes are provided in the DOE handbook for airborne release of materials (DOE 1994) as 1×10^{-2} and 1.0, respectively.

The ARF for polystyrene comes from experiments in which small, angular beads of polystyrene were coated with a solution of uranium nitrate hexahydrate (UNH). The report on the experiments with burning contaminated materials (Halverson, et. al. 1987) discussed the polystyrene experiments and stated that the uranium release from burning contaminated polystyrene occurred prior to ignition of the polystyrene. The report concluded that the uranium release was due to evaporation of the UNH solution. The release ceased after the polystyrene ignited and turned into a thick, viscous mass. The report concluded that the uranium which remained sunk down into and became entrapped in the mass of molten polystyrene. This implies that the plutonium encased in the polystyrene cubes in the case being analyzed here will not escape the polystyrene cube to any significant degree. The data in the report also shows that the ARF of 2×10^{-3} for the large quantities tested (35 g) was less than the ARF of 8×10^{-3} found for the small quantity tested (6 g). Since the polystyrene cubes are much larger than the beads used in the experiment, the ARF for the largest quantity of beads (2×10^{-3}) is initially used. In addition, since the plutonium is in a non-volatile oxide form within the polystyrene, not as volatile solution on the outside, the ARF is reduced by a factor of 5 to 4×10^{-4} based on the observation described for the experiment discussed above. While the factor of 5 is somewhat arbitrary, it is noted that the value of 4×10^{-4} is slightly larger than that for a release of uranium from a pool of kerosene - TBP burning to extinguishment as discussed in the DOE handbook (DOE 1994). The uranium in kerosene and TBP is an example where the radioactive material is within the organic material.

Applying these values to the quantity of plutonium in the cubes results in the following airborne release:

$$2{,}500 \text{ g} \times 4 \times 10^{-4} = 1.0 \text{ g}$$

Glovebox HA-23S is a large, tall glovebox containing 4 levels. The conveyor is shaped like a race track. The straight sections are 123 in. long. The glovebox is 48 in. wide. The radius of the curved section of the conveyor is 16 in. Each of the 4 conveyors are 346 in. long. On each conveyor are 11 pallets. The pallets are 13.5 in. in diameter and contain "T" shaped spacers so that up to 8 polyjars can be loaded on each pallet. The edges of the "T" are 2.5 in. tall. There is a metal plate that partially covers the top of the polyjars. The plate is bolted to the pallet. As a result, the polyjars are about half shielded from the top and three-quarters shielded on the sides from the direct flame. The pallets are located about 7 in. below the bottom of the plastic panels. The gloves are not in the gloveports under normal operation.

If a fire spreads through the glovebox, radiant heat from the plastic panels could impact the top of the polyjars and possibly the side near the windows. If the heat is great enough to ignite or melt the polyjars, some of the release will be captured within the structure of the pallet. At least two of the polyjars are near the center of the glovebox far from the fire.

The material within the polyjars could have organic associated with it as the polyjars can be used for sludges. The ARF most appropriate for this condition is that developed for the polycubes. The ARF developed was 4×10^{-4}. This value will be decreased to 10^{-4} to account for capture of the aerosol within the pallet structure and other melting or burning polyjars and the fact that some of the polyjars are far from the fire.

Using this value the release from Glovebox HA-23S is:

$$44{,}000 \text{ kg} \times 10^{-4} = 4.4 \text{ g}$$

The total quantity of plutonium released by the fire from the inventory of plutonium oxide powder, plutonium metal, plutonium in polystyrene cubes and the polyjars in Glovebox HA-23S is:

$$3.9 \text{ g} + 1.3 \text{ g} + 1.0 \text{ g} + 4.4 \text{ g} = 10.6 \text{ g}$$

This material is designated as Class Y lung clearance, as defined in Tables 9-46 and 9-47, and is assumed to contain >10% ^{240}Pu. The ^{240}Pu content assumption is conservative since it has the highest unit dose value.

With respect to the plutonium nitrate solutions in Glovebox HC-227S and Hood HC-227T, it is assumed that the solution in the tanks and containers in the glovebox and hood will boil as a result of the fire and be released to the building. The glass tanks containing solution in Glovebox HC-227S could fail and the solution could fall to the glovebox or room floor but it is still assumed to boil after the fall. The ARF resulting from such a fall of liquid is approximately 10^{-6} whereas the release fraction from boiling is about 10^{-3}. Therefore, the release of material from breakage of tanks and solution spilling is neglected.

The DOE airborne release handbook (DOE 1994) provides a bounding ARF of 2×10^{-3} for boiling of aqueous solutions with an RF of 1.0. The DOE handbook characterizes the value of 2×10^{-3} as very conservative and that a value of 1×10^{-3} also bounds the data. The data for the ARF for conditions in which boiling occurs ranges from an estimate of 2×10^{-3} to a measured value of 3×10^{-4}. Other similar data show even lower values.

The data from boiling solutions comes from experiments in which 100 ml of plutonium nitrate solution in a 180 ml beaker was heated by a hot plate. The beaker had a fully open top. Air was drawn up along the side of the beaker, over the top and then up a chimney. The solution was boiled for 60 min. The ARF ranged from 3×10^{-4} to 2×10^{-3}. The ARF for similar conditions but for conditions between simmering and boiling resulted in ARF values about a factor of 5 less.

For the conditions present in Glovebox HC-227S, the solution is held in long thin glass tanks, each 6 in. in diameter. The top of the tanks is capped; out of the top of the tank are three ½-in. stainless steel tubes. Out

of the bottom is a ¾-in. line. The glovebox is 2 ft 2 in. wide. The surface of the tanks is 10 in. from the glovebox.

A fire could heat the solution to boiling. That may be difficult due to the large surface area available for heat transfer to the air in the glovebox, and to the large mass of solution (tens of liters) typically in the tanks when in use. If the solution does boil and the fire is large, the tanks could fail. The solution would fall to the bottom of the glovebox where the temperatures are much less. Under these conditions boiling is much more difficult. The glovebox is large (about 12 ft wide and 2 ft deep). A 2 in. deep pool can hold over 100 L. The bottom of the glovebox is 1 ft above the floor. The nearest plastic panel is about 1.5 ft above the pool. The other panels are a greater distance above the pool. Once lit, the panels will need to burn for a very long period of time to boil away many liters of plutonium nitrate solution.

Because of the spread in the values of ARF discussed in the DOE Handbook, the effect of plateout of the aerosol, and the difficulty in boiling all of the solution. The ARF times RF is reduced a factor of 4 to consider a more realistic (but still judged to be conservative) value for ARF and the likely case that all of the solution will not boil. Using this factor yields a respirable release factor of 5×10^{-4} which is still above the measured experimental value of 3×10^{-4} and one-half of the bounding value of 10^{-3}.

Therefore, the respirable release from the boiling plutonium nitrate solution is:

$$24{,}500 \text{ g} \times 5 \times 10^{-4} = 12.3 \text{ g}$$

This material is designated as Class W lung clearance, as defined in Tables 9-46 and 9-47, and is assumed to contain >10% ^{240}Pu. This is conservative since >10% ^{240}Pu has the highest unit dose value.

The Magnesium Hydroxide Precipitation Process addendum to this FSAR (Carson 2000) provides the consequences of accidents involving that process. Section 3.4.2.2 of the addendum provides the analysis of the glovebox fire. The respirable release is given as 5.698 g. The major contributors to the release is the 5 g respirable release due to solutions boiling and entrainment of plutonium powder due to hot air. The ARF and RF for both accidents come from the recommended values from the DOE Handbook (DOE 1994). The solution boiling scenario is very similar to that discussed above. Release of 5 g of solution would be reduced by a factor of 4 as discussed above. However, an additional consideration here is that the fire is small because of the lack of combustibles inside of the glovebox and the case of wire glass panels. The ARF times RF for a "disturbed surface" (non-vigorous boiling) is 2×10^{-4} to 6×10^{-5}. This value is more appropriate as there is likely not enough heat to rapidly boil all of the solution. The respirable release fraction is, therefore, decreased by a factor of 10 to 2×10^{-4}. The respirable release quantity is:

5 g (Pu in solution released) x 0.10 (release factor reduction) = 0.5 g Pu in solution

The release of 0.698 g of powder due to heating exposed oxide is not adjusted as the oxide is in a furnace boat. As a result, the total respirable release from the fire in the Magnesium Hydroxide Precipitation Process is:

- 0.5 g Pu in solution
- 0.7 g Pu oxide

The calculation notes for the Bagless Transfer System (BTS) (FH 2000) provide the accident analysis associated with that process. Section 4.2 of the calculation notes discuss the BTS fire scenario. The respirable release is determined to be 1.14 g. The major contributors were the burning of plutonium metal (1.1 g) and entrainment of plutonium powder (0.036 g). Again, the ARF and RF used were the recommended values from the DOE handbook (DOE 1994). However, conditions for the respirable release of plutonium metal were the same as that discussed previously in this section. Therefore, the reduction of a factor of 5 is applicable as well. The release from hot powders is not reduced, as the quantity of powder is small. The resultant respirable release is:

1.1 g (1/5) + 0.036 g = 0.26 g of oxide

The addition of the respirable release from the Magnesium Hydroxide Process and BTS increases the respirable release of oxide from 10.6 g found previously to 11.6 g, and increases the respirable release of solution from 12.3 g to 12.8 g.

As stated in the scenario, hot gases and smoke generated by the fire would be exhausted via a combination of the E-3 and E-4 exhaust systems, both of which would provide at least one stage of HEPA filtration. The E-3 and E-4 filters are tested to verify a minimum removal efficiency of 99.95% which equates to 0.05% of material passing through the filters. Therefore, the quantity of respirable plutonium discharged from the 291-Z-1 stack is:

$11.6\ g \times 5 \times 10^{-4} = 5.8 \times 10^{-3}$ g of >10% ^{240}Pu, lung clearance Class Y

$12.8\ g \times 5 \times 10^{-4} = 6.4 \times 10^{-3}$ g of >10% ^{240}Pu, lung clearance Class W

The doses due to the release of the above quantities of plutonium are calculated as follows:

$$D(rem) = Q(g) \times X/Q'(s/m^3) \times R(m^3/s) \times C(rem/g)$$

where:

D = Dose, rem
Q = Quantity of plutonium released
X/Q' = Atmospheric dispersion coefficient for elevated release, 1.62×10^{-5} s/m^3 for onsite receptor and 5.73×10^{-6} s/m^3 for offsite receptor from Tables 9-39 and 9-40, respectively.
R = Breathing rate, 3.3×10^{-4} m^3/s from Table 9-48.
C = Dose conversion factor for plutonium, Class Y or W, >10% ^{240}Pu, from Tables 9-46 and 9-47.

Applying the atmospheric dispersion factors for an elevated release, the 90th percentile dose conversion factors for class Y material greater than 10% ^{240}Pu and class W material greater than 10% ^{240}Pu, and the breathing rate for an acute release, the onsite and offsite EDE and organ doses (bone) are calculated as follows:

>10% ^{240}Pu, Class Y

Onsite EDE:

$$(5.8 \times 10^{-3}\ g)(1.62 \times 10^{-5}\ s/m^3)(3.3 \times 10^{-4}\ m^3/s)(1.7 \times 10^{8}\ rem/g)$$

$$= 5.3 \times 10^{-3}\ rem$$

Onsite Organ:

$$(5.8 \times 10^{-3}\ g)(1.62 \times 10^{-5}\ s/m^3)(3.3 \times 10^{-4}\ m^3/s)(2.7 \times 10^{9}\ rem/g)$$

$$= 8.4 \times 10^{-2}\ rem$$

Offsite EDE:

$$(5.8 \times 10^{-3}\ g)(5.73 \times 10^{-6}\ s/m^3)(3.3 \times 10^{-4}\ m^3/s)(1.7 \times 10^{8}\ rem/g)$$

$$= 1.9 \times 10^{-3}\ rem$$

Offsite Organ:

$$(5.8 \times 10^{-3}\ g)(5.73 \times 10^{-6}\ s/m^3)(3.3 \times 10^{-4}\ m^3/s)(2.7 \times 10^{9}\ rem/g)$$

$$= 3.0 \times 10^{-2}\ rem$$

>10% ^{240}Pu, Class W

Onsite EDE:

$$(6.4 \times 10^{-3}\ g)(1.62 \times 10^{-5}\ s/m^3)(3.3 \times 10^{-4}\ m^3/s)(2.0 \times 10^{8}\ rem/g)$$
$$= 6.8 \times 10^{-3}\ rem$$

Onsite Organ:

$$(6.4 \times 10^{-3}\ g)(1.62 \times 10^{-5}\ s/m^3)(3.3 \times 10^{-4}\ m^3/s)(3.6 \times 10^{9}\ rem/g)$$
$$= 1.2 \times 10^{-1}\ rem$$

Offsite EDE:

$$(6.4 \times 10^{-3}\ g)(5.73 \times 10^{-6}\ s/m^3)(3.3 \times 10^{-4}\ m^3/s)(2.0 \times 10^{8}\ rem/g)$$
$$= 2.4 \times 10^{-3}\ rem$$

Offsite Organ:

$$(6.4 \times 10^{-3}\ g)(5.73 \times 10^{-6}\ s/m^3)(3.3 \times 10^{-4}\ m^3/s)(3.6 \times 10^{9}\ rem/g)$$
$$= 4.4 \times 10^{-2}\ rem$$

The total onsite and offsite radiological consequences are:

Onsite EDE = $0.01.2 \times 10^{-2}$ rem

Onsite Bone Surface = 2.0×10^{-1} rem

Offsite EDE= 4.3×10^{-3} rem

Offsite Bone Surface = $0.7.4 \times 10^{-2}$ rem

9.2.2A.4 Conclusion. A fire in the RMC/RMA Lines and adjacent areas is considered an anticipated event with an annual probability of 1.0×10^{-2}. However, due to the presence of several defense in depth features (e.g., automatic fire suppression systems, Halon and wet pipe sprinklers, glovebox airlocks, fire watches, and HFD), the potential for the fire to spread to the entire analyzed region is considered to have an annual probability in the range of 10^{-4} - 10^{-6}. Because the HEPA filters in the E-3 and E-4 filter rooms are not clogged or damaged by the fire and, therefore, provide filtration of any release, the calculated onsite and offsite consequences are below the Radiological Risk Acceptance Guidelines (Table 9-49) for essentially all probability categories. The doses for the RMC/RMA Lines fire are summarized in Table 9-1.

9.2.2B Hydraulic Oil Fire in Room 321.

Previous PFP SARs have analyzed a fire on the second floor of Building 234-5Z. Following upgrades to the building roof, it was concluded that a fire that started on the second floor and spread to the E-4 filter rooms via the roof was incredible (i.e., annual probability < 1 x 10^{-6}) based on the Class 1 roof construction, general construction of the building, low fire loading on the second floor, wet pipe sprinkler system, and HFD response.

The PFP FHA (McKinnis 1998) identified a hydraulic oil fire in Room 321 as the MPFL for the second floor of Building 234-5Z. In an unmitigated scenario, such a fire could potentially collapse the building roof assembly and spread to the E-4 filter rooms. The FHA recommended that a diked area be provided around the hydraulic elevator pump in accordance with NFPA 30, *Flammable and Combustible Liquids Control*. This facility modification has been completed. The following sections summarize the unmitigated analysis presented in the FHA and the mitigation provided by the diked area.

9.2.2B.1 Scenario. The FHA assumed that a breach occurs in the hydraulic elevator pump, piping, or reservoir located in Room 321 resulting in a spill of hydraulic oil. The oil is used in the elevator hydraulic lift, and the amount that can potentially spill into Room 321 depends on the location of the elevator. As a worst case scenario, all 150 gallons available is assumed to spill.

The FHA assumes that the oil is ignited. The size of the resulting fire would depend on the rate at which the fuel was spilled and the area in which the oil spreads out over the floor. Calculations presented in the FHA show that larger areas of oil yield more intense fires.

Most of the structural members on the second floor are exposed steel columns and beams. Typically, steel will begin to lose its structural integrity at temperatures of about 600°C. ASTM E-119, *Standard Methods for Fire Tests of Building Construction and Materials*, which is used to determine fire-resistive properties of materials and assemblies, specifies that no single point on the steel column can exceed 649°C and the average temperature cannot exceed 537°C during the fire exposure. For direct fire exposures, the FHA calculations show that the steel column temperatures would exceed both the ASTM E-119 single point and average temperature criteria within 2 to 5 minutes.

The number of unprotected members that would be directly exposed to the pool fire depends on the size of the pool. In the FHA, as a conservative estimate, it is assumed that exposed columns can withstand no more than a two minute hydrocarbon pool fire exposure. The maximum number of columns which can fail is determined by the largest size fire which will consume all 150 gallons of fuel in 2 minutes. This corresponds to a 970 ft^2 spill configuration having an equivalent diameter of 35 ft. While a number of spill configurations are possible, a circular spill centered at column Ba-15 will expose and fail columns A-14, A-15, -16, Ba-14, Ba-16, and C-16.

Multiple column failures resulting from direct flame exposure can potentially result in collapse of the Building 234-5Z roof assembly. This can have several impacts on the facility. For one, collapse of the roof can

provide an opening to the exterior. If areas of contamination are involved in the fire, this provides a means for releasing contamination to the outside. Second, failure of the columns and ceiling assembly can potentially cause the walls separating adjacent areas, including the backside of the facility, to collapse.

The FHA postulates that the fire spreads to the E-4 filters rooms but states fire spread to this area is unlikely due to the limited amounts of combustible materials present.

9.2.2B.2 Mitigation. The principal means of mitigation is the containment berm that has been constructed in accordance with the FHA recommendation. This berm consists of a 6 inch high concrete curb placed inside the wire mesh fencing that surrounds the hydraulic elevator components. The elevator components are mounted on or near a wall, such that the concrete berm comprises three sides of the containment, with the wall serving as the fourth. The berm is 13 ft long across the front and extends 7 ft back to the wall, and can hold a volume of 340 gallons. The berm limits the spread of the fire thereby limiting the number of steel columns exposed.

The hydraulic oil system is pressurized. It is likely that a system failure (e.g., pipe failure) would result in a spray of oil. Conceivably, such a spray could result in an accumulation of hydraulic oil outside the berm. To prevent oil from spraying outside the berm, guards have been placed around exposed, pressurized components. Should a spray occur, the oil would impact the guard and collect within the berm.

A combustible liquid oil fire presents a special problem in that water flowing from the sprinklers may carry the floating, burning liquid from the source to other areas. Although the sprinklers are not expected to extinguish the fire, sprinklers in adjacent areas would prevent fire spread. In addition, while the pool fire can spread out and continue to burn after sprinkler activation, the cooling effect of the water is expected to prevent significant damage to the structure.

9.2.2B.3 Probability. Taking credit for the containment berm, a hydraulic oil fire resulting in collapse of the 234-5Z Building roof assembly is judged to be an incredible event.

9.2.2B.4 Accident Analysis. Taking credit for the containment berm, there are no radiological consequences associated with a hydraulic oil fire in Room 321.

9.2.2B.5 Conclusion. The PFP FHA concluded that an unmitigated, worst case hydraulic oil fire in Room 321 could potentially result in collapse of the 234-5Z Building roof assembly. In accordance with FHA recommendations, a containment berm has been constructed. This passive, physical barrier limits the area of the fire thus limiting the number of steel structural members exposed to the fire.

The 234-5Z Building structure has been designated a Safety Class SSC. Because the containment berm serves to protect the building structure, it too is a Safety Class SSC (refer to Table 4-7).

9.2.2C Not Used

9.2.2D Waste Drum Events

This section presents a safety analysis for TRU temporarily stored within the fenced security area outside the PFP. The purpose of this section is to establish a limit on the amount of plutonium-equivalent TRU that can be stored within the fenced security area outside PFP to ensure that the radiological consequences of an accident involving this waste fall within the WHC Risk Acceptance Guidelines presented in Section 9.4.

9.2.2D.1 Process Description. Radioactive wastes from PFP, including waste to be handled by the Waste Isolation Pilot Plant (WIPP), non-WIPP TRU solid waste going to 20-year retrievable storage, and low-level waste (LLW) solid wastes are temporarily stored at the PFP in waste drums for eventual transfer. Based on previous safety analyses (Olson 1991, Cain 1991), the major hazard in outside storage areas is the release of TRU material following container rupture and fire. It was shown in these references that the contribution due to radiation doses from LLW, contained along with gram quantities of TRU material, is very small compared to the resulting dose from the release of the TRU. As a consequence, in this analysis where accidents or events affect material in storage, only the TRU release is considered.

Very few waste containers contain 100% of any one waste type. They typically include a mixture of combustible (e.g., paper, plastic, rubber) and noncombustible (e.g., metal and glass) materials. Table 9-18 is a summary of the contents of the waste drums transferred from the PFP from 1978 to 1988. It is anticipated that new waste generated from the PFP will be similar and that this description represents the container content for future waste to be stored outside the PFP.

The material in the waste containers consists mainly of combustible materials such as paper, metals, and rubber, with surface and/or internal contamination, packaged in multiple layers of plastics. Based on the fraction of combustibles for waste drums from Table 9-18, all scenarios involving the burning of waste container contents will assume that 85% of the material in the waste drums is combustible.

The waste drums containing newly generated TRU waste must meet the following requirements:

- Newly generated TRU waste must be placed in noncombustible packaging that meets DOT requirements (DOE Order 5820.2A and WIPP 1989). Liner(s) will be a minimum of 5 mils thick.
- All TRU waste drums must be equipped with a method to prevent pressure buildup (DOE Order 5820.2A).
- All waste packages shall be handled in accordance with 49 CFR Part 173 (DOT 1990) and/or *Test and Evaluation Document for DOT Specification 7A Type A Packaging*, WHC-EP-0558 (WHC 1992a).

Other considerations already impose limits on the conditions for storage of waste within the fenced security area outside the PFP. Plutonium, under the provisions of Section 51 of the Atomic Energy Act of 1954, has been determined to be SNM. As SNM, it is designated Category I, II, III, or IV based on the attractiveness level of the material and the amount of material present. Attractiveness level D in Category IV limits the storage of ^{239}Pu in the yard to 3 kg with no absorbed liquids exceeding 25 g/L (DOE Order 5633.3A). Establishing a limit greater than 3 kg would change the category designation and require additional safeguards.

In addition to the safeguard limits, there are also criticality safety-control limits for TRU storage in 55-gal drums.

- The TRU content of any 55-gal drum intended for storage at the Hanford Site cannot exceed 187 ^{239}Pu fissile gram equivalents based on HNF-EP-0063 (HNF 1993).

- Fissionable material totaling 3% of a minimum critical mass or less is exempt from criticality-safety packaging and transportation requirements. For ^{239}Pu, 3% of a minimum critical mass is 15 g. Outside storage of drums with 15 g or less ^{239}Pu fissile gram equivalent is exempt from additional nuclear-criticality safety controls (HNF-PRO-334, HNF-PRO-537)

9.2.2D.2 Accident Analysis. The analysis and acceptability of risk documented below are based on the implementation of specific controls on the storage of TRU in waste drums within the security area outside of the PFP. Key elements of the control program are as follows.

- All TRU waste drums stored within the fenced area outside of the PFP must meet DOT requirements for noncombustible packaging.

- All TRU waste drums will be equipped with a method to prevent pressure buildup.

- Outside storage of TRU mixed waste is not permitted. Mixed waste is defined by WAC-173-303, Dangerous Waste Regulations.

- The amount of transuranic material in any single 55 gallon drum stored outside a facility building shall be less than 15 g.

- The total amount of transuranic material stored outside in waste drums shall be less than 3,000 g.

Potential accidents dominating the risk to outside waste-drum storage have either high estimated probabilities or large estimated consequences. These events include the vehicle crash with ensuing fire, mechanical release due to puncture, and drum explosion (Crowe 1994). By limiting the amount of TRU waste stored within the security fence outside of the PFP, it will be shown that any release from these mechanisms will not expose onsite or offsite individuals to radiation doses above the Risk Acceptance Guidelines.

To evaluate the consequences of potential accidents, the limit of 3,000 g TRU is used for an outside drum-storage with no more than 15 g TRU in a single

drum. The validity of these limits is presented in the following subsections by demonstrating that radiological guidelines are met when these limits are followed.

9.2.2D.2.1 Scenarios.

9.2.2D.2.1.1 Fire Release. A vehicle crash with ensuing fire could potentially involve a number of the waste drums being stored outside. Therefore, vehicle crash with resulting fire is analyzed as bounding fire release in this section.

For the vehicle crash with ensuing fire, it is postulated that a vehicle traveling within the fenced security area of the PFP crashes into stored waste drums. Upon impact, the fuel tank of the vehicle ruptures and quickly releases its fuel. The fuel is ignited and burns as it spreads as a pool fire encompassing the storage containers breached by the crash. The pool fire lasts only a matter of minutes before the fuel is consumed. However as the vehicle fuel burns, the contaminated, combustible material from the breached containers begins to burn and release the contamination. Once released, the path for the contamination to the atmosphere is tortuous. It must pass through the residue from the uncontaminated combustible packaging and other debris before it can be released. Based on the average combustible material in the waste drums from 1978 to 1988, 85% of the breached container contents is assumed to be consumed in the fire.

An ARF of 5.0×10^{-4} with an RF of 1.0 is applicable as a conservative value for the combustible material based on the assumption that everything released is in the respirable range (Crowe 1994). No credit is taken for the steel drums. This provides a very significant degree of conservatism in the calculation. The recommended ARF of 1.0×10^{-2} with an RF of 0.001 for the release caused by thermal stresses is used for the noncombustible component. The resulting source term for the vehicle crash with ensuing fire is the product of the inventory of the storage containers, the percentage of material involved, and the ARF x RF. Based on a limit of 3,000 g of TRU stored outside, the upper bound of the source term for the vehicle accident is:

$$\begin{aligned} \text{Pu (respirable)} &= [(\text{amount stored})\ (\text{percent involved})\ (\text{ARF})\ (\text{RF})]_{\text{fire}} \\ &\quad + [\text{amount stored})\ (\text{percent involved})\ (\text{ARF})\ (\text{RF})]_{\text{stress}} \\ &= (3{,}000\text{ g Pu})\ (85\%)\ (5.0 \times 10^{-4}\text{ ARF})\ (1.0\text{ RF}) \\ &\quad + (3{,}000\text{ g PU})\ (15\%)\ (1.0 \times 10^{-2}\text{ ARF})\ (0.001\text{ RF}) \\ &= 1.28\text{ gm respirable plutonium oxide.} \end{aligned}$$

For the 3,000 g of TRU to be at risk requires at least 200 drums to be breached and burned.

9.2.2D.2.1.2 Mechanical Release. The release of contaminants from a waste drum breached by mechanical forces (e.g., vehicle impact without fire, over-pressurization, falling, forklift puncture) would be very limited because the items in the containers are enclosed in multiple layers of plastic. Some

contamination could be released from puncturing the container contents, but the amount would be much less than for a vehicle crash with ensuing fire. The velocity and volume of air available to entrain contaminants is much less than for a fire. Only a small fraction of the plastic packaging would be compromised resulting in a smaller material inventory subject to release.

An ARF x RF of $(5.0 \times 10^{-5}) \times (1.0)$ is used for the mechanical release (Crowe 1994). It is also assumed that two drums are punctured.

$$\text{Pu(respirable)} = \text{(amount stored) (percentage involved) (ARF) (RF)}$$

$$= (30 \text{ g Pu}) (100\%) (5.0 \times 10^{-5} \text{ ARF}) (1.0 \text{ RF})$$

$$= 1.5 \times 10^{-3} \text{ g respirable plutonium nitrate.}$$

9.2.2D.2.1.3 Drum Explosion. A drum pressurization or gas explosion should involve only a single container while a vehicle crash with ensuing fire has been seen to potentially involve a number of drums and most of their contents. The explosion accident scenario results in much higher releases than a pressurized drum that vents. Thus the explosion is the limiting case. A drum explosion could breach the container and scatter some of the contents of the container releasing some of contaminants to the atmosphere. The explosion could also ignite the combustible material in the drum releasing additional contaminants.

The ARF x RF value used for the explosion is 1.0×10^{-3} (Crowe 1994). The ignition and burning of the combustible contents of the containers following the explosion releases additional contaminants based on the fire ARF x RF of $(5.0 \times 10^{-4}) \times (1.0)$. An ARF of 1.0×10^{-2} with an RF of 0.001 for the release caused by thermal stresses is again used for the noncombustible component. Again, the use of these values is conservative as no credit is taken for the structural integrity of the steel drums.

Based on a limit of 15 g per waste drum, the source term for the drum explosion is

$$\begin{aligned}
\text{Pu (respirable)} = & \; [(\text{amount stored})\ (\text{percent involved})\ (\text{ARF})\ (\text{RF})]_{\text{explosion}} \\
& + [(\text{amount stored})\ (\text{percent involved})\ (\text{ARF})\ (\text{RF})]_{\text{fire}} \\
& + [(\text{amount stored})\ (\text{percent involved})\ (\text{ARF})\ (\text{RF})]_{\text{stress}}
\end{aligned}$$

$$\begin{aligned}
= & \; [(15\text{ g Pu})\ (100\%)\ (1.0 \times 10^{-3}\text{ ARF})\ (1.0\text{ RF})]_{\text{explosion}} \\
& + [(15\text{ g Pu})\ (85\%)\ (5.0 \times 10^{-4}\text{ ARF})\ (1.0\text{ RF})]_{\text{fire}} \\
& + [(15\text{ g PU})\ (15\%)\ (1.0 \times 10^{-2}\text{ ARF})\ (0.001\text{ RF})]_{\text{stress}}
\end{aligned}$$

$$\begin{aligned}
= & \; [0.015\text{ g respirable plutonium nitrate}] \\
& + [0.006\text{ g respirable plutonium oxide}].
\end{aligned}$$

9.2.2D.2.2 Accident Probabilities.

9.2.2D.2.2.1 Vehicle Crash.

9.2.2D.2.2.1.1 Sequence of Events for Vehicle Crash. For the vehicle crash with ensuing fire, it was postulated that a vehicle traveling within the fenced security area of the PFP crashes into the storage containers. Upon impact, the fuel tank of the vehicle ruptures and quickly releases its contents. The vehicle fuel is ignited and burns as it spreads as a pool fire encompassing the storage containers breached by the crash. The contents of the ruptured waste containers begin burning. The fire spreads to all the containers stored.

9.2.2D.2.2.1.2 Assumptions for Vehicle Crash.

- The drums are at a level and position where they can be impacted by a vehicle but are located away from the traffic lanes.
- All the drums stored are breached and burn. No credit is taken for the structural integrity of the drums or for their storage configuration. In reality only a few drums may be breached and their contents spilled and subsequently burn. The majority of the drums will retain their contents and not contribute to a release.
- The amount of TRU involved in the accident is the total amount being stored because no credit is taken for container integrity.
- The fire release fraction (ARF x RF) is (5.0×10^{-4}) x (1.0); the mechanical release fraction (ARF x RF) is $(1.0 \times 10^{-2)}$ x (0.001).
- Eighty-five percent of the breached containers' contents are combustible and are consumed in the fire. No credit is taken for container integrity.

- It is assumed that 60 gal (0.277 m^3) of fuel is spilled based on an estimate by WHC transportation personnel that the typical transportation vehicle has a fuel tank with a capacity of 30 to 50 gal.

- The drums are stored primarily on a porous surface, such as gravel or sand. On porous surfaces, the gasoline spreads in the range of 2 to 4 ft^2/gal depending on the porosity of the soil. On an impervious surface, the range is estimated to be 3 to 5 ft^2/gal (Mishima and Schwendiman 1973). A 60-gallon spill of this magnitude on an impervious surface would have a diameter of 15 to 20 feet (4.6 to 6.0 m). On a porous surface, the pool fire diameter would be 12 to 17 ft (3.8 to 4.6 m).

9.2.2D.2.2.1.3 Event Probabilities for Vehicle Crash.

Vehicle Crashes Within the Fenced Area--The probability of a truck accident occurring is 2.45×10^{-6} per mile (Clarke et al. 1976). Annual mileage for vehicles within the PFP facility is estimated to be about 6,400 km/yr (4,000 mi/yr) based on 3 to 4 vehicles per hour, 0.8 km of travel per vehicle and 2000 day-shift hours per year. Therefore, the annual probability of a vehicle accident within the fenced area is less than 1.0×10^{-2}.

Data specific to the Hanford Site have been used to develop accident frequencies and probabilities based on truck accident statistics. The Hanford Site had 114 reportable truck accidents (gross vehicle weight over 8,500 lb) over a period in which 26 million recorded miles were driven. Of these reportable accidents, 31 (27.2 percent) resulted in major damage. The annual probability of a major damage accident, based on 6,400 km/yr within the fenced area, is estimated from these statistics to be 5.0×10^{-3}. A major truck accident on the Hanford Site is about half as likely as that predicted from national transportation statistics.

Crashed Vehicle Impacts the Stored Waste Containers--A vehicle accident within the PFP fenced area would not necessarily involve the stored waste containers. A vehicle traveling around the PFP completes a loop of approximately 0.8 k (0.5 mi). Only half of the single vehicle crashes would be expected to be directed outward towards the waste containers stored along the fence perimeter. The waste containers will occupy only a fraction of the length of the fenced perimeter. For example, a storage location with a width of 50 m would cover less than 10% of the total perimeter of a 0.8-km (0.5-mi) loop. Therefore, less than 5% of the vehicle crashes with the fenced area should involve the stored drums.

Crashed Vehicle Ignites Due To Crash--Fires occur in approximately 1.6% of all truck accidents (Clarke et al. 1976) or a probability of 1.6×10^{-2}. Because the posted vehicle speed limit within the fenced area is 20 mph (32 km/hr), this probability is conservative relative to normal highway speeds.

Container Failure Results From Impact--The amount of TRU stored in an individual waste drum is limited by criticality safety requirements to

15 g TRU per waste drum for uncontrolled outside storage. It therefore requires a minimum of 200 drums to reach the outside storage limit of 3,000 g TRU. Since the posted vehicle speed limit within the fenced area is 20 mph, the possibility of breaching all the waste drums is incredible. However, for additional conservatism in this analysis, all the waste drums are assumed to be breached.

Crash Ignites Contents of Breached Containers--Since it is not possible to determine what fraction of the drums are involved in the fire, the analysis conservatively assumes the entire contents of the waste drums burn. Thus, the entire inventory at the location is at risk.

9.2.2D.2.2.1.4 Frequency of Vehicle Crash. A vehicle crash into the waste containers with or without a fire requires the combination of a number of unlikely events. For such an accident to involve the entire inventory of containers is judged incredible. However, instead of actually quantifying the likelihood, it is easier to demonstrate using risk acceptance guidelines for unlikely events and a deterministic analysis that the consequences of such an accident are acceptable when the total amount of TRU stored is limited to 3000 g.

9.2.2D.2.2.2 Drum Explosion

9.2.2D.2.2.2.1 Sequence of Events for a Drum Explosion. Many organic materials can decompose when exposed to radiation. Alpha radiolysis of organics in TRU wastes can cause gas generation and possible drum pressurization. Flammable gas also can be generated in waste containers containing radioactive materials and hydrogenous materials. Hydrogenous material is being used here to mean any material that can generate hydrogen through radiolytic degradation. For example, the radiolytic decomposition of plastic waste packages found in many waste storage drums can produce hydrogen and other flammable gases. For a closed, unvented waste container, the buildup of an explosive mixture of hydrogen and oxygen within the void space inside the container can be postulated. If this mixture were ignited, the ensuing explosion could breach the container, scatter some of the contents of the container, and release some of the contaminants to the atmosphere.

TRU waste containers are required by procedure to have either vent clips or filtered vents to prevent these potential hazards. Hydrogen-oxygen recombinant catalysts to deplete oxygen and prevent explosive concentrations of hydrogen and oxygen are also required in TRU waste containers.

9.2.2D.2.2.2.2 Assumptions for Drum Explosion.

- Outside storage is temporary and only used to support the storage of waste containers inside the PFP. Only a portion of the approximately 1,000 drums being transferred per year will be stored outside. (An average of 924 drums were transferred per year from the PFP to the burial grounds from 1986 to 1988 [Anderson et al. 1990]).

- The explosion release fraction (ARF x RF) is $(1.0 \times 10^{-3}) \times (1.0)$; the fire release fraction (ARF x RF) is $(5.0 \times 10^{-4}) \times (1.0)$; and

the thermal stress release fraction (ARF x RF) is (1.0×10^{-2}) x (0.001).

- The drum fails by blowing the lid, and the contents of the drum are ignited and burn. Surrounding drums are not breached based on historical evidence (DOE 1993).

- Plutonium is released from the explosion as a nitrate; the plutonium is released from the fire as an oxide.

9.2.2D.2.2.2.3 Event Probabilities for Hydrogen Explosion.

Vent Device not Installed--The waste is packaged per PFP Procedure Z0-170-015, which requires a 10 mil polyliner, a catalyst pack, and either a filtered vent or vent clip. Multiple vents are required if the gas generation rate is high (WHC 1993). Because of the simplicity of the design of the vent clip and filtered vent, it is unlikely that they will fail within the time period of the outside storage. However, the vent clip and filtered vent could fail to be installed. The failure of a worker to complete a task falls within the realm of human reliability. The probability depends on the complexity and time constraints associated with task and ranges, for a relatively simple task, from 1.0×10^{-2} to 1.0×10^{-3} per demand (Swain and Guttmann 1983).

Catalytic Recombiners not Installed--A catalyst pack is required by procedure to deplete the oxygen and prevent explosive concentrations of hydrogen and oxygen. Failure of the function of the catalytic recombiner because the combiner is not installed should range, for a relatively simple task, from 1.0×10^{-2} to 1.0×10^{-3} (Swain and Guttmann 1983). Failure of the catalytic recombiner while the waste drum is being stored is judged to be much less likely than the failure to install the device because it is a passive device which relies on physical principles.

Hydrogen Reaches an Explosive Concentration--In containers containing both radioactive materials and hydrogenous materials, hydrogen-oxygen is being generated by radiolysis. However, not all the waste containers will have sufficient quantities of both these materials to reach flammable concentrations of hydrogen and oxygen within the time period the waste containers are stored outside the PFP. An Idaho National Engineering Laboratory study (EG&G 1985) shows that of 184 RFP drums and 33 Los Alamos drums, only one drum (an eight-month-old drum) had an explosive mixture. These data give this event a probability of 4.6×10^{-3} per drum.

Flammable Mixture Ignited--The presence of an ignition source is required to ignite a flammable hydrogen-oxygen mixture. The most likely source is static electricity; this probability is assigned a value of 1.0.

9.2.2D.2.2.2.4 Annual Frequency for Waste Container Explosion. A drum explosion during outside storage requires the combination of a number of unlikely events. For example, a total of 37,641 waste drums were transferred to the burial grounds from all the sites, including the PFP, during the 19-year period from 1970 to 1988 (Anderson et al. 1990), and no explosions were reported. In addition, such an accident would involve the contents of only a single drum. However, again due to the complexity of actually quantifying the

likelihood, it is easier to demonstrate with a deterministic analysis that the consequences of such an unlikely accident are acceptable.

9.2.2D.2.2.3 Mechanical Release. The potential for single-drum rupture is greater than that for the previous accident scenarios and therefore is included. It is assumed that two drums with the maximum amount of TRU are punctured by a forklift. Some of the contents of the drum are released. The amount of contaminated material released by the puncture would be very limited, because the items in the containers are enclosed in multiple layers of plastic. Only a small fraction of the plastic packaging would be compromised resulting in a small material inventory subject to release.

Forklift Punctures Drum--Even though the forklifts are operated by qualified operators, this event is anticipated with a probability of (1.0×10^{-2} to 1.0×10^{-1}). The annual probability of 1.0×10^{-1} is used.

9.2.2D.2.3 $\bar{\chi}/Q'$ Calculations. The purpose of this section is to describe the way the atmospheric dispersion coefficients $\bar{\chi}/Q'$ were calculated for use in the waste drum fire accidents. They are based on identified release point, receptor location and atmospheric condition.

This release scenario is applied to a postulated ground level fire with an attendant plume rise such as that from stored combustible waste. The buoyancy of the plume depends upon the sensible heat generated.

Due to the short duration of the fire, no credit is taken for plume meander. Additionally, plume trapping due to building turbulence is invoked using the liftoff criterion. The buildings near enough to cause this effect are single story structures. A building height and width of 6.1 m (20 ft.) and 10 m (33 ft.) are used, respectively. Credit for building wake is taken if conditions prevent buoyant plume rise (i.e. plume trapping).

The distance to the onsite receptor is measured from the PFP perimeter fence to the nearest occupied onsite facility. It is assumed that such a fire occurs in waste drums stored in the southwest corner of the PFP fenced perimeter.

The waste drum mechanical rupture scenario involves two drums assumed to be breached and to release some portion of their contents. No credit is taken for any plume rise, wake effects or plume meander. This accident is modeled as a point source ground level release.

The estimation of $\bar{\chi}/Q'$ was performed with the computer program GXQ (Hey 1993a, 1993b, and 1994). The methodology and models used are briefly described in Section 9.3. For more detailed information on the GXQ's models and their applicability, the reader should refer to the above references.

Table 9-19 lists the calculated $\bar{\chi}/Q'$. Also given are the atmospheric conditions that most closely correspond to the 99.5% meteorology. For the waste drum mechanical rupture ground level release, the 99.5% meteorology corresponds to extremely stable atmospheric conditions and relatively low wind speeds. This is a typical result for ground level releases and receptors. Although the wind rose frequency plays a part, the maximum receptor is usually the closest.

The plume for the waste drum fire $\bar{\chi}/Q'$ calculation is initially at ground level and then rises. A relatively unstable (highly dispersible) condition was selected for the onsite receptor. This is due to the ability of a more dispersible plume to "touch down" at a shorter distance. A lower wind speed, in this case, gives the plume more time to spread out vertically before reaching the receptor. The letter designation represents the Pasquill atmospheric stability class, class A being the most unstable and class G being the most stable. The numerical value refers to the corresponding wind speed.

The receptor of concern is normally defined as a human having a standard breathing rate and metabolism. The standard man breathing rates are from recommendations from the International Commission on Radiological Protection, *Report of the Task Group on Reference Man* (ICRP 1975).

9.2.2D.3 Accident Consequences.

9.2.2D.3.1 Radiological Consequences. The diverse plutonium inventory in the PFP has been characterized in a safety document (Crowe and Szempruch 1994) and summarized in Section 9.3.5. Unit dose inhalation values (rem/g) are provided in the reference for plutonium for two ranges of ^{240}Pu content. The term unit dose describes the dose a person receives if they inhaled one gram of an isotope.

The principal exposure pathway in the PFP postulated accidents is via dispersion in air and subsequent inhalation by individuals.
Tables 9-46 and 9-47 present the committed EDE and the bone surface unit doses for plutonium compounds with two different lung clearance classes. Compounds other than oxide, such as plutonium nitrate, which have relatively short clearance times in the lungs are considered as Class W (Eckerman et al. 1988). Oxides of plutonium are considered as Class Y (Eckerman et al. 1988). It is assumed that the plutonium is being stored as nitrate; but, as a result of the postulated fire, would be released as an oxide.

The mass-weighted average unit doses from Tables 9-46 and 9-47 are used for calculating the consequences of the waste drum fire. Crowe and Szempruch (1994) demonstrate the acceptability of using average values when a significant number of Pu items (i.e., more than 16) are involved in the operation. When more than the minimum number of items is implicated, the Central Limit Theorem in the field of statistics provides a defense for the use of average values. This theorem describes mathematically that the distribution of the average of a series of random samples from a given population tends to be distributed with the mean of the averages equal to that of the parent population.

For the waste drum fire involving 3,000 g in a minimum of 200 drums, the use of the mass-weighted average to calculate the consequences is considered justifiable for the following reasons:

- First, it is assumed that all the drums are loaded to the maximum allowable TRU content.
- Second, the waste generated to fill 200 drums will typically involve several gloveboxes or operations (cleanup, decontamination, etc.) that should include a significant number of Pu items approaching a

random selection. A specific operation that nonrandomly selects the high activity plutonium will require an Unreviewed Safety Question screening to demonstrate the authorization basis and safety envelope are not exceeded.

- Third, it should be recognized that burning 200 drums is highly conservative. A more realistic fire, based on the size of a fire from the spill of the 60 gallons of gasoline, would more likely involve 20 drums. The dose consequence from 200 drums at the mass-weighted average is five times greater than 20 drums at the 90th percentile. The use of 200 drums at the mass weighted average provides a conservative way of addressing the uncertainty in the number of drums involved in the fire.

- Fourth, the mass weighted average of the >10% ^{240}Pu is roughly equal to the 65th percentile for the >10% ^{240}Pu and greater than the 80th percentile for the total inventory.

For the other accidents, involving single drums, the 90th percentile for the greater than 10% ^{240}Pu is used.

Consequence limits depend on the likelihood of the event. The Radiological Risk Acceptance Guideline curves presented in Figure 9-34 assign an acceptable consequence based on the frequency of an event. As seen in Table 9-20, all the consequences of the waste drum accidents fall within the risk guidelines. With the exception of the waste drum puncture, all the accidents identified for the waste drums storage emerge as "unlikely" to "extremely unlikely" based on a review of the anticipated annual frequencies.

9.2.2D.3.2 Nonradiological Consequences. TRU waste containing dangerous waste as defined in WAC 173-303-040 is packaged, labeled, and certified in compliance with *Hanford Site Solid Waste Acceptance Criteria*, WHC-EP-0063-4 (WHC 1993). Drums of mixed waste are not allowed to be stored outside. Therefore, the concentrations of nonradiological hazardous materials in TRU waste drums stored outside will be extremely low, and the offsite concentrations will be immeasurably low.

9.2.2D.4 Conclusion. Based on the release guidelines in Section 9.4, this section demonstrates that the maximum allowable gram quantity of contact-handled transuranic waste (CH-TRU) that may be stored in waste drums outside of the PFP is not limited by a waste drum accident but is limited by the following requirements:

- No more than 3,000 g of TRU stored within the security area based on SNM Control considerations.

- No single drum can contain more than 15 g of TRU based on criticality requirements.

Based on these limits, the onsite and offsite radiological dose consequences of a postulated release satisfy the Risk Acceptance Guidelines for an unlikely event (i.e., likelihood between 10^{-2} to 10^{-4}/yr). In addition, the exposure to an onsite worker is less than 5 rem EDE.

A significant accident involving the waste drums stored outside of the PFP requires the combination of a number of unlikely events to occur. For such an accident to involve all the stored waste drums is believed to be incredible (less than 10^{-6}/yr). However, due to the difficulty of actually quantifying the likelihood, it is easier to identify a storage limit and demonstrate with a conservative analysis that the consequences of the accident fall within acceptable limits for unlikely (10^{-2} to 10^{-4}/yr) events.

9.2.3 Criticality

Examination of dose consequences in Table 9-21 shows that a criticality in a facility ventilated by the 200-ft-tall stack would be below the guidelines for an event with an annual probability of 6.9×10^{-2}. The onsite and offsite radiological consequence of a criticality at the PFP is minimal because of the isolation of the plant within the Hanford Site and the large size of the site. This would be the case for a criticality in either of the main processing buildings, 236-Z or 234-5Z. A ground-level release (Table 9-22) would represent an event in either the 2736-Z complex or 241-Z and only exceeds the guidelines for an event with an annual probability of 3.8×10^{-2}. The probability of a criticality is shown to be less than 3.8×10^{-2}. In addition, arguments in Section 9.2.3.2 and in *25 Rem Boundary for PFP* (Brown 1989) show that the figure of 1×10^{19} fissions used in the analysis is high by a factor of at least three. Historical evidence and the arguments presented in Section 9.2.3.2 indicate that the actual number of fissions, in most instances, would be much lower.

The criticalities discussed in this section are limited to those that could result during plant operation and not as a result of an earthquake. The subject of earthquake-induced criticalities is discussed fully in Section 9.2.4, Seismic Event.

The conditions for an accidental criticality are most likely to occur during an off-normal condition when people are trying to cope with the obvious problem and in the process create another. Training and a variety of administrative controls, as well as good design, are used to minimize the chance of such a situation. Training classes emphasize that off-normal situations have been involved in the criticalities that did occur.

9.2.3.1 Scenario. No detailed scenarios were developed for criticality in the PFP. The parameters that determine criticality are multiple and exist as continua, so deciding on a particular set of errors at any of dozens of locations is exhausting. For example, in a typical solution system the variable parameters could be plutonium mass, plutonium concentration, nitrate ion concentration, moderation, and reflection. These parameters do not exist in discrete units. Criticality safety is achieved by limiting the extreme end of each parameter and not by trying to limit all the ways that the parameter could be varied. Instead of many separate scenarios, the design basis criticality from U.S. Nuclear Regulatory Commission (NRC) Regulatory Guide 3.35 (NRC 1979b) is used to assess the consequences. While fully developed scenarios are not presented, example cases are discussed.

9.2.3.1.1 Metal, Scenario. Plutonium metal can exist in the RMC Line gloveboxes during repackaging operations in amounts that could go critical

without flooding. This could only happen if a person were to willfully neglect or bypass all safety constraints operating and controls. Discussion in Section 9.2.3.4, Probability, shows that to do so would not only mean breaking formal rules but would be an awkward thing for an operator to do. In addition, security concerns require two people in attendance when handling category-1 material so a criticality involving Pu metal would take willful misconduct by two people. As bare metal, only a compact stacked, three dimensional array of plutonium buttons would reach criticality (Altschuler 1989b).

9.2.3.1.2 Powders, Scenario. No criticality scenario exists in the PFP involving dry PuF_4 or PuO_2 powder under the conditions of only nominal neutron reflection found in the dry air gloveboxes. *The Criticality Handbook*, ARH-600, Vol. 2, Figure III.A.9(100)-5 (Carter et al. 1969) shows PuO_2 in a spherical configuration at a density of 3 g/cm^3 to have a critical mass of 140 kg. Typical PuF_4 powders have bulk densities closer to 2 g/cm^3, which means a spherical critical mass would require 290 kg. A high figure for the total plutonium mass on the RMC Line as powder is that found in 12 powder pans at 2,500 g per pan, or 30 kg. Criticality safety limits are based on the addition of moderating and reflecting materials not normally encountered. For example, addition of water to an array of fissile material makes a profound difference in the mass required to achieve criticality. A spherical PuO_2-H_2O mixture with the same 3 g/cm^3 density as the dry material discussed above has a critical mass of only 18 kg. Given full water reflection and the same type and arrangement of material, the critical mass goes down to only 12 kg. The critical mass and spacing limits are based on an assumption of a mass or spacing violation concurrent with glovebox flooding or the presence of other moderating materials, such as finely divided polyethylene. Twenty-one different combinations of spacing, moderation, reflection, and mass involving PuF_4 powder were examined in order to establish bounding conditions (Altschuler 1989b). The only two arrangements with a k_{eff} greater than 1 involve: (1) a stacked array of three powder pans containing 2,500 g Pu as PuF_4 (k_{eff} = 1.0082) and (2) a powder pan of the same material with two stacked metal buttons in the middle (k_{eff} = 1.0701). To achieve the degree of moderation modeled, a conservatively high density is assumed for the powder as there is not enough space left in a powder pan of normal density powder to fit the required amount of moderating material. A simple spill or spacing error with dry powder that could result in a criticality is not credible as will be discussed further under probability in Section 9.2.3.4.2.

9.2.3.1.3 Liquids, Scenario. The majority of vessels in the PFP are constructed in a manner to maximize criticality safety. Gloveboxes cannot be of a critically safe geometry should they become flooded with water, but by enforcing strict administrative controls on mass, spacing, and the chemical or physical form of materials, the results of an accidental flooding are minimized and criticality prevented. Gloveboxes are equipped with drains and protected from plugging with large mesh screens, which help prevent flooding. However, simultaneous breakdown of several controls and flooding could result in a criticality.

One facility in the PFP complex is not equipped with critically favorable tanks. The vaults beneath the 241-Z Building contain four active and one inactive waste handling tanks. These are stainless steel with a diameter of

10 ft and a domed top approximately 12 ft high. They can hold about 15,480 L (5,000 gal) before overflowing to the D-7 overflow tank.

9.2.3.1.3.1 Operation of 241-Z Tanks. The operation summarized below is more completely described in Chapter 7.0, Section 7.2.2.2. Note that the PRF is inactive and that High Salt Waste (HSW) is no longer generated. The following analyses have been retained for historical purposes.

Solutions received in the 241-Z complex of tanks originate from three main sources as described in Section 7.5. These are the PRF (which is not in operation) and the two laboratories.

The CAW waste stream is the highly acidic waste from the PRF extraction column (CA column). The plutonium concentration is controlled by criticality specifications to no greater than 1 g/L. Normally the plutonium concentration ranges from 0.002 g/L to 0.2 g/L with a flowsheet concentration of 0.0057 g/L. The CUU and CXP solutions are generated from the organic cleanup process with flowsheet plutonium concentrations of 0.016 g/L and 0.01 g/L respectively.

The combined waste streams, are collected in TK D8 and neutralized with sodium hydroxide in TK D5 by a reverse strike caustic addition. The plutonium concentration in solution transferred to Tank Farms is limited to a maximum of 0.033 g/L (0.12 g/gal). The total plutonium in the tank, both in solution and as solids, is limited to 400 g. After treatment, the waste is sent to the Tank Farms. The reverse strike procedure is used to ensure that an excess of caustic is present throughout the mixing process to prevent precipitation of metal hydroxide solids from the HSW. In reverse strike, caustic is present in the receiving tank before the solution is added as $Al(OH)_3$ precipitate does not form under high pH conditions. The iron is added in order to assure that the concentration of neutron absorbers to plutonium is high enough, and that the concentration of combined hydroxide precipitates is low enough in plutonium to be noncritical in the large Tank Farms tanks.

9.2.3.1.3.2 Scenarios, 241-Z. Three general scenarios are envisioned for criticality in the 5,000-gal tanks of the 241-Z facility. Two involve transitory conditions that would exist only during introduction of liquid during a time when the agitator was not running. The third involves introduction of enough plutonium to cause a sustained series of pulses that would continue until enough liquid evaporated to cause spontaneous shutdown.

Before solutions are transferred from tank D-5 the acid waste solutions must be neutralized to avoid corrosion of the lines and tanks within the Tank Farm system. This is done through a process known as reverse strike in which NaOH is added to tank D-5 in preparation for receiving the waste solution. The amount of NaOH to be added is determined from a sample of the waste. The solution, following transfer, is required to have a excess OH^- concentration. During the waste addition the plutonium and iron forms a flocculent precipitate. The assumption used for the basis of criticality control is that the precipitate forms a conical pile. Such a pile with an apex angle of something less than about 140°, resting on the bottom of a tank that rests directly on a concrete pad, approaches the neutron loss properties of a hemisphere (Friar 1990). This assumed geometry coupled with assumptions as to density and safety factors is used in *Underground Waste Storage Tanks and Associated Equipment*, CSAR 79-007, Rev. 0 (Friar 1990) to establish the

criticality limit of 400 g. During a criticality in an aqueous system, the resulting burst of radiation causes intense ionization of the surrounding water with the formation of small bubbles. The bubbles and steam formation would disrupt the pile and spread it over a larger area of floor. The waste enters the D-5 tank through a riser located near the high side of the tank bottom that would facilitate spreading. At angles of less than about 150° the reactivity of the precipitate falls steeply and the system becomes noncritical.

The second scenario is for a criticality resulting from the addition of a solution with a concentration well in excess of the minimum critical concentration of 7.2 g/L to a tank when the agitator is not turning. As the solution drops into the tank it forms a roughly spherical cloud of solution and fine precipitate that momentarily achieves criticality near the point of entry into existing solution. Due to both the transitory nature of such a highly special geometry and formation of the micro-bubbles, the criticality stops without continued pulsing.

The third scenario involves critical concentrations uniformly distributed throughout the tank which, while possible, is even more unlikely than the first two scenarios. Such concentrations would require nearly half of the total inventory of the PRF, a piping modification, and numerous other independent errors and peculiar operating modes.

One such scenario might involve the inadvertent transfer of concentrated solution to tank D-8 from the laboratories or a stabilization process. The conditions for the lowest critical mass are taken from Carter et al. (1969), for 0M excess nitrate, 0% ^{240}Pu, and full water reflection. The minimum critical mass is reached with a total solution depth of 7 in. and an areal concentration of $\approx 245\ g/ft^2$. The floor of the 9.93-ft inside diameter tank has an area of 77.6 ft^2. The total amount of plutonium required to achieve sustained criticality in this tank is $77.6\ ft^2 \times 245\ g/ft^2 = 1.9 \times 10^4$ g. With a more realistic ^{240}Pu content of 5%, the minimum areal concentration is $\approx 270\ g/ft^2$ for a total of 2.1×10^4 g (Carter et al. 1969). This is considerably more plutonium than would be contained in a tank of product solution or laboratory container.

9.2.3.2 Mitigation. The primary mitigation of an accidental criticality is due to physical phenomena which result from the fission process itself. These phenomena include heat and bubble formation in liquids. The following calculations will help the reader comprehend the energy release from the 1×10^{18} fissions initial burst of the prescribed 1×10^{19} fission event (NRC 1979b). Each ^{239}Pu fission releases energy of approximately 200 MeV. The major portion, 84%, of the fission energy, 168 MeV, appears as kinetic energy from the fission fragments and is manifested as heat within the system.

The remaining 16% is released in the form of gamma rays and neutrons which effectively leave the immediate fissile system (Glasstone 1955). Thus, for 1×10^{18} fission, the heat to the fissile system is:

$$(1x10^{18}\ \text{fissions}) \times (168\ \text{MeV/fission}) \times (1.6x10^{-13}\ \text{W-s/MeV})$$

$$= 2.7 \times 10^{7} \text{ W-s}$$

$$\frac{2.7 \times 10^{7} \text{ W-s}}{3.6 \times 10^{3} \text{ s/h}} = 7.5 \times 10^{3} \text{ W-h}$$

$$7.5 \times 10^{3} \text{ W-h} \times 860 \text{ cal/W-h} = 6.4 \times 10^{6} \text{ cal}$$

This amount of energy is more than enough to change the geometry of most fissile systems. At the PFP, the prompt fissile system geometry changes result in lower reactivity. The 6.4×10^{6} cal are enough to bring 10.5 L of water from 25 °C to steam with a resulting volume of 1.8×10^{4} L. Thus, where reactivity will be achieved by damp materials, the system would be shut down before 1×10^{18} fissions were achieved through loss of water or other moderating materials, through evaporation, or by physical disruption of the system by steam. A more detailed discussion follows for each of the major material types; metal, powders, and liquids.

9.2.3.2.1 Metal, Mitigation. A bare array of alpha-plutonium metal buttons would lose reactivity by heat-related mechanisms. Since the metal density decreases as it is heated. The density of plutonium metal phases is shown in Table 9-23 (Wick 1967, 34, 36). Thus the stacked buttons, referred to in the scenario, would be physically pushed out of alignment by their sudden expansion. Although Pu metal will not be processed, this section is still required due to potential storage and repackaging operations.

The critical mass of a dry, unreflected system varies inversely as the square of the density. Expansion of the metal could cause a fissile system to shut down. Another possible shutdown of a metal system would be from melting. Based upon specific heat and heat of phase transition information (Wick 1967, pp. 34 and 37), the heat needed to melt a 2,000-g button from 25 °C would be 6.4×10^{6} cal (Fisher 1990). Normal methods of heating involve considerable heat loss by radiation, convection, and conduction; however, when 6.4×10^{6} cal is delivered from within the metal during a span of 0.5 s, heat loss mechanisms would be of little effect. Thus, if one assumes no heat loss, a 1×10^{18} fissions criticality could theoretically melt 100 2,000-g buttons.

A closely packed, unreflected, three-dimensional array of more than five 2,500-g buttons of 5% 240 content, on the floor of glovebox HC-21C would be needed to achieve criticality (Altschuler 1989b). Such an array could only be achieved by intentional stacking in gross violation of security, mass and spacing requirements. The hand doing the stacking would contribute some measure of reflection and might lower the number to something below 5. But, typical buttons have masses of 2,000 g to 2,200 g and a nominal ^{240}Pu content of 6% that would make them less reactive. As the last button was placed in the array, heat effects would be likely to shut down the criticality before it reached 1×10^{18} fissions. Force from the rapidly expanding metal would be likely to disrupt the array. The 6.4×10^{6} cal energy release from 1×10^{18} fissions is roughly equivalent to the daily energy expenditure of two actively working people. Thus even without a well-defined scenario, it is

clear that there is sufficient energy to perturb such a system and make it subcritical before all 1 x 10^{18} fissions are achieved.

9.2.3.2.2 Powder, Mitigation. If enough loose, dry powder could be found in the process to achieve criticality, shutdown would occur when the interstitial air heated and expanded rapidly. The powder would be widely scattered. A stacked array of cans filled with powder, if possible to assemble, would react similarly. Cans would swell and possibly burst from heated air, and very quickly perturb the critical array.

9.2.3.2.3 Liquid, Mitigation. In solutions, micro-bubble formation from radiolytic breakdown of the water molecules rather quickly lowers the density of the solution. In both solutions and in mixed solid and water systems, heat generated through the fission process can cause evaporation that may then lead to system shutdown. Nearly instantaneous formation of steam could, in some circumstances, be expected to physically disrupt the fissile materials into a nonreactive geometry.

The same design features that prevent criticality such as small size and mechanical spacing work to limit the extent of super criticality and the duration of phenomena such as the pulsing that took place in Recuplex in 1962.

9.2.3.2.4 Personnel, Mitigation. The standard criticality prescribes a certain amount of plutonium to be made airborne due to boiling of solution. The E-3 and E-4 filter systems mitigate the onsite and offsite dose. Mitigation of the effects to plant personnel following an accidental criticality is achieved by quickly putting distance between personnel and the reaction. Prompt medical help is provided to victims in order to mitigate the radiation effects. Radioactive particulates are filtered out of the Zones 3 and 4 gas streams, but gaseous iodine and noble gases are carried out the exhaust without effective mitigation.

9.2.3.3 Recovery. Formal recovery is required by procedure and would be performed under high-level Hanford Contractor and DOE scrutiny. All aspects would be performed in accordance with formal, written procedures. Any contamination in adjoining portions of the building could be cleaned quickly but cleanup of the immediate criticality site would, in all likelihood, have to be delayed until radiation levels to cleanup personnel from activation and fission products declined to acceptable levels.

9.2.3.4 Probability. The probability of criticality in the PFP can not be calculated without a detailed analysis for all the places where criticality is possible. But with the low consequences shown in this analysis it is sufficient to use statistics from the historical record of the six major DOE sites; Hanford, Idaho Falls, Rocky Flats, Los Alamos, Oak Ridge, and Savannah River. In the approximately 40 year history of these sites there were six criticalities involving chemical processing. Other criticality accidents happened with test reactors or test critical assemblies for research purposes (Stratton 1989). Of these, five took place through 1964 with the last one in 1978 at Idaho Falls. Thus with overall, raw statistics the annual probability of any one site suffering a criticality would be six in 240 site-years or 0.025. Lessons learned about criticality from DOE incidents have been rigorously applied so the probability of inadvertent criticality is actually much lower.

The present criticality prevention program, as defined by DOE Order 5480.24, has probability defined in terms of the double contingency principle. The contingencies considered in criticality analyses are discussed in Section 6.1.3.1. A contingency is the event or series of events considered in analyses which, should they take place simultaneously with other unrelated events, could lead to criticality. An example of an event might be assembly of all masses in one close-packed array. Administrative limits are set to require spacing between units of material. Implementation of administrative controls is based upon a concept in which action limits are set well before a full event is achieved. In this example, a particular location might have a spacing requirement of 10 in. between any two containers. Violation of spacing by even 1 in. is considered a serious matter that requires shutdown of the affected work area and a recovery plan authorized by Nuclear Facility Safety (NFS).

9.2.3.4.1 Metal Systems Probability. In dry systems, a considerable amount of attention is given to spacing requirements in order to limit the mass of material assembled in one place. For example, on the RMC Line materials are transported on pallets located along a conveyor. The pallets have a diameter large enough to maintain minimal spacing even if administrative rules are violated. The most sensitive location (assuming RMC Line is operating) would be glovebox HC-21C, where buttons were sealed in tuna cans for seal-out. In this glovebox, operators manipulated buttons with their gloved hands and the glovebox is free of any but administrative controls to place them in any configuration. The glovebox was limited to eight buttons. More buttons could be conveyed there, but this would require the cooperation of the control room operator who manipulated the conveyor controls. This information has been retained due to metal storage and packaging operations still occasionally undertaken. During normal working conditions, with no reflection present, more than 19 large, 2,500-g buttons with 5% ^{240}Pu could be crowded together, without stacking, on the glovebox floor without exceeding a K_{eff} of 0.92. As stated above, depending on the reflection provided by the hand, four or five buttons could be stacked without going critical. But other aspects of the work besides criticality rules limit the probability that this would happen. The nature of work flow or the physical arrangement of a work place can have more effect than management directives. Requirements for accountability control are present to keep an operator from assembling such an array of buttons in that numbers stamped on buttons must be read. The number was generally stamped on the convex surface as the most stable configuration while stamping is to have the flat side down. Since one of the faces is convex, stacking would not be an action that even a busy but preoccupied operator would be likely to do, even without the need to read the numbers, as the stack would tend to fall over. Also, a two-person rule means that an individual is not working alone and thus has someone present to correct gross errors. In crowded, awkward gloveboxes people have been known to push unit masses such as used sock filters into improperly spaced arrays in preparation for maintenance. The size and arrangement of the work space in glovebox HC-21C is such as to preclude the need to stack buttons in order to get them out of the way. In addition, the fixed-array wagon used to transport buttons is designed for only five positions so there is a tendency to send no more than five at a time to the glovebox by way of the glovebox HC-2 conveyer.

9.2.3.4.2 Powder Systems Probability. Spills or upsets of dry powder in RMC Line gloveboxes would not lead to a criticality. The critical mass of

dry, PuO_2 with 0% ^{240}Pu, nominally reflected, with a conservative density of 3 g Pu/cm^3, is 140 kg (Carter et al. 1969, 111.A.(100)-5). This is in contrast to the maximum mass of 8 kg that can be put into glovebox HA-21I. Criticality limits are based on the double contingency principle which, on the RMC Line, includes flooding the gloveboxes with water.

9.2.3.4.3 Solution Probability. The probability of solution system criticalities presents another set of control problems. For example, pipes, tanks, and other designed process containers can easily be made critically safe. They are officially referred to as geometrically favorable rather than geometrically safe as there are conditions under which criticality could be achieved. However, for the kinds of solutions and wet solids normally encountered, they are, for all intents and purposes, critically safe. On the other hand, solutions can travel from their intended locations by a variety of processes. The force of gravity can move fluids by vacuum, by syphon, or in an ordinary downward course. In addition, through the processes of evaporation, leaching, and solvent extraction, solutions can change their characteristics.

The probability of a criticality in the 241-Z tanks is governed by both formal criticality controls and the nature of the processes upstream. The nature of the upstream processes was originally governed in part by criticality prevention considerations but that has no bearing on present probabilities. As stated in Section 9.2.3.1.3.2, three different criticality scenarios are envisioned within the 241-Z tanks. The criticality prevention specifications for the tanks are based on the scenario involving the smallest critical mass. This would be a criticality involving a conical pile of precipitate. In addition to the conical shape, the plutonium is assumed to be all ^{239}Pu, fully water reflected, and the plutonium density in the pile is 30 g/L or 0.03 g/cm^3 (Friar 1990). The material assumed in Friar (1990) is a somewhat artificial material with a lowered plutonium density made necessary to maximize the water content. The precipitates formed in tank D-5 are of low viscosity and would tend to slump into a slab form rather than remain in a 140° cone. Even the concept of cone formation is largely the result of the need to establish conservative limits. The incoming solutions drop in through pipes that end near the top of the tank. For solution depths greater than 10 in. the agitator runs continuously and no pile could form. Below 10 in. the thought was that without stirring a cone of precipitate could form but this would be very unlikely to result beneath a stream dropping in from more than 10 ft above. If any regular geometric formation was to be created it would more likely resemble a low profile impact crater. Additional spreading would tend to occur because the inlet pipe is located on the side of the tank above the high side of the sloping floor so there would be a tendency for the crater to be distributed in a fan shape. Friar (1990, Figure 2) shows that at the 97.5% confidence level, $k_{eff} = 1$ for 1,040 g in a cone with an apex angle of 130°. The k_{eff} falls off rapidly as the cone flattens past this angle on its way to a slab shape. As stated in Section 9.2.3.1.3.2, the minimum areal mass for a criticality to occur in these tanks is approximately 245 g/ft^2. As long as the solutions are basic, precipitate will form with essentially no plutonium in solution as the solubility product constant for Pu(IV) hydroxide is 7×10^{-56} (Cleveland 1970, p. 83). Thus the areal concentration represents precipitate. It makes little difference whether or not the plutonium is present as a suspension or precipitated layer for, as stated in Section

9.2.3.1.3.2, there is less than half this amount of plutonium in the entire primary solvent extraction system.

The Criticality Specification for transfer of waste to the Tank Farms limits the plutonium concentration to 0.033 g/L. The specification also requires specific neutron absorber to plutonium ratios, and maximum and minimum percentages of solids in the transferred waste. This is to ensure that the waste additions of plutonium from PFP will remain noncritical in the large Tank Farm tanks.

Another scenario from Section 9.2.3.1.3.2 involves a criticality resulting when an acidic solution of high plutonium concentration from PRF (if operating) pours into a tank and forms a sphere-like region that goes critical. In no case could a solution of less than 7.2 g/L go critical as this is the lowest critical concentration for a 0% ^{240}Pu system (Paxton and Pauvost 1986, p. 59). One of the every 2 h surveillances on CA column operation is to monitor the color of the aqueous solution as it leaves the disengaging section at top of the column. This solution is readily visible as the top of the column is made of glass pipe and is located only a foot or so from viewing windows in the 6th floor column glovebox. A fractional gram/liter solution is essentially colorless. A 7-g/L Pu solution has a definite brown or blue color depending upon valence state. One of the procedural requirements is to note abnormal color and report it to supervision. Before CAW solutions are transferred to tank D-8 they are sampled and sent to the PFPAL for analysis of plutonium content among other attributes. During sample preparation laboratory technicians are trained to bring obvious differences in characteristics to the attention of their managers. Thus the unusual color would be a clue at this point, in addition to the analysis, that high concentration material was destined for tank D-8. In addition, such a high concentration of plutonium in the CAW would be indicative of a major upset in the solvent extraction system. Loss of significant amounts of plutonium out the top of the CA column would soon become apparent in a number of ways and would not likely be ignored because, if for no other reason, it would adversely affect production. The CAF is nominally only 4 g/L and a greater than 7.2 g/L escape through CAW represents nearly double this amount. Thus even if the formal criticality control mechanisms fail there are numerous operational controls in place which cause the probability of exceeding the minimum critical concentration to be very low.

Should a solution of greater than 7.2 g/L be discharged into a 241-Z tank there is a low probability that conditions would be right to cause a criticality. For solution depths of less than 10 in. the agitators are not on but as discussed with the precipitation scenario, there would be mechanical agitation due to the greater than 10-ft fall. With the agitator running, the event becomes incredible.

Certain laboratory sink drains lead to the 241-Z tanks but can not be considered as sources for the concentration or quantities necessary to generate a criticality.

Gradual solids accumulation is a potential source of unknown plutonium in the large tanks so NDA measurements are made on a regular basis. The analysis is designed to detect violations of the 400-g criticality limit. As was

discussed above, the probability of having a conical pile is very low, so in reality the analysis would only have to detect somewhat uniform deposits of plutonium approaching 19 kg. The probability that the NDA system would fail to detect such a quantity involves multiple failures. These kinds of quantities would only accumulate after the passage of many analyses. The addition of iron before transfer to Tank Farms is done to dilute the plutonium in the Tank Farm tanks to a subcritical concentration. The same tendency would be true in tank D-5. The presence of a voluminous, iron hydroxide insures that the plutonium hydroxide is kept in suspension so that it is transferred with the solution. Another aid to complete transfer is that the transfer lines are only 1/4 in. off of the tank floor.

As with solid materials, the criticality limits for liquid systems are enforced at a level far below a full contingency violation. But even close approach to the limit is considered a serious administrative matter and exceeding the value by even a fraction of a gram/liter requires shutdown of the affected process and implementation of a formal recovery plan.

The probability of a criticality during normal operating, maintenance, or emergency situations is considered to be very low due to the engineered barriers and multiple administrative barriers. Should a criticality occur, it would be most likely in concurrence with some otherwise highly unlikely situation. People whose attention was diverted by an emergency situation might attempt an apparent fix to the obvious problem and, as a result, create a situation that ends in a criticality. Another possibility is that plutonium, thought not to be present, might be placed in a critical array during decontamination and decommissioning (D&D) operations. Both of the above possibilities are considered extremely unlikely. Managers and operators undergo periodic training that highlights the fact that the historical criticalities took place during non-normal circumstances. Locations under going D&D are routinely surveyed by gamma scan to determine plutonium inventory and cleaned to very low levels of plutonium.

An extensive system of design controls is in place to reduce the probability that personnel could erroneously create a criticality in either a dry or liquid system. Before any configuration changes can be made, the design must be reviewed for criticality considerations by a specialist in criticality evaluation. Work control plans ensure that modification or maintenance is done properly and checked before use.

During day-to-day work, a set of general limits addresses such items as the size and location of containers or potential containers even on the outside of a glovebox or the use of plastic sheeting for covers or drapes. The number and size of cleaning rags are carefully controlled as a pile of saturated rags may approach an unfavorable shape and could draw solution by absorption. Gloveboxes are equipped with special drains that reduce the probability of deep accumulations of liquid occurring. The size of each drain is specified in relation to the potential for liquid flow and each drain is equipped with a large, coarse screen to prevent plugging. Some drains flow liquid onto the room floor and while such an event can cause a radiological problem, it does prevent formation of a critical system.

The volume of containers, both individual and total, is specified for each glovebox to reduce the probability of accumulating excess liquid. In

addition to process container volumes there are specifications that describe non-containers. At times in the past, hardware was brought into gloveboxes or hoods for purposes other than liquid handling which, in case of an accident, could become containers. For example, years ago a metal box or a quart ice cream carton were commonly used to store tools. Now such containers must have a specified number, size, and arrangement of holes near the bottom. People are taught that even a section of pipe set on end could contain liquid if the liquid was introduced faster than it would leak away.

Avoidance of a criticality depends upon people who are well trained so they can follow the rules of criticality safety even when unusual conditions are outside procedures. Compliance with rules by operators and technicians provides the primary enforcement of the criticality safety program. Probability of criticality is lowered when management strikes the correct disciplinary balance: a balance between enough tolerance to encourage voluntary reporting of posting violations, and the toughness and ingenuity to prevent such low-level violations from becoming prevalent and from escalating to more significant violations.

9.2.3.4.4 Transport and Storage, Probability. Once metal buttons are sealed in tuna cans, the probability of a criticality drops sharply due to the spacing provided by the cans. For buttons in undented tuna cans, the number needed to achieve criticality would be approximately 60, under low or no reflection conditions (Altschuler 1985). This far exceeds the number of buttons that would ever be found in this location because of considerations of criticality control, security, and radiation protection.

Spacing violations do occur during operations in gloveboxes. Normally, the violations involve only a few inches. In boxes which involve clumsy work positions, poor visibility, and crowding, violations of spacing are more likely.

The preceding discussion concerning probability was based on the assumption that the mistakes would be made during normal operating periods when water or other moderators were not present. In addition to normal operations and human errors, the glovebox limits are established with consideration for other contingencies (e.g., water flooding). The presence of water or other reflecting and moderating materials lowers the critical mass significantly so the limits are established with the assumption that the presence of these materials could happen concurrently.

Proper geometric design is used more frequently to control liquid systems but plays a part in dry systems also. Process equipment size and shape is dictated by criticality considerations when some other design might be more efficient from a processing standpoint. Storage vaults are typically equipped with individual storage locations that prevent stacking containers or placing them too close together.

As discussed with regard to bare metal buttons and plutonium powder, rules for handling of material during transport or storage involve contingencies for flooding. The probability of an operator or maintenance person making a mistake which would directly lead to a criticality is quite remote. For example, the critical mass of an array of large 2,500-g metal units, in 4.25-in. diameter by 7-in. high cans in a neatly stacked array,with

full concrete reflection on three sides, would be about 150,000 g. Without being stacked neatly in a corner of a concrete vault, the critical mass would be higher; however, the mass would be lower if the cans were dented in a way that provided less separation. The critical mass for 1,000-g units of $^{239}PuO_2$ in 7-in. cans at a bulk density of 2.6 g/cm^3 would be approximately 450,000 g with full water reflection and approximately 290,000 g for full concrete reflection (Carter 1987). While these are not highly refined numbers or conditions, it is clear that no transport wagon or single storage cubicle contains anything near this amount of material. No quick series of acts on the part a person could cause a criticality. Emphasis in this analysis is placed on the aspect of a short time for initiation and upon a short duration because the probability of a system being left in a nearly critical condition for very long is low also. Should material be left for long, the probability rises for another unrelated event (e.g., a water pipe break) occurring during this period.

9.2.3.5 Accident Analysis. The criticality analyzed is that presented in Regulatory Guide 3.35 (NRC 1979b).

9.2.3.5.1 Assumptions. This criticality produces an initial burst of 1×10^{18} fissions in 0.5 s followed successively, at 10 min intervals, by 47 bursts of 1.9×10^{17} fissions for a total of 1×10^{19} fissions in 8 h. The excursion is assumed to be in a liquid system that is terminated by evaporation of 100 L of solution.

Assumptions related to the release of radioactive materials are as follows:

- All of the noble gas fission products and 25% of the iodine radionuclides are released directly to a ventilated room with no holdup
- The criticality is assumed to occur in a solution; therefore, an aerosol is assumed to be released due to evaporation directly into the room atmosphere. The aerosol is assumed to comprise 0.05% of the salt content of the solution that is evaporated or 1 mg PuO_2
- Since Regulatory Guide 3.35 (NRC, 1979b) is intended for a reprocessing plant, the specified isotopic mixture contains approximately 28% ^{240}Pu rather than the normal weapons grade material with only 6%
- No credit is given for holdup mechanisms in the room or duct work, but the filter system is assumed to be functional. The transmission factor for a single stage of HEPA filters is used as 5×10^{-4}
- The gases and the small residual of plutonium are released to the environment through the 200-ft-high stack and the shorter stacks as a second case
- The amounts of radionuclides assumed to be produced are presented in Table 9-24.

9.2.3.5.2 Methods and Models. This accident includes two models. One is assumed to take place in one of the buildings ventilated via the 200 ft 291-Z-1 stack and the other via the short stacks. The two scenarios differ in the dose to onsite and offsite personnel due to differences in atmospheric dispersion and direct dose.

9.2.3.5.3 Calculations. For calculations, see the general discussion of the GENII code (Van Vleet 1990) and the following sections. The GENII code was used to calculate doses since the methods discussed in Section 9.3 are for inhalation dose, and the NRC accident considered releases noble gases with significant submersion doses.

9.2.3.5.4 Uncertainty. Not applicable as there are no specific scenarios. However, the NRC accident is considered bounding.

9.2.3.5.5 Concentrations Within Facility. As noted above, Regulatory Guide 3.35 (NRC 1979b) requires the assumption that the gases and plutonium aerosol from boiling be released directly to a room. Concentrations within the facility would depend upon the size of the room, exhaust flowrates and conditions from the prescribed model. The model calls for pulsing of the system till reactivity stops after 8 h due to evaporation of 100 L of solution. The event is assumed to take place in one of the smaller rooms. The volume of a small room is taken to be 1.8×10^2 m^3. The air is exchanged at a nominal rate of six changes per hour. The buildup in concentration follows a first-order function so that equilibrium is reached in about six changes or 1 h. Thus, the concentration of plutonium-americium inside the room would reach an equilibrium level and would remain at this level for the next 7 h assuming a constant generation rate. The calculation of the alpha emitting nuclides concentration from the Table 9-24 value is presented as follows:

$$\text{Volume of the room} = 19.5 \text{ ft} \times 33.9 \text{ ft} \times 10 \text{ ft} = 6.6 \times 10^3 \text{ ft}^3$$

$$6.6 \times 10^3 \text{ ft}^3 \times 2.8 \times 10^{-2} \text{ m}^3/\text{ft}^3 = 1.8 \times 10^2 \text{ m}^3$$

$$\frac{1.87 \times 10^{-2} \text{ Ci}}{8 \text{ h} \times 6 \text{ changes/h}} = 3.9 \times 10^{-4} \text{ Ci}$$

Each change is one room volume or 1.8×10^2 m^3.

Therefore:

$$\frac{3.9 \times 10^{-4} \text{ Ci}}{1.8 \times 10^2 \text{ m}^3} = 2.2 \times 10^{-6} \text{ Ci/m}^3$$

The equilibrium concentrations of fission product gases are summarized in Table 9-24. The noble gases were determined by dividing the 0.5 s to 8 h release period values by 7.5 to give the rate per hour; dividing by 6 to give the release per air change; and then dividing by 180 to give the concentration in Ci/m^3. The concentration of the iodine isotopes was calculated similarly except that the concentration was divided by 4, as stated in Section 9.2.3.5.1.

Filter buildup would be insignificant. There would be no ground-level release as all effluents would exhaust from the stack.

9.2.3.6 Dose. Dose calculations used the GENII computer code (Van Vleet 1990) and calculations of direct dose from NRC Regulatory Guide 3.35 (NRC 1979b).

9.2.3.6.1 Assumptions. Assumptions used in the calculations of airborne gases are summarized in Section 9.2.3.6.2. An assumption of the direct dose calculation is that the building offers no shielding. This is a significant conservatism for some locations as several concrete walls may be in the path. The figures given would be very much worst case.

9.2.3.6.2 Methods and Models. In addition to the dose due to the release of radioactive gases there is an external dose received from the prompt gamma rays and neutrons. In the absence of plant-specific calculations, Regulatory Guide 3.35 (NRC, 1979b) presents the following two semi-empirical formulas for the prompt gamma and the prompt neutron dose:

$$D_g = 2.1 \times 10^{-20} \frac{N e^{-3.4d}}{d^2}$$

$$D_n = 7.0 \times 10^{-20} \frac{N e^{-5.2d}}{d^2}$$

where: Dg = Gamma dose, rem
Dn = Neutron dose, rem
d = Distance, km
e = Base of natural logarithms
N = Number of fissions.

For the 2736-Z and 2736-ZB Buildings, the gamma dose is reduced by a factor of 2.5 and the neutron dose rate by a factor of 2.3 to account for the shielding afforded by 8 in. concrete walls. There would be no direct dose to onsite personnel from the 241-Z Building as the tanks are underground.

The submersion, inhalation, and ingestion doses were calculated using the GENII code (Van Vleet 1990). The concentrations of fission product gases and TRU aerosols were used as specified in NRC 1979b and summarized in Table 9-24.

The dose information summarized in Table 9-21 includes the fraction of the EDE due to the direct gamma and direct neutron radiation.

The workplace external to the PFP complex receiving the highest dose due to this criticality is 272-WA, which is 0.63 km to the west-northwest. For a release from the 200-ft-high stack, the onsite MI is expected to receive a 50-yr committed dose of 0.16 rem EDE and 0.27 rem to the thyroid. For a release from one of the short stacks, calculated as a ground-level release, the EDE is 0.73 rem and 2.4 rem thyroid. All onsite doses are below the dose guidelines (Section 9.4) for an event with an annual frequency of 0.1.

The place on the site boundary at which the highest dose is expected is located 13.2 km (8.2 mi) west-northwest of PFP. This also corresponds to a hypothetical site of food production. Thus, the receptor expected to receive the maximum dose due to passage of the cloud is also the receptor expected to receive the maximum dose due to the growing of all nourishment on this one contaminated farm. This person is expected to receive a 50 yr committed dose of 0.032 rem EDE and 0.97 rem to the thyroid from a 200-ft stack level release. For a ground-level or short stack release, the receptor who also lives there and grows all of his own food would receive an EDE of 0.053 rem and a thyroid dose of 1.6 rem.

9.2.3.6.3 Consequences. The consequences are summarized in Tables 9-21 and 9-22 and can be compared with the dose guidelines in Table 9-49.

Since no specific scenario was provided, no specific probability could be calculated. It should be noted however, that the onsite doses for release from the 200-ft-high stack or from the short stacks are below the guidelines for an event with a frequency of 1.0×10^{-1}/yr. The most limiting case is the offsite thyroid dose due to a release from a short stack, which meets the RAG (Section 9.4) for a frequency of 3.8×10^{-2}/yr.

9.2.3.6.4 Uncertainties and Conservatisms. Uncertainties in modeling such as that done in determining both the release fraction and the resulting dose calculation are better thought of as conservatisms. Uncertainties are generally thought of as some kind of a mathematically symmetrical distribution around a central, "best" or "true" value. The deviations from best value in these calculations are generally believed to be skewed entirely to the high side. Thus, the term conservatisms appears to be more appropriate. In addition to the conservatisms discussed in this section, see those in regard to the GENII code (Van Vleet 1990).

It is conservative to include the standard solution criticality for the 2736-ZB facility because solutions are not handled there and solutions tend to give a higher fission yield.

9.2.4 Seismic Event

9.2.4.0 Introduction. The seismic event as it affects the PFP has been reviewed on two separate occasions in the recent past. The results of this review have been presented in Rev. 0 of Marusich (1988a). The seismic event accident analysis presented in Marusich (1988a) was based on the presumed collapse of the facility resulting in large-scale destruction. The analysis presented in Rev. 2 of Marusich (1988a) was based on new, more detailed structural analysis which showed that the facility and the large internal concrete walls did not collapse in the event of a design basis earthquake (DBE); however, it was presumed that the gloveboxes toppled. Since that time some of the gloveboxes have been modified so that they will not collapse or topple.

The analysis of the seismic event presented in WHC-SD-CP-SAD-002, *Safety Assessment for PFP Inventory Sensitivity of the Seismic Event* (Marusich 1994) as incorporated into WHC-SD-CP-SAR-021, Rev. 0, provides the authorization basis for the inventory limits provided in LCO 3.3.1, of the *PFP Operational Safety Requirements* (WHC-SD-CP-OSR-010, Rev. 0). The authorization basis seismic event analysis (presented in Marusich 1994) shows an onsite dose of 20 rem for the 1.0×10^{-4} annual probability seismic event (See Table 5-1 of Marusich 1994). The glovebox inventories used in that analysis are provided in Table 9-61.

The analysis presented below is based on the present glovebox and hood CPS limits. The limits are less than that shown in Marusich (1994) as a result of the inactivation of a number of gloveboxes. The onsite consequences of a 1.0×10^{-4} annual probability seismic event are shown in Tables 9-32 and 9-33. Consequences of additional seismic event analyses are provided in Tables 9-34 and 9-36. The analysis of the seismic events presented in this section includes the effects from seismic induced fires in thermal stabilization Gloveboxes HA-21I and HC-21C, and the seismic effects on Buildings 241-Z and 232-Z. The releases and resultant consequences from the Laboratory Prototype Calciner due to a seismic event are summarized in Section 9.2.4.9 and the details are included in the Laboratory Prototype Calciner addendum to this FSAR. The contribution to the seismic event doses from the calciner are not included in the seismic event summary tables, Tables 9-32, 9-33 and 9-34, since the laboratory calciner is not authorized for operation. The seismic event impacts from operation of the calciner will be reevaluated and included, as appropriate, prior to any future authorization for operation.

For the seismic event, the initiating event is the DBE. However, the task of "choosing" one or more failures to maximize the release within the annual probability limit of 10^{-6} becomes quite difficult because the probability of the design basis natural phenomena is already low (10^{-3} to 10^{-4} annual probability). The PFP is safe without an operational ventilation system and without the operation of many other systems due to the low stored energy of the process, good choice of process materials, and intelligent grouping of process steps in particular gloveboxes. So if it is assumed that everything not "qualified" fails, the facility could still have acceptable consequences provided the facility remains intact (exterior and interior major walls and floors).

For the purposes of this Seismic Event accident analysis the assumption is made that if a component is not qualified, it will fail in the way that results in the largest release. The probability of the aggregate of these selected, specific, simultaneous failures in combination with the earthquake is judged to be extremely low. However, this cannot be proven. Therefore, the approach taken here is to assume the earthquake occurs and to choose failures so as to maximize the release.

The analyses assumed that the gloveboxes, hoods, and filterboxes that are seismically qualified will remain standing. Those that are not qualified are assumed to fail. Glovebox seismic qualification, shown in Table 9-25, is based on engineering analyses (Ocoma 1988, Ocoma 1990a, Ocoma 1990b, Marusich 1988a, Vollert 1987a, and Vollert 1987b). It has been shown that the facility structure will survive the effects of the earthquake. The situation presumed for this seismic accident analysis is one in which the facility structure remains upright, but within the structure and gloveboxes, it is referred to as "abnormal operation." Abnormal operation is taken as process operation under the conditions where, due to the earthquake:

- Normal flow streams may not be present
- Normally open active (not manual) valves may suddenly close or closed valves open
- Lines may sever
- Tanks may fail
- Glovebox panels may fall out
- Structures on the main facility (e.g., the covered walkway on the east side of 234-5Z Building) may fail
- Pumps which were off may start and continue operating.

9.2.4.0.1 Organization of Section. A seismic event is different from other events analyzed in Chapter 9.0 in that the seismic forces are applied simultaneously at all places in the facility. The 234-5Z Building was designed and built in the late 1940s when the technology of seismic evaluation and design was not as well developed as today. Subsequent structures were generally built to standards near to those in effect today but equipment design generally did not address seismic considerations. (Analyses performed for the section have determined that most facilities and much of the equipment will withstand seismic loads.) Thus, this section on the seismic event is large. The normal rules of paragraph designation become overburdened as the logic of organization sets up eight or nine levels of paragraphing. It becomes difficult for the reader to cope with such a string of alpha and numeric characters. Thus, at the lower levels of paragraphing, a dual system of decimal characters and word descriptions is used.

The paragraphing and logic behind it are presented in the sections as follows:

- **9.2.4.1**--Step 1 is presented to understand the response of each facility and glovebox to seismic loads. Facility or glovebox survival or failure is important to scenario development.

- **9.2.4.2**--Step 2 is presented as an examination facility by facility and, within each facility, glovebox by glovebox to determine what accidents can occur as a result of seismic loads. The accident scenarios are based on facility and glovebox response assuming that there are no preexisting failures and that the process is proceeding normally (e.g., flowsheet).

- **9.2.4.3, 9.2.4.4, 9.2.4.5, and 9.2.4.6**--Step 3 is presented to determine the release into each facility from the scenarios developed in Section 9.2.4.2. This is done by choosing the worst case accident scenario for each glovebox, applying appropriate release fractions, or developing a method which determines the release of plutonium into each facility. This is done for each glovebox within each facility. Section 9.2.4.6.3.12 summarizes the total release for each facility by room.

- **9.2.4.7**--Step 4 is used to present methods used to calculate the fraction transported out of the facility. Exhaust fan and wind pressure induced flow were investigated. Particle deposition was also factored into the release fraction.

- **9.2.4.8**--This section is presented to summarize the calculated doses due to the bulk of facility release. A refinement to the transport-out-of-the-facility method is presented and then the dose as a result of the release is calculated.

- **9.2.4.9**--This section presents the results of the seismic event analysis for the Laboratory Prototype Calciner in Room 188 of the PPSL. The results are not included in the seismic event consequence totals for the facility since the calciner is not authorized for operation.

- **9.2.4.10**--This section presents the contribution to the seismic event from the Magnesium Hydroxide Process in Glovebox HC-230C-3 and HC-230C-4.

- **9.2.4.11**--This section presents the contribution to the seismic event from the Bagless Transfer System Glovebox.

- **9.2.4.12**--This section presents the summation of the doses to the onsite and offsite receptors from a seismic event from Sections 9.2.4.8 (bulk of the facility including Buildings 232-Z and 241-Z), 9.2.4.10 (Magnesium Hydroxide Precipitation Process), and 9.2.4.11 (Bagless Transfer System).

9.2.4.0.2 Summary. The release of respirable Pu from PFP and Building 232-Z given the occurrence of a DBE is calculated for two cases. In the first case, the ventilation systems are assumed to be either failed off or shut down. In the second case, it is assumed that the exhaust fans continue running.

The radiological consequences associated with releases for these two cases are presented in Tables 9-32 and 9-33. The radiological consequences are below the Risk Acceptance Guidelines except the no ventilation onsite consequence. The seismic analysis related to the Laboratory Prototype Calciner is discussed in Section 9.2.4.9 and the details are found in the Laboratory Prototype Calciner addendum to this FSAR. The laboratory calciner is not currently authorized for operation. Therefore, the consequences of a seismically initiated release are not included in the total facility consequences for a seismic event.

The release of hazardous materials (specifically HNO_3) was also evaluated and found to be below the Risk Acceptance Guidelines.

9.2.4.1 Building Seismic Analyses.

9.2.4.1.1 Building Response During a Seismic Event. The older major structures, 234-5Z, 291-Z, 242-Z and 236-Z, and the stack at the PFP have been analyzed by J. A. Blume Engineers. The 2736-Z, -ZA, and -ZB structures were designed to withstand seismic forces. The 232-Z structure was analyzed and shown to have favorable load to capacity ratios but has not been qualified to withstand a DBE. The chemical storage tanks have not been analyzed for currently required seismic loads and, therefore, are assumed to fail in the analysis. The 241-Z facility has been analyze. A summary of the analyses taken from their reports follows.

234-5Z Building Response (URS 1987). Previous preliminary seismic analyses indicated that 0.25-g DBE motions may produce nonlinear responses and possible structural distress in the 234-5Z Building (i.e., the facility may collapse). It was recognized, however, that the building had considerable capacity to resist DBE loads in the nonlinear range. Therefore, the comprehensive linear and nonlinear 234-5Z Building seismic analyses and evaluation described here were undertaken. The objectives of this study included consideration of all the building elements that realistically contribute to its lateral (seismic) resistance and determination of whether the building could resist the DBE without collapse.

The scope of the seismic analysis and evaluation of the 234-5Z Building required a rigorous dynamic seismic analysis using a detailed, three-dimensional, nonlinear model of the building. Element properties for the model were based on detailed review and onsite measurements inside the building as well as mockup cyclic testing of beam-column connections to determine moment rotation relationships. Equivalent static analyses were conducted to understand details of the structure's lateral-force-resisting system. Seismic demand on the structure was calculated using direct integration time history dynamic analyses for three components of ground motion, including consideration of large displacement effects.

The results show that the DBE response of the building is mainly linear elastic. Only four beam-to-column connections yield, and remain comfortably below ultimate rotational capacities. The east-west displacements are small, 0.33 in. maximum at the roof. The maximum north-south displacement is over 7 in. at the roof. The north-south displacement at the second floor level is 3 in. maximum.

The main conclusions of the 234-5Z Building DBE analysis and evaluation follow.

- The building, as is, could resist DBE motions without collapse.
- Separation and some seismic pounding are expected between the second floor slab and the stairwells; shear cracks could develop in the stairwell walls. The integrity of the building and the use of the stairwells for egress will not be threatened.
- The north-south concrete walls along column lines 4 and 8, need to be isolated from the lateral load path such that the columns do not attract seismic shear forces that may exceed their capacity.

A further assumption is made that the building separates along Column 12 (the building joint) due to presumed differential motion between the east half and west half. In addition, the side panels were assumed to tear, buckle, or pull out of the girders at the attachments. This damage is slight on walls perpendicular to the earthquake direction and on walls nearer to the ground. The damage is more pronounced in walls parallel to the earthquake and at upper levels. Recently a test was performed on panels in which a bounding condition of the seismic loads was applied. The panels suffered only minor damage around some of the fasteners, therefore it is assumed in this analysis that the panels remain intact.

234-5Z Building Panel Response. The results of tests that were performed on sheet metal wall panels fabricated to be approximately the same as the 234-5Z Building existing wall panels are described in (Giller 1989b). The tests simulate the wall panel reactions to seismic displacements.

The series of panel drift tests (applies a displacement which changes a rectangular panel into a parallelogram) were designed to evaluate diaphragm shear strength of the wall panel due to building drift during a seismic event. The test results showed the panel section to be very rigid in diaphragm action. The effect on the panel after being subjected to 160% of the expected drift from a seismic load was elongation of some bolts holes by about 1/4 in. These tests qualify the building panels to remain attached to the building during a design basis seismic event.

291-Z Stack Response. Previous preliminary and conservative seismic evaluation of the 291-Z Building and stack indicated that the building was structurally adequate to resist the lateral forces due to the postulated DBE loading, but the stack showed overstress (URS 1980). The seismic demand of the stack was calculated by the linear elastic response spectrum procedure, assuming a fixed base.

In the present study, (URS 1988a) the demand on the stack was calculated using an equivalent stick model. The soil half space surrounding the structure was modeled by frequency-independent springs to account for soil- structure interaction (SSI) effects. The stack responses were calculated using the time history modal superposition procedure with the free-field time histories conservatively applied at the embedded basemat level. The calculated demand was then compared with the capacity of the stack. The stack's capacity to resist horizontal and vertical DBE loading was rigorously calculated on the basis of nonlinear behavior of concrete and reinforcement bars. The nonlinearities considered were concrete cracking, parabolic compression behavior of concrete with crushing and ultimate strain specification, and elastic-plastic behavior of reinforcing bars. The capacity for reinforcement bar yielding initiation and the

ultimate capacity were calculated for each section of the stack. The results of this study show that the stack has enough ultimate capacity to resist the postulated DBE loading with ductile behavior.

This study rigorously and conservatively evaluated the capacity of the 291-Z stack to resist the postulated DBE with a zero period acceleration (ZPA) of 0.25 g. Alternative calculations were also performed to show the conservatism of the present evaluation. The conclusions of this study may be summarized as follows.

1. The dynamic analysis and evaluation of the Hanford Site 291-Z stack demonstrates that the stack reinforcing has enough ductile capacity to resist the DBE loading without collapse.

2. The steel reinforcement in the lower section of the stack is expected to yield, but the calculated steel strain is much less than the failure capacity of steel.

3. The maximum horizontal and vertical displacements at the top of the stack have been shown to be less than 8 in. and 0.2 in., respectively.

4. The maximum horizontal acceleration at the top of the stack has been calculated to be less than 0.8 g.

236-Z Building Response. Seismic analyses and evaluations were performed for the 236-Z Building to determine whether it can resist the 0.25-g DBE. Three-dimensional, lumped-mass beam models of the building were developed. Seismic forces and moments for these models were computed by using the modal superposition response spectrum method of dynamic seismic analysis. The overall seismic forces and moments were distributed to the individual walls and diaphragms and evaluated against their calculated code-allowable capacities. The evaluation indicated that the 236-Z Building will meet the code requirement to resist the DBE motions postulated for the site. Specific conclusions for the key structural members are as follows.

1. **Roof**--The metal roof deck has a maximum demand/capacity ratio of 0.94, indicating that it meets the code requirement.

2. **Concrete Floor Slabs**--All the slabs meet the code acceptance criteria.

3. **North-South Walls**--All the reinforced concrete walls oriented in the north-south direction have demand/capacity ratios of less than 0.62 for shear and overturning moments. All the north-south walls meet the code requirement.

4. **East-West Walls**--All east-west walls, except one, have acceptable demand/capacity ratios of less than 1.0 for shear and overturning moment. East-west wall 4 has a ratio of 1.23 for overturning. However, this is a minor wall, and the loads from this wall can be carried by the adjacent east-west wall 3, which has more than adequate capacity to carry the additional overturning force.

5. **Concrete Block Wall**--The concrete block wall (4-in. and 8-in.-thick) at the south cell wall does not meet the acceptance criteria since it has a demand/capacity ratio greater than 1.0. This ratio is not based on

inspection since inspection results were not available. It is to be emphasized that this is not a load-carrying wall, and its performance will not affect the structural behavior of the building. The entire area of the concrete block wall has been covered with welded steel plates which overlap into the poured concrete wall. The plates were installed on the exterior side with anchor bolts and sealed all around to preclude a leak path.

2736-Z Storage Complex Response. The 2736-Z storage complex is comprised of three buildings: 2736-Z, 2736-ZA, and 2736-ZB. Building 2736-Z is connected to 2736-ZA via a short (i.e., approx. 5 ft) ventilation duct.

Building 2736-Z. The 2736-Z Building storage vault is a single-story, reinforced concrete structure with four individual vault rooms. Within each room Pu is stored in shipping containers, or in storage cans placed on racks or in concrete storage cubicles. This building was seismically qualified at the time of its construction in the 1970-1971 time frame in the *Seismic and Tornado Analysis of Buildings 224-T and 2736-Z*, Vitro-R-161 (Lien and Vollent 1972). The method used by Lien and Vollent (1972) was reaffirmed in 1991 by a study that independently verified the building as a rigid structure and the appropriateness of the modeling method used at the time of construction. The structure was reanalyzed in 1994 (Giller 1994a) for normal operating and natural phenomenon loads. Equivalent static methods (versus dynamic methods) were used as recommended by *Design and Evaluation Guidelines for Department of Energy Facilities Subject to Natural Phenomena Hazards*, UCRL-15910 (Kennedy et al. 1990) for simple regular structures that have uniform mass and stiffness distributions. All structural members of the 2736-Z building were found to have positive margins of safety with respect to the material design strengths.

Additional seismic considerations in the mid-1970's provided container integrity assurance through shaker table testing of the pedestal storage configuration, and the establishment of Operating Specifications for storage that provide controls on container contents and packaging materials. The seismic qualification of storage cubicals, pedestals and racks were reanalyzed in 1994 (Ocoma 1994). It was found that the precast concrete cubicals and the pedestals were adequate to withstand DBE loads as were the two different types of metal storage racks in vault 2 used for the storage of 7-in cans. However, it was found that the anchor bolt loads of the storage racks in vault 2 used for the storage of lard cans exceeded allowable load capacities. Consequently, modifications have been made to the facility to assure the cans remain on the storage racks in the event of a DBE. Specifically, bracing has been installed to prevent the racks from falling over and seismically qualified retaining devices (chains) are installed to prevent cans from falling off shelves.

Building 2736-ZA. The 2736-ZA Building was designed in 1976 to provide a stand alone two-stage HEPA filtered exhaust system for the Pu storage vault. This system replaced the original means of exhausting the vaults through one-stage HEPA filters via the 234-5 Building ventilation system. This one-story precast concrete building and its essential equipment were built to the Hanford Standard Design Criteria SDC 4.1, which specified a maximum horizontal ground acceleration of 0.25 g at zero period. The exhaust fans, filters, and diesel generator are mounted on seismic snubbers and were analyzed to be resistant to the design basis earthquake by the supplier using dynamic response analysis techniques.
The building was reanalyzed in 1994 (Giller 1994b) using an equivalent static

analysis method. All structural members of the building were found to have positive margins of safety with respect to the material design strengths.

Analyses of the storage vault exhaust system were also performed in 1994 (Ocoma 1994). The specific elements analyzed were: the exhaust stack, exhaust fan and HEPA filter assembly, diesel generator, and the exhaust interface duct assembly connecting Buildings 2736-Z and 2736-ZA. The diesel generator has since been removed and replaced with an intertie to the Building 2721-Z diesel generators. The exhaust stack, exhaust fan/motor assembly, and HEPA filter assembly were found to be adequate to withstand DBE seismic loading. Due to differential motions between Buildings 2736-Z and 2736-ZA of up to 0.216-in. in-line displacement and 0.17 in. lateral displacement, shear tearing failure of a light gage sheet metal portion of the interface duct assembly could occur leading to very small cracks. The duct, however, will remain in place and provide an acceptable flowpath after the DBE. Based on the above information, it was concluded in *Seismic Analysis of Safety Class 3 Equipment in 2736-Z Complex*, WHC-SD-CP-SA-026 Ocoma (1994) that the function and operability of the exhaust system was reasonably provided for, although by no means assured, following a DBE. However, an evaluation of the potential for a release of Pu through the cracks in the duct is shown in Section 9.2.4.6.3.6.E.

Building 2736-ZB--The 2736-ZB Building was designed in 1980 to provide support functions for the 2736-Z Pu storage vaults. These support functions include shipping/receiving functions, a nondestructive Pu assay laboratory, and a glovebox for repackaging cans of Pu to support the long term storage mission of the vault. The project design criteria required conformance to the Hanford Standard Design Criteria SDC 4.1 for the structure and the ventilation system because it acknowledged that Pu might be dispersed within the facility during a seismic event from failure of containment provided by the repackaging glovebox. The structure was analyzed using a rigid response method at 0.25 g. The stresses under static loadings were found to be low and within acceptable code limitations with adequate margins to be qualified. The approach used to qualify the mechanical equipment, such as the ventilation supply and exhaust systems, was to procure a frame mounted assembly that would be mounted on snubbers attached to embedments in the floor and seismically isolated from other ducts using flexible connections. The equipment assemblies were modeled and dynamically analyzed by the vendor, and shown to have acceptably low loads. The filter housing assemblies used in the ventilation equipment package are commercially available shaker-test qualified equipment.

Building 2736-ZB was reanalyzed in 1994 (Weiner 1994) using an equivalent static analysis method. All structural members of the building were found to have positive margins of safety with respect to the material design strengths. The repackaging glovebox was also analyzed in 1994 (Ocoma 1994). It was found that the glovebox support frame and anchorage was adequate to withstand DBE loadings, i.e, that the anchor loads and the stresses in the support frame members, connections between the support frame and the glovebox, and the filter housing support were less than the allowable values.

291-Z Building Response (URS 1980). Preliminary evaluation of the 291-Z Building for the postulated earthquake ground motion was based on the assumption that the soil surrounding the structure does not provide any lateral support to the building. This assumption leads to simplified and generally conservative results, but it does not consider the interaction between the soil

and structure (called SSI). In order to study SSI during an earthquake, the computer program FLUSH, which employs a finite-element analysis technique that takes into account the variation of ground motions and soil characteristics with depth, was used. The FLUSH code has the following analytical capabilities:

- It considers the variation of soil characteristics with depth
- It considers nonlinear and energy-absorbing characteristics of soil
- It considers variation of ground motions with depth
- It considers the three-dimensional nature of SSI
- It can consider the effects of adjacent structures on each other, although this aspect was not utilized in the present analysis.

The building was analyzed for ground motions only in the east-west direction, as this direction was judged to be more critical that the north- south. Also, the analysis was carried out only for the DBE motions, since it was expected that as a result of preliminary evaluation, the building would qualify for DBE loads.

The results of the analysis indicate that bending moments predominate. Shear forces are well within the ultimate shear capacity of the section. Axial forces are less the 4% of the ultimate axial capacity. For this reason, interaction between the axial forces and bending moments was found to be insignificant. Although it is difficult to accurately assess the capacity of chord reinforcement against lateral loads from the results of the FLUSH analysis, based on preliminary results, local yielding of chord reinforcement at the first floor level due to the DBE lateral loads is expected. However, overall structural integrity will be maintained due to redistribution of forces and moments to the adjoining walls, which are able to accommodate these forces. In other words, the results of confirmatory seismic analysis of the building for the DBE loads indicate that, except for the chord reinforcement in the first floor slab, the computed forces and moments are well within the ultimate section capacities. The chord reinforcement at first floor slab level would yield, leading to minor cracking of concrete; however, overall structural integrity would be maintained due to the ability of the walls to sustain the lateral loads through redistribution of forces.

242-Z Building Response. The building was evaluated in accordance with the requirements of HPS SDC 4.1, Revision 10, and DOE Order 6430.1A. The load combinations in this study included dead load, earthquake loads, and specified equipment live loads, not concurrent with snow or ashfall loads as justified by UBC 1994 and WHC 1991a, respectively. The study included preparation of a three-dimensional computer model in order to perform a dynamic modal analysis from which member stresses are computed. The evaluation showed that one base plate anchor is marginal but the others have ample strength and therefore in the "as-is" (cleaned out and no operations occurring inside) condition the building will survive.

232-Z Building Response. The building was evaluated in accordance with the requirements of HPS SDC 4.1, Revision 12, and DOE Order 6430.1A. Based on this evaluation, it is concluded that the building will withstand a 0.09-g seismic event but is not qualified for a DBE of 0.20-g. Consequently, subsequent seismic

scenario evaluations in this section of the SAR consider the effects of both seismic events on this structure.

9.2.4.2 Seismic Accident Scenarios. A large earthquake is assumed to strike PFP. The size of the earthquake is assumed to be 0.20-g. The 0.20-g is the design basis/DBE for Hanford based on WHC 1991a and is the event for which the facility analyses were performed (see also Marusich 1988a, pp. 4-33, 4-34). In addition, a 0.09-g seismic event was considered since the 232-Z Building may not withstand a larger seismic event and releases may occur with events greater than 0.09-g.

The earthquake affects the facility and the facility internals such as internal structures, gloveboxes, piping, ventilation ducts, pumps, motors, valves, control system logic and equipment, electrical power, and filters. The damage will be described on a room-by-room basis with the description centering on those events that could result in the dispersal of plutonium or toxic materials (including inert gases). This is not the only damage that could occur in an earthquake, but it is the only damage of interest for the FSAR. Toppling of gloveboxes is considered later for criticality implications. The potential for seismic-induced glovebox fires is also considered later. The following describes what events may occur as a result of the earthquake, and what the "worst case" events are. The consequences of this are found in Section 9.2.4.6. The facilities considered were:

- 234-5Z
- 236-Z
- 241-Z
- 242-Z
- 232-Z
- 291-Z
- 2736-Z, ZA, and ZB
- Outside tanks around 234-5Z and 236-Z.

Several gloveboxes and hoods were specifically excluded from analysis because they are inactive. Several conveyors were also specifically excluded because they are normally empty. The conveyors and inactive gloveboxes and hoods are identified in Table 9-25. The column entitled "maximum plutonium allowed per CPS" contains the values in place at the time of the analysis.

The inactive gloveboxes and hoods were not included in this analysis because the residual quantity of Pu material in them is small in comparison to the dispersible Pu inventories assumed for the active gloveboxes and hoods. Piping and vessels in inactive gloveboxes have been drained and flushed and the gloveboxes swept, vacuumed or slurped to remove the majority of accumulated Pu material, to minimize direct dose exposure to workers. The residual Pu inventories in inactive hoods have been similarly minimized. The residual material in inactive gloveboxes and hoods is electrostatically or chemically adhered to surfaces or is contained in crevices or the internals of equipment where it is much less susceptible to resuspension than bulk material in open containers in active gloveboxes or hoods. NDA results verify that residual Pu in inactive gloveboxes and hoods are small in comparison to the dispersible inventory limits assumed to be subject to release in active gloveboxes and hoods. For example, the best estimate of the residual inventory in Glovebox HC-10, based on NDA results, is 31 g, compared to the CPS limit of the adjacent active Glovebox HC-11 of 30,000 g. All active gloveboxes are assumed in this accident analysis

to contain their CPS inventory limit at the time of the seismic event, whether or not the gloveboxes are currently in use for storage or processing of material. This results in very conservative dose estimates for the active gloveboxes that more than offsets the potential material releases neglected for the inactive gloveboxes.

Conveyor gloveboxes are used for interglovebox material transfers. As stated above, conveyor gloveboxes are normally empty. Because active gloveboxes are assumed to be at their CPS Limits, it is logically consistent to exclude the conveyors from analysis (i.e., if material is in a conveyor, then at least one, and more likely two gloveboxes would have to contain less than the CPS limit).

In addition to the assumptions described previously, the Seismic Event Accident Analysis is based on the following:

- There is no processing in rooms 153, 145, and 149 of 234-5Z (previous SARs have discussed operations other than temporary storage)
- The AL only contains nominally one pound propane bottles limited to a total of six in 234-5Z, with no more than two simultaneously located in a single room.
- The inventories of plutonium present are assumed equal to the CPS limits as shown in Table 9-25, except as modified by Table 9-26. Table 9-26 presents administrative limits for select areas (e.g., the Standards Laboratory) or gloveboxes that are more restrictive (i.e., smaller) than the CPS limits. These administrative limits were derived specifically for the purposes of risk acceptance.
- Chemical storage is as described herein (molarity and concentration)
- There are no operations in the PPSL other than what is currently being performed (See Section 9.2.4.2.1.I.). Consideration of the PPSL Laboratory Prototype Calciner releases resulting from a seismic event are summarized in Section 9.2.4.9 and the details are shown in the Laboratory Prototype Calciner addendum to this FSAR. The calciner releases are not included in the total facility releases since the calciner is not currently authorized for operation.
- That $KMnO_4$ and glycerine are kept in separate rooms and that iodine and NH_4OH are kept in separate rooms.
- No plutonium metal production will take place.
- The E-3 and E-4 HEPA filters are not seismically qualified and are assumed to fall from the filter frames.

The scenarios are developed by reviewing the glovebox operations, design and support systems (air, chemicals, ventilation, etc.) used. The failures which could result in the dispersal of plutonium are listed. Qualitative arguments are used to narrow the list to the one or two "worst case" events. Section 9.2.4.6 discusses the worst event for the bulk of the facility. From the analysis it should be clear that this event does result in the largest dispersal of plutonium within that glovebox. Some attempt has been made to consider glovebox

interactions (i.e. an accident in one glovebox may make the accident in the other glovebox more or less severe), but it was almost always found that the worst case accidents were independent.

9.2.4.2.1 Accident Scenarios, 234-5Z Building.

9.2.4.2.1A Accident Scenario, 234-5Z Rooms 100 Through 130--These are offices, locker rooms, or rooms no longer in existence. No releases are postulated for these areas.

9.2.4.2.1B Accident Scenario, 234-5Z Rooms 131 Through 157, PFPAL--Laboratory analysis is performed in rooms 131 through 157 on samples received from PFP Operations or others. The samples are in the form of powder and solution. Measurements include fissile material content, impurities, isotopic content, SpG, sinterability, LOI for oxide powders, and particle size. The total dispersible Pu inventory in the PFPAL, PPSL, and standards lab is controlled to 12,450 g of which no more than 5,250 g is > 10% ^{240}Pu (see Table 9-26). Note that the sum of the local inventories allowed by criticality prevention specifications would be several times this amount. Some of the gloveboxes contain argon so that there could be an argon release to the room and through the laboratory. There are fire suppression systems in the laboratory so that an earthquake could result in a release of water to the laboratory. In addition, the following gloveboxes have had sources of energy in the past sufficient to disperse material to a greater extent than simple spilling.

- **Room 139**--Glovebox 5: storage of plutonium samples.
- **Room 143**--Hood 3 and glovebox 4: $C_2H_2O_4$ added to solution.
- **Room 144**--Hoods 7 and 8: storage of concentrated plutonium solution, and Hood 4: dissolve samples.
- **Room 145**--Sintering furnace.
- **Room 146**--Discussions with operations show H-1, -2, -3, and 4-146 are inactive. For H-5, which is still active, CPS-L-114-00020 (WHC 1991b) allows 2,500 g of dry Pu with no liquid present in the box or 1,000 g of dry Pu if up to 1 liter of liquid is in the box.
- **Room 149**--Dissolving plutonium compounds.
- **Room 152**--Glovebox 552: waste concentrator, caustic scrubber (Inactive).
- **Room 153**--Contains compressed air and nitrogen bottles, hydrogen generation system and piping, compressed air, liquid nitrogen and 150 to 250 g Pu per hood.

Due to changes in the laboratory operation, there is no processing in room 153 (no hydrogen generator, etc.), no sintering in room 145, nor is there any dissolving in room 149. The operation in room 143 is a manual laboratory operation (i.e., operator pours oxalic crystals, purges, then filters using bottles and beakers). The storage in room 144 is in polyjars inside tubes with taped-on tops. The storage in room 139 is in small vials about 5 or 10 mL. The

racks are metal and resemble test tube holders so that the vial is supported on the bottom by a metal plate and at mid-height by another metal plate.

Therefore the earthquake will be assumed to possibly result in:

- Containers in hoods "falling" out of the hood and onto the floor
- Containers in the gloveboxes falling over
- The shelves in glovebox 5 of room 139 falling, with subsequent dispersal into the room through the clear panels which are assumed to fall out (or shatter)
- Loss of argon into rooms
- Failure of the glass concentrator tank and pressurization of glovebox 552 (inactive) in room 152 due to a failure in the steam line
- Oxygen-aided fire in room 136 (arc from Quantimeter and oxygen release)
- One-pound propane bottle falls onto the floor and ignites (room 144).

9.2.4.2.1C Accident Scenario, 234-5Z Rooms 158 Through 165, 167, and 168--Shops or offices. No release postulated.

9.2.4.2.1D Accident Scenario, 234-5Z Room 166--Room 166 contains the plutonium solution storage gloveboxes HC-4 and HC-6, a hood (designated the "south" hood), and an encased plutonium solution transfer line. Neither glovebox is presently in use. Glovebox HC-4 contains six glass tanks, each containing up to 22 L of solution (water, nitric acid and plutonium nitrate). The criticality specification allows a total glovebox Pu inventory of 52.8 kg. Criticality is discussed in Section 9.2.4.2.11. Glovebox HC-4 is seismic qualified. Other events considered but judged not to be the most severe case are as follows:

- Failure of the tanks or piping (there is a criticality drain in the tank which does not appear to be able to be failed such that it will plug; however, criticality will be addressed later)
- Failure of the encased transfer line (the tanks have more volume than a transfer line does and will impact the floor from about the same height)
- Failure of the concentrated HNO_3 line (the room is locked and normally is not occupied--a more severe case would be a failure of the line somewhere else).

9.2.4.2.1E Accident Scenario, 234-5Z Rooms 169 and 170--Gloveboxes HA-40F and HC-46F are not in operation and contain no measurable plutonium inventory, so there is no contribution from these gloveboxes.

9.2.4.2.1F Accident Scenario, 234-5Z Room 171--Airlock.

9.2.4.2.1G Accident Scenario, 234-5Z Rooms 172 and 173-- Rooms 172 and 173 have floor storage of PR cans which will remain intact during a drop or fire.

9.2.4.2.1H Accident Scenario, 234-5Z Rooms 174 and 175--Rooms 174 and 175 are storage vaults containing cabinet (room 174) or pedestal (room 175) storage. Analysis shows that the pedestals will not fail, the anchors to the wall and floor will not fail, and the container will not come out of the holder (Vollert 1987a, 1987b). Ventilation is needed in these storage areas. Loss of ventilation could result in container pressurization due to energy buildup.

9.2.4.2.1I Accident Scenario, 234-5Z Rooms 179 through 189-- Rooms 179 through 189 comprise the PPSL. The gloveboxes in the rooms are used to support bench scale (mostly wet) chemical procedures to support process development. Examples of these procedures are dissolution, reclamation of plutonium from scrap, extraction, and small scale plutonium work such as using the scanning electron microscope (SEM), etc. The PPSL along with the analytical and standards labs have an administrative limit of 12,450 g dispersible Pu total of which no more than 5,250 g can be >10% ^{240}Pu. The gloveboxes and hoods in the PPSL are not seismically qualified. It will be assumed that the powders or solution spill onto the floor.

Consideration of releases resulting from a seismic event impacting the Laboratory Prototype Calciner are summarized in Section 9.2.4.9 and the details are presented in the Laboratory Prototype Calciner addendum to this FSAR. The laboratory calciner is not currently authorized for operation. Therefore, the releases are not included in the total facility release resulting from a seismic event.

9.2.4.2.1J Accident Scenario, 234-5Z Room 190--Room 190 contains pedestal storage. See Section 9.2.4.2.1H.

9.2.4.2.1K Accident Scenario, 234-5Z Rooms 192-A, 192-B, and 192-C-- Rooms 192-B and 192-C contain pedestal storage of plutonium compounds, and as such are similar to room 175. (See Section 9.2.4.2.1H.) Room 192-A has floor storage of Fast Flux Test Facility (FFTF) fuel pins and bundles in shipping containers which will not be ruptured during the seismic event.

9.2.4.2.1L Accident Scenario, 234-5Z Rooms 191, 192-D Through 221-B-- Offices, shops, etc.

9.2.4.2.1M Accident Scenario, 234-5Z Rooms 221-C, 221-D, and 221-E-- Rooms 221-C, 221-D, and 221-E are the Radiochemical Standards Laboratory. The Radiochemical Standards Laboratory contains NDA equipment, balances, blenders, etc. for the making up of standards. The plutonium is in liquid or oxide form, but is normally doubly contained, except for that being used. Dispersal is similar to that in rooms 131 through 157.

9.2.4.2.1N Accident Scenario, 234-5Z Rooms 222, 223, 224, and 226--Except for room 224, no radioactive materials are present in these rooms. Storage of special containers (PR cans, L-10s, etc.) is allowed in room 224. The multiple-confinement features of these containers preclude release of the contained fissile materials.

9.2.4.2.1O Accident Scenario, 234-5Z Room 225--Room 225 is a storage vault. Fixed array storage in cubicles is allowed for laboratory standards samples. Seismic evaluation of the vault (Vollert 1987b) recommended installation of struts between the vault east and west walls and attached to the top of all shelve units

to ensure seismic resistance of the shelve storage units (cubicles). Inspection of the vault (Letter 1AK00-00-005, R. A. Giller to R. E. Gregory and M. D. Talbot, 2/22/2000) indicates the recommended struts were installed. The shelve cubicles are equipped with locking doors. The locking cubicle doors prevent material containers from falling from cubicles and the struts ensure the shelve units do not tip together at their tops as a result of a seismic event. Ventilation is needed in these stroage areas. Loss of ventilation could result in container pressurization due to overheating. This is discussed further in Section 9.2.4.6.3.1I.

9.2.4.2.1P Accident Scenario, 234-5Z Room 227--Plutonium solutions from PRF are pumped into the tanks in HC-227S. Plutonium solutions are also drawn from PR cans using equipment in HC-227T, which also pumps the solution to HC-227S tanks. The worst case event in this room is the failure of the discharge line of the pump used for recirculation of the solution near the top of the tank, coupled with a failure of the glovebox panels and creating a fountain-like situation. Other failures considered were line break, tank failure, and trolley falling onto a PR can in HC-227T. The trolley will likely not tip the PR can over as the trolley is small. Since the PR can is used in shipping, it must be able to withstand impact loads so that if tipped there should be no spill. If there is a spill, the amount of solution made airborne is much smaller than the case where the discharge leg of the pump fails. A similar case can be made for the line break and tank failure. Criticality will be discussed later in Section 9.2.4.2.11.

9.2.4.2.1Q Accident Scenario, 234-5Z Room 228-A--Room 228-A is one of the three rooms which house the RMC Line. It contains gloveboxes HC-7, HC-9B, HC-10, HC-11, and conveyor HC-1. Each glovebox will be considered separately.

Accident Scenario, 234-5Z Room 228-A HC-7. Glovebox HC-7 contains equipment to chemically adjust plutonium-HNO_3 solutions [convert any (VI) or (III) to (IV) and achieve the proper HNO_3 balance and molarity], and adjust the offgas and filtrate from the processes in HC-9B. Failures that were considered were:

- The HNO_3 transfer line break
- The H_2O_2 line failure
- Failure of tanks in the glovebox
- The $KMnO_4$ line failure inside or outside the glovebox
- A larger and more rapid addition of H_2O_2 to the Pre-Reduction Tank (PRT), as compared to the flowsheet (pressurization of the tank)
- Discharge leg failure on the pump that transfers the solution out of the Transfer Head Tank (THT) to HC-9B (either coupled with encasement failure or glovebox panel failure--could also be coupled with failure in the valve between the PRT and the THT, resulting in additional solution dispersed).

The worst case radiological events will be either the fast addition of H_2O_2 to the PRT [H_2O_2 reacts with PuO_2 $(NO_3)_2$] to liberate oxygen which could pressurize the tank] or the failure of the discharge line on the pump. Both will be investigated. The worst case toxicological release is considered to be the

reaction between $KMnO_4$ and H_2O_2. The reaction liberates some oxygen but not enough to pressurize the room; however, the failure of the peroxide line may result in a toxic material release.

Accident Scenario, 234-5Z Room 228-A HC-9B. Glovebox HC-9B contains the chemical reactor, the screw calciners, and the offgas equipment (condenser, vacuum receiving tank, etc). In the reactor, plutonium HNO_3 was reacted with $C_2H_2O_4$ to make plutonium oxalate. In the screw calciners, the plutonium oxalate was converted to PuO_2. Failures that were considered are:

- Failure of the transfer line to the chemical reactor
- A 90-lbf/in^2 air line fails inside the glovebox
- Calciner screw stops but heat addition continues
- Buildup on the vacuum filter
- Oxalic acid flood in glovebox if the valves upstream of the spray nozzles above the vacuum drum filter (VDF) fail open
- Buildup of PuO_2 in the glovebox if the line to the second-stage calciner fails closed or the line clogs
- Release of calciner offgases into the glovebox [rather than the condensate receiver tank (CRT)]
- Failure of 90-lbf/in^2 air (PRV) coupled with the Hopper Feed Control (BANJO) valve failure results in dispersed PuO_2.

To determine the worst case events, many arguments were considered.

Seismically induced criticality is incredible in this glovebox. A criticality may only be possible if many batches of plutonium oxalate or PuO_2, remain in this glovebox without notice. Even then, it is necessary that other containers not part of the actual process be brought in close proximity to the process and therefore there are no other containers in the vicinity to result in a critical mass. The assumption made for the seismic event is normal processing is occurring just before the earthquake.

Cessation of the rotation of the calciner screw results in hot oxide. Glovebox floods are no real concern because flooding is not an efficient dispersal mechanism. The room drains are safe with respect to criticality. Failure of the 90-lbf/in^2 air in the glovebox will not cause any damage as the panel will just pop out, or the gloves pop off, or the sphincter covers fly off because the lines are of small diameter and there are many flow paths out of the glovebox. The worst radiological case is a failure such that unregulated 90-lbf/in^2 air flows into the calciner coupled with a failure of the BANJO valve or calciner discharge line, resulting in a spread of plutonium powder (or both). Both will be investigated.

Accident Scenario, 234-5Z Room 228-A HC-10. Glovebox HC-10 was historically used to weigh powder pans of PuF_4. The glovebox is currently inactive. No release is postulated for this glovebox.

Accident Scenario, 234-5Z Room 228-A HC-11. Plutonium storage glovebox HC-11 has 12 storage locations, with a CPS limit of one 1.7-L powder pan or one 0.5-L slip-lid can per location. Each container is limited to 2.5 kg Pu, as dry PuO_2 powder.

The potential for a seismically induced criticality for the possible accumulation of fissile material in glovebox HC-11 is evaluated in Section 9.2.4.2.11.B, under "Accident Scenarios-Criticality." In view of the multiple error conditions or other pre-existing contingencies required, a criticality caused by seismic effects is judged not credible for this glovebox.

The glovebox remains standing so the only dispersal mechanism is if the powder pans move out the side that connects with glovebox HC-1; and if the panels on glovebox HC-1 fall off, some of these pans may fall to the floor.

9.2.4.2.1R Accident Scenario, 234-5Z Room 228-B--Room 228-B contains gloveboxes HC-12S, HC-15A, B, C, and HC-16CC, all of which are inactive. Glovebox HC-13MD is used as a seal-in/seal-out location for materials entering or leaving the thermal stabilization process. There is a CPS limited 2500 g plutonium and the glovebox is not seismically qualified. The 2500 g are assumed to be available for release.

9.2.4.2.1S Accident Scenario, 234-5Z, Room 228-C--Room 228-C contains gloveboxes HC-17DC, HC-17P, HC-17SBB, HC-18BS, and HC-18M. Gloveboxes HC-17-SBB, HC-17DC, and HC-17P are inactive.

Accident Scenario, 234-5Z Room 228-C HC-18BS. Glovebox HC-18BS contains 20 locations for slag storage of PuO_2 in 0.5-liter slip-lid cans or 1.7-liter powder pans. Storage of metal buttons was also allowed, up to 50 kg total, as a carry-over from previous operations. However, as containerized compound powders, the critically specifications permit a maximum of only 20 kg Pu total in the glovebox. The conveyer is not seismically qualified but it is considered extremely unlikely that a seismic event would generate sufficient vertical force for a can to jump out of the storage location. Even if a can were to fall to the floor and rupture, also an unlikely event, the glovebox is seismically qualified and so the release would be insignificant.

Accident Scenario, 234-5Z Room 228-C HC-18M. Sieving, grinding, sampling, packaging, weighing and bagging out of thermal stabilization product material is performed in this glovebox. The glovebox has a total Pu inventory limit of 10,000 g. This material is subject to release in a seismic event due to potential failure of the glovebox.

9.2.4.2.1T Not Used

9.2.4.2.1U Accident Scenario, 234-5Z Rooms 230-A and 230-B--Room 230-A contains glovebox HC-21C; room 230-B contains glovebox HC-21A. The contents are assumed to exit the gloveboxes and fall to the floor.

9.2.4.2.1V Accident Scenario, 234-5Z Room 230-C--Room 230-C contains glovebox HC-60, which is inactive. Room 230-C also contains glovebox HC-230C-2, which is used for plutonium-bearing solution stabilization, and conveyor glovebox HC-3.

The Magnesium Hydroxide Precipitation Process gloveboxes, HC-230C-3 and HC-230C-4, are located in this room. The effect of a seismic event on these gloveboxes is discussed in Section 9.2.4.10.

Accident Scenario, 234-5Z Room 230C, Gloveboxes HC-230C-2 and HC-3. Glovebox HC-230C-2 was added to the RMC Line after the analyses originally developed for this section were completed. The potential release mechanisms associated with the radiological inventory in glovebox HC-230C-2 are developed separately in Section 9.2.9.4. Conveyor glovebox HC-3 only contains PuO_2 powder in slip lid cans on a very short-term basis--just long enough to transfer the powder to glovebox HC-18M for packaging. No release is postulated from conveyor glovebox HC-3 in the seismic event as it is unlikely to contain any radiological material at the time of the event.

9.2.4.2.1W Accident Scenario, 234-5Z Room 232--Room 232 contains glovebox HA-46, which is inactive.

9.2.4.2.1X Accident Scenario, 234-5Z Room 235-A-3--Room 235-A-3 houses the oxide section of the old RMA Line, which is inactive. It is assumed that all of the gloveboxes in this room will topple because they are last on the list to be strengthened (as the line is cleaned out and inactive). The old RMA line is inactive. The gloveboxes were cleaned out in preparation of deactivation and decommissioning activities. As with the 242-Z Building discussed in Section 9.2.4.2.7, the residual material in the old RMA line is expected to be contained within process equipment and to be tightly adhered to surfaces. The releases from the gloveboxes in this room would be small in comparison to the releases from active areas of the plant and are not included in the dose consequences analysis for the seismic event.

9.2.4.2.1Y Accident Scenario, 234-5Z Rooms 235-A1 and 235-A2--Rooms 235-A1 and 235-A2 house gloveboxes which are inactive.

9.2.4.2.1Z Accident Scenario, 234-5Z Room 235-B--These contiguous rooms constitute a single area and contain gloveboxes HA-19, HA-20MB, HA-21I, HA-22B, HA-23S, conveyor HA-28, 235-B-2, 235-B-3, and part of conveyor HC-4. Only gloveboxes HA-21I, HA-22B, HA-23S, HC-4, and HA-28 are active. Glovebox HA-20MB may be used for future processing and is included in the accident scenarios. Conveyor HA-28 and HC-4 are normally empty.

Accident Scenario, 234-5Z Room 235-B HA-19--HA-19 is assumed to contain up to 2,500 g PuO_2 for conservative analysis purposes.

Accident Scenario, 234-5Z Room 235-B HA-20MB. Glovebox HA-20MB is used for cementation of low-level radioactive waste. The material is subject to disperal in the glovebox.

Accident Scenario, 234-5Z Room 235-B HA-21I. Glovebox HA-21I is used for reactive material stabilization. The material is subject to dispersal in the glovebox.

Accident Scenario, 234-5Z Room 235-B HA-22B. Glovebox HA-22B may be used for seal-in or seal-out of material stored in Glovebox HA-23S, or to stage materials destined for processing or just processed in glovebox HA-21I. The

Pu inventory limit for the glovebox is 2,500 g. Glovebox HA-22B is seismically qualified.

Accident Scenario, 234-5Z Room 235-B HA-23S. Glovebox HA-23S is used to store scrap. The material is stored in polyjars placed in storage carousels. Criticality considerations are discussed later in this section. Dispersal within the glovebox is also possible.

The Bagless Transfer System glovebox, HA-53BTS, is also located in this room. The release from this glovebox as a result of the seismic event is discussed in Section 9.2.4.11.

9.2.4.2.1AA Accident Scenario, 234-5Z Room 235-C--Room 235-C houses gloveboxes 235-B-2, 235-B-3, and 235-B-4.

9.2.4.2.1BB Accident Scenario, 234-5Z Duct Level--The 234-5Z duct level contains E-3 and E-4 ducts, filterboxes, chemical addition piping, and gas piping. Forces from the earthquake can result in piping failures with subsequent liquid or gas release, suspension of radioactive material within the duct and filterbox, or potential failure of the supply ducts. The E-4 ducts do not fall to the floor as a result of the earthquake, according to the latest structural calculations. It is also assumed that the seismically qualified filter boxes remain standing. The case of the filterboxes falling is in the *B Plant Preliminary Accident Analysis*, WHC-SD-WM-TI-385 (Marusich 1989) and 9.2.4.6.3.1W. The plenum downstream of the filter rooms also contains some radioactive material which could either be suspended within the intact duct or suspended in the duct level when the duct fails. Process vacuum lines around the plant contain about 4.3 kg plutonium total. This material is not dispersible as it is tightly (and possibly chemically) adhered to the vacuum lines (Schilling 1989).

9.2.4.2.1CC Accident Scenario, 234-5Z Second Floor--The second floor (third level) contains offices, chemical makeup tanks, and the filter rooms. The seismic forces could result in filter failures, loss of filter integrity, or chemical solution release (see Section 9.2.4.6.3.1.X.b). It will be assumed that the room filters fail in such a manner that they provide no filtering ability.

9.2.4.2.1DD Accident Scenario, 234-5Z Pipe Tunnels--The tunnels beneath the building house the drain lines which take waste solutions from the first floor and direct them to the waste tanks in 241-Z. Seismic forces may result in drainpipe damage. The transfers in these pipes are small, about 200 L, and have low Pu concentrations. This scenario is assumed to be bounded by failure of the 241-Z tanks analyzed in Section 9.2.4.6.3.8.

9.2.4.2.2 Accident Scenario, 236-Z PRF. The PRF processes are no longer operational. The seismic accident analysis for the PRF assumes the facility is fully operational, the accident analysis will be updated to reflect the current shutdown condition of the facility in a future revision to this FSAR. Assuming a fully operational PRF results in conservative seismic release estimates for the PRF that adequately represent or bound releases that could occur from failed piping or tanks during cleanup of the facility.

The accident scenarios postulated for the 236-Z facility are listed below. The assumptions are the same as were used in 234-5Z. Additional assumptions are as follows.

- The seismic forces result in random valve actuation, interlock failures, etc. The worst case combination will be considered here.
- The seismic-force-induced piping or duct failures are assumed to occur if the consequence of having intact piping or ducts is less severe.

- The facility gloveboxes are in operation and running smoothly. This is assumed because the probability of off-normal conditions coupled with the earthquake is considered incredible.

As a result, the approach used to determine hazardous conditions brought on by seismic forces is an investigation of release mechanisms due to abnormal processing (e.g., operation of a column without one of the inlet streams).

9.2.4.2.2A Accident Scenario, 236-Z Solvent Extraction--The solvent extraction portion of the PRF included the canyon, the east and west gloveboxes, the third floor instrument gallery, and the fourth, fifth, and sixth floor extensions of the CA and CC column glovebox. The chemical addition system in the east and west gloveboxes is also included.

Criticality considerations were built into the design. This analysis considered the above as well as other events. Table 9-27 provides a listing of the events considered.

9.2.4.2.2B Accident Scenario, 236-Z MT--Gloveboxes MT-1, MT-5 and MT-6 were the only gloveboxes with hazards that could be seismically induced. Glovebox MT-1 (inactive) was used for inspection (scrap burning is no longer done); MT-3 (inactive) was used for electrolytic dissolution; MT-4 (inactive) was used for the distillation of polystyrene cubes but is not operational; MT-5 (inactive) was used for dissolution; and MT-6 (inactive) was used for centrifuging the PRF solutions as well as storing dissolved solutions. The hazards postulated are as follows:

- Fire in MT-5 (9.2.4.2.12.A)

- Seismic initiated criticality in MT-5 (9.2.4.2.11.M)

9.2.4.2.2C Accident Scenario, 236-Z S&C--S&C is no longer in operation.

9.2.4.2.2D Accident Scenario, 236-Z Remainder of PRF Facility--Seismically induced hazards for the remainder of the PRF are:

- Tank or line break in chemical preparation area

- Chemical reactions due to the mixing of two or more solutions in chemical preparation

- Crane derails over tanks in canyon.

- Seismic-induced criticality in West Gallery glovebox (9.2.4.6.3.2.A.a)

9.2.4.2.3 Accident Scenario, Product Handling at 234-5Z and 236-Z. The product handling aspects of 234-5Z and 236-Z are, for the most part, immune to seismic forces. Spills of powders or solutions could occur if the earthquake occurred at the time of filling of the PR cans, for example. Usually the powders and solutions not in the process are in either gloveboxes, hoods (in the labs), or in storage rooms. If these materials are stable (as compared to reactive), they are packed in sealed containers and stored. If they are reactive they are placed in vented containers and stored in gloveboxes or, if the containers are PR cans, in storage rooms (the vent has a filter in the vent path). The seismic forces cannot result in a release of stabilized material as the packing or storage will preclude damage, given that the facility is not damaged. That is, PR cans stored on the floor will not tip over, and double-packed containers will not fail if they fall out of the storage location. This determination is based on tests in which slip-lid cans filled with 400 to 600 g of damp sand or basalt cuttings that were dropped from heights from 4 to 14 ft without any loss of material or can damage (Reichmuth 1988).

Releases can occur due to reactions, such as scrap fire in room 170 of 234-5Z or the release of plutonium solutions. Fire is considered in Section 9.2.4.2.12. The releases due to the breaking open of bulged drums or dropping of a PR can on the dock cannot be seismically induced and are not considered credible.

9.2.4.2.4 Accident Scenario, Vaults. There is no release of plutonium from the vaults because of the following considerations. There are vaults in 234-5Z that contain pedestal storage, a vault that contains shelf cubicle storage, and vaults that contain floor storage. The vault structures are not damaged by seismic forces (Marusich 1988b) and the containers do not fall out of the pedestals (Vollert 1987a, 1987b). Recommended upgrades to vault 225 shelf cubicle storage (Vollert 1987b) were performed. The shelf cubicle storage units remain upright during the seismic event and locked cubicles prevent containers from falling to the floor. The PR cans will not tip over. Loss of ventilation results in a slow heatup of containers, which could result in pressurization; but by the ideal gas law, a rise in temperature of 200 °F only results in a pressure increase to 19.8 lbf/in^2 (absolute). The can is able to withstand this [Szempruch (1984) containers can withstand up to 100 lbf/in^2]. In the unlikely event that a can fails, the second container, being much larger, will see a much smaller pressure increase. Note that the ventilation will only be off a short period of time (maybe weeks) compared to the time it takes to bulge a container. See Chapters 5.0 and 8.0 for further discussion concerning container features for the various vaults in 234-5Z.

9.2.4.2.5 Accident Scenario, Other (234-5Z and 236-Z). A walk through the 234-5Z and 236-Z Buildings revealed other potential hazards. These are:

- The HNO_3 storage tank failure
- Failure of the drain lines between 241-Z and 234-5Z

- Failure of a high pressure nitrogen tank (south side near the west corner of 234-5Z)

- Internal floods resulting from fire line failures

Note that the HNO_3 storage tank has been drained and it is not in service. An analysis of the impacts of a HNO_3 spill has been retained as it represents, from a historical perspective, the bounding chemical hazard (see Section 9.2.4.6.3.5.D).

9.2.4.2.6 Accident Scenario, 2736-Z Complex. The 2736-Z complex consists of 2736-ZA, -B, and -Z. Potential hazards are:

- Argon release due to an argon pipe failure to displace air in a room
- Flooding due to a failure in the fire system
- Container heatup due to ventilation failure
- Criticality (see Section 9.2.4.2.11).

In addition to the above hazards, a plutonium-release in 2376-Z due to the seismically-induced failure of a storage container is postulated. As discussed in Section 9.2.4.1.1, Building 2736-Z is seismically-qualified as are the storage racks contained therein. Therein, for this release to occur the seismic event must be coupled with a human error such that a storage container falls from the rack.

9.2.4.2.7 Accident Scenario, 242-Z. This facility was discussed in Marusich (1988a). The conclusion drawn was that the particles of plutonium left after cleanout of these gloveboxes are tightly adhered to the surfaces. The oxide powder left is hygroscopic and, as a result, has increased in size and diameter. Therefore, the portion of respirable particles is less than in-process powders and, as shown in Marusich (1989), the release fraction for contamination of glovebox walls is small.

The *242-Z Seismic Analysis*, WHC-SD-CP-DA-020 (Giller 1989a) indicates that the 242-Z facility will survive the DBE seismic forces. Although the gloveboxes may collapse, there is no additional dispersive force (building collapse).

Haas (1990) concludes that the plutonium in 242-Z was originally present in the form of residues or sludges associated with wet processes. The estimated holdup is 330 g, but formal Nuclear Materials Accounting records show no plutonium in 242-Z. Therefore, the holdup is dispersed. Two-thirds of the holdup is estimated to be in 9 tanks (20-30 g per tank) and one third on floors and hoods (Haas 1990). It is also believed that the holdup estimate is a factor of 8-10 high based on the fact that all the solution was transferred to the PRF and the columns were drained and the rashing rings disposed (Haas 1990). For purposes of accident analysis 110 g are assumed to be on walls and in the hoods. The quantity in the tanks will not be dispersed.

9.2.4.2.8 Accident Scenario, 232-Z. The 232-Z Building has been cleaned out but still contains some residual contamination. The facility is no longer in use. The structure has been analyzed to see if it will survive the seismic forces. Based on the analysis, it is concluded that the structure will

survive a 0.09-g seismic event but is not qualified for a 0.20-g event. Therefore, releases may be expected to occur for seismic events greater than 0.09-g. Consequently, for both the 0.09-g and 0.20-g events, it is conservatively assumed that the building will collapse and that some of the contamination will become airborne (see Marusich 1988a for assumptions for contaminated gloveboxes).

9.2.4.2.9 Accident Scenario, 291-Z. The 291-Z structure has contamination in it. The structure can survive the earthquake (URS 1980), but the seismic forces might dislodge some of the contamination.

9.2.4.2.10 Accident Scenario, Building 241-Z. The 241-Z structure contains waste tanks in cells covered with coverblocks. Constructed above the cells is a pre-engineered steel structure to provide weather protection and support for monorail crane hoist (see Section 5.2.4). It is assumed that the weather enclosure will withstand a UBC, no analyses have been performed. Therefore, this analysis assumes the structure will fail given an earthquake at or above 0.09 g horizontal with a frequency of 2×10^{-3}/yr. The coverblocks have been restrained so that they do not fall into the tanks. No analyses have been performed to determine if the coverblocks will remain intact if the crane, crane support structure or the building support structure collapse and strike the coverblocks. If the coverblocks fail due to the collapse of the steel structure or the crane falls there is a potential for a release to the atmosphere and soil column (see Section 9.2.4.6.3.8).

9.2.4.2.11 Accident Scenarios-Criticality. Areas in which a seismically induced criticality is conceivable are those that already contain a critical mass which is separated into several subcritical masses during operation. This condition comes as a result of the assumption of normal processing (no double batching) and no pre-existing failures (operator brings another container close by). Critical masses are taken from the figures in the Criticality Handbook (Carter et al. 1969):

- A 24-kg Pu powder sphere (unreflected, 3% ^{240}Pu, density is 2 g/cm^3, Figure III. A.9 (97)-4). Note that the value is about the same for density up to 10 g/cm^3
- A 11-kg Pu powder sphere (fully reflected, 3% ^{240}Pu, density is 2 g/cm^3, Figure III.A.9(97)-4)
- A 17-kg Pu powder sphere (reflected by 1 in. of water, 3% ^{240}Pu, density is 2 g/cm^3, Figure III.A.9(97)-4.

Note that Figure III.A.9(100)-5 shows, that if the powder is dry the values are about a factor of 20 higher.

- A 9.5-kg Pu metal sphere (unreflected, 3% ^{240}Pu, Figure III.A.9(97)-4, density is 19.6 g/cm^3)
- A 5-kg Pu metal sphere (fully reflected, 3% ^{240}Pu, Figure III.A.9(97)-4, density is 19.69 (g/cm^3)
- A 2-kg to 10-kg Pu solution (function of concentration, molarity of solution, reflection, and depth).

Examples for a plutonium (3% ^{240}Pu) nitrate solution are:

- Critical slab, full reflected requires an aerial concentration of 350 to 450 g/ft^2 and a 12 in. deep pool (p. III.A.8.100-1)
- Infinite cylinder, fully reflected 7- to 8-in.-diameter cylinder with 150 g/L or 9- to 10.5 in.-diameter cylinder with 30 g/L (p. III.A.4.97-1).

There are a relatively small number of gloveboxes in which a critical mass or concentration of Pu is conceivable. The locations where there are potential quantities of materials in excess of a critically safe mass (if all the material in the form allowed in the glovebox were to somehow be gathered into the optimum configuration and reflected) are:

- Vaults in 234-5Z and 2736-ZB
- HC-11
- HC-18BS
- HA-23S
- HC-4
- HC-227S
- 2736-Z
- HC-21A
- HC-21C
- HA-21I
- HC-18M
- Glovebox 5 in room 139
- HC-7
- HC-6 (inactive)
- Glovebox 522 in room 152
- MT-5 (inactive)
- West glovebox PRF
- HC-9B in room 228A
- MT-6 in 236-Z (inactive)
- Glovebox HC-230C-2 in room 230C

The above identified locations are analyzed in the following subsections. Criticality considerations for the Magnesium Hydroxide Precipitation Process gloveboxes, HC-230C-3 and HC-230C-4, are discussed in the related addendum (Carson 2000) to this FSAR. Criticality considerations for the Bagless Transfer System glovebox, HA-53BTS, are discussed in the related calculation notes (FH 2000).

9.2.4.2.11.A Accident Scenario-Criticality, Vaults (see also Sections 9.2.4.2.1H, 9.2.4.2.1L, and 9.2.4.2.11.F)--The criticality considerations in the design of the vaults have been discussed previously. Shelf storage cubicles will not tip together and containers will not fall from the cubicles; the storage pedestals will not fail and the containers will not pop out of the pedestals. Even if a water line broke, the spacing is such that a criticality is not possible. None of the vaults in 234-5Z have water lines in them. Only the 2736-Z room 2 has a water system, and this room has shelf storage (containers cannot float to the top of the room even if it is conservatively assumed that the room fills with water). Building 2736-ZB, rooms 638, 641, and 642 contain shipping containers (similar to a 55-gal drum), and they

contain a wet pipe sprinkler system. Shipping limit requirements and spacing will preclude a criticality even if the water line fails. Therefore, there are no seismically induced criticalities in the vaults.

9.2.4.2.11.B Accident Scenario-Criticality, HC-11--Glovebox HC-11 could contain 12 powder pans, each containing 2,500 g PuO_2. The total quantity of powder, if placed into a sphere, is not critical; but if wetted and moderated, it is. The total quantity of PuO_2 cannot be dispersed into a spherical shape (or be thick enough to be a critical slab) because of the following.

- The powder pans are relatively large with respect to all the glovebox dimensions (i.e., when all 12 pans are in the box, there is little room left as each pan chamber is about one-fourth of the glovebox diameter and about one-half of the available height).
- The pans are not filled to the top.
- The structure that supports the pan conveyor is made of three layers of thick channel or angle iron welded into a squat structure that almost fills the glovebox. The conveyor structure may bounce around but will not collapse (Ocoma 1990a). Collapse on one side only is needed to get the powder to "flow" down to one end (or corner).
- Glovebox HC-11 is completely open on one end to HC-1 and HC-11 floor is about 6 in. above HC-1 floor. Glovebox HC-1 has a criticality drain on the far end. Any powder that is wetted will tend to follow the stream, but since the powder is heavier than water, it will deposit along the way. It would require many very specific failures for the assumed water "supply" to the glovebox to wash the necessary amount of powder out of the powder pan (like washing and out of a bucket) to result in a criticality as the only water is a fire main near the glovebox.
- The assumed water supply is the fire protection piping in 228-A. If this pipe fails as a result of the earthquake, the stream of water will likely be directed downward or along the axis of the pipe. The pipe failure would have to be a split in the pipe in the exact location as the glovebox. That is, a split about 3 ft wide or less would have to occur in line with HC-11 and nowhere else. There is no stress intensification factor at this location (no anchor, elbow, etc.).
- The top glovebox panel would not fail completely. The top panel will likely crack or drop into the box, neither of which allows the assumed water supply to sluice out all the powder.

As a result, a criticality in HC-11 is incredible.

9.2.4.2.11.C Accident Scenario-Criticality, HC-18BS--RMC Line area Glovebox HC-18BS is used to receive boats of dry plutonium bearing materials from the thermal stabilization process. Canned plutonium bearing materials are also expected to be stored in the glovebox, as well as multiple boats containing plutonium and/or uranium in metal or oxide forms. The CPS allows for 20 containers each containing 2500 g Pu, or 50,000 g total in the

glovebox. HC-18BS is a "dry" glovebox where no internal solution lines are present. Except for a maximum of 50 ml of lubricants, no free liquids are allowed in the glovebox. The CPS also establishes specific spacing, H/Pu, container volume, and unit mass limits where appropriate.

The glovebox is seismically qualified. The structure supporting the glovebox does not collapse as a result of a DBE. HC-18BS is constructed in a similar manner to HC-11, in that the conveyor that holds the powder in slip lid cans or powder cans is supported by three levels of thick angle iron and "C" channel so that it will not collapse. The containers are supported by a metal cup-like holder that is surrounded by a thick, large-diameter ring. Furnace boat holders are used to support and restrain boats that are placed onto a pedestal position. The material containers are separated on the conveyor by pins about 5/8 in. long. The CSER credits the conveyor pedestal design with limiting the number of containers that may fall to the glovebox floor as a result of a DBE. The CSER identifies there are two sprinklers of the non-seismically qualified room fire suppression system above the glovebox. During a DBE, the top panels of the glovebox may be breached and water entry into the damaged glovebox is likely. Full flooding of the glovebox is avoided either by the failure of attached non-seismically conveyor gloveboxes HC-1 and HC-2, or the function of the glovebox HC-1 and HC-5 criticality drains. The CSER documents that under DBE conditions with fire suppression water entering the glovebox, four dislodged containers on the glovebox floor directly below another similar container on the conveyor would not result in unacceptable material interaction k effective.

Therefore, as a single contingency, a seismically induced criticality in Glovebox HC-18BS is not credible. Additional violations of CPS limits combined with a DBE would have to occur simultaneously before a criticality is possible.

9.2.4.2.11.D Accident Scenario-Criticality, HA-23S--A seismically induced criticality will not occur in glovebox HA-23S. In this case the conveyors are on four levels within the glovebox. However, the conveyors are supported by (i.e., welded to) the side walls or the floor. The support is angle iron with thick channel spanning each half of the elliptical conveyor. The containers are slip-lid containers which are vented. The containers sit in a bucket whose sides are at least half as long as the cylinder. The basket is positioned in the ring which is positioned on the conveyor using metal rods (3/4 in.). The radioactive material does not fill the container. There is no water near the glovebox, and the glovebox is mostly metal. Because of the above, there is no reasonable mechanism to pile enough containers together to get a critical mass.

In addition, the Criticality Safety Evaluation Report (CSER-91-007) for this glovebox shows that if all of the material presently stored (0.5-L polyjars with 1000 g maximum) fell to the floor, the areal density of plutonium (grams per square foot) is not high enough to result in a criticality. Jumbled containers would actually be confined to their original level.

9.2.4.2.11.E Accident Scenario-Criticality, HC-4 and HC-227S--The following data is summarized from various Criticality Safety Analysis Reports (CSAR) covering HC-4 and HC-227S (Doto 1989).

Glovebox	Glovebox floor area	Minimum Critical Solution Depth (cm)	Solution volume at critical depth (L)	Total tank volume (L)
HC-4	25,300 cm^2	9.65	244	142
HC-227S	22,326 cm^2	9.65	215	190

Criticality would require additional solution or water over that contained in the tanks. This would require a plugged criticality drain and the addition of liquid from an external source.

The actual depth required for criticality depends on the amount of plutonium on the floor. If sufficient plutonium is not available, criticality cannot be achieved at any depth. According to the Criticality Handbook (Carter et al. 1969), Figure III.A.8.95-2, an infinite slab of plutonium nitrate (5 wt% 240) would have a minimum critical areal density of 270 to 400 g Pu/ft^2 depending on reflection conditions and the amount of excess nitrate ion. This would correspond to a minimum somewhere between 6.5 and 10.9 kg Pu on the floor of these gloveboxes.

Based on the above, criticality due to solution on the floor would require the following steps.

1. Have an adequate amount of plutonium in the glovebox (greater than 6.5 kg). Adequate amounts exist periodically in HC-227 and HC-4.

2. Plug the criticality drain. (A pre-existing failure.)

3. Leak the plutonium solution to the floor.

4. Add enough other liquid from an external source to achieve a critical depth. This would require breaching the upper part of the box to allow the entry of liquid (e.g., water from a fire main) while the lower part remains sound to contain the liquid. This is more than 22 L in glovebox HC-227S and greater than 116 L in HC-4.

In HC-227S, there is a chemical addition tank that has a motor-operated valve on the downstream leg. It is assumed that the earthquake causes opening of the valve, the draining of this tank into the glovebox, and the breaking of the storage tanks. It is further assumed that the criticality drain remained plugged. These failures do not result in a criticality in HC-227S because the tank only contains 3 L.

A similar situation to HC-227S is HC-4, but the valve on the downstream side of the tank is a manual valve and thus will not fail open. In addition, far more additional solution is needed for this glovebox to go critical (about a hundred liters as compared to tens of liters). The chemical addition tank does not have sufficient volume to result in a criticality. Processes associated with HC-4 are currently inactive.

Therefore, there are no seismically induced criticalities in gloveboxes HC-227S or HC-4 since their support structures are seismically qualified so that toppling or tipping does not occur.

9.2.4.2.11.F Accident Scenario-Criticality, Criticality in 2736-Z or 2736-ZB Due to Flooding--The containers and storage in 2736-Z and -ZB cannot go critical assuming water or water spray addition as the quantities in storage are limited by criticality prevention specifications to be safely subcritical under these conditions (see Breaking of a Fire Main in an Area with Room Storage of Fissile Material (Altschuler 1989a).

Room storage is currently allowed in the presence of fire mains. The question arises as to the effect on criticality safety should the main break, flood the room, and cause the storage containers to float off the floor.

This accident condition requires that the rooms be sufficiently water-tight and that the flow from the broken main is not shut off in a timely fashion.

It is assumed that arrays consisting of more than one layer are spread out into a one-layer array unless restricted by the size of the room. This will tend to lower the surface density (the amount of fissile material per unit area of floor) and thus the reactivity.

Should the fire main fail and flood the room, the array will now be reflected by water on all sides instead of concrete walls and floor. The water between the containers will add a reflecting moderator. When sufficiently thick (i.e., the containers drift about 6 in. apart) the containers will be neutronically isolated from each other.

Presumably any containers that fill with water, either because of leaks or an open outer container, will sink to the floor of the room. An accident in which fissile solution can leak into the water requires a preexisting failure which is not considered in this report.

For the case where the fissile material stored is highly moderated, the actual surface density is less than 100 g Pu/ft^2. The minimum surface density required for criticality is 240 g Pu/ft^2. The exception to this is for solution containers (i.e., PR cans, L-10s, etc.). These are limited to 10 L which is well within the limits of surface density in liter per square foot for fissile solution.

Amounts up to 4,500 g Pu stored as slightly moderated material (H/Pu<20) in birdcages will be safely subcritical. The water surrounding the water-tight containers will be sufficient to isolate the fissile units from each other. The minimum critical mass for full water reflection is a 5.4 kg alpha metal sphere (Carter et al. 1969, pages III.A-2). The actual critical mass required will be larger since the fissile density may be lower, the shape is less ideal than a sphere, and the container walls will absorb neutrons.

For slightly moderated material stored in L-10s or L-3s, the only reactivity effect would be caused by the moderation and reflection of water between the barrels. The 6- to 8-in. air gap between the water and fissile material will appreciably reduce this effect. From the geometry, the

probability of a neutron reflected by the water striking fissile material is at least as low as one-third and more likely less than a tenth. Monte Carlo calculations have been made using the MONK code and the UKAEA cross-section library. These modeled an infinite array of DOT-6Ms with two 2.5-kg Pu metal buttons one atop the other on the bottom of the container. For conservative results, no ^{240}Pu or structural material was used. The DOT-6M was smaller than L-10s or L-3s and would have a higher reactivity and thus be a more conservative case. Results for K_{eff} were 0.8787 $\pm$0.0081 (MSA247), 0.9866 $\pm$0.0081 (MSA248), and 0.8798 $\pm$0.0075 (MSA251) for the array in air on a concrete floor, water added between the containers which are still on the concrete floor, and floating with water between and underneath the containers, respectively.

For slightly moderated material in lard cans, the actual surfaces density is 1,600 g Pu/ft^2 or 14.5 L/ft^2. For 55-gal drums, these values are 476 g/ft^2 and 4.3 L/ft^2. Floating should reduce these values by a factor of four (to 400 g Pu/ft^2 or 3.63 L/ft^2 and 119 g Pu/ft^2 or 1.1 L/ft^2, respectively) as the four layers spread out to form a layer only one storage container thick. These latter values for a one-layer array are acceptably low. These will only be achieved after the water has surrounded the lower layer(s) sufficiently to provide enough buoyancy to float a container. A Monte Carlo calculation of a floating infinite array of large cans stacked four layers high has a k_{eff} of 0.9356 $\pm$0.0077 (MSA250). The 400 g Pu/lard can is distributed as a 1-cm-thick layer on the surface of the stack so as to give the maximum reactivity effect due to moderation when the water is present. The conservative assumptions for the DOT-6Ms have been also made for this case.

From the preceding discussion, the breakage of a fire main in the presence of a room storage array will not cause a criticality even in the unlikely event that flooding occurs. There also is no potential for criticality due to pedestal failure as the pedestals can withstand seismic loads (see Section 9.2.4.2.1H).

9.2.4.2.11.G Accident Scenario-Criticality, HC-21A and HC-21C--RMC Line area gloveboxes HC-21A and HC-21C are used for stabilization of miscellaneous scrap plutonium bearing materials. Glovebox HC-21A is used for material preparation activities and contains a can opener, sieve, electronic scale and a mortar and pestle for crushing material if necessary. Cans of feed materials are opened in this glovebox, inspected, weighed, and placed in furnace boats for transfer to muffle furnaces. Glovebox HC-21C contains two muffle furnaces where stabilization takes place. The CPS's for the gloveboxes allow for processing of various forms of plutonium materials. Each material form, (i.e., oxides, metals, or sludges) has a specific criticality safety limit set. Both are "dry" gloveboxes where no internal solution lines are present. Except for a maximum of 50 ml of lubricants, no free liquids are allowed in either glovebox. The CPS's in effect as of May 2000 allow for 7100 g Pu oxide and compounds, 2500 g Pu sludges, or 4800 g Pu metal, metal corrosion products, oxidized metal, and product quality oxides in Glovebox HC-21A. Glovebox HC-21C is allowed 5000 g Pu oxide and compounds, 2500 g Pu sludges, or 4800 g Pu metal, metal corrosion products, oxidized metal, and product quality oxides. Each limit set has specific spacing, H/Pu, container volume, and unit mass limits where required by material type.

Neither glovebox is seismically qualified due to their supports not being anchored to the floor. During a DBE, the structures supporting the gloveboxes are assumed to collapse, allowing all fissile material to collect in one corner of the glovebox. It is assumed that a DBE sufficient to collapse the glovebox support will also damage the glovebox itself and the room fire suppression system. Under these conditions, fire suppression water may enter the glovebox and saturate and surround the fissile material accumulated in the glovebox corner. Each criticality safety limit set has been established to ensure that material interaction k effective remains acceptable under this DBE scenario.

Therefore, as a single contingency effect, a seismically induced criticality in gloveboxes HC-21A and HC-21C is not credible. Additional violations of CPS limits combined with a DBE would have to occur simultaneously before a criticality is possible.

9.2.4.2.11.H Accident Scenario--Criticality, Glovebox HA-21I--RMA Line area Glovebox HA-21I is used for stabilization of miscellaneous scrap plutonium bearing materials. The glovebox contains three muffle furnaces where stabilization takes place after material is transferred from Glovebox HC-21A. The CPS for the glovebox allows for processing of plutonium in the form of oxides and metals (processing of sludge in HA-21I is prohibited due to process limitations). HA-21I is a "dry" glovebox where no internal solution lines are present. Except for a maximum of 50 ml of lubricants, no free liquids are allowed in the glovebox. The CPS and CSER in effect as of May 2000 allows for 8000 g of Pu oxides and other compounds. Additional limits have been established for Pu metal, metal corrosion products, oxidized metal, and product quality oxides. Each limit set has specific spacing, H/Pu, container volume, and unit mass limits where required by material type.

The glovebox is not seismically qualified due to its supports not being anchored to the floor. During a DBE, the structure supporting the glovebox is assumed to collapse, allowing all fissile material to collect in one corner of the glovebox. It is assumed that a DBE sufficient to collapse the glovebox support will also damage the glovebox and the room fire suppression system. Under these conditions, fire suppression water may enter the glovebox and saturate and surround the fissile material accumulated in the glovebox corner. Each criticality safety limit set has been established to ensure that material interaction k effective remains acceptable under this DBE scenario.

Therefore, as a single contingency effect, a seismically induced criticality in glovebox HA-21I is not credible. Additional violations of CPS limits combined with a DBE would have to occur simultaneously before a criticality is possible.

9.2.4.2.11.I Accident Scenario-Criticality, Glovebox 5 in Room 139: Glovebox 5 in Room 139 of the PFP Engineering Laboratory provides storage for dry plutonium metallic or compound samples in what is called a Carousel, a semi-fixed array upon a motor-operated multiple rack assembly. The storage elevator resembles a "ferris wheel" with 50 removable trays mounted on chains which pass over sprocket pulleys near the top and bottom of the glovebox. Each tray has 42 fixed positions to hold sample bottles. The sample bottles each hold 25 to 35 ml of material. The CPS limits any sample bottle to 50 grams maximum Pu, but also limits each tray to 840 Pu grams maximum and the

total carousel to 20,160 grams Pu. Another 840 grams is allowed in the glovebox but off the elevator in a container not exceeding 2 liters volume.

Glovebox 5 is not seismically qualified, due to lack of anchorage and need of some structural welds. It is uncertain how the trays of samples might respond under seismic motions, but it is plausible for a sizeable fraction of the sample bottles to get piled up and for some of these being shattered open. The effective volume-averaged density of the contained material, by the maximum allowed per bottle, is at most 2 g Pu/cm^3, meaning that the bottles are essentially 80% void space. For a more full tray the clustered bottle density average for the Pu is only 0.8 g/cm^3, and about 0.4 g/cm^3 for a full carousel inventory of clustered bottles. As dry material at this low density with such large void fractions, mixed with glass, the minimum critical mass for Pu is certainly over 50 kg.

The seismic impacts as a single contingency cannot therefore produce a criticality with the Room 5 glovebox loadings. The potential for water entry into the intact array is not a problem, and it is doubtful (because of the high bottle void contents) that a pileup of bottles plus flooding would cause criticality.

9.2.4.2.11.J Accident Scenario-Criticality, HC-7--Processes associated with Glovebox HC-7 are currently inactive. It has Pu nitrate solution tanks for feeding the Pu oxalate production process in HC-9B and also tanks for receiving the filtrate drawn from drum filtering of the oxalate to a damp cake. The 16.5-L, 6 inch diameter glass PRT and THT can both be loaded with 450 g/L Pu-nitrate solution, the CPS limit (actual flow sheet values would be on the order of 200 g/L). The filtrate-kill, -catch and -storage tanks, of up to 33 liters each, normally contain no plutonium. Occasionally, a faulted drum filter may pass Pu oxalate through to the Filtrate Kill Tank (FKT), settling as "solids" to the bottom and into the U-shaped pipe connection to the Filtrate Catch Tank (FCT). The Pu concentration in the oxalate solids could be up to 600 g/L.

Glovebox HC-7 is 98-inches long by 36-inches wide by 118-inches tall and sits on a grout pad with the bottom of the box 2 inches above the floor of Room 228A in 234-5Z. Table 9-25 states this glovebox is qualified against seismically induced structural failure. Its frame has been anchored to the floor. The criticality drain for HC-7 is a 2.5-inch hole at the bottom of the north panel, with a soft-plastic tube/steel roller bar arrangement on the room floor outside. The bottom of the drain hole is 2.188 inches above the floor of the glovebox. Mesh-steel cages protect the drain apparatus both inside and outside of the glovebox.

Glovebox HC-7 has a number of liquid-bearing input pipelines, besides the lines for vacuum transfer of Pu nitrate solution from HC-227S. There are four lines for accessing makeup chemical supply tanks, for H_2O_2, $KMnO_4$ and two strengths of nitric acid. There is also an internal fire-suppression sprinkler fed by two 2.5-gallon water canisters above the glovebox.

The 14.85-kg total of Pu in the tanks allowed by the CPS combined with a limit of 3 kg for that in containers gives nearly 18 kg of Pu (with a minimum of 5% ^{240}Pu). The CPS also permits 1/2 inch of solids or solution on the glovebox floor, which conceivably could be 600 g Pu/L oxalate, with a total of

17 kg of Pu, or even higher density-nitrate sludge. However, such heavy floor solids accumulations would never be permitted from ALARA considerations and because the CPS requires cleanup of spills before continuing operations. The more likely floor residue might be 7 or 8 kg, maximum, which would represent a batch of oxalate which had drained out of the FKT after a drum-filter breach. Thus, the maximum total Pu in glovebox HC-7 is 25 to 26 kg.

As common-cause faults induced by seismic stresses, one could postulate dumping of one or two of the Pu nitrate solution feed tanks, activation of the internal sprinkler (5 gals. maximum), and/or leaks from one or two of the chemical makeup lines. These are conservative assumptions considering the seismic qualification, and the chemical feed lines are more likely to sever outside the glovebox.

Tilting of the glovebox is precluded by the new anchoring. Addition of exterior-source water, as from window breaking in conjunction with activation of room overhead sprinklers, is considered a secondary contingency of low likelihood. Blocking of the criticality drain also is considered a secondary contingency, either pre-existing or from the low likelihood of something falling on the drain box. (Actually, the first seismic effect would be rolling off the steel bar which seals the drain bag during normal conditions).

Criticality thus would involve a solution slab, if sufficiently deep, on a level floor. With up to 26 kg of Pu available, the potential areal density (1061 g/ft^2), is about three times the minimum for criticality. However, calculations for HC-7 reported in the CSER for the adoption of the 5-gallon internal fire sprinkler system (WHC 1990), show that, with 26 kg of Pu (5% 240) in a uniform nitrate solution, the depth would have to exceed 3.4 inches before losing the required margin of subcriticality (bias-adjusted k-value not more than 0.95). The volume of all the tanks and cans in HC-7 plus the 5 gallons of sprinkler water is insufficient to provide the 197 liters for this slab thickness.

Flooding to 3.4 inches deep would require a constant-flow liquid input sufficient to yield a 1.2-inch head over the bottom of the criticality drain hole. According to the flow/head correlations for 2- and 3-inch ports graphed in *Criticality Drain Performance*, RFP-2222 (Lehmkuhl 1974), a 1.2-inch head requires a flow rate of 5.5 gpm. None of the chemical lines with full supply tanks would discharge at more than 3.2 gpm, and the most from two of these lines combined is 5.3 gpm.

Therefore, a criticality in Glovebox HC-7 as a result of plausible common-cause faults, as a single contingency, incurred during an earthquake is not credible. With the drain blocked, as a second contingency, criticality could ensue with any of the chemical lines discharging, given at least 7 kg of Pu in solution. (This conservatively neglects the neutron poisoning effects from nitrogen if it is nitric acid discharging). An exterior-flooding scenario (room sprinkler water into broken windows) might also insert water at up to 4 gpm.

9.2.4.2.11.K Accident Scenario-Criticality, HC-6--Glovebox HC-6 in Room 166 of Building 234-5Z contains two long, 6-in. diameter steel tanks, with the round-end sections protruding out of the glovebox. In the past these tanks were used for storage of a Pu nitrate solution, but, being no longer in

service, the connections thereto have been blanked off. The glovebox is currently inactive. The analysis that follows assesses the potential for a criticality to occur in the glovebox based on past operations where plutonium nitrate solutions were transferred from the 236-Z Building through piping that traversed the glovebox.

Glovebox HC-6 is 67-inches long by 27-inches wide and sits on the room floor, with the glovebox floor sloping slightly down toward the criticality drain end (the east panel). There are actually two drains, the lowest of which is piped to two 60-liter, geometrically favorable overflow tanks in the floor of the room. (These floor tanks could accommodate dumping of the glovebox tanks). The total glovebox holdup with flooding to the bottom of the room drain would be 190 liters.

As for RMC operations, the solution in transfer through HC-6 or in samples may have Pu concentrations of up to 450 g/L. The specifications also allow two 0.5-L cleanup containers and eight sample bottles. Up to 0.5 inches of solution or solids is allowed on the floor, but with required cleanup procedures the amount of residual plutonium to be left on the glovebox floor is not significant. With the plausibility of nitrate-sludge-filled cans in the glovebox, the total inventory might typically be on the order of 1 to 2 kg Pu.

One prospect for criticality in HC-6 involves the potential for pipeline or valve leakage flooding the floor of the glovebox with Pu nitrate solution. However, such leaks would break the vacuum transfer force and quickly terminate flow, and the source tanks could not provide enough solution to flood to the height of the room's floor drain anyway.

Glovebox HC-6 is not anchored to the floor, so there is the possibility for tilting or toppling during a seismic event. Extensive tilting would more likely sever the plutonium solution piping outside of the glovebox, to spill directly to the room floor. The seismic scenario might also postulate the shattering of glovebox windows with an additional contingency of water entry from activation of the room fire sprinkler. In this case the worst orientation would be tilting 45 degrees on the south edge. To be critical as a 90-degree trough, there would have to be at least 2,500 g of Pu available in solution. Given the multiplicity and severity of fault or error conditions required, a criticality in Glovebox HC-6 is not credible.

9.2.4.2.11.L Accident Scenario-Criticality, Glovebox 522 in Room 152-- Glovebox 522 in the PFPAL was previously used to concentrate waste laboratory plutonium solutions. However, its concentrator vessel has been isolated and will not be used pending a major redesign and resolution of safety issues. Also the glovebox will not be used to transfer waste fluids from the PFPAL to the PRF.

The 8-ft by 22-inch by 6.5-ft glovebox is along the north wall of Room 152. Adjacent to its eastern end is Hood 521, a standard, open faced fume hood which was used for vacuum transfers of waste solutions into Glovebox 522. The base of Glovebox 522 is supported three inches off the room floor by a frame table with leveling bolts on circular pads. This frame is not anchored to the floor and is not seismically qualified.

There are eight fixed, 6-inch diameter pyrex tanks and one 3-inch diameter scrubber in Glovebox 522. The concentrator and its associated condenser, scrubber, and distillate storage tanks are out of service with their connections blanked off. For the waste liquid transfers, the only vessels expected to contain fissile solution were the Aqueous Storage (A), Organic Storage (O), Miscellaneous Storage (M), and Load-Out (L) tanks. The rounded-bottom, 16-L storage tanks are just one inch off the floor, and the 10-L loadout tank and the vacuum trap are near the top of the glovebox.

All solution load-ins and load-outs were achieved via vacuum transfer, and liquid lines (water and chemical makeup) to the glovebox have been blanked off. An oil-pool type criticality drain at the bottom of the south panel services the glovebox, operability inspections are subject to OSR requirements.

The current criticality specifications for Glovebox 522 allow Pu solution concentrations of up to 450 g/L, which is higher than previous waste liquid transfers. For the total glovebox there is a limit of 3,400 g of Pu. No containers, other than a 1-inch-deep catch pan, are permitted. Thus, the configuration for a possible criticality would have to be a solution on the floor of the glovebox. Dumping the contents of the three storage tanks (A, O and M) plus the load-out tank (for a total of 58 liters) would only flood the level floor to a depth of 1.7 inches, which is insufficient for criticality. With the allowed 3,400 g of Pu spread out on the level glovebox floor, the areal density would be 232 g Pu/ft^2, which is below the minimum critical slab thickness even if fully reflected.

A criticality in Glovebox 522, therefore, would require extra error conditions in addition to dumping of tank contents to the floor. For an upright box there would have to be more than 3,400 g of Pu available (on the order of at least 5,000 g) plus extra flooding by liquid from outside of the glovebox. A seismic event might activate an overhead fire sprinkler and also break windows to provide water entrance. However, the combined probabilities of the DBE, the box being overloaded, the sprinkler tripping and spray entering the box make this not credible.

Tilting of the glovebox due to seismic-induced faults, however, could lower the fissile amount needed for criticality by providing a non-slab pool shape. One extreme scenario, probably prevented by pipe and ductwork attached at the top, would be the glovebox toppling forward: in this event, the worst position would be at 45 degrees so that an 8-ft-long, 90°, solution-filled trough is created. For a 90° trough with the bottom edge horizontal on the concrete floor, it would take about 4,000 g of Pu for criticality (~500 g/ft x 8'). The more likely fault would be sheared leveling bolts so that the front edge or one corner of the glovebox drops three inches.

Specific calculations of plausible tilting configurations with glovebox 522 have not been performed. Until such an analysis is carried out, it is appropriate to conservatively limit the fissile inventory for unanchored gloveboxes such as 522 to not more than 2,000 g. This is based upon calculations for an optimally oriented corner pool, with the side and bottom edges all at the same angle to the horizon, forming an equilateral pool surface. The minimum critical mass for such corner pools, with nominal reflection on the pool surface and concrete below, is 2,100 g of Pu (as PuO_2-

water and 3% minimum ^{240}Pu). The minimum occurs at a concentration of about 32 g/L Pu, so that a liquid volume of nearly 65 liters is needed.

With the limit on total fissile inventory reduced to 2,000 g, a criticality in glovebox 522 of Room 152 becomes a multiple contingency event, requiring errors like overloading, tanks dumping, entry of extra liquid from outside, and/or drastic reorientation of the glovebox by seismic stresses. The combined probabilities for these errors concurrently gives an incredible scenario.

9.2.4.2.11.M Accident Scenario-Criticality, Glovebox MT-5--Glovebox MT-5 in the MT facility (room 41 of the 236-Z Building) was used for dissolving and leaching of plutonium bearing scrap in pot dissolvers. The dissolution and leaching process is currently inactive and not authorized for operations or interim storage of Pu material. The following analysis determines the inventory limit necessary to preclude a criticality if the glovebox is reactivated.

Glovebox MT-5 has six, 32-inch long by 36-inch wide sections. Each of five dissolver sections has a hotplate, 4-liter dissolver beaker and a reflux condenser. The east end section has two chemical makeup tanks, a 6-liter ANN addition tank and an 8-liter "B" Acid addition tank. This tank end section, where the conveyor box is attached, is also used for can storage. 1-liter and 0.5-liter containers are allowed as cans, polyjars, beakers, etc. A steel framework supports the glovebox 31-inches off the room floor, with bolts ($\frac{3}{4}$-in. diam.) spacing the frame 3-inches from the box and also from the floor anchors. The anchors are secured to the concrete room floor with $\frac{5}{8}$-in. bolts.

The criticality drain for MT-5 is on the floor about five inches from the east end of the glovebox, and about midway from front to back. It is a 3-inch diameter pipe extending 2 inches above the floor and going down nearly to the room floor to feed a 1.5-inch diameter horizontal header, which also drains MT-4 and MT-6. Water cooling for the reflux condensers was provided by the PRF Closed Loop Cooling System (Hess, 1993a). A total of 364 liters (96 gallons) of water was available from the cooling circuit, and the flow rate into MT-5 limited to 5 gpm by a flow restrictor on the cooling line input to the glovebox.

The CPS for MT-5 currently limits the glovebox contents as follows;

- Per dissolver station: 4,000 g Pu, maximum; two containers, maximum
- Per dissolver pot: 2,000 g Pu, maximum
- Tank section : 6 containers, maximum
- Limits on containers: 1,500 g in 0.5 L units; 800 g in 1.0 L units

In normal operations, however, the glovebox contents have been typically 400 g Pu loads in dissolvers and 2,000 grams total in other various containers.

The *PFP Safety Systems and Components Seismic Evaluation - Phase II*, WHC-SD-CP-SA-007, (Ocoma 1990b) determined that MT-5 is not seismically qualified due to weakness in its anchoring to the room floor, where bending/yielding could give vertical displacements of up to 2.3 inches. This seismic study examined the stress response of the MT-5 support features as a

stand alone glovebox. As such, it is not determined if motions by the other MT gloveboxes, interconnected with the conveyor glovebox, might further stress the MT-5 support structure. Also, toppling of gloveboxes MT-4 and MT-6 (which are not anchored and not analyzed) could impact MT-5.

Studies of the vulnerability of Glovebox MT-5 to a seismically induced criticality are reported in CSER 93-003 (Hess, 1993b). The hazard depends on how much plutonium is available, the extent of glovebox floor tilting, and the volume of liquid leaked to the floor. The basic accident scenario is the following;

1. The event dumps the Pu-nitrate solution from all of the five 4-liter dissolvers. Open containers in all the sections are also spilled.

2. Enough of the lower framework bolts are bent or sheared to disconnect the box from the frame, but with its east end staying upheld by the conveyor box. The west end of the glovebox then angles downward away from the drain, with a drop ranging from a few inches to all the way to the floor.

3. The seismic stresses may also dump the ANN and acid tanks, adding 14 liters of fluid. The extra acid dissolves the solids from spilled cans.

4. A break of the condenser cooling device and/or the internal cooling circuit lines might also be caused by the seismic stresses.

However, the chance for discharging such cooling water into MT-5 decreases as the box becomes more tilted (becoming more likely to break loose outside). The same conditions would apply to the ANN and acid supply lines. In addition, the makeup chemical lines would seldom be pressurized (only during the occasional pumped load-in transfers). The postulated entrance of room overhead fire sprinkler water into the glovebox would depend not only on the chance for activation in Room 41, but also the probability of the event cracking large holes in the upper windows (which are wire-safety-glass) without creating drainage openings below. Also, the fire water main may rupture elsewhere. Thus, the entry of sprinkler water into MT-5 has to be considered an unlikely, extra contingency.

The CSER 93-003 studies (Hess, 1993b) modeled MT-5 tilted lengthwise and back-to-front to various degrees, and the subcritical margins were calculated using the Monte-Carlo codes MONK5 and MONK6A. The severest scenario studied had the front west corner of the glovebox dropped 31 inches to the concrete floor, tilting the box in two directions, the front edge of the box angling upward at 9.2° and the west face of the box tilted 45°, forming a trough-wedge shaped pool. The following table summarizes the details and results of the corner drop calculations most pertinent to the evaluation.

MONK CALCULATION RESULTS FOR GLOVEBOX MT-5 WITH CORNER DROPPED TO FLOOR

Set #	Case #	Solution Wedge Details[a]			Total Pu, g	MONK5 Results	
		Maximum Depth, inches[b]	Volume, L	Density of Pu, g/L		k_{eff}	Std. Dev.
1	MT5D08	8.32	20.0	300.0	6,000	0.8202	0.0049
2	MT5D01	9.93	34.0	88.24	3,000	0.9385	0.0052
3	MT5D07	11.29	50.0	30.00	1,500	0.8986	0.0049
	MT5D04	12.43	66.7	30.00	2,000	0.9616	0.0051

[a] Glovebox bottom edge angling 9.2° from floor, west face rotated 45°.
[b] From dropped corner to surface of pool. Concrete reflector below corner.

The first two case results in the table are for liquid volumes limited, respectively, to the 20 L available from the dissolvers, and to the 34 L of the dissolvers plus tank contents. It is seen that the prospect for spillage of the ANN and acid liquids reduces the allowed available Pu to 3,000 g. For the last two cases in the table, it is assumed that extra water is spilled to the floor, either closed loop cooling water or liquids from outside the glovebox. The Pu concentration is optimized at 30 g/L (for minimizing the critical mass), and the pool depth and volume varied. The k-effective of 0.96 for a 67 L solution pool with 2 kg Pu (case MT5D04) is a few percent over the normal acceptably-subcritical criterion. However, the configuration represented goes far beyond a simple one contingency event (the earthquake with dissolvers dumped). The full corner drop is much less likely than the small vertical displacements found by the stand-alone seismic-response study, and the discharge of extra water into MT-5 is not a for-certain occurrence.

Overall, the study results indicate that a 2,000 g limit on the total Pu inventory in glovebox MT-5 is adequate to provide assurance against any conceivable scenario for earthquake-caused criticality with glovebox MT-5 not seismically qualified. A higher limit, on the order of 10 kg, could readily be justified if additional seismic analyses for the coupled, interconnected MT gloveboxes show no support failures which tilt the glovebox to an extent that pools more than 7 inches deep could form.

Glovebox MT-5 is currently designated inactive (see Table 9-25). Based on NDA results the glovebox is estimated to contain $\leq$350 g of residual plutonium. A criticality in Glovebox MT-5 is thus not credible.

9.2.4.2.11.N Accident Scenario-Criticality, West Glovebox, PRF-- On the walls of the PRF canyon (or cell) are several bank-tanks for various process plutonium solutions, with allowed concentrations of up to 450 g Pu/L. Leakage from these tanks within the cell is not a direct criticality hazard, because spreading of the solution over the expansive floor area will give a solution depth below the minimum needed for criticality.

However, control of the process tank flows is accomplished with piping through the cell walls into the cell-access gloveboxes on two floors to the east and west of the cell. These access gloveboxes contain some smaller tanks, piping and various control valves. Leakage from these equipment items could conceivably result in a solution criticality on the first floor of the access gloveboxes, with smaller areas for spreading. Liquid spills (if significant) in the second-floor access gloveboxes and from the 4th, 5th and 6th-floor column gloveboxes could also be involved, which all drain through various pipe chases

and gaps down to the first floor could also be involved. There are also closed-loop cooling water lines that, if leaking, could contribute to liquid accumulations on the first floor.

On the first floor, the 63-ft-long east and west access boxes are 30 inches above the room floor, except for the two 32-in.-long, north-end sections (designated WW/WZ and EW/EZ) where the bottom of the box is only 7.5 in. off of the room floor. In these lower sections are the criticality drains, 2.5-in.-dia pipes going horizontally out of the north-end panels into the process cell. The bottom of each drain hole is 1.75 in. above its glovebox floor. The wire-mesh cage protecting the drain hole on the inside of the glovebox extends 4.2 in. from the wall and is 5.5 in. tall by approximately 10 in. wide. The 1/2 in. square mesh grid of 16-gauge steel wires allows easy flow without chance of clogging by debris. At the back of both the east and west north-end regions, at approximately 2 in. off of the floor, there are also older, 1-in.-dia drainholes going directly into the cell.

Liquid discharges into other than the north-end glovebox sections would first have to fill the associated 64-in.-long by 23-in.-wide floor "trays", or catch basins formed by the 2.5-in.-high weirs between every two sections, before spilling over into the drain section. Each tray can hold approximately 60 liters at a depth of 2.5 in., which is less than the minimum critical slab thickness for any plausible solution or sludge concentration. A floor solution criticality is thus precluded in most sections of the four cell-access gloveboxes, except for the lowered-floor drain sections on the first floor.

The four cell access gloveboxes are assessed as seismically qualified (see Table 9-25). They will incur no structural damage during a DBE. This is attributed to being well anchored to the thick concrete cell walls and to the floor. Thus no significant tilting would be expected as a result of a DBE, nor is it likely that the criticality drain pipes could be crimped. Also, inside the glovebox it is unlikely that falling objects would damage the guard screen on the criticality drain entrance to a degree which would impede the action of the drain.

It is postulated that a source of plutonium for a criticality on the floor results from seismic stress-induced failures on some of the process lines or tanks within the gloveboxes. In the east-access glovebox, there is a closed-loop cooling water line in Section ET, the product from the filtrate concentrator in Section ER, closed-loop cooling water lines in Section ES, and so on. On the west side, the product concentrator tank is at Section WS, the CRT in Sections WT, WV, and WS, along with other liquid lines. It is assumed that only one-third of the floor catch basins (trays) need to be filled before they overflow into the drain section, based on the abundance of liquid lines and concentrated plutonium solutions in this third of the glovebox. Pages 2-22 through 2-26 of *Plutonium Reclamation Facility Engineering Technical Reference*, WHC-SD-CP-TI-122, (Kronvall 1988) show that there are easily 200 liters that could drain into the glovebox if the tank process lines therein broke.

In either of the north-end drain sections, a pool of plutonium solution or slurry deep enough for criticality could result, from blocking of the criticality drain or by a leak overflow rate in excess of the flow capacity of the drain. A slow discharge yielding a pool up to the bottom of the drain (1.75 in.) would certainly be safe. The minimum critical slab thickness, for Pu

(3% of ^{240}Pu) nitrate solution with nominal reflection, would be 4.4 in. (per Carter et al. 1969), graph III.A.5.97-2. This is over the top of the drain hole and would require approximately 14 kg of Pu in 106 liters of liquid.

Thus, for just the plausible liquid-line discharges from common-cause, seismic-stress equipment faults considered as a single contingency, a DBE-induced criticality is not credible unless flow through the criticality drain is blocked or severely impeded. Such impediment of the drain action would have to be considered an extra contingency of low probability, either a pre-existing blockage, or the result of some abnormal occurrence that provides metal, plastic or cloth panels covering all faces of the drain screen structure. A plausible scenario for incurring such coverage is not evident.

If the drain was effectively blocked, criticality would require as little as 3.2 kg of Pu in a solution pool of 9-in. depth, requiring 217 liters of liquid at 14.6 g Pu/L (Carter et al. 1969), graph III.A.8.97-2. A critical pool depth might also result because the total overflow rate into the drain section is excessive (more than 15 gpm). Such excessive flow rates are not likely, considering that it requires multiple line faults, that the spreading of the liquids into the other section trays reduces the flow, and that massive ruptures are more likely to occur within the cell.

By whichever mode criticality occurs, if it were to occur, the dose would be bounded by that determined in Section 9.2.3.

9.2.4.2.11.0 Accident Scenario-Criticality, HC-9B--Glovebox HC-9B houses equipment for the previous RMC Line process of converting plutonium in nitrate solution into plutonium fluoride powder, with intermediate stages as damp oxalate and as oxide powder. The glovebox has three levels, the highest of which contains the reactor-precipitator and vacuum drum filter (VDF) for generation of plutonium oxalate, and a calciner which reduces the oxalate to Pu-oxide powder.

As fluoride production no longer takes place, the fluorinator, in the middle level of the glovebox could be used as a second-stage calciner, operating up to 500 °C. The plutonium oxide powder churned out by the top level calciner drops directly down through a floor opening into the second-stage calciner, the output of which is collected in 1.7-liter powder pans or 0.5-liter slip-lid cans or polyjars in the middle level.

The bottom level of HC-9B contains a tank to collect condensate from the calciner off-gas system, a tank for temporary storage of the filtrate to be sent to glovebox HC-7, a tank to collect overflow from the vacuum drum filter, and two pumps to handle transfers from the latter two cited tanks. Except for upset situations, the lower section tanks and pumps would not contain significant amounts of plutonium. Storage of plutonium oxide in as many as four 1.5-liter containers is allowed in the lower level.

Sources of liquids into the glovebox are in the upper level. Feeding the reactor-precipitator are the Pu-nitrate solution line from HC-7, the oxalic acid line and a distilled water line. The process feed rate is only 6 liters/hour, and a leaking input line would have a maximum of only 16 liters of fluids available. There is also a wash solution line for the VDF. The divider floors between the upper/middle and middle/lower levels have central drain holes with

cover screens, so that there is effectively no holdup of liquids if such are spilled in the upper and middle sections. On the bottom level there is a screened criticality drain pipe going out very nearly at the floor level of the glovebox, which sits on the floor. With no liquid holdup in the upper two levels, and with the low criticality drain arrangement in the bottom section, a solution criticality in glovebox HC-9B is not plausible.

Glovebox HC-9B was determined to be seismically qualified, meaning that structure or equipment damage would not occur as the result of a DBE (Ocoma, 1990b); thus, the glovebox stays upright and the equipment supports and pipelines do not fail. In such events, the reactor vessel and the calciner operating in the continuous feed mode will remain geometrically favorable, as qualified by the criticality safety analysis supporting the CPS. In addition, the material entrained within the reactor and calciner would be dumped out by the shaking.

Seismic motions, however, could tumble containers of plutonium compounds and/or accumulations of material allowed beneath equipment or on the section floors. Considering the small diameter of floor drains, it is not plausible for much of the material to move between levels. In the upper level, all of the loose or canned materials should be hydrated plutonium oxalate, as a result of spills going from the drum filter to the calciner inlet. Since fluorination no longer is done in the middle level, there is less need to use the recycle inlet hopper at the end of the upper-level calciner. Thus, containers of oxide powder are not routinely expected in the top level.

The criticality safety specifications allow 1.6 kg Pu as oxalate under the drum filter, four full, 1.5-liter containers, and 1/2-inch of material on the top floor. As a matter of SNM accountability and ALARA considerations, the floor accumulation would not be over 1 kg of Pu. The calciner inlet chute is also allowed a maximum of 1 kg of oxalate. Assuming all material as hydrated Pu-oxalate cake, at 600 g Pu/L, gives a maximum of 7200 g Pu available in the upper level, of which perhaps 1,800 would be in closed cans.

The criterion for a dry material in a glovebox allows 12 kg of Pu before it is considered vulnerable to a seismic-induced criticality. The "dry" stipulation allows for slight moderation, with an H/Pu ratio less than 15. At stoichiometric conditions, hydrated Pu-oxalate has an H/Pu ratio of 12, and if compacted to 600 g/L of Pu, would have a void fraction of 54%. Verification that 12 kg of Pu-oxalate would be safe is documented in CSER 88-006 (Hess, 1990), which determined that a conical pile so loaded would not approach the subcritical limit until the free water content exceeds 35% by volume. For the assumed retention of fluid line integrity, there would be no source for the extra moderation. However, even if such was available, the near saturation of the oxalate would not allow a self-supporting cone, but provide an easily flowing slurry which flattens and/or drains to the lower level. With a maximum of 7.2 kg of Pu as oxalate available exterior to the calciner, there is no chance for criticality in the top level of glovebox HC-9B.

For the lower levels, the amount of plutonium available, as oxide and perhaps some oxalate, is even less and the consequent risk for criticality lower still.

9.2.4.2.11.P Accident Scenario-Criticality, MT-6--Glovebox 6 in the Miscellaneous Treatment facility (room 41 of the 236-Z Building) contains equipment to vacuum transfer process solutions and to centrifuge solids from such solutions. The solutions were received from the MT-5 pot dissolvers discussed previously in Section 9.2.4.2.11.L, and also from operations in the process cell. Four of six 32-inch long by 36-inch wide sections of the glovebox were utilized; the middle two sections with centrifuges, and the two tank sections to the east. Viewed from the south, the box is stepped shaped. The two tank sections on the right rest on the room floor, while the other four sections are supported 31 inches above the floor by a table frame. No floor anchors are provided, but the east face of the glovebox is bolted to the MT conveyor box.

Inside, near the back of the tank sections are four 6-inch diameter tanks, co-axial vertical tanks C-3 and C-5, and tanks C-2 and C-6 on another vertical axis 32 inches away. The receiver tanks C-2 and C-3 are each 30-in high Pyrex vessels which loaded with the transferred Pu-nitrate solution and possibly solid precipitate. Reagents could also be added to C-2 and C-3 to precipitate impurities, which were then removed by running the solutions through Centrifuge C in the central glovebox section.

Toward the front are the vacuum pump and associated trap tank C-1. The pump was cooled by water recirculated through a 30-inch tall heat-exchanger tank C-4, in which the heat was transferred to a cooling coil fed by the PFP Closed Loop Cooling System discussed in the section about MT-5.

In the central two glovebox sections are four, levelable, 1-ft square centrifuge platforms, about 7 inches above the section floor. Only three centrifuges are inplace, the 'C' unit in the northeast quadrant for the C-2, C-3 output, and the B1 and B2 units on the south side.

The criticality drain for Glovebox MT-6 sits right on the concrete floor of Room 41. The drain is a 1.5-inch diameter pipe coming out of the end panel and centered at about 1.6 inches above the bottom of the box. This drain feeds 5 ft of 1.5-inch pipe (with two 90° bends) running horizontally over to the 1.5-inch lateral header for the MT drain system. With this arrangement, a flow restrictor device was required on the Closed Loop Water inlet to limit flow to 5 gpm and limit the flooding depth in the double end section to 3.2 inches in case of a cooling water line break.

A previous CPS for MT-6 provided limits on the fissile contents of the receiver tanks, centrifuge bowls, and "unit masses" (an assemblage of containers with up to 2.7 liters of total volume). Spacings of 10 inches were required between these various fissile accumulations, bowls and tanks. It had been shown in CSER-88-006, *Solid Limits for Receiver Tanks in Glovebox MT-6*, (Hess 1990) that 5 kg of Pu could be allowed in each of tanks C-2 and C-3 without concern for how much settled solids were present. Previously, before consideration of the impact of seismically-induced faults, the number of subcritical masses was limited to two, and each to no more than 3,000 g Pu.

Glovebox MT-6 was not included in the Ocoma study of glovebox seismic responses and is deemed not seismically qualified because of its lack of floor anchoring. Thus, it is plausible that MT-6 could topple. Another aspect with

the possibility of the box moving is the potential for crimping the long, lateral criticality drain header.

Considering that up to 46 liters of Pu solution plus water could be present in tanks C-2, C-3 and C-4 within the glovebox, and subject to dumping in the seismic event, a criticality can be precluded only by limiting the total fissile inventory in the tanks plus the solids available in open containers. Tilting due to seismic stresses will give a more reactive pool geometry than a uniform thickness floor slab. It could be argued, because of the tank section sitting right on the room floor, that MT-6 is less likely to incur the edge-drop configuration considered for MT-5. However, tilting 45° in one direction could yield a 6-ft long, troughlike pool, for which a minimum linear critical concentration of 500 g/ft would mean only allowing 3 kg total Pu.

Glovebox MT-6 is currently designated as inactive and contains $\leq$700 g of residual plutonium. There is no plausible critical pool geometry which could be formed by seismically-induced displacements given the rectangular box structure and the lack of significant reflector formation.

9.2.4.2.11.Q Accident Scenario-Criticality, HC-230C-2--Glovebox HC-230C-2 will contain greater than a critical mass of Pu when activated (the glovebox is currently inactive). The vessels in the glovebox are sized and separated in a manner that precludes criticalities during normal operation. Fissile inventory in the glovebox vessels and in open containers on the glovebox floor is administratively controlled. The glovebox is qualified for the DBE and will not topple or collapse. Should vessels rupture inside the glovebox during the DBE and spill to the floor of the glovebox, a criticality drain is provided to prevent the accumulation of a critical geometry of moderated solution within the glovebox. The criticality drain protects against a criticality in the event fire water infiltrates into the glovebox following the DBE. A DBE-induced criticality in glovebox HC-230C-2 is not considered to be credible.

9.2.4.2.11.R Accident Scenario-Criticality, HC-18M--RMC Line area glovebox HC-18M is used as part of the stabilization process for product sieving, grinding, sampling, weighing, and seal-out (or transfer to another glovebox for seal-out). The glovebox contains electronic scales, mortar and pestle, and a sieve shaker. Stabilized plutonium bearing material is transferred to this glovebox where it is prepared for packaging and sampled. The CPS for the glovebox allows for preparing, sampling, and packaging dry plutonium compounds. Glovebox HC-18M is a "dry" glovebox where no solution lines are present. Except for a maximum of 20 ml of lubricants that must be capped when not being used, no free liquids are allowed in the glovebox. The CPS in effect as of May 2000 allows for 10000 g of dry plutonium compounds. The CPS also establishes specific spacing, H/Pu, container volume, and unit mass limits. The CPS recognizes that approximately one-fourth of a metal plutonium item may unintentionally be introduced into the glovebox and requires that it be promptly removed if introduced.

The glovebox is not seismically qualified due to its supports not being anchored to the floor. During a DBE, the structure supporting the glovebox is assumed to collapse, allowing the material containers to freely tumble to one end, spilling and accumulating their contents into a single volume. The CSER for the glovebox analyzes a central sphere of dense fissile material with up to two spherical shells around it. The spheres are assumed to be surrounded by one

inch of water reflection. The CPS limits have been established to ensure that material interaction k effective remains acceptable under this DBE scenario. The CSER recognizes the presence of a non-seismically qualified fire suppression system and the potential for glovebox window breakage. However, the evaluation also determines that the probability of fire suppression water entering the glovebox and not leaking back out would be small. This small probability, in combination with the small probability that sufficient fissile material assembles into a compact enough configuration was judged to be too low to be considered credible.

Therefore, as a single contingency effect, a seismically induced criticality in Glovebox HC-18M is not credible. Additional violations of CPS limits, and unlikely configurations caused by a DBE, would have to occur simultaneously before a DBE induced criticality is possible.

9.2.4.2.11.S Accident Scenario-Criticality, Conclusion--There are no criticalities possible as a result of seismic loads alone. If there are preexisting criticality drain failures, a criticality is possible only in the west gallery glovebox. Given the presence of a criticality safety program and the arguments in Section 9.2.4.2.11.N, the likelihood of a criticality during a seismic event is much less than the likelihood of the seismic event. Even if a criticality did occur, the onsite and offsite doses are only 5% of the total doses and, therefore, insignificant to those individuals far from the facility. For these reasons, the criticality doses are not included in the doses determined for the seismic event.

9.2.4.2.12 Accident Scenarios-Fire. Fires are conceivable as a result of scrap processing, spontaneous ignition, electrical shorts, flammable liquids, or contact of combustibles with hot equipment (Marusich 1988a). Each will be discussed.

9.2.4.2.12.A Accident Scenario-Fire, Scrap Processing. In order to get a seismically related process upset fire, ignitable process solutions are required to contact a heat source. Ignitable process solutions are organic or nitrated organic solutions. Solutions like this and heat sources (hot plates) existed in glovebox MT-5. Glovebox MT-5 is no longer used for scrap processing, and large quantities of organic are not present. There are no ignitable process solutions present to contact heat sources in the PFP.

9.2.4.2.12.B Accident Scenario-Fire, Spontaneous Ignition. Spontaneous ignition at the time of the seismic event is not considered credible as it requires spontaneous ignition of trash or rags at the same time as the seismic event. In addition, the seismic event will not cause spontaneous ignition of the trash.

9.2.4.2.12.C Accident Scenario-Fire, Electrical Shorts. Fires due to electrical shorts may start in areas of high fire loading during the initial building vibrations prior to internal failure, assuming that the electrical power remains intact. As discussed in *Correction for MT-5 Hotplate Power in Design Basis and Small Earthquakes* (Weiner 1992), the probability that electrical power remains on is greater than 10^{-1}/event.

The fires that are assumed to be started in high-fire-loading areas such as the changeroom or offices are not near any gloveboxes. The air draw caused by

these fires should not disturb any material on the floor because the velocity across the rubble is small. Fires could possibly be started in the area of the gloveboxes due to shorts and arcs in the high current lines going to the scrap stabilization furnaces in Gloveboxes HC-21C and HA-21I. Electrical shorts are very unlikely to start a fire in a glovebox. This is because the electrical short must occur in the very near vicinity of combustible material and must remain energized for a time sufficient to cause ignition. The high energy and long duration shorts necessary to ignite glovebox panels will likely cause the breaker to trip, thereby removing the short. Typically combustible material is stored well away from electrical sources as part of proper housekeeping. Excessive glovebox motion (such as toppling) could cause combustible material to come in contact with sources of electricity. However these same motions will likely cause the wires to fail or short elsewhere.

9.2.4.2.12.D Accident Scenario-Fire, Flammable Liquids. Flammable liquids are only present in PFP facilities in small quantities stored in specially designed flammable material storage cabinets away from the processing areas. These may be damaged during the seismic event but the lack of ignition source, the presence of debris all around, and the solution present (water may also be present) could result in only small local fires, if any.

9.2.4.2.12.E Accident Scenario-Fire, Contact with Hot Equipment or Hot Material. The calciners in Glovebox HC-9B are inactive, as are the induction furnaces in Gloveboxes HC-15A, -15B, and -15C. No fire threat from contact of hot equipment with combustibles or glovebox panels exists in these gloveboxes. Section 9.2.10.5 addresses the potential for a seismic induced fire in Gloveboxes HC-21C and HA-21I, which contains muffle furnaces that may be operating at 1000°C at the time of an earthquake.

Gloveboxes HC-15A, -15B, and -15C contain inactive induction furnaces, so no fire threat exists. The gloveboxes have been analyzed and found to remain upright during a seismic event. Therefore, there is no seismically induced fire for gloveboxes HC-15A, -15B, and -15C as a direct result of the DBE.

9.2.4.2.12.F Accident Scenario-Fire, Fire Due to Seismic Event The preceding sections provide discussions of the potential seismically induced fire ignition sources. From these discussions it can be seen that a seismically induced fire in the RMC/RMA Line is most likely caused by contact of hot equipment (muffle furnace) with combustibles or with the glovebox panels (viewing windows) in Gloveboxes HC-21C and HA-21I.

The fire scenario due to a seismic event assumes that fires start in glovebox HC-21C and HA-21I.

The fire is presumed to start in Gloveboxes HA-21I and HC-21C due to the presence of hot furnaces and the assumed interaction with the panels. It is noted that the furnaces are insulated by firebrick held in place by a metal case. The door is counter-weighted so it takes some force to open it. The vacuum exhaust piping and filter are also insulated except for small portions.

Ignition of the plastic panels requires the following:

- A furnace must be at a temperature above the ignition temperature of the plastic panels

- The seismic event causes a furnace to move and come in contact with a panel

- An area of the furnace that is above the ignition point of the plastic panel comes in contact with it and remains long enough to ignite the panel.

The above sequence can only reasonably occur if the seismic event results in glovebox motions strong enough to knock off the insulation of the offgas line, knock off the metal case and fire brick or if the seismic event results in a hot furnace boat being forced out of a furnace and coming into contact with a panel. Seismic motions this strong probably result in glovebox toppling. Certainly, spilling the hot boat from the furnace which then comes into contact with a plastic panel requires the glovebox to topple. The furnaces are free to move within the glovebox (that is, they are not fixed to the glovebox floor). Since an analysis of furnace motions as a result of the earthquake has not been performed, it is conservatively assumed that a hot surface of a furnace comes in contact with a plastic panel in Glovebox HC-21C and in Glovebox HA-21I.

Contact of a hot surface of a furnace with a panel can have a number of differing outcomes. The most benign outcome is that a small portion of the panel melts, but is not ignited so that a fire does not propagate over the remainder of the plastic panel. Alternatively, the panel could ignite and the fire could propagate through the panel. The resulting energy release could cause ignition of other plastic panels both in the glovebox initially burning and other gloveboxes near the burning glovebox. Section 7.4.3 of the FHA (Mckinnis 1998) states that a glovebox having PMMA panels can be ignited by a burning glovebox having PMMA panels if the separation is less than 10 ft.

In the most severe case, the entire RMC and RMA Lines could be involved in the fire as discussed in Section 9.2.2A. This case requires that a number of conditions relative to fire propagation from glovebox-to-glovebox as well as room-to-room be satisfied. It is judged that a seismically initiated fire of this magnitude is very unlikely due to the number of unqualified process gloveboxes and conveyor gloveboxes, the mix of PMMA and polycarbonate panels, which are much harder to ignite than PMMA, the large distances between gloveboxes in some areas, the presence of doors between rooms that are maintained closed for ventilation control, and the potential for some portion of the fire protection system to partially or fully perform its function especailly with respect to the Halon systems for the seismically qualified gloveboxes.

As a result, it is judged that a reasonably conservative, seismically-induced fire scenario starts in Gloveboxes HC-21C and HA-21I. The fire in Glovebox HC-21C is assumed to burn all of the panels. The fire is then judged to propagate to Glovebox HC-21A via the conveyor. It is judged that the fire does not propagate into Room 230-C which houses the Magnesium Hydroxide Precipitation Process gloveboxes, HC-230C-3 and HC-230C-4. The wall and door between the rooms are 1-hour fire barriers and do not burn. The door is assumed to be closed. The conveyor glovebox, HC-2, from Room 230-B (Glovebox HC-21A) runs into Room 230-C. The fire in Room 230-B will not propagate into Room 230-C via the conveyor because of the closed airlock in the conveyor just downstream of Glovebox HC-21A. In addition, the fire initiated in Glovebox HA-21I cannot propagate to the precipitation process gloveboxes from conveyor HC-4 because the fire door on the ventilation inlet to the Magnesium Hydroxide Precipitation

Process glovebox, HC-230C-3, will close, thereby preventing the fire from entering the glovebox.

The fire in Glovebox HC-21C is judged not to propagate to the remainder of the RMC Line (toward Glovebox HC-18BS) due to the presence of a 1-hr fire barrier between Room 230-A and Room 228-C (assuming the doors between these two rooms are closed), due to the long length of unqualified conveyor between Glovebox HC-21C and Glovebox 18-M and due to the other reasons discussed previously regarding the mix of PMMA and polycarbonate panels and glovebox fire protection features.

The fire initiated in Glovebox HA-21I can propagate to Glovebox HA-20MB due to radiant heating. Section 7.4.3 of the FHA states that a glovebox having PMMA panels could be ignited by a burning glovebox if that glovebox were less than 10 ft away. Glovebox HA-20MB is 4.5 ft from Glovebox HA-21I. Similarly, Glovebox HA-19 could be ignited by Glovebox HA-20MB, and Glovebox HA-22B could be ignited by Glovebox HA-21I.

Propagation of the fire to Glovebox HA-23S is not likely. First, the glovebox is more than 10 ft away from Glovebox HA-21I so that it will not ignite due to radiant heating. Second, the water walls (iron tanks that when full provide a 1 ft water shield around the glovebox) also prevent ignition heating of the panels when the walls are in place. The walls are typically in place, so credit is taken for the walls. Third, even if the fire could propagate toward Glovebox HA-23S via the conveyor, it would be very unlikely that it would propagate into the glovebox itself. The glovebox walls containing the flammable panels are separated from the conveyor by about 4 ft. In this area are the sweep mechanisms that take containers from the conveyor and place them on the lift assembly that raises or lowers the container to the appropriate level within the glovebox. Fourth, the plastic panels of the glovebox are perpendicular to those of the conveyor. Therefore, the view factor (used in radiant heat transfer calculations to account for geometry) is much less for this geometry than it is if the panels were parallel. If a panel can ignite another panel when they are parallel and less than 10 ft away, a distance of 4 ft with perpendicular panels is likely to be insufficient to cause ignition.

Based on the above discussion, the postulated fire in Glovebox HA-21I is assumed to propagate to Gloveboxes HA-20MB, HA-19 and HA-22B but not to Glovebox HA-23S.

Because of the above reasons, it is judged that the seismically initiated fire does not involve the entire RMC/RMA Line but only portions of it. This is characteristic of PFP fires which have the potential to release plutonium out of the facility; if they occur at all, they are small and do not propagate through the process lines.

Based on the above discussions, the seismic induced fire is assumed to involve the following groups of gloveboxes:

- Gloveboxes HA-19, HA-20MB, HA-22B and HA-21I. This group is ignited by the furnaces in Glovebox HA-21I.
- Gloveboxes HC-21C and HC-21A. Glovebox HC-21A is ignited by the furnace initiated fire in Glovebox HC-21C.

The seismically induced glovebox fire as described above involves the following gloveboxes (The releases are determined using the data and methods described in Section 9.2.2A.):

HC-21C 0.30 g (unprotected oxide - ARF * RF = 6×10^{-5}; inventory = 5000 g)

HC-21A 0.43 g (unprotected oxide - ARF * RF = 6×10^{-5}; inventory = 7100 g)

HA-21I 0.48 g (unprotected oxide - ARF * RF = 6×10^{-5}; inventory = 8000 g)

HA-20MB 0.06 g (protected oxide - ARF * RF = 6×10^{-6}; inventory = 10000 g)

HA-19 1.00 g (polycubes - ARF * RF= 4×10^{-4}; inventory = 2500 g)

HA-22B 0.02 g (protected oxide - ARF * RF = 6×10^{-6}; inventory = 2500 g)

The total release into the facility is therefore 2.29 g of oxide. This release must be added to the seismic release due to glovebox toppling as the fire could spread as described above even if the gloveboxes topple.

The release into the rooms will be transported through the 291-Z-1 Stack due to ventilation exhaust airflow (if the exhaust system is running) or, in cases where there is no exhaust flow, to other portions of the 234-5Z Building due to fire-induced air currents and flow out the penetrations in the room walls and paths around doors due to room pressurization.

In the situation where the ventilation exhaust system operates, the fire induced release out of the room is assumed to be transported out of the facility through the 291-Z-1 Stack in the same manner and to the same extent as the plutonium release due to glovebox toppling. In the case where the exhaust system does not operate, it is assumed that half (about 1.15 g) of the suspended plutonium remains within the rooms and half is transported out of the room due to room pressurization and fire-induced air currents. This assumption is considered to be reasonable because there is no large open flow path out of the rooms. Flow is out relatively narrow openings in the doors and other penetrations. Under these conditions, there is additional time for the suspended aerosol to be deposited on surfaces due to impact, settling and thermal gradients over that in the exhaust system operating case. The half of the release that is transported into the other portions of the facility outside the RMC/RMA Line areas is removed in the same manner and to the same extent as the release of the other material in the case where the ventilation exhaust system is not operating.

9.2.4.2.13 Accident Scenario-Separation of Walls and Floor in 234-5Z. The *Seismic (SSE) Evaluation for the 243-5Z Building at the Hanford Site*, (URS 1987) identified a need to separate the vertical walls in column line 4 and column line 8 to preclude damage to the facility. Without this separation the following occurs (north-south earthquake).

The relatively massive second floor slab is excited by seismic forces and moves. The force generated by the slab acceleration is transferred to the column (bearing load) and to the floor beam (by friction). The movement of the

column and floor beam creates loads in the vertical concrete walls in Column 4 (between Columns A through E) and Column 8 (between Columns C and D). If the vertical walls were weak (like plaster board), they would crumble and the east side of 234-5Z would move just like the west side and the stresses would be within limits. The walls are strong, so the load is transferred to the column base plate. Since there are few base plates to carry the load, they become overstressed. The failure mode without the separation is: failure of the base plate and spalling of the vertical wall (with possible gross failure).

The equipment that would be impacted by the failure of the wall is the inactive HF scrubber, a few empty rooms, and some piping in the duct level. There is no significant dispersal of plutonium into the facility as a result of the failures.

9.2.4.3 Mitigation. The PFP has been reviewed for seismic resistance many times. At each review, many modifications have been made which assist in mitigating the consequences of accidents that could occur. These modifications also assist in preventing or reducing the likelihood of these accidents. A short list of modifications that were made based on previous analyses are:

- Automatic shutdown of building ventilation supply fans
- Removal of propane piped gas substituted by use of small bottles. [See Section 9.2.1F - Flammable Gas Explosion]
- Removal of methane gas
- Removal of hydrogen fluoride gas
- Modifications as necessary to show that certain gloveboxes, ducts from the gloveboxes to the first testable filter bank, and filterboxes holding this filter bank remain upright.

9.2.4.4 Recovery. The recovery from a seismic event will involve facilities other than PFP and may involve personal injury as well as radioactive and toxic material release. The injured personnel (if any) would be removed from the facility soon after the event. Since they could be contaminated, special medical facilities will need to be used. After (or during) the removal of the personnel, the processes will be stabilized (probably by disconnecting the electricity since electrical power is not needed for safety over the short term). There will likely be work proceeding next to provide for confinement and to assess damage. Confinement will be important if glovebox panels have failed or if an explosion occurred. Next, cleanup of the inside can proceed as well as identification and stabilization of sources outside. All of these actions will be planned and the potential releases calculated, accepted, and coordinated with other facilities.

9.2.4.5 Probability. The probability of the DBE (the one to be used in design per the DOE Order 6430.1A, *General Design Criteria*,) is 2×10^{-4} yr^{-1} per Kennedy et al. (1990). The *Natural Phenomena Hazards Modeling Project: Seismic Hazards Models for DOE Sites*, URCL 52582 (Coats and Murray 1984) present additional data (and is referenced for the DBE in Kennedy et al. [1990]) that show that the probability of a 0.2-g earthquake is 10^{-4} yr^{-1} and a 0.25-g at 4×10^{-5} yr^{-1}

(extrapolated). These are all best estimate values. Table 9-29 presents the standard deviations to these estimates.

The determination of the probability of the release is very complicated because it involves the determination of the probability of failure of the individual components. It is further complicated by the fact that to get the release calculated, the failure must be exactly as indicated.

The values of the individual component failures range from very nearly 1.0 (e.g., a very poorly restrained glovebox or an electrical transformer) to as low as 10^{-3}. The earthquake probability ranges from 10^{-3} to 10^{-4}. The value of 10^{-3} was argued in *Details Concerning Development Use and Impact of the Quantity of Material in the E-4 Ducts*, EDT 100843 (Marusich 1988b) to be the probability of the smallest earthquake that could result in damage.

Because of the difficulty of properly assigning a probability to the earthquake and individual component failures, the difficulty of combining them, and the perception that if a component is not specifically qualified to withstand seismic forces, it must be considered to fail with a probability of 1.0, the annual probability of the release calculated in Section 9.2.4.6 is taken to be 10^{-4} for the 0.20-g seismic event. For the 0.09-g seismic event, the annual probability is taken to be 2×10^{-3} based on the same references discussed above.

9.2.4.6 Seismic Accident Analysis.

9.2.4.6.1 Accident Analysis Assumptions. The accident analysis was performed assuming that the failures that were described in Sections 9.2.4.1 and 9.2.4.2 occur with the earthquake.

As stated in Section 9.2.4.2, the inventories of plutonium present are assumed equal to the CPS limits as shown in Table 9-25, except as modified by Table 9-26. Table 9-26 presents administrative limits for select areas or glove boxes that are more restrictive than the CPS limits. Facilities, processes, and locations are analyzed as defined in Section 9.2.4.2.

9.2.4.6.2 Accident Analysis, Methods and Models. Most of the methods and models are the same as those used in Marusich (1988a). Some extensions of the models have been developed and are used where necessary. The extension is described where it is used. Generally, most of the release fraction data come from experiments or empirical data with a small additional amount coming from "first principles." The scenario developed will be compared to the various experiments or empirical fits. The one that matches closest to the scenario is used for the release fraction.

An element common to the majority of the scenarios presented in Section 9.2.4.2 is the spilling of plutonium powders or solutions associated with gloveboxes or hoods. To simplify the analysis, four cases have been examined and the associated release fraction determined.

Case 1--Involves a seismically qualified glovebox. Containers of Pu can tip over because of vibratory motion, but the vibratory motion is insufficient to force the container through the walls, windows, or floor of the glovebox. Therefore, there is no release outside the glovebox. There is negligible Pu

suspension within the glovebox because the resuspension factor, caused by tipping of the container, is very small. Powders could be suspended should a process air line fail; however, the filters at exhaust outlets will minimize the release into the ventilation ducts to an insignificant amount. Thus, it is assumed that seismically qualified gloveboxes do not contribute to the release.

Case 2--Involves a glovebox that is not seismically qualified and could tip over or open up as a result of an earthquake. The floors of most gloveboxes are about 1 m (3 ft) off the floor of the room; therefore, a fall from 1 m (3 ft) represents the typical glovebox accident. Previously, Rev. 0 of Marusich (1988a) used a fall from 3 m (10 ft) to account for the added energy caused by the impact of falling concrete from damaged floors overhead. This approach is now judged to be overly conservative because it has been subsequently determined that the concrete floor on the third level above these gloveboxes does not fail (URS 1987).

For this analysis, the release fraction is based on a 2-m (7-ft) fall. A 2-m fall is selected versus a 1-m fall as some of the energy associated with the toppling glovebox could be transferred to a container of Pu. This value is further justified in Appendix 9.A.

The experimental data found in Table B.3 of NUREG CR-2139, *Aerosols Generated by Free Fall Spills of Powders and Solutions in Static Air* (NRC 1981), demonstrates the maximum respirable release fraction for depleted uranium oxide (DUO). DUO is expected to behave similarly to Pu oxide. For a 1-m (3-ft) drop the respirable release fraction is 4×10^{-5}, and for a 3-m (10-ft) drop it is 5.9×10^{-4}. The values found in Table B.2 of NRC (1981) for a 10 g/L uranium solution are 1.6×10^{-5} for a 1-m (3-ft) drop and 8.3×10^{-5} for a 3-m (10-ft) drop. The release fraction for a 2-m drop is found by taking the square root of the product of the 1-m and 3-m data. Applying this approach, the respirable release fraction for a 2-m drop of powders is 1.5×10^{-4} and for solutions it is 3.6×10^{-5}.

Case 3--Involves a seismically qualified fume hood. The release fraction is based on the 1-m (3-ft) fall data because of the assumption that the vibratory motion can make the container "walk" over the lip of the hood and fall to the floor below.

Case 4--Involves a fume hood that is not seismically qualified. The situation is similar to Case 2, but the release fraction is based on a 1-m (3-ft) drop as the hoods weigh much less than the gloveboxes and, therefore, the additional energy imparted to the material is smaller.

9.2.4.6.3 Accident Analysis-Calculations. It is helpful if the accident scenario section (Section 9.2.4.2) pertaining to the room or glovebox of interest is reread prior to reading about the accident analysis for that room or glovebox.

9.2.4.6.3.1 Accident Analysis-Calculations, 234-5Z.

9.2.4.6.3.1.A Accident Analysis-Calculation, Analytical Laboratory, Plutonium Processing Support Laboratory, and Standards Laboratory--The Analytical Laboratory contains 26 gloveboxes (two of which are inactive) and 42 hoods. The Analytical Laboratory is contained in rooms 131 through 157. The

PPSL contains nine gloveboxes (two of which are inactive) and eight hoods (two of which are inactive). The PPSL is located in rooms 179 through 188. The Standards Laboratory contains ten combination glovebox/hoods and is located in Rooms 221-C, 221-D and 221-E. An administrative limit of 12.45 kg of dispersible plutonium (of which not more than 5.25 kg is >10% ^{240}Pu) has been established for all three labs. This material, as either a powder or solution, could be present in gloveboxes, hoods, or both.

For this analysis, it is assumed that all of the allowable inventory is present in gloveboxes that are not seismically qualified (e.g., gloveboxes 1 through 6 in room 139, gloveboxes in Room 179, Glovebox 3 in Room 221-C). This assumption is conservative in that the release fraction is larger for unqualified gloveboxes than for unqualified hoods. It is further assumed that all of the material present is a powder. This assumption is conservative in that the release fraction is larger for powders than for solutions. Lastly, it is assumed that the maximum allowable quantity of >10% ^{240}Pu is present. This assumption is conservative in that the dose conversion factor is larger for >10% ^{240}Pu than it is for <10% ^{240}Pu. Therefore, of the 12.45 kg limit of dispersible plutonium, the material is assumed to be in the following forms:

- 5,250 g as plutonium oxide with ^{240}Pu content greater than 10%
- 7,200 g as plutonium oxide with ^{240}Pu content less than 10%.

Applying the Case-2 (Section 9.2.4.6.2) release fraction, the release of respirable Pu into the three PFP laboratories is calculated as follows:

a) <10% ^{240}Pu fraction

$$7{,}200 \text{ g } (1.5 \times 10^{-4}) = 1.08 \text{ g}$$

b) >10% ^{240}Pu fraction

$$5{,}250 \text{ g } (1.5 \times 10^{-4}) = 0.79 \text{ g}$$

Of the 5,250 g of plutonium oxide with ^{240}Pu content greater than 10% in gloveboxes in the laboratories, 0.79 g is released into the facility based on applying the Case 2 release fraction of 1.5×10^{-4}. Also of the 7,200 g of plutonium oxide with ^{240}Pu content less than 10% in the gloveboxes in the laboratories, 1.08 g is released into the facility based on applying the Case 2 release fraction of 1.5×10^{-4}.

The accident analysis for the seismic event impacts on the PFP laboratories does not include seismically initiated releases due to the Laboratory Prototype Calciner in the PPSL since the calciner is not authorized for operation. The releases from the laboratories due to a seismic event and considering operation of the calciner are presented in Section 9.2.4.9 and in the Laboratory Prototype Calciner addendum to this FSAR. However, these releases are not included in the total facility releases from the seismic event evaluated in this analysis.

9.2.4.6.3.1.B Accident Analysis-Calculation, 234-5Z Room 145--See analysis presented in Section 9.2.4.6.3.1.A.

9.2.4.6.3.1.C Accident Analysis-Calculation, 234-5Z Room 139--See analysis presented in Section 9.2.4.6.3.1.A.

9.2.4.6.3.1.D Accident Analysis-Calculation, 234-5Z Room 152--The laboratory waste concentrator in room 152 is no longer used. If future use of the concentrator is required the section will be analyzed and incorporated.

9.2.4.6.3.1.E Accident Analysis-Calculation, 234-5Z Argon Release--Argon lines can fail as a result of the earthquake but there are only consequences for the facility worker.

9.2.4.6.3.1.F Accident Analysis-Calculation, 234-5Z Room 144--In room 144, electric heat is used to heat a sample disk to red hot.

9.2.4.6.3.1.G Analysis-Calculation, 234-5Z Room 136--The Quantimeter was a mixture of argon and oxygen in a steel enclosure to support a small arc near a tiny cup of plutonium oxide (looks like an all-metal automobile fuse). The arc vaporizes the impurities in the powder which are analyzed. The argon flowrate is 10 to 60 times the oxygen flowrate. An oxygen aided fire is not possible as the flow is primarily argon and the plutonium available for release is very small.

9.2.4.6.3.1.H Accident Analysis-Calculation, 234-5Z Room 166--Room 166 contains gloveboxes HC-4 and HC-6 and the South Hood. Glovebox HC-6 is inactive and is not considered further.

Glovebox HC-4--A previous analysis of glovebox HC-4 calculated a significant release from glovebox HC-4 based on the assumption that the front glovebox panel came out because the glovebox was not seismically qualified. The motive force for the release was a recirculation pump assumed to be operating at the time the seismic event occurred. The glovebox has been modified such that it remains standing and the panels remain in place. Although failures could occur such that the recirculation pump sprays Pu solution, there is no release outside of the glovebox per Case 1.

South Hood--The South Hood has a CPS limit of 400 g of Pu. There are no restrictions on isotopic composition; thus, it is conservatively assumed that the entire 400 g is >10% ^{240}Pu.

The respirable release fraction for solutions applied to hoods (either Case 3 or 4) is 1.6×10^{-5}. The release into Room 166 is calculated as follows:

$$400g\ (1.6x10^{-5}) = 0.01g$$

9.2.4.6.3.1.I Accident Analysis-Calculation, 234-5Z Rooms 174, 175, 190 and 225--Rooms 175, and 190, contain pedestal storage, room 174 contains cabinet shelf storage, and room 225 contains cubicle shelf storage, and cubicle storage (room 174). The criticality specifications generally allow 2,500 g (H/Pu<2) of plutonium in each storage location. Exceptions to this are documented in

individual ciriticality prevention specifications (CPS's) and postings. Storage is in carbon steel containers. Loss of ventilation may result in overheated and thus pressurized containers. The following calculations show that the containers will not fail.

The analysis first starts with a determination of the heat rate due to decay. Using the heat rate, the temperature across the container is determined. The heat rate is put into the room and the wall temperature is determined over time. The container temperature is then determined from the wall temperature.

The heat rate for each container is:

$$\text{Heat rate} = (2{,}500\ \text{g})(0.67\ \text{Ci/g})\left(3.7\text{x}10^{10}\ \frac{\text{dis}}{\text{s-Ci}}\right)\left(5.5\ \frac{\text{MeV}}{\text{dis}}\right)\left(\frac{10^6\ \text{eV}}{\text{MeV}}\right)$$

$$= 3.4\text{x}10^{20}\ \text{eV/s}$$

where: 2,500 g = Amount of plutonium in a container
0.67 Ci/g = Activity (Marusich 1988a, p. A-3).

The power is:

$$3.4\text{x}10^{20}\ \frac{\text{eV}}{\text{s}}\left(1.6\text{x}10^{-12}\ \frac{\text{erg}}{\text{eV}}\right)\left(10^{-7}\ \frac{\text{W-s}}{\text{erg}}\right) = 54.4\ \text{W}$$

Note that this value is much higher than the facility figure of 5-10 W based on 6% ^{240}Pu. The value of 54.4 W differs from 5-10 W because ^{241}Pu, which comprises about 90% of the total Curies, is not an alpha emitter. However, the value will continue to be used because there is some material in the storage rooms that does not have 90% of the total curies as ^{241}Pu. Some packages are as high as 25 W.

$$54.4\ \text{W}\left[\frac{3.4\ \text{Btu}}{\text{h-W}}\right] = 185\ \frac{\text{Btu}}{\text{h}}$$

To find the temperature in the container, the room and plutonium container are modelled like a nuclear reactor fuel element (cylinder with distributed source). The containers are separated by 4 in. of air if measured between one side of the pedestal and the other and 1 to 2 ft in between pedestals. Using the *Principles of Nuclear Engineering*, p. 662 (Glasstone 1955) the temperature distribution through the container is:

$$T - T_c = \frac{Q}{4k}(a^2 - r^2)$$

where: T = Temperature within the container, °F
T_c = Temperature at edge of container, °F
Q = Volumetric heat rate, Btu/h-ft^3
k = Thermal conductivity, Btu/h-ft^2 °F
a = Radius of container, ft
r = Radius within container, ft.

therefore,

$$V = \frac{\pi}{4}\left[\frac{2 \text{ in}}{12 \text{ in/ft}}\right]^2 \frac{6 \text{ in}}{12 \text{ in/ft}} = 0.011 \text{ ft}^3$$

$$Q = 185 \frac{\text{Btu}}{\text{h}}\left[\frac{1}{V}\right] = 1.68 \times 10^4 \frac{\text{Btu}}{\text{h-ft}^3}$$

$$k = 0.023 \text{ cal/s-°C-cm}$$

$$= 5.56 \frac{\text{Btu}}{\text{h-ft-°F}}$$

$$a = \frac{2 \text{ in}}{12 \text{ in/ft}} = 0.16 \text{ ft.}$$

$$T - T_c = \frac{1.68 \times 10^4 \frac{\text{Btu}}{\text{h-ft}^3}}{4(5.56)\frac{\text{Btu}}{\text{h-ft-°F}}}(0.16 \text{ ft})^2 = 19 \text{ °F, if } r = 0$$

When r = 0, T = centerline temperature.

So the temperature distribution through the powder is essentially uniform. The temperature in the container must now be determined. Heat is transferred through the container by conduction, through the air by radiation and into the concrete wall or cubicle by conduction. The temperature difference between the container outer surface and the room wall assuming radiation heat transfer (free convection heat transfer is small compared to the radiation heat transfer) is (Parker et al. 1974):

$$q = (0.1718 \times 10^{-8})\, A\, F_{12}\, (T_c^4 - T_w^4) + hA\,(T_c - T_w)$$

where: q = Heat rate of the container, Btu/h
A = Surface area of the container, ft^2 = π(dia.)(height) =

$\pi(4 \text{ in.})(6 \text{ in.})/144 \text{ in}^2/\text{ft}^2 = 0.52 \text{ ft}^2$
h = Heat transfer coefficient = $0.22 (T_c - T_w)^{0.33}$ for natural circulation
T_c = Outside surface temperature, °R (°R = °F + 460)
T_w = Wall temperature, °R
F_{12} = Fraction of radiation exchanged between surfaces 1 and 2 (between the surface and the wall).

The wall temperature under conditions of constant heat rate from the container assuming an infinitely thick wall is:

$$T_w = \frac{2q}{K_w A}\left[\frac{at}{\pi}\right]^{0.5}$$ (Jakob 1957, p. 258)

where: T_w = Wall temperature, °F
t = Time, h
q = Heat rate of the container, Btu/h = 185 Btu/h
A = Area of the wall irradiated by the container and is chosen to be the area over which the heat falls perpendicularly = 1 ft^2
k_w = Thermal conductivity of the wall, Btu/h-ft-°F = 0.79 Btu/h-ft-°F (Parker et al. 1974)
a = Thermal diffusivity = k_w/pC_p = 0.021 ft^2/h (Parker et al. 1974)
p = Density of the wall, lb/ft^3
C_p = Specific heat of wall, Btu/lb-°F.

Choose one container and use 36 h after loss of ventilation as representative of the time over which power is lost:

$$T_w = \frac{2\ (185)}{0.79\ (1)}\left[\frac{0.021\ (36)}{\pi}\right]^{0.5}$$

Solving yields

$$T_w = 229.8 \text{ °F}$$

Since the room is at 70 °F, the wall temperature will be 300 °F.

Now to determine T_c the equation for natural convection radiation must be solved. Assume $F_{12} = (1/0.429)$, which is from Marusich (1988a), p. A-9, a

similar case where containers of PuO_2 are stored in a concrete room in the Fuels and Material Examination Facility.

Solving:

$$185 = (0.1718 \times 10^{-8})(0.52\ ft^2)\ (1/0.429)\ \ [(T_c + 460)^4$$

$$- (300\ °F + 460)^4] = 0.22\ (T_c - 300\ °F)^{0.33}$$

$$x\ (0.52\ ft^2)\ (T_c - 300\ °F)$$

Solve by substitution:

T_c	Left-hand side (correct values of T_c gives 185)
350 °F	221
340 °F	173
330 °F	126

So the container wall temperature is about 343 °F at 36 h.

The internal pressure has then increased due to temperature rise. At a concrete temperature of 70 °F (about normal) the container temperature is found by solving the equation above using T_w = 70 °F. The container temperature under these assumptions is 180 °F. The initial pressure is 17.7 lbf/in^2 assuming initial air was 70 °F, and assuming the ideal gas law applies ($P_2/14.7$ = [460 + 180]/[460 + 70]) the internal pressure at 36 h increased to:

$$\frac{P_2}{17.7\ lb/in^2} = \frac{(460 + 343)}{(460 + 180)}$$

where: P_2 = 22.2 lbf/in^2.

The *Initial Concepts on Energetics and Mass Release During Non-nuclear Explosive Events in Fuel Cycle Facilities*, NUREG/CR-4593, p. 11 (Halverson 1986) gives an equation for stress covered by expansion as:

$$\sigma = \frac{PD}{2t}$$

where: σ = Ultimate tensile strength, lb/in^2 = 65,000 for carbon steel
P = Burst pressure, lbf/in^2
D = Diameter, in. = 4 in.

t = Thickness, 0.009 in. (Szempruch 1984).

$$65{,}000 \text{ lb/in}^2 = \frac{P \text{ (4 in.)}}{2 \text{ (0.009 in.)}}$$

$$P = 292 \text{ lbf/in}^2.$$

Since the pressure in the container is 22 lbf/in^2 it will not fail due to pressure. *The Effectiveness of Corrective Actions Taken to Preclude Events Involving Tin Cans and Plutonium*, RHO-HS-SA-59P (Szempruch 1984) also points out on p. 23 that containers can hold up to 100 lbf/in^2 and do not bulge until 40 lbf/in^2 g. Note that more recent studies suggests bulging begins at approximately 15 psig and that containers may vent at the seam between 30 and 50 psig (Figure 9-37).

Historically, containers have failed due to alpha radiolysis of moisture or organics in the powder, phase change in the metal or oxidation of the metal (turns metal into powder with a significant volume increase) due to air in-leakage. The assumption in the seismic event is that the containers are good and they are filled with material which meets specifications; therefore, none of the above is assumed to occur with the earthquake (the probability of an earthquake big enough to shut off the ventilation coupled with the storage of "bad" containers is incredible).

9.2.4.6.3.1.J Accident Analysis-Calculation, 234-5Z Plutonium Processing Support Laboratory, Rooms 179 through 188--The release from the PPSL, other than from the Laboratory Prototype Calciner, is calculated along with the releases from the Analytical and Standards Laboratories in Section 9.2.4.6.3.1.A. The release from the PPSL from the Laboratory Prototype Calciner is discussed in Section 9.2.4.9 but are not included in the total facility releases due to a seismic event since the calciner is not authorized for operation.

9.2.4.6.3.1.K Accident Analysis-Calculation, Rooms 192-A, 192-B, and 192-C--Rooms 192-B and 192-C contain pedestal storage locations similar to those in rooms 174 and 175. Room 192-A contains floor storage of FFTF fuel pins and fuel elements in special shipping containers.

9.2.4.6.3.1.L Accident Analysis-Calculation, 234-5Z Standards Laboratory, Rooms 221-C, 221-D, and 221-E--The release from the Standards Laboratory is calculated along with the releases from the Plutonium Processing Support Laboratory and the Analytical Laboratory in Section 9.2.4.6.3.1.A.

9.2.4.6.3.1.M Accident Analysis-Calculation, 234-5Z Room 227--Room 227 contains Glovebox HC-227S and Hood HC-227T.

Glovebox HC-227S. Referring to Section 9.2.4.2.1P, the accident scenario for Glovebox HC-227S is a pressurized release of solution due to a recirculation pump discharge line failure.

The release fraction as a result of the rapid opening of a pressurized container into a test vessel 3 m tall and 3 m in diameter was determined in

Aerosols Generated by Releases of Pressurized Powders and Solutions in Static Air, PNL-4566 (Sutter 1983). The aerosol in the test vessel, which resulted from depressurization, and the aerosol that formed when liquid transported to the ceiling by the initial depressurization fell to the floor, was measured. The maximum respirable fraction is 10^{-5} for 100 cm^3 uranyl nitrate nonahydrate sources at 50 lbf/in^2 (gauge) (Sutter 1983, Table B-5). The discharge pressure of the HC-227S recirculation pump is 40 lbf/in^2 (gauge). Because room 227 is larger than the test vessel, the release fraction will be larger. The release fraction will also be larger because the material will be airborne for a greater period of time. To account for this, the release fraction for 250 lbf/in^2 (gauge)$_5$ (i.e., the next test pressure used by Sutter) is used: a value of 4×10^{-5}.

Assuming the entire 20,000 g allowable inventory is present, and applying a respirable release fraction of 4×10^{-5}, the release into room 227 from Glovebox HC-227S is calculated as follows:

$$20{,}000g\ (4x10^{-5}) = 0.8\ g$$

Hood HC-227T. Hood HC-227T is used for Pu nitrate load-in and load-out with a single solution container limited to a maximum of 4,500 g of Pu for the transfer. Vacuum is used to make the transfers. Most of the time the outer carrier lid is off. The inner solution container remains in the carrier although there are times that the inner container with solution is removed using a hoist. The height of the container during these activities is nominally 2 m. In a seismic event the worst possible release of Pu to the room would be caused by a drop of the inner container loaded to 4,500 g of Pu from a height of 2 m. The associated release fraction is 3.6×10^{-5} (per Case 2 for solutions). The release of plutonium into Room 227 from Hood HC-227T is shown by the following equation:

$$4500g\ (3.6x10^{-5}) = 0.16\ g$$

It should be noted that it would be unlikely for both Glovebox HC-227S and Hood HC-227T to be at maximum plutonium inventory limits. There must be room in an empty solution container in Hood HC-227T to receive the loadout material. However, for conservatism it is assumed that maximum inventories are present in both gloveboxes. Therefore, 0.96 g is the maximum release into Room 227 from any scenario involving Hood HC-227T and Glovebox HC-227S. This material is assumed to be > 10% ^{240}Pu as there are no restrictions on isotopic composition.

9.2.4.6.3.1.N Accident Analysis-Calculation, 234-5Z Room 228-A--Room 228-A contains gloveboxes HC-1, HC-2, HC-7, HC-9B, HC-10, and HC-11.

Conveyor glovebox HC-1 extends into rooms 228-A, B and C. Conveyor glovebox HC-2 extends into room 228-C and rooms 230-A and B. These conveyors are normally empty and thus are not considered further. Glovebox HC-10 is also not considered further because it is inactive.

Glovebox HC-7. Glovebox HC-7 is inactive except when used as a portion of the solution transfer system from HC-227S to 236-Z. The scenario is assumed to

be identical to that for HC-227S; i.e., a pressurized release of solution due to a recirculation pump discharge line failure. Using the preceding information for HC-227S, the release is 0.20 g. It is important to note that solution is present in HC-7 only during transfers from HC-227S. Accordingly, the release of 0.20 g can be assigned to either HC-227S or HC-7, but not both simultaneously.

Glovebox HC-9B. Glovebox HC-9B is seismically qualified; thus, there is no release outside of the glovebox per Case 1.

Glovebox HC-11. Glovebox HC-11 is seismically qualified; thus, there is no release outside of the glovebox per Case 1.

9.2.4.6.3.1.O Accident Analysis-Calculation, Room 228-B--Room 228-B contains gloveboxes HC-1, HC-12S, HC-13MD, HC-15A, HC-15B, HC-15C, and HC-16CC all of which are inactive, except HC-1 and HC-13MD. Conveyor glovebox HC-1 is normally empty. Glovebox HC-13MD is used for seal-in or/and seal-out of plutonium bearing materials to or from the thermal stabilization process. The glovebox is not seismically qualified. Maximum plutonium allowed in glovebox HC-13MD is 2,500 g. The material is assumed to be PuO_2. Applying a release fraction of 1.5×10^{-4} as established in release case 2 (Section 9.2.4.6.2), the release to Room 228-B is 0.38 g.

9.2.4.6.3.1.P Accident Analysis-Calculation, 234-5Z Room 228-C--Room 228-C contains gloveboxes HC-17-SBB, HC-17DC, HC-17P, HC-18BS, HC-18M, and conveyor gloveboxes HC-1, HC-2, and HC-5. Gloveboxes HC-17-SBB, HC-17DC, and HC-17P are inactive. Conveyor gloveboxes HC-1, HC-2, and HC-5 are normally empty.

Glovebox HC-18BS--Glovebox HC-18BS is seismically qualified thus there is no release outside the glovebox per Case 1.

Glovebox HC-18M--Glovebox HC-18M is not seismically qualified. The CPS limit is 10,000 g. The material is assumed to be >10% ^{240}Pu as there are no restrictions on isotopic composition. Applying a release fraction of 1.5×10^{-4} per Case 2, the release is calculated as follows:

$$10{,}000g\ (1.5x10^{-4}) = 1.50\ g$$

9.2.4.6.3.1.Q Accident Analysis-Calculation, 234-5Z Room 230-A--Room 230-A contains glovebox HC-21C. The glovebox has a CPS Limit of 5,000 g. The material is assumed to be >10% ^{240}Pu as there are no restrictions on isotopic composition. Applying a release fraction of 1.5×10^{-4} per Case 2, the release is calculated as follows:

$$5000g\ (1.5x10^{-4}) = 0.75\ g$$

The above calculation accounts for the direct, mechanical release of Pu from Glovebox HC-21C. The thermal stabilization process in the glovebox poses potential fire and flammable gas hazards in the seismic event as well. These hazards are addressed in Sections 9.2.10.3 and 9.2.10.5. Section 9.2.10.3 concludes that a small flash fire may result from failure of the glovebox furnaces if PuO_2 containing plastic contaminant is being stabilized at the time

of the seismic event. The additional airborne release of Pu from the flash fire is shown to be insignificant compared to the mechanical release estimated above. The flash fire release is therefore ignored in this analysis.

Sections 9.2.10.5 and 9.2.4.2.12.F conclude that a fire may occur in Glovebox HC-21C as a result of a seismic event which results in hot furnace equipment contacting and igniting the glovebox Lexan™ panels. The additional Pu released from the glovebox in the fire is determined in Section 9.2.4.2.12.F.

9.2.4.6.3.1.R Accident Analysis-Calculation, 234-5Z Room 230-B--Room 230-B contains conveyor gloveboxes HC-2 and HC-3 and glovebox HC-21A. Glovebox HC-21A has a CPS limit of 7,100 g. The material is assumed to be >10% ^{240}Pu as there are no restrictions on isotopic composition. Applying a release fraction of 1.5×10^{-4} per Case 2, the release is calculated as follows:

$$7{,}100\ g\ (1.5 \times 10^{-4}) = 1.07\ g$$

9.2.4.6.3.1.S Accident Analysis-Calculation, 234-5Z Room 230-C--Room 230-C contains glovebox HC-60 and conveyor gloveboxes HC-3 and HC-4. Glovebox HC-60 is inactive and conveyor gloveboxes HC-3 and HC-4 are normally empty.

Glovebox HC-230C-2 was added to the end of the RMC Line in room 230C after the analyses contained in this Section (9.2.4) were originally developed. The worst-case seismic release scenario for glovebox HC-230C-2 is described and analyzed separately in Section 9.2.9.4.

The Magnesium Hydroxide Precipitation Process gloveboxes, HC-230C-3 and HC-230C-4, are located in this room. The effect of a seismic event on these gloveboxes is discussed in Section 9.2.4.10.

9.2.4.6.3.1.T Accident Analysis-Calculation, 234-5Z Room 232--Room 232 contains glovebox HA-46. This glovebox is inactive.

9.2.4.6.3.1.U Accident Analysis-Calculation, 234-5Z Room 235-B--Room 235-B contains glovebox HA-19, HA-20MB, HA-21I, HA-22B, HA-23S, conveyor glovebox HA-28, and part of conveyor HC-4. Conveyors HA-28, and HC-4 are normally empty.

Glovebox HA-19--Glovebox HA-19 is not seismically qualified. It has a CPS limit of 2,500 g. The material is assumed to be >10% ^{240}Pu as there are no restrictions on isotopic composition. Although the glovebox is not qualified, no release is postulated because the Pu present is in the form of polycubes.

Glovebox HA-20MB--Glovebox HA-20MB has been determined to be seismically qualified. Therefore, per case 1, there is no release.

Glovebox HA-21I--Glovebox HA-21I is not seismically qualified. It has a dispersible inventory limit of 8,000 g (Table 9-26). The material is assumed to be >10% ^{240}Pu as there are no restrictions on isotopic composition. Applying a release fraction of 1.5×10^{-4} per Case 2, the release to room 235-B is shown in the following calculation:

$$8{,}000\ g\ (1.5 \times 10^{-4}) = 1.20\ g$$

The above calculation accounts for the direct, mechanical release of Pu from Glovebox HA-21I. The thermal stabilization process in the glovebox poses potential fire and flammable gas hazards in the seismic event as well. These hazards are discussed in Sections 9.2.10.3 and 9.2.10.5. Section 9.2.10.3 concludes that a seismically induced deflagration results in negligible release.

Sections 9.2.10.5 and 9.2.4.2.12.F conclude that a fire may occur in Glovebox HA-21I. The Pu released from the glovebox in the fire is determined in Section 9.2.4.2.12.F.

Glovebox HA-22B--Glovebox HA-22B is seismically qualified. Per Case 1, no release is postulated for this glovebox.

Glovebox HA-23S--Multilevel Glovebox HA-23S is used to store miscellaneous scrap material (e.g., sludge residues collected from PRF gloveboxes, floor sweepings from gloveboxes, samples and standards collected from the lab gloveboxes and hoods, process heel material, etc.). The scrap material is stored in polyjars, which are placed in storage carousels in the glovebox. The polyjars have screw-top lids with a small center hole to allow venting of radiolytically generated gases from the containers. There are eleven storage carousels located on each of four horizontal racetrack-shaped conveyors in the glovebox. The conveyors are spaced 34 in. apart, vertically. The conveyors are supported by floors constructed of 1/4 in. plate and 4 in. x 4 in. x 1/4 in. angle iron braces welded together. Half inch wire mesh fills in large openings in each floor located below the center of each racetrack conveyor.

Each carousel is designed to hold eight polyjars, giving a total of 352 storage positions for the 11 carousels on each of the four conveyors in the glovebox. Only one polyjar may be inserted or removed from the carousel at a time. This is achieved by aligning the desired storage position beneath a cutout in the top plate of the carousel. T-shaped holders in the bottom circular plate of the carousel and the top circular plate of the carousel secure the polyjars in the event the carousel is overturned (e.g., due to contact with glovebox glove during conveyor operation).

The CPS for Glovebox HA-23S limits the quantity of Pu in each carousel to 1000 g and limits the maximum Pu quantity in each container to 1000 g. The total CPS inventory for the glovebox is 44 kg. For the purposes of this analysis, all of the carousels are assumed to be loaded to their 1000 g limit, giving a glovebox inventory matching the CPS limit at the time of the seismic event.

Glovebox HA-23S is seismically qualified (see Table 9-25), meaning it is not expected to topple in the seismic event. However, it is unknown whether the conveyor supports will survive the seismic event. The carousels are not bolted or otherwise secured to the conveyor and may topple or shift from their positioning pins during the seismic event. This may cause carousels to slide into and impact each other. This problem would be exasperated if the conveyor/floor supports failed causing glovebox floors to drop. If the supports survive, it may still be possible for carousels to "hop" over the conveyor rails and fall through the floor openings (depending on the integrity of the wire mesh) or through the elevator area of the glovebox. Impacts or

falls involving carousels may cause individual polyjars to be ejected from the cutout position of the carousel. The carousel would be expected to contain the remaining polyjars due to its design.

Impact of unsecured carousels and ejected polyjars into glovebox equipment, and freefall drops of carousels and polyjars could cause failure of multiple polyjars. The polyjars may be especially susceptible to rupture due to radiation embrittlement during long term storage. Impact damage also imparts energy that can suspend respirable material into the glovebox air through the failed containers. Glovebox windows are assumed to fail due to equipment impacts allowing released material to enter Room 235B.

For the purposes of this analysis, all the material in the polyjars is assumed to be dispersible plutonium oxide powder at the time of the seismic event. As discussed above, much of the material stored in Glovebox HA-23S originates from sludges, process heels, or relatively large solids materials (metal alloys) that are much less dispersible than plutonium oxide. Assuming the inventory is all plutonium oxide ensures a conservative release estimate.

The release fraction used for plutonium oxide powders in containers in other gloveboxes in this seismic accident analysis is overly conservative for the material contained in the polyjars of Glovebox HA-23S. It is possible for the plutonium oxide material in Glovebox HA-21I analyzed above to be in open boats at the time of the seismic event, for instance. The material in Glovebox HA-23S is in closed polyjars (with very small vents). Although the polyjars are assumed to fail, the release fraction for the material in the container would be expected to be significantly less than that postulated for open containers in other gloveboxes.

To account for the material being in closed containers, the Case 2 release fraction of 1.5E-4 is adjusted downward by a factor of 2. The release to the glovebox air is calculated as follows:

$$44{,}000\ \text{g}\ (1.5\text{E-}4)(1/2) = 3.30\ \text{g}$$

This release estimate is judged to be conservative for the following reasons:

- The glovebox is assumed to be loaded to its CPS inventory limit. It normally contains considerably less than this amount.
- All the material is assumed to be dispersible plutonium oxide powder. The inventory typically in Glovebox HA-23S contains sludges, process heels, lab samples, metal alloys and other scrap materials that are much less dispersible than PuO_2.
- All containers (polyjars) are assumed to be impacted and damaged in the event. Based on the design of the carousels, conveyor supports and glovebox floors, only a fraction of the containers would be expected to be damaged.

Conveyor Glovebox HA-28--Conveyor glovebox HA-28 is not seismically qualified. The CPS limit is 2,500 g. The material is assumed to be >10% ^{240}Pu as there are no restrictions on isotopic composition. Applying a release fraction of 1.5 x 10^{-4} per Case 2, a release of 0.38 g is calculated as follows:

$$2500g\ (1.5x10^{-4}) = 0.38\ g$$

The Bagless Transfer System glovebox, HA-53BTS, is also located in this room. The release from this glovebox as a result of the seismic event is found in Section 9.2.4.11.

9.2.4.6.3.1.V Accident Analysis-Calculation, 234-5Z Room 235-C--Room 235-C contains glovebox 235-B-2. Glovebox 235-B-2, with a CPS limit of 2,500 g, is not seismically qualified. The material is assumed to be >10% ^{240}Pu as there are no restrictions on isotopic composition. Applying a release fraction of 1.5 x 10^{-4} per Case 2, a release of 0.38 g is calculated as follows:

$$2500g\ (1.5x10^{-4}) = 0.38\ g$$

9.2.4.6.3.1.W Accident Analysis-Calculation, 234-5Z Duct Level-- Releases from the duct level result from the presence of plutonium in the E-4 ventilation system ducting and filterboxes 7A and 9A.

E-4 Ducting--Based on NDA measurements, there are 6,000 g of Pu present in the E-4 ventilation system ducting. The *PFP Remediation Project Management Plan*, WHC-SD-CP-PMP-003, Figure 1 (Schilling 1989) shows schematically the location of contaminated E-4 ducts. Attachment II of Marusich (1988b) shows specifically the holdup in the E-4 ducts of the RMC Line.

To reduce the risk associated with Pu holdup in E-4 ducts, sections of ducting have been modified in accordance with Herzog (1991) to withstand seismic forces. The quantities of Pu involved are 1,800 g (in the FB-9B bypass duct) and 1,893 g (in two other duct sections near HC-9B and FB-9B). The quantity of material at risk is therefore 2,307 g. For the purposes of this analysis, the entire 2,307 g (6,000-1,800-1,893) is assumed to be present in the form of suspendable powders. This assumption is judged to be conservative based on plant experience indicating that a significant fraction of the material is tightly adhered to internal duct surfaces. Specifically, scraping of a segment of ducting removed only 4 out of 7 g present as measured by NDA. In addition recent ductwork remediation efforts have greatly reduced the amount of plutonium in the E-4 ventilation system.

A resuspension model is used to estimate the quantity of Pu released versus application of release fractions based on powder spills from either a 1- or 3-m height. A resuspension model is judged applicable given the anticipated seismically induced vibration of the ducts. NRC (1981) provides a list of resuspension factors. Sutter provides a resuspension factor from 0.01 m^{-1} to 0.04 m^{-1} for vigorous sweeping in an unventilated room. Because the energy imparted to the Pu from the seismic event is envisioned to be much less than from vigorous sweeping, the lower bound of the data (i.e., 0.01) is used. The release is calculated as follows:

$$\frac{\text{g suspended within duct volume}}{\text{volume}} = \frac{\text{0.01 g on surface}}{\text{surface area}}$$

$$\frac{G_v}{\frac{\pi}{4} d^2 L} = 0.01 \frac{G_s}{\pi d L}$$

where: G_v = g suspended in volume
G_s = g on the surface
d = duct diameter, m
L = duct length, m

Cancelling out the common terms gives:

$$G_v = 0.01 \ (G_s) \ \frac{d}{4}$$

Since the diameter of the ducts is 10 in., d is equal to 0.25 such that:

$$G_v = 0.01 \ (0.25) \ G_s = 0.0025 \ G_s$$

Given G_s is equal to 2,307 g, the quantity of Pu resuspended is 5.77 g. Of this mass, 20% or 1.15 g is respirable. Based on the operating history of the facility, the material is assumed to be <10% ^{240}Pu.

Filterboxes 7A and 9A--Filterboxes 7A and 9A are not seismically qualified. Based on NDA measurements, the inventory of Pu present is 26 g and 66 g respectively. Based on the operating history of the facility, this material is assumed to be <10% ^{240}Pu.

The release from the filter boxes is calculated using the model presented in Marusich (1988a), p. 4-43, in which structural failures are assumed to result in crushing of the filter boxes. Based on the difference observed from removal of the filter from filter box 9A, 85% of the Pu is assumed to be associated with the filter. Release from the filter is treated as in *Source Term and Radiation Dose Estimates for Postulated Damage to the 102 Building at the General Electric Vallecitos Nuclear Center*, PNL-2844 (Mishima et al. 1979b), with 10% of the of the Pu on the crushed filters made immediately available for suspension. Of these particles, 10% are assumed to be respirable (Wodrich 1984). The release associated with crushing of the filters is 0.78 g:

$$92\text{g} \ (0.85) \ (0.1) \ (0.1) = 0.78 \text{ g}$$

The amount of respirable Pu contributed by the filter boxes (versus the filters) is based on a concentration of 15 mg/m^3 assumed to be present following

shaking of the boxes by seismic forces. Given each filterbox has an approximate volume of 1.5 m^3, the release is 0.05 g:

$$2\,(1.5)\,(15 mg/m^3)\,(1x10^{-3} g/mg) = 0.05g$$

The total release associated with filter boxes 7A and 9A is therefore 0.83 g.

The calculations above are judged to be very conservative. This judgement is based on the fact that the model developed in Marusich (1988a) presumed severe structural failures resulting in collapse of the duct and second level floors. Revised structural analyses have shown the floors do not collapse. Thus, the filters are not crushed.

9.2.4.6.3.1.X Accident Analysis-Calculations, Second Floor (Third Level) 234-5Z.

9.2.4.6.3.1.X.a Filter Rooms--The E-3 and E-4 filter rooms are located on the second floor of 234-5Z. There are two E-4 filter rooms each containing 128 filters. There are seven E-3 filter rooms each containing 112 filters. Because the HEPA filter frames are not seismically qualified, it is assumed that all of the filters (a total of 1,040) fall to the floor. This assumption is judged to be conservative as the filters are bolted into the filter frame and it is unlikely that all 1,040 filters would be dislodged.

The amount of Pu present on the HEPA filters can be estimated from recent non-destructive assays performed following a HEPA filter change-out of one of the E-4 filter rooms, i.e., room 310 (Fazzari 1994). The removed filters had been in service for fourteen years, during seven of which major 234-5Z processes were operated. The measured Pu loading of 129 individual filters averaged 5.4×10^{-3} g. Based on this information, it is assumed that the E-4 filters contain a total of 2.76 g of Pu as shown by the following equation:

$$(256 \text{ filters}) \times (0.0054 \text{ g/filter}) \times (2) = 2.76 \text{ g}$$

where:

- 256 represents the total number of E-4 filters
- 0.0054 represents the average filter loading
- 2 represents a factor accounting for potential future increases in HEPA filter loading. Application of a factor of two is judged to be conservative as the room 310 data is believed to be representative of future filter loadings based on the 14-year service life of the filters.

The E-3 filters are assumed to contain a total of 4.23 g of Pu as shown by the following equation:

$$(784 \text{ filters}) \times (0.0054 \text{ g/filter}) = 4.23 \text{ g}$$

where:
- 784 represents the total number of E-3 filters
- 0.0054 represents the average filter loading.

The value of 0.0054 is applied as there is no current filter loading data for E-3 filters. Use of this value is judged to be conservative as the E-3 filter rooms draw the atmosphere of rooms while the E-4 filter rooms draw the atmosphere of gloveboxes. Therefore, the E-3 filters would logically contain less Pu as glovebox interiors would produce much more filter contamination. Accordingly, the factor of 2 is not applied to the E-3 calculation as it was to the above E-4 calculation.

The release from the filter rooms is calculated using the model presented in Marusich (1988a), page 4-43, in which structural failures are assumed to result in crushing of the filters. Ten percent of the material on the filters is assumed to be suspended of which 10% is assumed to be respirable. (Note that this is equivalent to the 0.01 respirable release fraction applied in the filter drop scenario, Section 9.1.5A). The release is therefore 0.07 g Pu:

$$(2.76g + 4.23g) \times (0.10) \times (0.10) = 0.07g$$

Based on the operating history of the facility, this material is assumed to be <10% ^{240}Pu.

Accident Analysis-Calculations, Downstream Plutonium--There is plutonium powder downstream of the final filters. Schilling (1989) states that, excluding the exhaust stack, the estimated plutonium accumulation in the section downstream of the final filters is 2 to 20 g. Of this, between 0.16 g and 1 g is contained in the sheet metal exhaust plenums inside the 234-5Z Building. This material is also "tightly held" (Schilling 1989). The earthquake forces will cause the ducting to vibrate vertically, horizontally, and there may even be torsional forces. These forces may result in the loosening of this material and possibly its resuspension.

The situation described above can be viewed as being similar to resuspension due to moving a dolly over a contaminated surface or walking over a contaminated surface. Resuspension factors (Curies per cubic meter above surface divided by Curies per square meter contaminated) for these cases are 2×10^{-4} m^{-1} (NRC 1981). The total E-4 and E-3 duct area is ≈13,000 ft^2 (Fulton 1989). The stack manifold volumes can be estimated using dimensions from Figures 9-24, 9-25, and 9-26. The E-3 volume is ≈510 m^3 and E-4 volume is ≈96 m^3.

From *Transmittal of Results on Plutonium Holdup Downstream of Final Filtration at the Plutonium finishing Plant*, Attachment 1 (Fulton 1989) the areal plutonium concentrations for the E-3 and E-4 duct surfaces can be calculated. Using the high side of the error bound for the amounts present and by lumping floor and nonfloor surfaces the areal concentrations are calculated as follows:

$$\text{E-3} \quad \frac{3 \times 10^{-1}\ \text{g}}{12{,}000\ \text{ft}^2} = 2.5 \times 10^{-5}\ \text{g/ft}^2\ (2.7 \times 10^{-4}\ \text{g/m}^2)$$

$$\text{E-4} \quad \frac{6 \times 10^{-1}}{1{,}300\ \text{ft}^2} = 4.6 \times 10^{-4}\ \text{g/ft}^2\ (5 \times 10^{-3}\ \text{g/m}^2)$$

The amount of plutonium suspended in each system is the product of the suspension factor, the areal concentration, and the volume.

$$\text{E-3} \quad 2 \times 10^{-4}/\text{m} \times 2.7 \times 10^{-4}\ \text{g/m}^2 \times 510\ \text{m}^3 = 2.8 \times 10^{-5}\ \text{g}$$

$$\text{E-4} \quad 2 \times 10^{-4}/\text{m} \times 5 \times 10^{-3}\ \text{g/m}^2 \times 96\ \text{m}^3 = 9.6 \times 10^{-5}\ \text{g}$$

Adding the amount for each duct system gives the total suspension.

$$2.8 \times 10^{-5}\ \text{g} + 9.6 \times 10^{-5}\ \text{g} = 1.2 \times 10^{-4}\ \text{g suspended}$$

Vibrating the duct is not an efficient way to disperse plutonium. The release from the duct surfaces is small compared to the other releases calculated in this section and is ignored.

9.2.4.6.3.1.X.b Chemical Storage Area--The chemicals stored in rooms 336, 337, and 338 are those needed for routine processes. Other chemicals that may be needed are purchased in small quantities to satisfy immediate needs. An active inventory of all chemicals used at the PFP is maintained per 40 CFR Part 355 (SARA).

Rooms 336 and 337 contain numerous chemical makeup and storage tanks previously used in support of RMA and RMC Line operations (see Chapter 5, Section 5.4.13). The majority of these tanks are empty. Currently, Tank C in room 336 is used for the storage of 57 wt% HNO_3. This tank has a volume of 600 L. Tanks G-1 and G-2, also in room 336, are used for the storage of dilute (1.8-2.2 M) HNO_3. These tanks each have a volume of 175 L. Room 336 may also be used for the storage of drums of KOH. Although HNO_3 and KOH can react violently, the concrete sumps around the storage tanks would effectively prohibit mixing given a seismic event. The onsite and offsite consequences of seismic-induced HNO_3 spill within room 336 are bounded by those presented in 9.2.4.6.3.5.D.

Room 338 is used for the storage of the dry chemicals. Chemicals include activated charcoal, portland cement, and sodium carbonate (see Table 9-30). The inadvertent mixing of these dry chemicals would not result in a hazardous reaction.

9.2.4.6.3.2 Accident Analysis-Calculations, 236-Z, PRF.

9.2.4.6.3.2.A Solvent Extraction.

9.2.4.6.3.2.A.a Accident Analysis-Calculations, 236-Z Criticality--An analysis of the potential for a criticality in 236-Z is contained in Section 9.2.4.2.11.N.

9.2.4.6.3.2.A.b Accident Analysis-Calculations, 236-Z, Solvent Extraction, Na_2CO_3 and HNO_3 Reaction--If the line carrying Na_2CO_3 to the CX column fails, and if the lines carrying HNO_3 fail and if these solutions mingle, the following reaction takes place:

$$Na_2CO_3 + 2HNO_3 \rightarrow 2NaNO_3 + CO_2 + H_2O + Heat$$

No reactive gases are released and the effects of the heat and gas can be easily accommodated in the gallery glovebox, the canyon (through holes between the gallery glovebox and the canyon), and the ventilation system/piping.

There is no large blowback from the CX column where Na_2CO_3 and HNO_3 are mixed in the process, because both streams are very dilute. Piping failures outside of the column can result in the mixing of higher concentration solutions.

9.2.4.6.3.2.A.c Accident Analysis-Calculations, 236-Z, Solvent Extraction, Pipe or Tank Failure in Canyon or Glovebox--A pipe or tank failure in the canyon would result in a resuspension of plutonium droplets as described in the 234-5Z analysis. The spill in the canyon was covered in Marusich (1988a), pp. 4-75 and -76, and was determined to be 0.40 g.

9.2.4.6.3.2.A.d Accident Analysis-Calculations, 236-Z, Solvent Extraction, Overflows of Solution to the 52 Tanks--Overflows of solution to the overflow tanks are of two kinds, mix of chemicals that react (like Na_2CO_3 and HNO_3) and those that do not react (water and organic). Any or all of the chemicals used in PRF-Solvent Extraction could be present in these tanks. If reactive mixtures are present, the release of gas and energy can again be accommodated by the glovebox, the canyon, and/or the glovebox ventilation piping. There are no mixtures that result in explosive gases or in flammable solutions.

9.2.4.6.3.2.A.e Accident Analysis-Calculations, 236-Z, Solvent Extraction, NaOH Reacting with HNO_3 (TK-17, -18)--The reaction of NaOH and HNO_3 results in the release of heat. Tank A-103 contains a 50% solution of NaOH. Tank A-105 contains a 57% mixture of HNO_3. Tank 17 is 234 L, and is a makeup tank for stream CAF (feed to the CA column). These are very concentrated solutions and have the potential to generate much heat. This heat would pressurize TK-17 (if the valves opened due to seismic forces or seismically induced failure). The chemical addition lines are connected to TK-17 via a funnel break, so that there is no backflow potential up into these lines (Drawing H-2-28021). Blowing the contents of TK-17 to the overflow, vent, or drain results in a flow to TK-52.4 or -52.3 (the overflow tanks, see

Drawing H-2-28032) which in turn overflows to the gallery glovebox (the place of the assumed criticality). If the tank ruptures, there is a release into the canyon that is of little consequence to those inside or outside the facility. While a reaction between two concentrated, reacting chemicals inside a tank is normally an excellent way to disperse the tank solution, it does not appear that any of the dispersed solution will get out of the glovebox.

Note that the funnel breaks are very important to the safety of the occupational worker in this case.

9.2.4.6.3.2.A.f Accident Analysis-Calculations, 236-Z, Solvent Extraction, Failure of the Air Pulser--The columns are pulsed by an air pulser in which air is alternately applied and vented on a 1-in. pulse leg connected to the bottom of the column and extending up to the sixth-floor glovebox. The pulsing is produced using a Hannifin valve, and the pulsed columns are vented. A failure in the Hannifin valve as a result of the earthquake could result in air being constantly applied. A simultaneous failure of the PRV could result in 90-lbf/in^2 air entering the column. Pressurization of the column would result in a mixture of air and solution out the vent (solution will flow to the drain), process solution generally flowing forward to the next step in the process (for those flows originally flowing away from the column), and flow in the reverse direction for those flows normally flowing to the column. Since the pulser pipe is only 1 in. in diameter, and it enters the column far from the source of air (friction along the path), and since there are numerous paths out, all of which are in the gallery glovebox, there is no release from the increased air pressure to a location outside the glovebox or canyon.

9.2.4.6.3.2.A.g Accident Analysis-Calculations, 236-Z, Solvent Extraction, Failure of the Lines in the Pipe Chase--There is a pipe chase in the fourth floor of the PRF, along side the CA and CC column glovebox. The chase has a plastic viewing window on it. Within this pipe chase is:

- The column air pulse legs
- The CCP stream
- The CA column intermediate scrub (CAIS) stream
- The CAX stream
- The CCDP stream
- The column aqueous waste (CAW) stream
- The CUX stream.

The CCDP, CCP, and CAIS streams contain moderately concentrated plutonium aqueous solutions. The CAW stream contains the waste products from the CA column. The CUX and CAX contains chemicals but no plutonium. The CAIS stream is pumped to the CA column using the CAIS Pump Tank contents and pump 36-MOP-B (Drawing H-2-28019). The CCP and the CCDP stream is forced out of the CC column by the action of the air pulser. There is not much force behind this flow unless the Hannifin valves fail. The result of this accident is a spray of plutonium solution from the CAIS stream should this line rupture and the pump remain running and the plastic panel pop out. The CCP and CCDP stream will overflow from the pipe chase if these lines fail and the feed pump continues to run and the panel pops off the pipe chase. It is important to note that the CCP leaves the CC column on the 6th floor and flows by gravity to the 5th floor where there is a stream splitter. When the proper Pu

concentration is reached, part of the flow is diverted via the stream splitter to the CCD tank. The CCDP and CCP both flow down from the 5th floor through the 4th floor pipe chase under a gravity head.

The spray release from the pipe chase is modeled the same as the spray release from glovebox HC-227S, i.e., a release fraction of 4×10^{-5} based on experiments documented in Sutter (1983) (see Section 9.2.4.6.3.1.M). The CCDP stream flows to the CAIS tank, which contains 57 L (Drawing H-2-28019). The CCP stream flows to TK 58 which holds 6 L. The CCP and CCDP streams contain 60 g/L Pu. The release is therefore:

$$(57 \text{ L} + 6 \text{ L}) \times (60 \text{ g/L}) \times (4 \times 10^{-5}) = 0.15 \text{ g Pu}$$

9.2.4.6.3.2.A.h Accident Analysis-Calculations, 236-Z, Solvent Extraction, Transfer Line Failure Outside of Column Glovebox--There is a transfer line that runs from the centrifuges in glovebox MT-6 to the fourth floor column glovebox. The line carries centrifuged CAW stream (Drawing H-2-28040). There are 230 L of CAW with one batch having 0.02 g/L of Pu in it. If a failure of the Hannifin valve occurs so that the column is flooded, and the flood goes out of the CAW line to the centrifuge and then to the surge tank, and the CAW pump continues to pump and the transfer line fails in the room with the CA/CC column pipe chase, then a mixture of organic and solution will come out of the opening. The release fraction will be the same as that for glovebox HC-227S. The CAF stream has a concentration of 4 g/L of Pu but there may be recycle from CCP. The analysis assumes the CA column contains plutonium at 2 g/L (half is CAF and half is non-plutonium solution). The CAF pump tanks contain 220 L each (Kronvall 1988). Assuming only one is in use, the release is:

$$220 \text{ L}(2 \text{ g/L})(4 \times 10^{-5}) = 0.02 \text{ g Pu}$$

The MT-6 glovebox has been declared inactive since the above analysis was originally performed. The release estimate is retained for conservatism, pending a future update to the entire seismic accident analysis.

9.2.4.6.3.2.A.i Accident Analysis-Calculations, 236-Z, Solvent Extraction, Failure of the Drain Lines--Beneath the east and west gallery gloveboxes are the drain lines. The drain lines carry condensate from condensers and from evaporators used in the process. A failure in a drain line will result in a puddle on the floor and not much else.

9.2.4.6.3.2.A.j Accident Analysis-Calculations, 236-Z, Solvent Extraction, Failure of Pipes Between the Second Floor Glovebox and the First Floor Glovebox--There are many lines that travel between the second-floor glovebox and the first-floor glovebox, through access ways in the second floor. Failure of this piping would result in a waterfall down the face of the first-floor glovebox. All of the concentrated plutonium solutions are in the first-floor glovebox, with the exception of the CCP and CAIS streams which were already involved in an accident on the fourth floor. The first-floor glovebox top is 10 ft above the top of the floor (Drawing H-2-29936). The

release fraction for solutions falling 3 m was given previously (room 166) as 2×10^{-5}. In order to get 0.1 g respirable, the amount of solution would need to be (assuming 1 g Pu/L)

$$("x" \text{ L})(1 \text{ g/L})(2 \times 10^{-5})(0.50) = 0.1 \text{ g}$$

where: "x" L = 10,000.

Since there is not this much plutonium solution, the release from the waterfall is negligible.

9.2.4.6.3.2.A.k Accident Analysis-Calculations, 236-Z, Solvent Extraction, Reaction of Hydroxylamine Nitrate with HNO_3--If the CCX flowrate increases, there is excessive carryover of hydroxylamine nitrate to the CAIS pump tank. The CCX flow rate can be increased by a speedup of pump 30-MOP-B (CCX pump tank pump). Low plutonium concentration could also result in carryover of hydroxylamine nitrate. Low plutonium concentration could occur if the CAP pump failed or if the tank became diluted (addition of cooling water as a result of a leak or poor CA column extraction, etc.). The solution in the CAIS tank is mixed with 12M HNO_3 to adjust molarity (WHC-CM-4-29, p 11). The CAIS tank holds 37 L. Assuming that 0.4M hydroxylamine nitrate (WHC-CM-4-29, p. 7) gets to the tank and reacts with 12M HNO_3, the reaction is (Kronvall 1988, pp. 3-37)

$$4NH_2OH + 2HNO_3 \rightarrow 3N_2O + 7H_2O$$

The flowsheet states that this reaction is exothermic and vigorous where the technical reference (Kronvall 1988) implies on pp. 3-37 that the solution must be heated first. The flowsheet will be used as the basis for this analysis. The CCX stream comes from tank A-109 and flows into TK-30, which holds 57 L. Assume that 56 L of hydroxylamine nitrate get to the CAIS tank, as well as 1 L of 12M HNO_3. Fifty-six liters of hydroxylamine nitrate equals 22.4 mol. This will react with 11.2 mol of HNO_3. The reaction will liberate 16.8 mol of N_2O and heat that could result in some steam production. If the cooling water also fails there will be additional heat. The CAIS pump tank contains a vent and an overflow. The chemicals enter the tank via a funnel break. There could be backflow to the CC column. This could be the driving force for the spray in the fourth floor instead of the pump. The conservatisms in that analysis would cover this situation as well. Note that this line does not travel between the first and second-floor gloveboxes.

9.2.4.6.3.2.A.l Accident Analysis-Calculations, 236-Z, Solvent Extraction, Pumping Process Solution Through the Cooling Water Lines--If a pump on one of the pump tanks (like TK-36 or TK-120 on Drawing H-2-28019) continues to run, and the solenoid valve between the tank and the column closes (flow controller system fails somewhere due to seismic forces), and the cooling jacket water flow ceases and depressurizes (line break, etc.) **and** the cooling water piping in the jacket fails, there is no backflow through the

cooling water system because the cooling water jacket surrounds (is outside of) the process pipe (Gibson 1989).

9.2.4.6.3.2.A.m Accident Analysis-Calculations, 236-Z, Solvent Extraction, Steam Line Break in Glovebox--A steam line could fail inside of the glovebox but there would be no consequence of this action since the gloveboxes are quite large. There are holes that connect the gloveboxes with the canyon and the gloveboxes contain a large-diameter ventilation line. Steam condensate would collect on the glovebox floor. In the case of a steam line failure on the second level or third level, the liquid would drain through various pipe chases and gaps to the first-floor gloveboxes.

9.2.4.6.3.2.A.n Accident Analysis-Calculations, 236-Z, Solvent Extraction, Gases Produced in Plutonium-HNO_3 Solutions. Tanks containing plutonium solutions are constantly evolving gas products, primarily hydrogen, as the result of radiolysis. These gas products are vented off from the process tanks through individual vent lines connected to the ventilation system. The ventilation system is operated at a negative pressure relative to the process tanks to maintain the venting. Loss of the ventilation would increase the hydrogen levels in both the process tanks and vent lines. Tank TK-45, examined in this section, contains significant quantities of concentrated plutonium nitrate solutions and is considered to be representative of a worst case situation. This tank is characteristic of the process receiver tanks (TK-45, TK-46 and TK-128) used to receive product solutions from the product concentrator (TK-43).

The starting conditions and assumptions used in this analysis are presented with a discussion of any conservatism associated with them.

- **Plutonium Concentration** -- A concentration of 450 g/L is the upper limit and is based on criticality considerations. The normal operating range is 100 to 400 g/L.

- **Batch Size** -- The operating procedures show a batch size of 40 liters of plutonium product stored in the tank.

- **Plutonium Isotopic Composition** -- The assumed isotopic composition of the plutonium mixture is given in Table 9-7. This composition is characteristic of plutonium with greater than 19% ^{240}Pu. Based on inventory record estimates, less than 6.2% of the plutonium presently being stored at PFP has this high of burnup (Crowe and Szempruch 1994).

- **Tank TK-45** -- Tank TK-45 consists of cylinders constructed of pipe with a diameter of 12.7 cm (5 in) and a height of 114 cm (45 in.). The overflow capacity of the tank is 57 L. A 40 L batch of plutonium solution leaves a head space volume of 17 L.

  Each of the four 5 in. cylinders comprising TK-45 has a vent line (1/2 in. diameter tubing, 0.065 in. wall), an overflow line (1/2 in. diameter tubing, 0.065 in. wall), a pump recirculation line (1/2 in. schedule 40 pipe) and a pump suction line (1 in. schedule 40) pipe. The cylinders and all the piping are made of 304L stainless steel.

The piping from tank TK-45 runs through the process cell wall into the adjacent west corridor, first floor glovebox. The glovebox contains the pump and valves associated with the operation of the tank. This glovebox is seismically qualified (see Table 9-25). From here, there are lines going to the second floor glovebox and beyond.

- **Ignition present** -- Postulating the presence of an ignition source while the ventilation system has been down for an extended period is conservative. A seismic event would result in a shut down of the processes and evacuation of Zone 3. Time would be required for hydrogen to reach flammable concentrations and then an ignition source would have to be introduced or created.

  The most likely source of ignition of the hydrogen in the head space would be a deflagration or explosion somewhere else in the vent system that propagates back through the vent lines to the process tanks. At each tee connection in the vent system, the flame front might be able to propagate down the side line but not as a detonation, only as a burn. A distance of at least 10 pipe diameters would be required to re-establish the detonation conditions. The 3 in. long entrance lines from the 1/2 in. vent line into the 5 in. cylinders do not provide sufficient distance for this to occur. In addition, the critical tube diameter for hydrogen is 7.5 in. for propagation from a tube into a large open space (Camp et al. 1983). Since the vent line is only 1/2 in. in diameter, the vent tube could not initiate a detonation in the head space. Therefore, even if a detonation were to occur the in 1 in. vent header, it would not ignite a detonation in the process tank. The gas in the process tank might be ignited and burn but it does not detonate.

- **Hydrogen generation Rate** -- Henrie and Flesher (1986) provide hydrogen generation rates as a function of the specific gravity. For tank TK-45, the specific gravity for the 6M HNO^3 plutonium solutions with concentrations up to 450 g/L will be greater than 1.7 (Kronvall 1988). For a specific gravity of 1.7, the hydrogen generation rate, $G(H_2)$, is estimated to be 0.06 molecule/100 eV (Henrie and Flesher 1986). Using this value and the data from Table 9-7, the rate of hydrogen generation per gram of plutonium in solution can be calculated as follows:

$$1.557 \frac{Mev}{dis} \frac{Ci}{g\ Pu} \frac{3.7 \times 10^{10}\ dis}{Ci} \frac{2\ g\ H_2}{6.023 \times 10^{23}\ molecules} \frac{0.06\ molecules}{100\ ev}$$

$$= 1.15 \times 10^{-10} \frac{g\ H_2}{g\ Pu\ \text{sec}}$$

Hydrogen generated by radiolysis and released from the solution would collect in the head space volume. Over time, the hydrogen concentration in the head space would increase if the ventilation system was not functioning. Eventually, the lower flammability level would be reached. Since the tank contains no readily apparent ignition sources, the hydrogen concentration would continue to increase until the rate of diffusion of hydrogen out of the

tank matched the rate of hydrogen generation or until the ventilation is restarted. A batch of 40 liters with 450 g Pu/liter reaches a flammable level of 4% in about eight hours.

$$\frac{(4\%)\ (17\ \ell)}{\left(1.15 \times 10^{-10}\ \frac{g\ H_2}{g\ Pu\ sec}\right)\left(\frac{23.4\ \ell}{2\ g\ H_2}\right)\left(450\frac{g\ Pu}{\ell}\right)\ (40\ \ell)} = 7.8\ hours$$

It is postulated that the hydrogen in the vapor space of tank TK-45 is ignited from the vent system. If ignited, the hydrogen in the head space would burn, but due to the large expansion at the entrance and the short distance in the head space, a detonation would not be possible. The tank would pressurize from the hydrogen burn. The peak over pressure due to a hydrogen burn is expected to be eight times the original pressure for a stoichiometric mix (Camp et al. 1983). Halverson and Mishima (1986) give a relationship for the bursting strength of a vessel as a function of the diameter and wall thickness. For tank TK-45, constructed of 5 in. schedule 40, 304L stainless steel pipe with a wall thickness of 0.258 in., the calculated burst pressure is 7,600 lbf/in^2. Since this burst pressure is many times the peak pressure anticipated from the hydrogen burn, the tank will not burst.

The pressure in the tank would be relieved primarily by venting gas through the vent line and also by forcing liquid out the pump suction line at the bottom of the tank. For a release, the liquid must travel out of the tank, through the process cell wall into the first floor glovebox, through the pump, a remote-operated valve, and three manual valves, up to the second floor glovebox and then out of the glovebox. Even at this point, the transfer lines are encased so failure of two barriers would be required for a release.

Estimating the amount of liquid that flows out of the tank that could potentially be released requires calculating the length of time the head space is pressurized. Bird, Stewart and Lightfoot (1960) present a solution for the venting of a tank with expansion of an ideal gas through a frictionless, adiabatic orifice. The gas flow rate from a pressurized tank depends on the pressure at the exit opening. For lower tank pressures, the exit pressure is equal to the ambient pressure or vent line pressure. At higher tank pressures, the exit pressure is independent of the ambient pressure. The critical pressure ratio is defined in terms of gamma, γ, the ratio of specific heats. For a gamma equal to 1.4, the critical pressure is:

$$P_{crit} = \frac{P_{ambient}}{\left(\frac{2}{\gamma + 1}\right)^{\frac{\gamma}{\gamma - 1}}} = \frac{14.6\ psia}{0.528} = 27.8\ psia = 191\ kPa$$

For pressures less than the critical pressure, the mass flow rate and discharge time to reach any specific mass fraction of the original gas are given by the following equations:

$$w = A_h\, C_d \sqrt{2\, P_1\, \rho_1 \left(\frac{\gamma}{\gamma - 1}\right) \left[\left(\frac{P_2}{P_1}\right)^{\frac{2}{\gamma}} - \left(\frac{P_2}{P_1}\right)^{\frac{\gamma + 1}{\gamma}}\right]} \qquad (2)$$

where: w = *instantaneous mass flow rate*

A_h = *area of orifice opening* = $\pi \dfrac{(\textit{vent diameter})^2}{4}$

C_d = *discharge coefficient* = 0.5

γ = *heat capacity ratio of vapor* = $\dfrac{C_p}{C_v}$ = 1.4

P_1 = *pressure inside the tank*

ρ_1 = *vapor density in tank*

P_2 = *pressure at vent line*

ρ_2 = *vapor density at vent line*

$= \rho_1 \left(\dfrac{P_2}{P_1}\right)^{\frac{1}{\gamma}}$; *for an adiabatic expansion of an ideal gas*

$$t = \frac{\dfrac{V}{A_h\, C_d}}{\sqrt{2\left(\dfrac{\gamma}{\gamma - 1}\right)\left(\dfrac{P_1}{\rho_1}\right)}} \int_{\frac{\rho_1}{\rho_0}}^{1} \frac{d\eta}{\sqrt{\left(\dfrac{P_2}{P_1}\right)^{\frac{2}{\gamma}} \eta^{\gamma - 1} - \left(\dfrac{P_2}{P_1}\right)^{\frac{\gamma + 1}{\gamma}}}} \qquad (3)$$

where: t = *discharge time*

V = *tank volume*

ρ = *vapor density in tank at time t*

η = *mass fraction of fluid left in tank at time t* = $\dfrac{V\,\rho}{V\,\rho_0}$

There is no simple analytical solution to this integral, so the calculation of this time must be done numerically.

For pressures greater than the critical pressure, the corresponding equations for mass flow rate and discharge time to reach any specific mass fraction of the original gas are given by the following equations:

$$w = A_h\, C_d \sqrt{\gamma\, P_1\, \rho_1 \left(\frac{2}{\gamma + 1}\right)^{\frac{\gamma + 1}{\gamma - 1}}} \qquad (4)$$

To solve for the length of time the tank actually vents, equation 5 is used to calculate the venting time starting when the tank is pressurized by the hydrogen burn (P_1 equals about 8 atmospheres) to the time when the critical pressure is reached (P_2 equals about 2 atmospheres). Equation 3 is

$$t = \frac{\frac{V}{A_h\ C_d}}{\sqrt{\gamma \left(\frac{P_1}{\rho_1}\right)\left(\frac{2}{\gamma + 1}\right)^{\frac{\gamma + 1}{\gamma - 1}}}} \left(\frac{2}{\gamma - 1}\right)\left[\left(\frac{\rho_2}{\rho_1}\right)^{\frac{1 - \gamma}{2}} - 1\right] \qquad (5)$$

then used to calculate how long the remainder of the venting takes.

Using the characteristics of air for the gas in the head space of the tank, equation 5 predicts that it takes 0.54 seconds for the tank to vent to the critical pressure.

$$t = \frac{\frac{(0.017\ m^3)}{(1.27\ x\ 10^{-4}\ m^2)\ (0.5)}}{\sqrt{(1.4)\left(\frac{810\ kPa}{1.18\ \frac{kg}{m^3}}\right)\left(\frac{2}{2.4}\right)^{\frac{2.4}{0.4}}}} \left(\frac{2}{0.4}\right)\left[\left(\frac{0.42\ \frac{kg}{m^3}}{1.18\ \frac{kg}{m^3}}\right)^{\frac{-0.4}{2}} - 1\right]$$

$$= \frac{(268\ m)}{\left(567\ \frac{m}{sec}\right)}\ (5)\ (0.229)$$

$$= 0.54\ sec$$

From equation 3, it takes another 0.40 seconds to finish de-pressurizing the tank.

$$t = \frac{\frac{(0.017\ m^3)}{(1.42\ x\ 10^{-4}\ m^2)\ (0.5)}}{\sqrt{2\left(\frac{1.4}{0.4}\right)\left(\frac{1.9\ x\ 10^5\ Pa}{0.43\ \frac{kg}{m^3}}\right)}} \int_{0.423\ \frac{kg}{m^3}}^{0.269\ \frac{kg}{m^3}} \frac{d\eta}{\sqrt{\left(\frac{1.92\ x\ 10^5\ Pa}{1.01\ x\ 10^5\ Pa}\right)^{\frac{2}{1.4}} \eta^{0.4} - \left(\frac{1.92\ x\ 10^5\ Pa}{1.01\ x\ 10^5\ Pa}\right)^{\frac{2.4}{1.4}}}}$$

$$= \frac{(268\ m)}{\left(1.782\ x\ 10^3 \frac{m}{sec}\right)} \int_{0.634}^{1} \frac{\delta\eta}{\sqrt{(0.402\ \eta^{0.4} - 0.335)}}$$

$$= 0.40\ sec$$

Assuming turbulent flow, the amount of liquid forced out of the tank during the venting is given by the following equation (Crane 1957):

The outlet piping going to the pump suction has a diameter of 1 in. From the discharge of the pump, the solution would have to travel up to the second floor and horizontally out of the glove box. The vertical run is about 15 feet and the horizontal run is about 25 feet. There are three manual valves

$$q_s = 0.525\, d^2 \left(\frac{\Delta P}{K\, \rho_s}\right)^{0.5} \qquad (6)$$

where: q_s = *flow rate of solution* $\left(\frac{ft^3}{sec}\right)$

d = *diameter of outlet piping (in)*

ΔP = *pressure difference* $= \frac{(initial\ \Delta P + final\ \Delta P)}{2}$

K = *resistance coefficent*

$= 0.015 \left(\frac{length\ of\ piping}{diameter} + length\ equivalent\ for\ valves\right)$

ρ_s = *weight density of solution* $\left(\frac{lb}{ft^3}\right)$

and one motor operated valve in this run. Four globe valves (each equivalent to 340 feet) and 40 feet of 1 in. pipe give a resistance factor, K, equal to 33.

As the tank vents, the pressure decreases and the driving force for pushing the liquid out of the tank decreases. The pressure difference is taken as the average of the initial and final pressure differences. The final pressure is the pressure required to lift 1.7 M solution a height of 10 feet or about 26 psig. Since this pressure is about the same as the critical pressure, P_{crit}, the time of 0.54 seconds calculated by equation 5 is also representative of the length of time solution is forced from the tank.

Using equation 6, the average volumetric flow rate of liquid out of the bottom of the tank is 0.059 ft^3/sec.

$$q_s = 0.525\ (1\ in)^2 \sqrt{\frac{44.9\ psi}{33\left(106 \frac{lb}{ft^3}\right)}}$$

$$= 0.059\ \frac{ft^3}{sec}$$

The total amount pushed out over 0.54 seconds is about 0.032 ft^3 of solution. This volume of fluid is small compared to the volume of gas flowing out of the vapor space through the vent. This confirms that the length of time required to vent the pressure is determined by the characteristic of the gas flow out of the vent line and not the liquid flow.

At 450 g/liter, a maximum of about 410 g of Pu could be released as a liquid spill into 236-Z for complete break of the 1 in. solution pipe. For a viscous solution with less than a 3-m fall, DOE (1994) suggests a release

fraction of 3 x 10^{-5} with a respirable fraction of 70%. Therefore, the respirable amount of Pu released to the second floor of 236-Z would be:

$$410\ g\ Pu\ (3.0 \times 10^{-5})\ (0.7) = 0.009\ g\ of\ respirable\ Pu$$

This analysis neglected the effect of the inertia of the solution so the calculated release is significantly higher than what would actually occur. This event requires that a transfer be occurring at the same time as the seismic event, long term loss of the ventilation system, ignition of the gas in the vent line with the propagation back into the tank and a failure of encased lines. Considering the conservative assumptions in the above calculations, this release is negligible.

Room 27 maintenance glovebox and shelf storage have been declared inactive since the above analysis was originally performed. The release estimate is retained for conservatism, pending a future update to the entire seismic accident analysis.

9.2.4.6.3.2.A.o Accident Analysis-Calculations, 236-Z, Solvent Extraction, PRF AMU Room and Storage Rooms-- Potentially vigorous interactions between spilled tank contents and/or reagent package contents are:

1. The HNO_3 and hydroxylamine nitrate solutions (solution removed)
2. The HNO_3 and NaOH and Na_2CO_3.

The hazards at PRF have been addressed further in HNF-SD-CP-HA-001, "Plutonium Finishing Plant Chemical Hazard Assessment" (BWHC 1997)

Hydroxylamine Nitrate and HNO_3. When hydroxylamine nitrate, as an about 17 wt% solution, is added in small increments to a large reservoir of 12.2M HNO_3, it is decomposed rapidly after each incremental addition with smooth evolution of small bubbles of colorless gas. After the solution has warmed due to heat evolved upon decomposition, it then reacts to successive additions of 17 wt% hydroxylamine nitrate solution rapidly with vigorous evolution of large bubbles of brown-red gas and copious but transitory foaming. Concentrated HNO_3 additions to 17 wt% hydroxylamine nitrate solutions exhibit no effects except slight warming due to heats of dilution up to terminal acidities of about 9M. Above that level, rapid decomposition occurs with vigorous evolutions of large bubbles of brown-red gas and copious but transitory foaming. Addition of a relatively large quantity of concentrated HNO_3 to a concentrated hydroxylamine nitrate solution leads promptly to vigorous evolution of reddish-brown gas with little foaming.

Explosions and fires are not anticipated. Personnel would suffer chemical burns and severe inhalations of HNO_3 and oxides of nitrogen.

HNO_3 and NaOH and Na_2CO_3 Solutions and Solids. Vigorous neutralization reactions are observed between HNO_3 and basic materials. Steam formation and splattered corrosive liquids can occur and overpressurization could occur. Personnel could experience scalding and chemical burns, and inhalation of HNO_3 vapors and various corrosive mists.

9.2.4.6.3.2.B Accident Analysis Calculations, 236-Z, S&C. The slag and crucible process is no longer required for production at the PFP. Therefore, the Slag and Crucible process is not presently in use. If future use is required, the accident will be analyzed.

9.2.4.6.3.2.C Accident Analysis Calculations, 236-Z, Balance of Facility.

9.2.4.6.3.2.C.a Accident Analysis-Calculations, 236-Z, Crane Falls in Canyon--Same as in Section 9.2.4.6.3.2.A.c.

9.2.4.6.3.2.C.b Accident Analysis-Calculations, 236-Z, Chemical Preparation--See Section 9.2.4.6.3.2.A.o.

9.2.4.6.3.2.C.c Accident Analysis-Calculations, 236-Z, Miscellaneous Treatment Gloveboxes--Room 41 contains five MT gloveboxes (MT-1, MT-3, MT-4, MT-5, and MT-6). These gloveboxes are connected via a conveyor. These gloveboxes are inactive and the conveyor is normally empty. No release is postulated for these gloveboxes.

9.2.4.6.3.2.C.d Accident Analysis-Calculations, 236-Z, Room 27--Room 27 contains the maintenance and product handling glovebox and storage shelving (currently inactive) for packaged plutonium containers, neither of which are seismically qualified. The CPS limit for the glovebox is 1,000 g and the room limit (i.e., glovebox plus storage) is 5,500 g. This material is assumed to be >10% ^{240}Pu as there are no restrictions on isotopic composition. A release fraction of 1.5×10^{-4} is conservatively applied per Case 2. Application of this release fraction to the entire inventory is judged to be conservative in that the plutonium container packaging is not expected to fail should it fall from the shelving. The release is calculated to be 0.83 g:

$$5500g\ (1.5x10^{-4}) = 0.83g$$

9.2.4.6.3.3 Accident Analysis-Calculations, 236-Z, Product Handling. The release as a result of solution spills was described in the analysis of the PFPAL and room 166 of Building 234-5Z (9.2.4.6.3.1.H). The release, even for very concentrated solutions falling from great heights, is small and will be considered as negligible.

9.2.4.6.3.4 Accident Analysis-Calculations, Vaults. In addition to the arguments presented in the scenario section and the calculation presented for rooms 174, 175, and 190, *Parametric Heat Transfer Study - Loss of Air Circulation in the Plutonium Storage Vault, 2736-Z Building*, (Allen 1981) and *Control of Thermal Loading in Plutonium Storage Vaults, Building 234-5Z*, (Panesko 1976) show that a loss of ventilation does not lead to excessive container pressures.

9.2.4.6.3.5 Accident Analysis-Calculations, Outside Building.

9.2.4.6.3.5.A Accident Analysis-Calculations, Outside, HF--HF is no longer used in large quantities at the PFP, but it may be used in small quantities for experimental purposes.

9.2.4.6.3.5.B Accident Analysis-Calculations, Outside, Nitrogen Tank--The nitrogen tank may be propelled off its stand if the tank fails in the right location. Failure of the tank and release of its contents do not create a significant hazard.

9.2.4.6.3.5.C Accident Analysis-Calculations, Outside, Drain Lines--Failure of the drain lines between Buildings 234-5Z and 241-Z could result in some release to the ground if the trench also fails or cracks. The consequence to the offsite individual is very small and is considered in the Hanford Defense Waste - Environmental Impact Statement (DOE 1987, Appendix R).

9.2.4.6.3.5.D Accident Analysis-Calculations, 2735-Z (Outside Facility), Failure of the HNO_3 Storage Tank--Although the HNO_3 storage tank has been drained and is not in service, the analysis has been retained to present a bounding toxic chemical release. Since the outside HNO_3 storage tank is not seismically qualified, it is assumed to fail and release HNO_3 to the retention basin. A seismic event causing a failure of the storage tank is analyzed in Section 9.2.8.

9.2.4.6.3.6 Accident Analysis-Calculations, 2736-Z Complex.

9.2.4.6.3.6.A Accident Analysis-Calculations, 2736-Z Complex, Argon Release. Argon lines can fail as a result of the earthquake, but there are only consequences for the facility workers. Facility workers will evacuate should an earthquake occur. The out-of-facility releases will be diffused due to flow through the facility prior to release.

9.2.4.6.3.6.B Accident Analysis-Calculations, 2736-Z Complex, Flooding. If a fire line fails in the room, it may be possible to flood the room. Provisions are made so that the room drains, but these may have failed or been made less effective as a result of the earthquake. Flooding the room will not result in a criticality.

9.2.4.6.3.6.C Accident Analysis-Calculations, 2736-Z Complex, Criticality. See Section 9.2.4.2.11.F.

9.2.4.6.3.6.D Accident Analysis-Calculations, 2736-Z Complex, Container Heatup. The 2736-Z complex contains plutonium in two buildings; 2736-Z and 2736-ZB. The plutonium storage in the 2736-ZB Building consists of floor storage of waste drums and cubicle storage of SNM containers within open-faced cabinets. Due to the size of the rooms and the openness of the storage cabinets, the heatup of containers stored in the 2736-ZB Building is bounded by the heatup of containers stored in the 2736-Z Building.

In 2736-Z there are four storage vaults. Vault 1 contains pedestal storage in thick concrete cubicles. The cubicles are solid concrete except for the top which is the exhaust duct for the cubicle. The cubicle contains double front doors which are concrete and overlap tightly when closed. A small gap in the front at the bottom of the cubicle lets air into the cubicle. The cubicles are butted one to another and hold 45 containers of plutonium each. If the ventilation is lost, the containers will start to heat up.

The heatup calculation will follow the equations and data in Section 9.2.4.6.3.1.I with the following assumptions.

1. Heat transfer will only be allowed out the front of the cubicle. No heat transfer is allowed out the sides or back due to the presence of heating containers in these cubicles.

2. Credit will be taken for convection inside the cubicle. The convection is due to natural convection from the floor (which is cold) into the cubicles through the gap in the bottom of the door and out the exhaust ducts.

3. Each container generates 15 W and there are 45 containers per cubicle.

4. Assume 48 h of heatup time.

The same equations and data as in Section 9.2.4.6.3.1.I will now be used.

$$T_w = \frac{2g}{kA}\left[\frac{at}{3.14}\right]^{0.5}$$

where:

$$q = \text{Heat rate, in Btu/h} = \left[\frac{15\ W}{\text{container}}\right]\frac{3.4\ \text{Btu}}{W\text{-}h}\ (45\ \text{containers})$$

$$= 2{,}295\ \text{Btu/h}$$

k = Thermal conductivity = 0.79
a = Thermal diffusivity = 0.021
A = Area on which heat impacts = 8 ft by 2 ft = 16 ft^2
t = Time, h = 48
T_w = Temperature rise on inside of wall, °F.
T_w = 205.7 °F

The room ambient temperature is assumed to be 100 °F (normally around 75 °F). Therefore, the temperature on the inside of the concrete door is 305.7 °F.

To find the container temperature this equation is solved.

$$q = (0.1718 \times 10^{-8})\ A\ \frac{1}{0.429}\ [(T_c+460)^4 - (T_w+460)^4]$$

$$+ 0.22\ (T_c-T_w)^{0.33}\ (0.5)(T_c-T_w)$$

where: A = Surface area of the containers = 0.52 ft^2(45) = 23 ft^2
T_w = Wall temperature = 305.7
q = Heat rate = 2,295 Btu/h.

Solving for T_c yields 320 °F. Computer code calculations from Allen (1981) show 346 °F using 18-W containers. Using the same calculations as above but assuming 96 h the container temperature is 405 °F.

Again, using the data of Section 9.2.4.6.3.1.I, the possibility of container failure can be assessed. At t = 0, the container is at 17.7 lbf/in^2. When T_c = 320 °F, the container pressure is

$$\frac{P}{17.7} = \frac{(460+320)}{(460+180)} = 1.22$$

$$P = 21.6 \text{ lbf/in}^2$$

When T = 405 °F, P = 23.9 lbf/in^2.

So by the calculations and reasoning used previously the containers will not fail.

The containers in Vaults 3 and 4 will be less hot because there are fewer locations per cubicle (28 versus 45) and the doors are not solid. They contain about a 4-in. wide floor-to-ceiling perforated metal covering.

9.2.4.6.3.6.E Accident Analysis-Calculations, 2736-Z Complex, Storage Container Failure. Building 2736-Z, Vault 2 houses metal racks used for the storage of Pu containers. Two different types of racks are used: one for the storage of 7-in. cans and one for the storage of lard cans. The storage racks are seismically qualified.

Although the storage racks are seismically qualified (i.e., they do not fall over), it is conceivable that storage cans could fall to the floor due to seismically-induced movement of the racks. Accordingly, engineered features have been designed and installed that prevent cans from falling from the racks. In the case of the 7-in. can storage racks, each storage location is provided with a positioning ring into which the can is set. In addition, the racks are equipped with 20-gauge diagonal-mesh metal doors. The lard can racks are not provided with positioning rings or doors; however, they are provided with chains that run across the face of each storage shelve.

For this analysis it is assumed that an operator fails to properly latch one of the lard can storage rack retaining chains such that it swings open during the seismic event. A lard can rack was chosen for analysis as the 7-inch can racks have redundant means of preventing cans from falling (i.e., sleeves and doors). Each lard can storage rack has four shelves on which cans are stored three across and two deep. It is assumed that six cans fall from the top shelf to the floor, a distance of 61.5 inches, or approximately

5 feet. Note that six cans randomly falling from a shelf does not constitute a criticality concern. Criticality Prevention Specification CPS-Z-165-80100 permits the storage of lard cans in an infinite array stacked four high (see Section 9.2.4.6.3.6.C).

Plutonium stored in lard cans is provided with a minimum of two containment barriers. As required by Operating Specification Document OSD-Z-184-00013, "Special Nuclear Material Storage," Pu stored in lard cans must first be packaged in a series of two mechanically sealed food pack cans. The permitted exception is S&C fragments which may be sealed in a single untinned steel can. Additionally, cans stored inside lard cans are typically enclosed in one or more plastic bags.

For a release of Pu to occur, both the inner packaging (i.e., food pack cans) and outer packaging (i.e., lard can) must fail due to the fall from the shelf, or, alternatively, the inner and outer packaging must be in a failed condition prior to the seismic event. Tests have been conducted (Hammond 1976a) in which food pack cans filled with nonradioactive materials (to simulate can loading) were dropped from a height of ten feet. Although deformation occurred, in no case were any of the can seams split open. Drop tests have also been conducted on lard cans (Hammond 1976b). In contrast to the food pack cans which have mechanically sealed lids, the lid on a lard can is taped into place. A seam failure occurred when a can loaded with 90 pounds was dropped from a height of 80 inches. In addition, a short length of the lid was almost pushed out of the tape seam. It is important to note that the 90 pound test weight exceeds the weight of any lard can currently in storage. Based on storage records, the mass of lard cans in stored vault 2 is on the order of 30 pounds.

As stated above, a release of Pu could also occur given the inner and outer cans are in a failed condition prior to the seismic event. Failure of the cans could result from either corrosion, pressurization, or mechanical stress (e.g. punctures). Packaging requirements stipulated in OSD-Z-184-00013 are intended to prevent internal corrosion and pressurization. Specifically, corrosive salts and other materials that are reactive with iron over short or indefinite periods of time are not permitted. To prevent pressurization, reactive materials (i.e., those which may easily generate gasses in their containers) are not permitted. Examples of such materials include Pu oxalate and centrifuge solids. A LOI criteria of a weight loss of one percent or less has also been established for stored materials. In addition, each lard can is inspected on a monthly basis for corrosion, penetrations, dents, or bulging. A container is considered bulged if a straight rod can be placed across the lid seams and the center of the lid touches the rod.

Considering the above discussion, it is assumed that one of the six lards cans postulated to fall to the floor contains a failed inner container and the fall to floor breaches the lard can tape seal. The quantity of Pu stored in a lard can is limited to 400 g by CPS-Z-165-80100. The respirable release fraction applied to powder spills from a height of 2 m is 1.5×10^{-4} (see Section 9.2.4.6.2) For this analysis, a release fraction of 1.5×10^{-5} is applied. This order-of-magnitude reduction accounts for several facts:

- The material-at-risk is contained during the drop; in contrast, the release fraction value of 1.5×10^{-4} was derived from the free drop of powders
- Although the inner container(s) are assumed to be failed, it is believed that an actual breach due to corrosion or overpressurization would be small in size such that the majority of the Pu would be retained in the inner container and thus not available for release
- Although the lard can tape seal is assumed to be breached, it is believed that the lid would remain in place such that the release pathway would be relatively small.

Applying a release fraction 1.5×10^{-5}, the release of Pu to vault 2 would be 0.006 g,

$$(400\ g) \times (1.5 \times 10^{-5}) = 0.006\ g$$

Given a release of 0.006 g Pu into Vault 2, the quantity of Pu released to the environment depends on the operability of the HEPA-filtered ventilation system. As stated in Section 9.2.4.1.1, the post-DBE function and operability of the system is reasonably provided for based on the structural integrity and anchorage/stability of the equipment. As the system is expected to be functional and operable, the 0.006 g would be released via two stages of HEPA filtration, effectively reducing the release to zero. If the supply air fans and exhaust fans were both inoperable, there would be no significant motive force to transport the airborne Pu outside of the facility, and the release would be essentially zero. Lastly, it is conceivable that the exhaust fans could fail while the supply fans continued to operate. This is a very specific failure mode and would also require failure of the existing instrumentation and control system which would otherwise remove power to the supply fans given loss of the exhaust fans. Two supply fans provide a total of 11,000 cfm to Building 2736-Z. Given failure of the exhaust fans, the majority of this air would still exit 2736-Z via the 20-in. by 38-in. exhaust duct and, thus, be HEPA filtered. However, as the building would be at a positive pressure relative to atmospheric, leakage through unfiltered pathways would occur. For example, the seismic analysis of the HEPA filter system predicts the opening of very small holes in the interface duct assembly between 2736-Z and 2736-ZA, and Figure 9-18 shows 1,000 cfm of inleakage via unspecified pathways. Based on (1) the ratio of normal inleakage to normal supply air, and (2) the ratio of the area of a 0.5 in. opening about the circumference of the interface duct (116 in^2) to the area of the duct itself (840 in^2), it is estimated that from 10-25 percent of the airborne Pu, or from 0.0006 to 0.0015 g, could be released via unfiltered pathways. A release in this range has a negligible impact on the radiological consequences of a seismic event relative to releases from other PFP facilities. Even if it were conservatively assumed that all 0.006 g airborne within Vault 2 was released, the impact would still be negligible as 0.006 g represents approximately 0.3% of the total Pu release from other PFP facilities.

9.2.4.6.3.7 Accident Analysis-Calculations, 242-Z. As discussed in Section 9.2.4.2.7, it is estimated that there are 110 g of Pu remaining on walls and in hoods in Building 242-Z. Applying a release fraction of 1.5×10^{-4} per Case 2 yields 0.017 g of airborne respirable Pu. However, the Pu present is that remaining following cleanout activities. As such, it is not present as process powders or solutions in storage containers or process vessels, but rather it is comprised of thin layers of pu deposited over large surface areas. Such material adheres tightly to the surface on which it is deposited such that a release fraction significantly lower than 1×10^{-4} (which is based on the free fall of powders) would be applicable. Accordingly, the contribution of Building 242-Z to the total release from all PFP facilities is negligible.

9.2.4.6.3.8 Accident Analysis-Calculations, 241-Z. A potential release from Building 241-Z was discussed in the Plutonium Finishing Plant FSAR Safety Evaluation Report (DOE 1995). As discussed in Section 5.2.4 the coverblocks, as well as the support walls are seismically qualified and will not fail given a 0.2-g DBE. However, the pre-engineered steel structure, monorail and monorail supports are not seismically qualified. Thus there is the potential for interaction events.

A failure of the pre-engineered structure or crane supports and crane have the potential to dislodge the coverblocks. Assuming a coverblock is dislodged and falls into a tank, one-half of the contents in the tank may be ejected to the atmosphere, due to piston effects. The bounding ARF/RF values (1E-4 and 1.0, respectively) (DOE 1995) for a release of this type were applied to determine the mass fraction of droplets 10um or less in diameter. DOE 1995 applied the ARF/RF values to the maximum plutonium content contained in all 5 tanks. Assuming each tank contains 400 grams Pu (criticality limit) 2,000 grams Pu in the 5 operating tanks. Assuming half of the contents are released due to piston effects, and applying the bounding ARF/RF values, 0.10 grams respirable of greater than 10% ^{240}Pu would be released to the atmosphere from spilled liquids. The doses resulting from this release are discussed in Section 9.2.4.8.

Transfers to Building 241-Z have very low plutonium concentration (0.033 g Pu/L) and the amount of liquid transferred is on the order of 200 L. It has been assumed that the release to the soil column from liquid spills that do not become airborne will be under or adjacent to the structure and little will rise to the surface, thus limiting exposures to the facility worker, and onsite and offsite individual.

9.2.4.6.3.9 Accident Analysis-Calculations, 291-Z. The analysis for the filter rooms and upstream duct work of 234-5Z (9.2.4.6.3.1.X) showed the release from vibratory motion of the duct to be small. The same will be true in 291-Z because the number of grams on the surface and the surface area are similar. The release from the previous section was less than 0.01 g.

9.2.4.6.3.10 Accident Analysis-Calculations, 232-Z. Building 232-Z originally contained a series of process enclosures housing equipment used for the recovery of plutonium from various waste substrates. Since deactivation of the facility, some of these enclosures (e.g., the leaching gloveboxes and sorting hood) have been removed. Remaining enclosures include:

- Scrubber cell
- Filterboxes 1 and 2
- One multisection glovebox (sometimes referred to as the "Incinerator") made up of 3 sections. For purposes of this report these sections are identified as separate gloveboxes as follows:
  - Feed glovebox
  - Incincerator glovebox
  - Ash glovebox.

The 232-Z Building has recently been cleaned out. The facility has a maximum total holdup of 661 g based on NDA measurements performed following equipment removal and cleanout. The majority of this material (i.e., 405 g) is located in the incinerator. The cyclone separator contains 102 g, the scrubber cell contains 77 g, and the remaining 77 g is located in miscellaneous glovebox ventilation ducting.

A review of operations, process tests and cleanup activities, showed the following:

- Holdup in the incinerator is likely in the form of thick slag coatings on the combustion chamber walls.
- Holdup in the cyclone separator is likely in the form of fixed material.
- It is possible that ash exists outside the combustion chamber but inside the glovebox.

Accident Scenario. The postulated bounding accident is a seismic event that causes damage to the existing plutonium containments and collapses the building. The effects of the seismic event on the foundation of the 232-Z Building are displacements and forces in both the horizontal and vertical direction. These displacements and forces are transmitted to the walls and roof of the structure and to the gloveboxes contained therein. Based on glovebox analysis presented in the FSAR, it appears that the incinerator glovebox as originally constructed would topple. This assumption is reasonable given the large mass associated with the firebrick and the relatively long glovebox support legs. Recently, additional glovebox bracing was installed to preclude toppling, however, this analysis takes no credit for it and conservatively assumes damage to the glovebox from toppling.

In the analysis credit was taken for a "leak path factor" out of the glovebox, into the facility. The leak path factor is based on testing of a shipping container subjected to various drop tests. *The Safety Analysis Report for Packaging: CI 6712 Container (HCS-058-003-00)*, RHO-SD-RE-SAP-009 (Cahow 1982) and *Evaluation of the CI 6712 Shipping Container and Burial Container for Onsite Use*, RHO-CD-1523 (Van Meter 1981) describe a shipping container of similar size to the glovebox. The tests showed that the body of the container suffered very little damage. The energy of the 4 ft drop of the shipping container is greater than that of the toppled glovebox and, therefore, the damage should be comparable. Keep in mind also that the

glovebox, being 10 ft tall, will fall onto other pieces of equipment, the wall, or columns if it falls. However, credit is not taken for the reduction in energy afforded by these obstacles. To establish a bounding maximum consequence of the accident scenario the analysis assumes roof collapse at earthquakes greater than 0.09-g (even though structural calculations show favorable load to capacity ratios for 0.20-g earthquakes). This coincides with an annual probability of the event being less than 2×10^{-3}. It was assumed that the leak path factor for the building is 1.0.

Since the roof will not likely free fall due to the partial restraining action of the columns and the walls, the energy is judged to be similar to that of the "4-ft drop." That is, the effect on the glovebox of the roof falling onto it will be similar to the damage sustained by the shipping container dropped 4 ft onto an unyielding surface. Since, the damage to the shipping container was minor, the damage to the glovebox is judged to be minor as well.

Consequences and Probability. For the purposes of this analysis, the source term is defined as the quantity of respirable plutonium released to the environment. The quantity released is a function of the initial inventory, the ARF, the RF of the material made airborne, and facility leakpath factors (LPF). The source term released from the facility is comprised of the release from the multi-section glovebox, scrubber cell, and the ducts.

For the purposes of this analysis, the following is assumed:

- Total holdup in the multisection glovebox is 405 g.
- Scrubber cell contains 77 g.
- Total holdup in the cyclone separator is 102 g.
- The ducts contain 77 g of plutonium.
- Ducts are a maximum of 13 ft off of the floor.

One of the activities undertaken in the 232-Z remediation activity involved cleaning of the cyclone separator. In order for this activity to progress, it was first necessary to remove the asbestos insulation that surrounded the cyclone separator assembly. Upon removal of the insulation, the collection canisters (two) that were located directly beneath the tapered portion of the cyclone chambers were removed and checked for ash. Neither one of the canisters contained material. The operators then inserted a steel rod vertically through the bottom of the tapered portion of the cyclone chambers up to the 2 1/2-in. return pipe (approximately 30 in.) and rodded out this portion. This activity failed to produce ash material. The operators then tapped the cyclone separator assembly and associated piping with a hammer. Nothing came out of the open cyclone chambers. The operators then gave it two more vigorous hits. At this point the conclusion was drawn that the separator assembly was indeed empty. Therefore, if there is material in the cyclone separator, it is likely in the form of tightly adhered material on the wall and not subject to being released.

It is assumed that during the seismic event the glovebox falls. As the glovebox falls, some of the ash and insulating material (depending on the magnitude of the friction forces holding it in place as compared to the forces tending to draw it out of place) is simply suspended into the open space. Should this material impact the brick, and be allowed to rebound, unimpeded, the release fraction would be that for spilled powder. However, at impact, the bricks from one side impact the bricks and combustion chamber on the other side of the open portion in the center of the glovebox. The impacting bricks will intercept most of the suspended ash, and therefore, there is no (or very little) release due to "free fall of powders". The effect of a single brick on a pile of ash is to suspend it via aerodynamic stresses (DOE 1994, Section 4.4.3.3.2, "Large Falling Object Impact or Induced Air Turbulence") or by response of the solid substrate (DOE 1994, Section 4.4.3.3.1, "Vibration Shock").

For this case, the most appropriate resuspension data are those from *Simulated Seismic Event Release Fraction Data - Progress Report - April 1987*, RFP-4161 (Langer 1987). In Langer's experiments, 2 to 4-lb rocks, were dropped 3.7 m onto 1,000 g of powder lying free on a piece of plywood, or in an open can propped at a 60° angle to assure spilling. These conditions resemble bricks and blocks falling onto ash lying on other bricks and blocks. Langer's data for objects falling onto free powder would be appropriate for the case of a single brick. In this case, however, many bricks are falling onto many smaller quantities of powder. As a result, there is an inhibiting effect of the neighboring bricks on the release from a single brick, since the aerodynamic stresses are less (interruption of the air flow), the neighboring bricks will capture some of the material suspended (impaction or capture), and prevention of the substrate from fully responding.

Langer's data for a stone being dropped on to free powder shows an airborne release fraction of 1.2×10^{-3} and respirable fraction of 0.27 for drops onto aluminum oxide. This powder has properties very similar to the ash since the density (4 g/cm^3) and fraction of small particles (24% less than 25 μm vs 15% less than 10 μm for plutonium ash) are close. As a result, the RF suspended is 3.2×10^{-4}.

The RF released into the glovebox and carried out, will be less than that determined by Langer, who dropped stones onto free powder. The reduction is know as the LPF. This reduction is due to:

- The smaller volume for resuspension (the glovebox volume is limited to a total of 3×10^4 in^3). The effective volume into which ash suspended by the drop of one brick is much less.
- The presence of the other block that hinders the ability of the air to carry it away.
- Air flow for only a short period of time (if at all).

These factors are taken into account by assigning a LPF of 0.20 for a bounding scenario.

The release of plutonium from the multi-section glovebox falling and the roof hitting the glovebox is:

$$\text{Release} = 405\ \text{g}\ (3.2 \times 10^{-4})\ (0.20) = 2.6 \times 10^{-2}\ \text{g}$$

The release of plutonium contained in the ducts and scrubber is modeled based on a spill from 4 m (13 ft). Release fractions for spills of powders from 1-m (3-ft) and 3-m (10-ft) heights are presented in *Aerosols Generated by Spills of Powders and Solutions in Static Air* (Sutter et al. 1981). The total release fraction (both respirable and nonrespirable powders) for a 1-m spill was 7×10^{-5}, and 7×10^{-4} for a 3-m spill. From these values, a release fraction of 7×10^{-3} can be derived for a 4-m spill via extrapolation. However as shown in the *Nuclear Fuel Cycle Facility Accident Analysis Handbook*, NUREG-1320 (Ayer et al. 1988), the release fraction is proportional to "H^2", where "H" is the height of the fall in centimeters. Using this relationship and a release fraction of 7×10^{-5} for a 1-m spill, the value of a 3-m spill is nine times more, or 6.3×10^{-4} (which approximates the value of 7×10^{-4} given in Sutter et al. [1988]). The value for a 4-m spill is 16 times more, or 1.1×10^{-3}.

Langer (1987) shows respirable release fractions of 3.3×10^{-4} to 2.5×10^{-6} for situations where concrete blocks were dropped onto containers holding sand, sand and Al_2O_3, Al_2O_3 alone, or nickel (to simulate PuO_2). The blocks were dropped from 3.7 m (12 ft). Scaling the result of 3.3×10^{-4} (Langer 1987) by the ratio of $(4\ \text{m})^2$ to $(3.57\ \text{m})^2$ yields 4×10^{-4}. This value is within a factor of four of the value of 1.1×10^{-3}. Therefore, a release fraction of 1.1×10^{-3} is judged appropriate for use in this accident analysis. Given an inventory-at-risk of 154 g, collapse of the ceiling results in a release of:

$$\text{Release} = 154\ \text{g}\ (1.1 \times 10^{-3}) = 1.7 \times 10^{-1}\ \text{g}.$$

This value is conservative since the scrubber is a cell (like a "hot cell") and resembles more of a small room than a glovebox. It contains two scrubbers, two demisters, and two HEPA filter housings. In addition, there is much conservatism in the release fraction for the ducts. The free-fall spill of powders is based on ball-milled powder, almost all of which is less than 10 μm in diameter. It was shown that Langer's data could also be used, resulting in a factor of three reduction in the release fraction. Recent duct cleanout (see attached letter G. B. Chronister to J. J. Roemer) shows that not all of the material is loose; much is adhered to the piping.

The plutonium held up in the cyclone separator is probably slag adhered to the walls of the separator since there is no location where large quantities of loose powder can remain and still escape the rodding and impacting done during cleanout. The only location in which loose powder can be held up are the horizontal sections that are fairly short. Recall that 1 kg Pu equals 50 to 300 in^3. As a comparison, DOE (1994) presents the results of impact of hard objects onto brittle materials. This is a closer approximation to slag on walls. Jardine performed experiments in which a weight was dropped onto spheres of brittle material. This case is similar since the impact of the cyclone separator having adhered material imparts

somewhat similar forces. The respirable release fraction is a function of "E/V" where "E" is in Joules and "V" is in cm^3. In this case:

$$E/V = mgh/(m/\rho)$$

where: m = mass of powder and cyclone separator, kg
g = 9.8 m/sec^2
h = height of fall, m
= 3 m
ρ = density of iron, g/cm^3
= 7.9

Solving yields "E/V" equal to 0.23 J/cm^3. The RF is found to be 3×10^{-5}. This is believed to be a more representative case than that of "cans containing powder" shown above. This is because the material is believed to be adhered to the walls of the separator. The LPF is taken to be 0.5 since not all of the suspended material will get out of the cyclone separator due to the many turns and small openings. The release from the cyclone separator is:

$$\text{Release} = 102\ g\ (3.0 \times 10^{-5})\ (0.50) = 1.5 \times 10^{-3}\ g$$

The total release is therefore 0.20 g (0.026 g + 0.17 g + 0.0015 g). The above discussion shows that the value of 0.20 g for the bounding accident is conservative.

As shown in Vogt (1994), Section 9.2.4A.8, the onsite bone-surface dose is limiting. That is, the onsite bone-surface dose more closely approaches the WHC Risk Acceptance Guidelines (see Table 9-49) than do the onsite EDE or the offsite EDE or bone-surface doses. The onsite bone-surface dose is calculated by multiplying the source term by:

a) a bone-surface mass-weighted average unit inhalation dose conversion factor of 3.2×10^8 rem/g, which is the same as that used in the FSAR for release from 232-Z [from Table 9.3.5-7 of Vogt (1994)]. This value contains the peak calculated value for ^{241}Am based on aging.
b) an onsite atmospheric dispersion coefficient of 8.72×10^{-4} s/m^3 (from Table 9.3.4-2 of Vogt (1994))
c) and a breathing rate of 3.3×10^{-4} m^3/s (from Table 9.3.6-1 of Vogt (1994)).

Applying these values, the onsite bone-surface dose is calculated to be 18 rem for the 0.20 g release (bounding analysis).

$$(0.20\ g)\ (3.2 \times 10^8\ rem/g)\ (8.72 \times 10^{-4}\ g/m^3)\ (3.3 \times 10^{-4}\ m^3/s) = 18\ rem$$

The offsite bone-surface dose is calculated to be 0.34 rem for the 0.20 g release.

$$(0.20\ g)\ (3.2 \times 10^{8}\ rem/g)\ (1.62 \times 10^{-5}\ g/m^3)\ (3.3 \times 10^{-4}\ m^3/s) = 0.34\ rem$$

The onsite EDE is calculated to be 1.61 rem as follows:

$$(0.20\ g)\ (2.8 \times 10^{7}\ rem/g)\ (8.72 \times 10^{-4}\ g/m^3)\ (3.3 \times 10^{-4}\ m^3/s) = 1.61\ rem$$

The offsite EDE is calculated to be 0.03 rem as follows.

$$(0.20\ g)\ (2.8 \times 10^{7}\ rem/g)\ (1.62 \times 10^{-5}\ g/m^3)\ (3.3 \times 10^{-4}\ m^3/s) = 0.03\ rem$$

Section 9.2.4.5 states that the smallest earthquake that will cause damage is the earthquake with a frequency of 1×10^{-3}/yr. This is consistent with the discussion above based on 2×10^{-3} (a more likely event). As a result, earthquakes of greater frequency than 2×10^{-3}/yr will not result in significant damage to the building or gloveboxes within the rest of the PFP.

Tables 9-32 through 9-36 summarize the results of the PFP seismic analyses, including the contributions from the 232-Z structure for both a 0.09-g (annual probability 2×10^{-3}) and a 0.20-g (annual probability 1×10^{-4}) seismic event.

9.2.4.6.3.11 Accident Analysis-Calculations, Criticality. Previous sections have shown how a criticality may be possible in the west gallery glovebox. A criticality in this area is assumed.

9.2.4.6.3.12 Accident Analysis-Calculations, Release Into Facility. See Section 9.2.4.6.4.

9.2.4.6.3.13 234-5Z and 236-Z Gloveboxes and Ducts. The seismic accident analyses in Section 9.2.4.6 have been modified from previously issued versions to account for gloveboxes standing or falling in accordance with their seismic qualification as given in Table 9-25.

9.2.4.6.4 Summary of Releases into Facilities. Section 9.2.4.6.3 presented accident analysis calculations that quantified the release of respirable plutonium into facilities. The specific subsections and associated facilities are as follows:

- Section 9.2.4.6.3.1: Building 234-5Z, excluding the release from the Laboratory Prototype Calciner which is addressed in Section 9.2.4.9 but is not authorized for operation. Also excludes the releases from the Magnesium Hydroxide Precipitation Process Gloveboxes, HC-230C-3 and HC-230C-4, and BTS glovebox, HA-53BTS.

These are discussed in Section 9.2.4.10 and 9.2.4.11 respectively.

- Section 9.2.4.6.3.2: Building 236-Z
- Section 9.2.4.6.3.3: Building 236-Z, Product handling
- Section 9.2.4.6.3.4: Vaults
- Section 9.2.4.6.3.5: Outside areas
- Section 9.2.4.6.3.6: 2736-Z complex
- Section 9.2.4.6.3.7: Building 242-Z
- Section 9.2.4.6.3.8: Building 241-Z
- Section 9.2.4.6.3.9: Building 291-Z
- Section 9.2.4.6.3.10: Building 232-Z

Table 9-31 summarizes the results of the analyses contained in the above listed sections. Table 9-31 shows the total release into the PFP facilities, as a result of a seismic event, excluding the Laboratory Prototype Calciner release which is discussed in Section 9.2.4.9 but is not authorized for operation. Therefore, seismic initiated releases from the calciner are not included in the total facility releases. Releases from the Magnesium Hydroxide Precipitation Process gloveboxes and BTS gloveboxes are discussed in Section 9.2.4.10 and 9.2.4.11.

9.2.4.7 Accident Analysis, Release Out of the Facility. In the previous section, the release of respirable Pu into the facility resulting from various accident scenarios was calculated. To perform dose consequence calculations, the release of Pu out of the facility must be determined. For Buildings 291-Z and 232-Z, the release out of the facility is assumed to be equal to the release into the facility (i.e., 0.01 g for 291-Z and 0.20 g for 232-Z). For buildings 234-5Z and 236-Z, the release out is determined in the following subsections for two cases. In the first case, it is assumed that the 234-5Z and 236-Z ventilation systems shut down. In the second case, it is assumed that the supply fans shut down, that the E-3 and E-4 HEPA filters fail (e.g., fallen from filter frames) and that the exhaust fans continue to run.

9.2.4.7.1 "No Ventilation" Case. In the event of a design basis earthquake, it is anticipated that the 234-5Z and 236-Z ventilation supply and exhaust systems will shut down due to a loss of normal electrical power. Redundant systems (one automatic, one manual) are in place to shut down the ventilation systems should normal electric power not be lost. Although diesel-generators are provided in Building 2721-Z to provide backup power to either exhaust fan EM-1 or EM-2 on loss of normal power, it is possible that the earthquake could cause failure of the backup power system. Hence, a "no ventilation" condition is possible in the 234-5Z and 236-Z Buildings during the design basis earthquake.

To estimate the release from the facility given loss of the ventilation systems, a model has been developed based on airflow into and out of 234-5Z through open doors. A detailed description of the model, which includes particle deposition, is presented in Appendix 9.C. The doors and frames respond as follows. The door frames are metal and all of the exterior doors (and airlocks) contain strong door closers. If the door is closed at the time of the earthquake, the base of the door frame will move with the floor as the floors in 236-Z Building and 234-5Z Building move parallel with the ground (vertical motion is very small per *Seismic (SSE) Evaluation for the 236Z*

Building at the Hanford Site (URS, 1987 and URS, 1988b). The top of the frame moves more than does the base. The movement is as large as three-fourths of an inch (234-5Z Building, ground floor, half of movement of the duct level floor with respect to the ground). The maximum in plane displacement of the top of the door is 3/4 in. with respect to the base of the door. The door frame will also tend to move out of plane. The maximum movement is 0.1 in. If the door is closed initially, the movement may cause it to buckle. A buckled door is assumed to be warped and contain "wrinkles." Doors with glass panels, in addition to buckling, will be damaged by the glass breaking. It may not be possible to open the door if it buckles. If it can be opened, it may close (if the buckling is in the top of the door such that the base clears the floor) or it may not close (if the buckling is in the bottom of the door such that the base digs into the floor). Airlock doors contain one door with a glass window. It is assumed that the doors with the windows will close again but that the glass has shattered. The 234-5Z doors are as follows:

Door number	Type[a]
103	A
828	E
105A	frequently blocked open
105	F
122	A
124A	A
124	F
123	A
125	F
126	A (it is not F)
720	B
129	F
113	F
131	A
133	A
135	F
135A	F
137	A
138	A
712	F
139	Like A but with small glass panels
101	glass door
107	A
128	A

[a] Type A doors are metal with no glass window and are 2 ft 6 in. wide by 7 ft tall. Type F doors are two Type A doors side by side. Type E doors are like Type A doors but with a 2-ft by 3-ft glass window. The Type A and F doors appear to be either hollow metal or metal shell with a filling.

The doors in Building 236-Z are similar to Type A doors. There are concrete blocks above the doors on the first, second, and fourth floors. The blocks cover an area of about 3 ft wide and 2 ft tall.

For Building 234-5Z, it will be assumed that half of the Type A and Type F doors buckle such that they close but have an opening of 1.75 ft^2 (10% of the door area) and half are opened but wedge in the open position. The open position is assumed to be half open so the flow area is 9 ft^2 (half of 17.5 ft^2 opening). Doors at 236-Z are assumed to fully close based on seismic qualification of the structures; thus, there is no contribution from 236-Z for the no-ventilation case.

It was found that the concrete walls which surround the RMA and RMC Lines will withstand the seismic forces but data does not exist on the other walls. It is assumed that they collapse so that the first floor of Building 234-5Z is basically open except for the vaults and the RMC/RMA Line areas. Vault doors are very thick and latch much more positively than room doors. Therefore, it is assumed that the vault doors suffer no damage.

Room 166 is a vault and room 227 has vault-like doors. The doors of room 227 are in the RMC concrete wall and will not see shearing motion. The bending is small (URS 1987) and people are not usually in this room. It is therefore assumed that the doors in room 227 do not fail. The doors in the RMC Line are similar and therefore will not fail either. Releases in rooms 166 and 227, RMC, RMA, and HA-23S will therefore remain in those rooms.

If the wind is from the south (blowing north) there are six doors through which the wind can blow. The wind will cause a flow through the building, but it will flow from the south side to the RMC Line concrete wall (Column 7 to Column 22), go around the concrete wall, and leave the building out the front. The flow area is 3 doors at 9 ft^2 and 3 doors at 1.75 ft^2 or 32 ft^2. Using the equations in Appendix 9.C, the flowrate for east-west flow is found to be 14,080 ft^3/min. The area of the flow is that from Columns 1 to 24 and A to G minus C to E and 7 to 22 (H-2-16138) or (138 x 440) minus (52 x 300) or 45,120 ft^2. The ceilings are 9 ft high, so the volume is 406,080 ft^3.

Using these data and applying the model from Appendix 9.C for a 5 mi/hr wind:

$$M_{out} = M_{bo} \exp\left[-\frac{14,080}{406,080} + \frac{vel\ (45,120)}{406,080}\right] t$$

or

$$M_{out} = M_{bo} \exp\ [-(0.035 + 0.111\ vel)t]$$

The total carried out of the building, M_{tot}, over time is:

$$M_{TOT} = \frac{A}{-b} = \frac{0.035\ M_{bo}}{0.035 + 0.111\ (vel)}$$

where: M_{out} = mass flowrate out of the building
M_b = mass of powder dispersed in the building at any time
vel = settling velocity
t = time

The quantity available on the first floor of Building 234-5Z (given that the release within the RMC Line and Room 166 is "protected") is from the analytical lab, plutonium process support lab and standards lab. The total release from these three labs is 1.87 g (1.08 g + 0.79 g = 1.87 g) (Section 9.2.4.6.3.1.A).

Using 2.2-mi/h wind rather than 5 mi/h gives a flow of 6,195 ft^3/min rather than 14,080 ft^3/min and

$$M_{TOT} = \frac{0.015\ M_{bo}}{0.015 + 0.111(vel)}$$

Using the data for deposition velocity

Particle size (μm)	%	M_{bo}	vel (ft/min)	M_{TOT} 5 mi/h	M_{TOT} 2.2 mi/h
0 - 2	12	0.22	0.024	0.20	0.19
2 - 3	21	0.39	0.15	0.26	0.18
3 - 5	67	1.25	0.38	0.57	0.33
		1.86*		1.03	0.70 g

* Difference from total release value of 1.87 due to rounding.

Since dose is a function of grams released divided by wind speed, the dose from the 2 mi/h wind is over 1.5 times greater than the dose from the 5 mi/h wind.

$$\frac{0.70\ g/2.2\ mi/h}{1.03\ g/5\ mi/h} = \frac{0.318}{0.206} = 1.54$$

Therefore, the release (0.70 g) due to the 2.2 mi/h wind is used in this analysis for conservatism.

Of the 1.87 g release into the facility from the three laboratories, 1.08 g (or 58%) is defined as <10% ^{240}Pu (Table 9-31). Therefore, of the associated 0.70 g released out of the facility due to the 2.2 mi/h wind, 0.41 g is <10% ^{240}Pu, and 0.29 g is >10% ^{240}Pu. It is noted that the 0.70 g released out of the facility is approximately 37% of the amount (1.87 g) released into the facility.

In the duct level, it is assumed one door is buckled and wedged. Therefore, it is assumed the door is half open. Since the flowrate for the 9 ft^2 flow area is 28% of that for the 32-ft^2 opening, the previous equation for M_{TOT} for the 2.2 mi/h wind is modified by the ratio of the opening (28%) as follows:

$$M_{TOT} = \frac{0.004\ M_{bo}}{0.004 + 0.111\ (vel)}$$

As shown in Table 9-31, the release into the duct level consists of 1.15 g from the E-4 ducting and 0.83 g from filterboxes 7A and 9A for a total of 1.98 g released into the duct level. In addition, 0.07 g is released from the filter rooms on the third floor, as shown in Table 9-31, for a total release into the facility of 2.05 g respirable plutonium. Using the equation for M_{TOT} the release out of the duct level and third floor is 0.35 g. All of the duct level and filter room material is defined as <10% ^{240}Pu. Accordingly, the releases from Building 234-5Z are as follows:

<10% ^{240}Pu, labs	0.41 g
<10% ^{240}Pu, duct level and 3rd floor filter rooms	0.35 g
>10% ^{240}Pu, labs	0.29 g
Total	1.05 g

The release shown above from Building 234-5Z does not include seismically induced releases from the Laboratory Prototype Calciner in Room 188 of the PPSL. The releases related to the laboratory calciner are discussed in Section 9.2.4.9 but are not included in the facility releases since the calciner is not authorized for operation.

9.2.4.7.2 "Ventilation" Case. Although redundant systems are in place to shut down the electric supply fans, the electric-driven exhaust fans could continue to operate due to failure of software interlocks which are not specifically designed to withstand a DBE. If the exhaust fans are shut down as intended, standby power could be provided by diesel-generators located in Building 2721-Z to operate either exhaust fan EM-1 or EM-2 provided the exhaust fans, diesel-generators and control system survive the DBE. For this analysis, it is conservatively assumed that all of the exhaust fans are running (the supply fans have been shut down by the automatic shutdown switch). It is further assumed that the exhaust flow is 228,000 ft^3/min (Section 9.1.7A).

Then:

$$M_{out} = M_{bo} \exp\left[-\left(\frac{228{,}000}{2.19 \times 10^6} + \frac{vel\ (1.46 \times 10^5)}{2.19 \times 10^6}\right) t\right]$$

$$= M_{bo} \exp [-(0.10 + 0.067 \text{ vel})t]$$

Where 2.19×10^6 is the approximate volume of the Zone 3 areas of Buildings 234-5Z, 236-Z, and 242-Z (i.e., 728,640 times 3) and 1.46×10^5 is the area of the floors of those zones. The term "vel" is based on particles with a density of 4 g/cc. As in the "no ventilation" case,

$$M_{TOT} = \frac{0.10\ M_{bo}}{0.10 + 0.067\ (vel)}$$

The plutonium released into Buildings 234-5Z and 236-Z is 15.25 g respirable plutonium as shown in Table 9-31. All of this is available for release. It is assumed that the size distribution is the same as for the case of wind blowing through the facility.

Particle size (μm)	Percent	M_{bo}	vel (ft/min)	M_{TOT} electric exhaust fans
0 - 2	12	1.83	0.024	1.80
2 - 3	21	3.20	0.15	2.91
3 - 5	67	10.22	0.38	8.15
		15.25		12.86

The release from Buildings 234-5Z and 236-Z is 12.86 g. Therefore, approximately sixteen percent of the release settled out within the buildings due to gravity and 84% is released from the buildings.

Of the 15.25 g released into Buildings 234-5Z and 236-Z, 3.13 g (or 20.5%) is defined as <10% ^{240}Pu (Table 9-31). Therefore, of the associated 12.86 g released out of these buildings, 2.64 g is <10% ^{240}Pu, and 10.19 g is >10% ^{240}Pu.

The release of 12.86 g respirable from Buildings 234-5Z and 236-Z is extremely conservative because:

- It assumes that the entire E-3 duct system is intact but the filters in the filter rooms and filterboxes have fallen to the floor or are failed for some other reason
- No credit is taken for loss to impaction in duct at the bends or on the walls due to turbulence
- The air flow patterns with no supply fan flow and some internal damage is assumed to be exactly the same as that during normal operation

- No credit is taken for agglomeration either at the point of release or inside the ducts.

The releases discussed above from Buildings 234-5Z and 236-Z exclude the Laboratory Prototype Calciner in Room 188 of the PPSL in Building 234-5Z. The releases related to the laboratory calciner are discussed in Section 9.2.4.9 but are not included in the facility releases since the calciner is not authorized for operation.

9.2.4.8 Dose Calculations.

9.2.4.8.1 "No Ventilation" Case. The radiological consequences for the "no ventilation" case are based on:

a) a release of 0.76 g <10% ^{240}Pu, lung clearance Class Y, from labs, duct level and filter rooms in Building 234-5Z (See Section 9.2.4.7.1)

b) a release of 0.29 g >10% ^{240}Pu, lung clearance Class Y, from labs in Building 234-5Z (See Section 9.2.4.7.1)

c) a release of 0.10 g >10% ^{240}Pu, lung clearance Class W, from Building 241-Z (See Table 9-31)

d) a release of 0.01 g <10% ^{240}Pu, lung clearance Class Y, from Building 291-Z (See Table 9-31)

e) a release of 0.20 g <10% ^{240}Pu, lung clearance Class Y, from Building 232-Z (See Table 9-31)

f) a release of 0.42 g >10% ^{240}Pu, lung clearance Class Y, from Building 234-5Z (based on a release of 2.29 g into the rooms in the RMC/RMA Line area from the seismically initiated fire, 50% of that release escaping into other portions of the facility and 37% of that amount being released out of the facility - See Section 9.2.4.2.12.F)

g) the mass weighted average unit inhalation doses presented in Tables 9-46 and 9-47

h) atmospheric dispersion coefficients for a ground level release with building wake and plume meander (Tables 9-39 and 9-40) applied to releases (Tables 9-39 and 9-40) from Buildings 234-5Z and 291-Z

i) atmospheric dispersion coefficients for a ground level release without building wake and plume meander (Tables 9-39 and 9-40 values for release from Building 232-Z and point source ground level, respectively) applied to the release from Buildings 232-Z and 241-Z.

The resulting doses to the onsite and offsite maximally exposed individuals are shown in Table 9-32. These doses meet the Risk Acceptance Guidelines summarized in Table 9-49 for an event with a frequency of 1×10^{-4}/yr which is the estimated frequency of the Design Basis Seismic Event. The doses shown in Table 9-32 exclude the Laboratory Prototype

Calciner in Room 188 of the PPSL. The seismically initiated doses related to the laboratory calciner are discussed in Section 9.2.4.9 but are not included in the facility totals since the calciner is not authorized for operation.

9.2.4.8.2 "Ventilation" Case. The radiological consequences for the "ventilation" case are based on:

a) a release of 2.64 g <10% ^{240}Pu, lung clearance Class Y, from Building 234-5Z (See Section 9.2.4.7.2)

b) a release of 10.19 g >10% ^{240}Pu from Buildings 234-5Z and 236-Z; total includes 1.29 g from nitrate solutions (84% released from facility of the 1.54 g of solutions released into facility from Table 9-31), lung clearance Class W and 8.90 g powder, lung clearance Class Y.

c) a release of 0.10 g >10% ^{240}Pu, lung clearnace Class W, from Building 241-Z (See Table 9-31)

d) a release of 0.01 g <10% ^{240}Pu, lung clearance Class Y, from Building 291-Z

e) a release of 0.20 g <10% ^{240}Pu, lung clearance Class Y, from Building 232-Z

f) a release of 1.92 g >10% ^{240}Pu, lung clearance Class Y, from Building 234-5Z (based on 84% release from facility of 2.29 g released into facility from the RMC/RMA Line seismically initiated fire - See Section 9.2.4.2.12.F).

g) the mass weighted average unit inhalation doses presented in Tables 9-46 and 9-47. Class Y lung retention is assumed for the majority of the release that comes from PuF_4 or PuO_2 powders. Class W lung retention is assumed for the small fraction of the release that originates from $Pu(NO_3)_4$ solutions.

h) atmospheric dispersion coefficients for an elevated release applied to releases from Buildings 234-5Z, 236-Z, and 291-Z

i) atmospheric dispersion coefficients for a ground level release without building wake and plume meander (Tables 9-39 and 9-40) applied to the release from Buildings 232-Z and 241-Z.

The resulting doses to the onsite and offsite maximally exposed individuals are shown in Table 9-33. These doses meet the Risk Acceptance Guidelines summarized in Table 9-49 for an event with a frequency of 1×10^{-4}/yr, which is the estimated frequency of the Design Basis Seismic Event. The doses shown in Table 9-33 exclude the Laboratory Prototype Calciner in Room 188 of the PPSL. The seismically initiated doses related to the laboratory calciner are discussed in Section 9.2.4.9 but are not included in the facility totals since the calciner is not authorized for operation.

9.2.4.9 Analysis of Seismically Initiated Releases and Consequences from the Laboratory Prototype Calciner. This section summarizes the doses from the

seismic analysis of the Laboratory Prototype Calciner in Room 188 of the PPSL. The determination of worst case accident scenario (seismic event with concurrent fire) over other scenarios and details of release calculations and dose calculations are found in the Laboratory Prototype Calciner addendum. Since the calciner is not authorized for operation, the seismically initiated doses are not included in the facility totals for a seismic event.

The doses related to the seismic effects on the Laboratory Prototype Calciner are shown in Tables H-1 to H-8 in the Laboratory Prototype Calciner addendum to this FSAR. Table H-5 presents the maximum total dose consequence for the Laboratory Prototype Calciner in the "no ventilation" case. The maximum total dose consequence values from Table H-5 are as follows:

Onsite		Offsite	
EDE	23.62 rem	EDE	0.50 rem
Organ	282 rem	Organ	6.02 rem

Table H-7 presents the maximum total dose consequence for the Laboratory Prototype Calciner in the "ventilation" case. The maximum total dose consequence values from Table H-7 are as follows:

Onsite		Offsite	
EDE	1.78 rem	EDE	0.63 rem
Organ	21.36 rem	Organ	7.55 rem

The consequences from the Laboratory Prototype Calciner due to a seismic event are not included in the seismic event summary tables, Table 9-32, 9-33, and 9-34, since the calciner is not authorized for operation. The consequences will be reevaluated and included, as appropriate, prior to any future authorization for operation.

9.2.4.10 Contribution to the Seismic Analysis from Operation of the Magnesium Hydroxide Precipitation Process.

The Magnesium Hydroxide Precipitation Process addendum to this FSAR (Carson 2000) describes the operations and equipment involved in the Magnesium Hydroxide process and the potential accidents postulated for that process. Section 3.4.2.4 of the addendum provides the analysis of the seismic event.

The gloveboxes containing equipment necessary for the Magnesium Hydroxide process are seismically qualified. However, seismically induced releases into the facility can still occur. The seismically induced release scenarios are shown below. In each case, the release into the facility is obtained by multiplying the inventory times the appropriate airborne release fraction (ARF) and respirable fraction (RF) both obtained from the DOE handbook on airborne release fractions (DOE 1994). The resultant release values are as follows:

- Release of precipitate due to vibration – 0.093 g

- Release due to falling precipitate – 0.0022 g
- Release due to falling Pu nitrate solution – 0.008 g
- Release due to boiling nitrate solutions – 0.049 g
- Entrainment of Pu during boiling – 0.015 g

The total release into the facility is 0.167 g. The release out of the facility is 84% of the release into the facility which are results in a release to the environment of 0.14 g.

The consequences of the release are obtained using the methodology of Section 9.2.4.7. The plutonium in the release is assumed to contain >10% ^{240}Pu, lung clearance Class W. The results are as follows:

No Ventilation case -

No release outside the facility per Section 9.2.4.7.

Ventilation case -

Onsite EDE:	0.15 rem
Onsite Organ:	2.7 rem
Offsite EDE:	0.05 rem
Offsite Organ:	0.96 rem

9.2.4.11 Contribution to the Seismic Analysis from Operation of the Bagless Transfer System Glovebox.

The calculation notes for the Bagless Transfer System (BTS)(FH 2000) describe the BTS Glovebox process, equipment and postulated releases as a result of accidents. Section 4.3 of the calculation notes provides the releases as a result of accidents including those resulting from a seismic event.

Section 4.3.1 of the calculation notes (FH 2000) shows that the BTS glovebox is not seismically qualified. The release into the facility is based on the ARF and RF from the DOE handbook on released fractions (DOE 1994) for falling powders. The respirable release into the facility from the glovebox is 0.75 g. Of this amount, 84% is released from the facility which results in a release to the environment of 0.63 g.

The consequences are determined using the methodology developed in Section 9.4.3.4. The plutonium accompanying the release is assumed to contain >10% ^{240}Pu, lung clearance, Class Y. The results are as follows:

No Ventilation case -

No release outside the facility per Section1.2.4.7.

Ventilation case -

Onsite EDE:	0.57 rem
Onsite Organ:	9.1 rem
Offsite EDE:	0.20 rem
Offsite Organ:	3.22 rem

9.2.4.12 Total Facility Seismic Dose Consequence. This section presents the summation of the doses to the onsite and offsite receptors from a seismic event from Sections 9.2.4.8 (bulk of the facility), 9.2.4.10 (Magnesium Hydroxide Precipitation Process) and 9.2.4.11 (BTS).

9.2.4.12.1 "No Ventilation" Case. The radiological consequences for the "no ventilation" case for the total facility involves summing the consequences from 9.2.4.8.1 and from 9.2.4.10 and 9.2.4.11. The resulting doses to the onsite and offsite maximally exposed individuals are shown in Table 9-32. It is noted that the Magnesium Hydroxide Precipitation Process gloveboxes and BTS glovebox do not contribute to the seismic doses for the "no ventilation" case since the gloveboxes are located within the RMC and RMA Lines which confine the material inside the facility when the ventilation exhaust system is not operating.

9.2.4.12.2 "Ventilation" Case. The radiological consequences for the "ventilation" case for the total facility involves summing the consequences from 9.2.4.8.2 and from 9.2.4.10 and 9.2.4.11. The resulting doses to the onsite and offsite maximally exposed individuals are shown in Table 9-33.

9.2.5 Strong Wind

The primary buildings and some of the auxiliary buildings of the PFP were analyzed for potential damage by the design-basis, 90-mi/h wind delineated in SDC-4.1 (WHC 1991a). SDC-4.1 indicates that a 90-mi/h steady wind is to be considered for the Hanford Site rather than a tornado.

The 234-5Z and 236-Z Buildings and the 291-Z-1 stack were analyzed in *Extreme Wind Analysis PFP Structures 236-Z, 291-Z, 234-5Z*, WHC-SD-CP-DA-023, (Giller 1989c), and found to be capable of withstanding both the wind forces and the standard missile assumed to be associated with the wind. Buildings 242-Z, 291-Z, 2736-Z, 2736-ZB and the 291-Z/234-5Z stack manifold were also shown to withstand both wind and missile forces (Giller 1990). The building sheltering the 241-Z cover blocks and below-grade tanks would not withstand the wind, but no damage is expected to the tanks due to the presence of the heavy concrete cover blocks. The anhydrous HF building, 2734-ZL, is vulnerable to missile strikes but no longer contains any hazardous materials. The gas-bottle storage bay, 2734-Z (see Figure 9-5), offers little or no protection from strong wind-related hazards, but the stored gas bottles are equipped with the normal protective caps designed to withstand transportation accidents at highway speeds. Most of the remaining outside structures at the PFP either do not contain hazardous materials or store small amounts of common chemicals (i.e., a number of 1-gal cans of primer, acrylic lacquer, paint, etc.) are located in NFPA fire cabinets in 2715-ZL. The outside holding

tanks, 2735-Z, used to be exceptions. One tank used to hold HNO_3 and the other tank used to hold ANN. The contents of these tanks have been removed from the Hanford Site. Nitric acid is now supplied in 55-gal drums. The analysis of a storage tank rupture is retained as a bounding strong-wind event.

The HNO_3 and ANN storage tanks, designated as 2735-Z, are 7,000-gal tanks and are located in a retention basin that is deep enough to contain a 14,000-gal spill. A spill from 2735-Z would be contained in the retention basin. ANN is a hydrated aluminum salt solution with a very low vapor pressure. While a small amount could be aerosolized due to the dynamics of a spill and the strong wind, the solution water would preferentially evaporate leaving hydrated aluminum nitrate salt crystals. Therefore, an ANN spill should be bounded by the HNO_3 spill and will not be analyzed. As a result, only HNO_3 will be discussed further.

9.2.5.1 HNO_3 Storage Tank Rupture.

The acid has been removed; however, this accident analysis has been retained for future considerations (e.g., Decontamination & Decommissioning).

9.2.5.1.1 Scenario. The postulated event for the handling accident consists of a strong, steady-90 mi/h wind that propels a 15-lb., 2-in. by 4-in. plank at 50 mi/h. The missile breaches the transfer piping at the bottom of the HNO_3 storage tank in the 2735-Z area. The analysis conservatively assumes that the HNO_3 storage tank contains the maximum 7,000 gal and the entire contents of the tank are released through a break in the 1-in.-dia transfer pipe (see Drawing H-2-77854) at the base of the tank. As the solution exits the tank, 10% is assumed to aerosolize due to the dynamics of the spill and aerodynamic entrainment by the 90-mi/h wind. As the remaining HNO_3 solution fills the retention basin, it begins to evaporate, and the vapor is dispersed by the strong wind.

9.2.5.1.2 Mitigation. The most likely failure mode for the tank is through a puncture by the wind-generated missile. Thus, mitigation of the event is best achieved by good housekeeping of the outdoor areas of the PFP.

9.2.5.1.3 Recovery. Little could be done for recovery until the strong wind subsided. The bulk of the release is due to the aerosolization of 10% of the tank contents. In addition, a relatively small amount of the HNO_3 in the retention basin would have evaporated and been dispersed by the time the wind subsided. Once the spill was detected, day shift operations would initiate cleanup procedures.

9.2.5.1.4 Probability. The HNO_3 storage tank is protected to the north and west by the 234-5Z Building. A myriad of pipes, tanks, ladders, walkways, etc. shelter the south side of the basin. The only clear paths for a missile strike are from the east or from above. A missile approaching from the east could only compromise the tank integrity by penetrating the tank shell. Ultrasound measurements (Sequin 1987) verify that the minimum tank wall thickness is 0.14 in., which is sufficient to withstand a strike from a 15-lb., 2-in. by 4-in. plank travelling at 50 mi/h (WHC 1989b). The 1-in.-dia pipe and associated valve used to transfer HNO_3 solution from the storage tank are located on the west side of the tank near the bottom of the basin. No

analysis exists to show that the valve and transfer piping can withstand a missile strike, so they will be considered vulnerable to failure during a strong wind. A missile would, however, have to strike the tank from above or pass through the obstructions south of the tank to strike the valve and piping. When the barriers around the tank are considered together with the annual frequency of a strong wind, a large HNO_3 spill is likely an incredible event. Rather than quantify the above argument, however, a bounding analysis will be presented in the following sections that demonstrates that a total release of the HNO_3 tank contents is within the Toxicological Risk Acceptance Guidelines for both onsite and offsite individuals, even for events with an annual probability of 10^{-2}.

9.2.5.1.5 Accident Analysis.

9.2.5.1.5.1 Assumptions. It is conservatively assumed that the tank contains the maximum 7,000 gal of 57% HNO_3 solution and that the tank is breached at the transfer pipe near the bottom of the tank. The temperature of the surrounding air is assumed to be 40 °C, corresponding to a very warm day for the Hanford Site. Since the wind speed is very high and the boundary layer above the pool is turbulent, any difference between the air temperature and the pool temperature should equilibrate quickly. Thus, the temperature of the liquid HNO_3 is also assumed to be 40 °C (104 °F). The effects of evaporative cooling will act to lower the pool temperature and are conservatively neglected. As will be verified in the conclusions of the following analysis, the effects of solar radiation and conduction from the ground when the surface temperature is higher than the air temperature are small, so these heat transfer modes will also be neglected.

Data on aerodynamic entrainment due to strong winds are scarce so the magnitude of this effect is difficult to quantify. DOE(1994), Section 3.2.4.1 discusses data from aerosolization measurements over large outdoor bodies of water. Data are provided for wind speeds up to 15 m/s. The data suggest that as the wind speed is doubled, the entrainment rate increases by an order of magnitude. Extrapolating the 15 m/s data to 40 m/s (90 mi/h) implies that, for a pool the size of the retention basin, aerodynamic entrainment suspends approximately 0.01% of the spilled liquid. Thus, 1% is likely a bounding estimate of the aerosolization rate. To ensure a bounding analysis, however, another order of magnitude is included and the aerosolization rate is assumed to be 10%. Thus, as the tank drains, 10% of the effluent is assumed to aerosolize due to the dynamics of the spill and the strong wind. The remainder of the tank contents is released into the retention basin.

9.2.5.1.5.2 Release Rate. The source term consists of two parts; the 10% of the tank contents that is immediately aerosolized as it leaves the tank, and the evaporation of the remaining 90% of the solution.

The storage tank is 14 ft high and 10 ft in diameter. Using Torricelli's formula, the discharge velocity out of the pipe is:

$$V \approx (2gh)^{\frac{1}{2}}$$

where V is velocity, g is the acceleration of gravity, and h is the height of liquid. Applying conservation of mass to the liquid in the tank,

$$\frac{dh}{dt}A_1 = -VA_2$$

where A_1 is the cross-sectional area of the tank and A_2 is the cross-sectional area of the pipe. Solving the above simultaneous equations for h as a function of time, and using the initial condition that the tank is full (h = 14 ft and t = 0),

$$h = \left[(14')^{\frac{1}{2}} - \frac{A_2}{2A_1}(2g)^{\frac{1}{2}}t\right]^2$$

Setting h = 0, the time to drain the tank is:

$$t = \frac{2(14\ \text{ft})^{\frac{1}{2}}(A_1)}{(2g)^{\frac{1}{2}}A_2}$$

$$= \frac{2(14\ \text{ft})^{\frac{1}{2}}(10\ \text{ft})^2}{\left[(2)\left(32.17\frac{\text{ft}}{\text{s}^2}\right)\right]^{\frac{1}{2}}\left(\frac{1}{12}\ \text{ft}\right)^2}$$

$$= 13400\ \text{s}$$

The maximum mass flow rate of HNO_3 vapor occurs at t = 0. The flow rate drops as t increases until at t = 13400 s the flow of liquid stops. Using the fact that 57 wt% HNO_3 solution has a density of 1,235 kg/m^3, the peak mass flow rate of HNO_3 solution is:

$$\dot{Q} = \rho V_o A_2$$

$$= \left(1235\frac{\text{kg}}{\text{m}^3}\right)\left[(2)\left(32.17\frac{\text{ft}}{\text{s}^2}\right)(14\ \text{ft})\right]^{\frac{1}{2}}\left(\frac{\pi}{4}\right)\left(\frac{1}{12}\ \text{ft}\right)^2\left(0.3048\frac{\text{m}}{\text{ft}}\right)^3$$

$$= 5.725\frac{\text{kg}}{\text{s}}$$

Per the above assumption regarding the aerosolization rate, 10% of the flow out of the tank is immediately aerosolized. Of this aerosol only 57% is HNO_3, so the peak flow rate of HNO_3 vapor to the environment is 0.3263 kg/m_3.

The HNO_3 solution that is not aerosolized is retained in an irregularly shaped basin that has an area of 976 ft^2 (90.7 m^2) (see Drawing H-2-77439). The evaporation rate is calculated using the method described by *A Simple Formula for Estimating Source Strengths from Spills of Toxic Liquids*, ESL-TR-83-03 (Clewell 1983). This method uses the following empirical formula:

$$\dot{Q} = 0.08u^{0.75}AZ[1 + [4.3\times10^{-3}T_p^{\,2}]]$$

where: $\dot{Q}$ = Evaporation rate, kg/hr
u = Wind speed, m/s
A = Spill area, m^2
Z = Volatility factor
T_p = Temperature of liquid, °C

Note that the above equation is empirical and not dimensionally consistent. For the accident considered here:

u = 40.2 m/s (90 mi/h), $\dot{Q}$ is conservatively maximized by using the strong wind for the entire evaporation time, rather than assuming the 90-mi/h wind was a gust and using some lower average wind speed

A = 90.7 m^2 (976 ft^2)

T_p = 40 °C (104 °F), the pool temperature is assumed to be equal to the air temperature

Z is the volatility factor of HNO_3 in relation to hydrazine and is calculated using:

$$Z = \frac{P_{vb}M_b}{P_{vh}M_h}$$

where: P_{vb} = 3.1 mm Hg, partial pressure of HNO_3 at 40 °C
P_{vh} = 34.7 mm Hg, partial pressure of hydrazine at 40 °C
M_b = 63 g/gmole, molecular weight of HNO_3
M_h = 32 g/gmole, molecular weight of hydrazine.

Thus,

$$Z = \frac{(3.1 \text{ mm Hg})\left(63 \frac{g}{gmole}\right)}{(34.7 \text{ mm Hg})\left(32 \frac{g}{gmole}\right)} = 0.18$$

Finally, a conservative value for the evaporation rate is given by:

$$\dot{Q} = 0.08(40.2)^{0.75}(90.7)(0.18)[1 + [4.3\times10^{-3}(40°C)^2]]$$

$$= 164 \frac{kg}{hr}$$

$$= 0.046 \frac{kg}{s}$$

The preceding calculation neglected the effects of solar radiation, ground conduction, and evaporative cooling. The neglect of evaporative cooling is clearly conservative. Approximating the thermal conductivity and heat capacity of the pool of 57% HNO_3 with water properties, conservatively using the maximum solar radiation flux on the 45th parallel of 1,070 W/m^2 (NRC 1991, Table 2.1), and assuming the ground temperature is 20 °C higher than the air temperature, the HNO_3 pool temperature would increase by only 2 °C/h. This temperature difference would then drive convective heat transfer from the pool to the air, which, given the presence of the strong wind, would easily remove enough heat to keep the pool at the air temperature.

The mass-release rate due to aerosolization should not be affected by the evaporation of the pool in the retention basin. The evaporation rate is a function of the pool surface area, so during the initial stages of the spill, the evaporation rate will be lower than calculated above, since the pool takes some time to spread over the entire retention basin. The peak mass flow rate from the combined release processes is calculated by assuming that the evaporation contribution has reached its steady state level and adding the peak (t = 0) aerosolization release rate. Thus, the peak mass release rate is 0.372 kg/s.

9.2.5.1.6 Dispersion Calculation. The mass release rate of HNO_3 to the atmosphere was maximized by using the peak aerosolization rate and basing the evaporation rate from the pool of HNO_3 in the retention basin on a constant 90-mi/h wind. Since the 90-mi/h wind is likely to be a gust rather than a steady wind, and the HNO_3 release will occur for at least several hours, the average wind-speed of the highest wind speed bin in the meteorological joint frequency database (19 m/s) is used to calculate the dispersion. This conservatively reduces the effectiveness of the atmospheric dispersion.

The density of HNO_3 vapor is roughly twice the density of air, so dense gas effects may be important in the dispersion calculation. This is determined by calculating the Richardson number for a continuous release.

$$Ri_o = \frac{g(\rho_{rel} - \rho_a)\dot{V}}{\rho_a u^3 d}$$

where: g = acceleration of gravity, $9.81 \frac{m}{s^2}$

ρ_{rel} = density of the released vapor, $\frac{kg}{m^3}$

ρ_a = density of the ambient air, $\frac{kg}{m^3}$

$\dot{V}$ = volumetric release rate of vapor (Q/ρ_{rel}), $\frac{m^3}{s}$

u = wind speed, 19 $\frac{m}{s}$

d = initial length scale of release (i.e. diameter of the pool), 10.7 m

Using the perfect gas law, the density (at 40 °C) of the released HNO_3 vapor can be calculated as 2.454 kg/m^3. Using this density and the previously calculated mass flow rate due to evaporation, along with the density of air at 40 °C, the Richardson number is calculated as

$$Ri_o = \frac{9.81(2.454 - 1.225).152}{(1.225)(19^3)(10.7)} = 2.0 \times 10^{-5}$$

Since the Richardson number is quite small (<0.003), the HNO_3 vapor is considered a passive tracer and the normal Gaussian dispersion model is appropriate.

Since the meteorological joint frequency data is not applicable for extremely rare conditions such as a 90 mi/h wind, a simple straight-line Gaussian dispersion calculation was performed using conservative, very stable (Stability Class F) atmospheric conditions. The downwind concentration for a ground level release is given by

$$C = \frac{\dot{Q}}{\pi u \sigma_y \sigma_z}$$

where: $\dot{Q}$ = evaporation rate, kg/s
u = wind speed, m/s
σ_y = horizontal dispersion coefficient, m
σ_z = vertical dispersion coefficient, m

The dispersion coefficients are functions of distance and stability class. As shown in Section 9.3, the nearest onsite receptor is located at 272-WA, 550 m west north-west of 234-5Z and the nearest offsite receptor is located 12.5 km west of 234-5Z. Conservatively neglecting building wake effects and using the methodology described in DOE-TIC-11223 (Hanna et al. 1982) the dispersion coefficients are calculated below:

$$\sigma_y = \sigma_a x f(x)$$

where: x = downwind distance, m

σ_a = standard deviation of horizontal wind fluctuations in radians,

$$\sigma_a = (30.0^\circ - 2.5^\circ N_s)\left(\frac{2\pi}{360^\circ}\right)$$

N_s = 11, Class F wind stability (Hanna et al. 1982)

$$f(x) = \frac{1}{1 + 0.031(x)^{0.46}} \quad \text{for } x \le 10 \text{ km}$$

$$= 0.33\left[\frac{10000}{x}\right]^{0.5} \quad \text{for } x > 10 \text{ km}$$

Thus, the horizontal dispersion coefficient for the nearest onsite receptor is

$$\sigma_y = 550(30.0^\circ - (2.5^\circ)(11))\left(\frac{2\pi}{360^\circ}\right)\left[\frac{1}{1 + 0.031(550)^{0.46}}\right] = 15 \text{ m}$$

Using the distance to the nearest offsite receptor, the horizontal dispersion coefficient is σ_y = 162 m.

For class F stability, the vertical dispersion coefficient is given by

$$\sigma_z = \frac{0.02x}{(1 + 3.0\times10^{-4}x)}$$

where x is in meters. Thus, the vertical dispersion coefficient for the nearest onsite receptor is σ_z = 9.4 m and for the nearest offsite receptor is σ_z = 53 m.

Finally, using the Gaussian dispersion equation from the beginning of this section, the peak concentrations of HNO_3 experienced by the nearest onsite and nearest offsite individuals are 4.4×10^{-5} kg/m^3 and 7.3×10^{-7} kg/m^3, respectively.

9.2.5.1.7 Consequences. The severity of the release is determined by comparing the calculated HNO_3 concentrations to the Toxicological Risk Acceptance Guidelines in Table 9-53. The guidelines specify Emergency Response Planning Guideline (ERPG) values at various frequencies. By definition, ERPG values are 1-h averages. For added conservatism, however, the calculated peak concentrations will be compared to the guidelines rather than 1 hour average concentrations. In addition, the concentrations calculated above must be converted to ppm for comparison to the Toxicological Risk Acceptance Guidelines. The conversion formula is taken from *Guidelines for Process Equipment Reliability Data with Data Tables*, p.93 (AICHE 1989).

$$C_{ppm} = C\frac{RT_a}{PM_0}\times10^6$$

where: R = 0.082 atm-m^3/K/kgmole, gas constant
P = 1 atm, ambient pressure
M_0 = 63 kg/kgmole, molecular weight
T_a = 313 K (= 40 °C), ambient temperature

Thus, the onsite individual is exposed to

$$C_{ppm} = 4.4\times10^{-6}\frac{kg}{m^3}\frac{\left(0.082\frac{atm\text{-}m^3}{K\text{-}kgmole}\right)(313\ K)}{(1\ atm)\left(63\frac{kg}{kgmole}\right)}\times10^6 = 18\ ppm$$

Similarly, for the offsite individual,

$$C_{ppm} = 7.2\times10^{-7}\frac{kg}{m^3}\frac{\left(0.082\frac{atm\text{-}m^3}{K\text{-}kgmole}\right)(313\ K)}{(1\ atm)\left(63\frac{kg}{kgmole}\right)}\times10^{6} = 0.29\ ppm$$

The onsite concentration is below the Toxicological Risk Acceptance Guidelines, shown in Table 9-53, for an event with the strong-wind annual frequency of 10^{-2}. Even with the numerous conservatisms in the above analysis, the maximum concentration that the offsite receptor is subject to is well below the guidelines even for an event with an annual frequency 1.

9.2.6 Flood

Flood is categorized in two ways: internal and external, neither of which pose significant risk.

9.2.6.1 External Flood. External flood is addressed in Chapter 3.0. Flood from rivers or streams is shown clearly to be of very low probability due to the plant's location on the 200 Area plateau and above the depression to the east of the plant. The probability of localized flood due to heavy precipitation has not been formally evaluated. The design basis rainfall is 11 in. during a 24-h period, with an annual probability of 1×10^{-6} (Section 3.4.2.3). This is in contrast to the maximum 24-h rainfall for the area (recorded in the period 1912 to 1980) of 1.91 in. during October 1957, and the annual average for the same period of 6.3 in. (Stone et al. 1983, p. iv). Without a formal study of the surface hydrology it is not possible to state definitely that an 11-in. rainfall would drain away from the facility. Informal inspection indicates that there is drainage to the east, along the roads on the north, and south of the 234-5Z Building (Figure 9-5). The landscape around the PFP is gently sloped, and drainage paths are not readily evident.

A rain of such unusual intensity would not go unnoticed. Below grade portions of facilities would receive flood prevention attention. The consequences would be similar to those of internal flood discussed below.

9.2.6.2 Internal Flood. The three below-grade locations sensitive to problems of internal flood are the pipe tunnels under the 234-5Z Building, the 241-Z vaults, and 291-Z. In addition, gloveboxes in the various facilities have the potential of flood from within, by process chemicals or water lines, and externally from fire-fighting activities.

The pipe tunnels under the 234-5Z Building contain no equipment sensitive to water, other than 110-V lights and outlets. The primary equipment consists of the stainless steel drain pipes.

The vaults under the 241-Z Building contain the six, 5,000-gal "D" tanks. Flooding a vault with an empty or partially empty tank can cause the tank to

float, and in the process rip pipes loose. Each vault contains a sump equipped with a liquid level detection and alarm system that annunciates in the 241-ZA Sample Building.

Flooding of 291-Z could ultimately result in loss of exhaust ventilation and the various vacuum systems. The effect of exhaust system loss is detailed in Section 9.1.8.

The most sensitive portion of the 291-Z Facility to flood is the electrical equipment room containing transformers, breakers, and switch gear. The room is equipped with a water deluge system for fire suppression. Should a clean break of a water line occur, there is not enough capacity in the two sump pumps to handle more than approximately 10% to 20% of the flow (Teal 1990). Loss of the electrical supply to the facility would be noted in the power control room located on the third level of the 234-5Z Building. Automatic shutdown of the supply system would occur to prevent pressurization of the buildings (see Section 9.1.7). Failure of the electrical system would occur at a lower water level than that which would effect the instrumentation lines. Any activation of the deluge system would be detected by the supervision system that sends a signal to the 200 Area Fire Station. The HFD would respond and shut off the water. Lesser leaks could probably be handled by the sump pumps. In addition, the leaks would take a considerable time to fill the facility. The 291-Z Facility is inspected hourly by the Hanford Patrol and at least once per shift by a Power Operator. They would notify the responsible manager, who in turn would have the water turned off.

9.2.6.3 Glovebox Flood. Glovebox flood could result from process line breaks or fire fighting activities. In order to prevent such floods, gloveboxes containing process liquid lines are generally equipped with sumps, sump alarms, and some system to remove the liquid. All "wet" gloveboxes (for solution handling or where liquids are piped in) are equipped with criticality drains to prevent accumulation of more than approximately 2 in. of liquid. These drains are equipped with coarse, large-area screens to prevent them from plugging. In addition, the outside portion of the drain system is equipped with guards to protect the mechanism from damage.

Glovebox flood is considered as one of the contingencies in criticality-control documentation.

9.2.7 Aircraft Accident

Airspace above the Hanford Site is used by many types of aircraft, typically on a limited basis. Currently, the Hanford Site airspace is used by commercial air carriers, air taxis, general aviation, military aviation, contracted pesticide and herbicide aerial applicator aircraft, and Hanford Site bioscience surveillance aircraft. Commercial aircraft are considered the most credible threat to the PFP on the basis that commercial aircraft are the largest craft to routinely overfly the site. These aircraft are analyzed in Section 9.2.7.1.

In addition to commercial and military air traffic, helicopter overflights of the Hanford Site have been performed for the purposes of gathering radiological survey data. These flights, which differ from those

described above since the helicopter intentionally flies at low altitudes and in relatively close proximity to nuclear facilities, are analyzed in Section 9.2.7.2.

9.2.7.1 Commercial Aircraft and Contract Aerial Applicator Operations. The cumulative probability of an aircraft accident involving the PFP has been determined to be incredible (less than 10^{-6}, or 1.28×10^{-8}).

9.2.7.1.1 Airport and Airways in Hanford Vicinity. There are no public, military, or high-volume airports within 20 mi of the PFP, and no federal airways pass directly over the PFP. There are several low-altitude federal airways and one military training route that either cross above or just at the margin of the Hanford Site, all of which are only lightly used. Airways in the vicinity of the PFP are federal low-altitude airway V187, 6.5 statute miles (smi) northeast; federal low-altitude airway V497, 6.5 smi northwest; federal low-altitude airway V204, 10.5 smi south; and military training route VR1350, 9 smi west. Federal low-altitude airways are 8 nautical miles (nmi) in width (4 nmi on either side of center); therefore, none pass directly over the PFP.

The PFP is located in a remote area with no airports in the immediate vicinity. There are three private airports located northwest of the PFP; the closest airports are at 13 to 17 smi to the PFP. These are private fields listed on the charts as having emergency or landmark value and are only lightly used by light civilian or agricultural aircraft. The Richland airport, 17,500 operations (arrivals and departure) per year, is located 22.5 smi south-southeast of the PFP; and the Pasco airport, 88,500 operations per year, is located 33 smi southeast of the PFP. See Section 9.2.7.1.5 for distances to all airports and official airways.

9.2.7.1.2 Federal Airspace Usage Restrictions. The Hanford Site is classified as uncontrolled airspace by the Federal Aviation Administration (FAA). Aircraft are required to maintain 1,000-ft clearance over the highest obstacle in a congested area or 500-ft clearance from any person, structure, or vehicle in an uncongested area. Aircraft operating above the Hanford Site are requested by the FAA, for reasons of national security, to avoid flight below 2,400 ft mean sea level (MSL) over the site, as stated on the *Seattle Sectional Aeronautical Chart*, (DOC 1989).

The Hanford Site airspace usage is extremely light due to its remote location, distance from any airports, and general expanse. The Pasco airport is the largest airport in the proximity of the Hanford Site and serves several commercial air carriers, an air taxi, and general aviation traffic. The probabilities of an aircraft incident that could involve the PFP were investigated and analyzed for several of the most credible or consequential categories of overflights. The largest users of the Hanford Site airspace (both in terms of gross weight and volume of traffic) would be those aircraft departing the Tri-Cities area on instrument flight rule (IFR) flights to the Seattle-Tacoma area on the V187 airway. Aircraft on IFR flights to the Tri-Cities area from the west use the V204 airway, which lies on the southern edge of the Hanford Site. All other airways and the military training route are not as significant a hazard to the PFP when compared to airway V187, either due to volume of traffic and/or due to proximity to the PFP. Only one airway comes as close to the PFP as airway V187 and all other airways

historically have experienced smaller volumes of traffic and smaller-sized aircraft.

9.2.7.1.3 Air Traffic Patterns in Vicinity of the PFP and Hanford. The aircraft departing the Tri-Cities area and using airway V187 on flights to the Seattle-Tacoma area, principally the commercial aircraft and some general aviation light aircraft on IFR flights, make up a small percentage of the flights originating in the Tri-Cities. In addition, due to federal flight-safety airspace-separation requirements, approximately half of the commercial aircraft departing the Pasco airport to Seattle use a radar standard instrument departure (SID) before they intercept the V187 airway. The SID takes them east and then north of the site, far from the PFP.

Flights using airway V187 are at distances and altitudes that, by the time they reach the vicinity of the PFP, are historically the safest segments of a flight. Flight crews in the Hanford Site area must take into consideration the necessity to ensure vertical clearance over the highest point on the Hanford Site (Rattlesnake Mountain at 3,629 ft MSL) and the Cascade Range farther west (mountaintops are 6,000 to 8,000 ft MSL, with one peak at 14,410 ft MSL). Generally, commercial air-carriers would be at an altitude of 10,000 ft MSL and general aviation would be above an altitude of 4,000 ft MSL in the vicinity of the PFP.

Review of National Transportation Safety Board (NTSB) accident data reveals that the PFP is located in an area that has experienced the lowest rate of aircraft accidents of any type. Most aircraft accidents occur within several miles of an approach to or departure from an airport. Using the available data, the probability of an aircraft accident involving the PFP has been determined to be highly incredible. An analysis of probabilities of all aircraft accidents is in Section 9.2.7.1.7.

9.2.7.1.4 Hanford Contract Aerial Applicator Aircraft Operations. The contracted biosciences and pesticide/herbicide aerial-applicator aircraft that operate occasionally above the Hanford Site is another category of aircraft operations that could pose a threat to the safety functions of the PFP. The actual flights above the site are infrequent and normally are not done in the vicinity of the PFP. Based on a conservative assumption of flights in the immediate vicinity of the PFP, it has been judged that an accident involving the PFP was incredible (less than or equal to 1.29×10^{-9}/yr). See Section 9.2.7.1.6 for analysis of applicator aircraft accidents.

9.2.7.1.5 FAA Airway Chart Review to Identify Airways Above the Hanford Site. The FAA airway charts (DOE-RL 1985; DOC 1989; NOAA 1989a, 1989b) were reviewed to determine if any federal airways passed over or near the PFP. A review was also made to determine if there were any airspace restrictions over the Hanford Site and, if so, what the restrictions were. With the aid of the FAA charts and the Hanford Site Map, measurements were made to determine distances from the PFP to identified airways and airports in the proximate area of the Hanford Site.

The following features were identified and distances to the PFP calculated.

1. There are no jet airways directly over the Hanford Site; the closest approach to the PFP is in excess of 25 nmi.

2. Low altitude federal airway V187 passes over the Hanford Site directly above the 609 Fire Station (100 Area) on a grid azimuth of 140°/320°. Airway V187 is used primarily by Visual Flight Rules (VFR) traffic departing the Pasco or Richland airports and destined for Seattle.

3. Low altitude federal airway V497 passes over the Hanford Site directly above the junction of Route 6 and State Highway 240 (Gate 127) on a grid azimuth of 025°/205°. Airway V497 is assumed to be used primarily by VFR traffic between Grant County Airport (Moses Lake) and destined for The Dalles, Oregon airport.

4. Military training route VR1350, a low-altitude military-controlled airway, passes slightly more than 4 smi west of the junction of Route 6 and State Highway 240 (Gate 127) on a grid azimuth of 004°/184°. Traffic on this route includes military traffic en route to the Boardman Restricted Area R-5701.

5. Low-altitude federal airway V204 passes over the southern edge of the Hanford Site directly above the peak of Rattlesnake Mountain on a grid azimuth of 109°/289°. Airway V204 is used primarily by IFR traffic arriving in Pasco or Richland airports from the Seattle area.

9.2.7.1.6 Probability of Contract Aerial Applicator Crashes Involving the PFP. The probability of a contracted herbicide or pesticide aerial-applicator aircraft or helicopter striking any critical building structure or piece of equipment at the PFP (and thereby causing a release of materials in excess of 10 CFR 100, "Reactor Site Criteria" (10 CFR 100) limits) must be evaluated. If an aerial-applicator crash involving the PFP can be shown to be an incredible event (less than 10^{-7}/yr) further analysis is not required in accordance with the criteria of Regulatory Guide 1.70 *Standard Format and Content Guide for Nuclear Power Plants*, (NRC 1978), Section 2.2.3.1. The criteria in *A Guide to Radiological Accident Consideration for Siting and Design of DOE Nonreactor Nuclear Facilities* (Elder et al. 1986) use less than 10^{-6}/yr.

The following assumptions are made where data do not exist, in order to provide a basis for calculating the credibility of an aerial-applicator accident involving PFP.

1. The *Standard Review Plan for the Review of Safety Analysis Reports for Nuclear Power Plants*, NUREG-0800 (NRC 1987) data relating to general aviation accident data are applied to the conduct of a contracted herbicide or pesticide aerial-applicator aircraft or helicopter, and that fatal crash data would represent sufficient energy to potentially penetrate or disrupt a PFP safety system.

2. An aerial-applicator accident might potentially cause a penetration of the PFP roof or walls at a critical location, or the aircraft fuel could breach the PFP roof or walls at a critical location and

lead to a release. This assumption is considered to be very conservative since the PFP is a substantial structure and the probability of striking a potentially critical location and violating the structural integrity or functions of safety systems is remote.

3. Less than 50 contract herbicide or pesticide aerial-applicator aircraft or helicopter flights are made in the vicinity of the PFP per year.

Following is the calculated probability of a contract herbicide or pesticide aerial-applicator aircraft or helicopter crash into PFP, that is significant enough to potentially cause a release in excess of 10 CFR 100 citing guidelines. For civilian and military airports and heliports, the probability of an aircraft crashing into site is given by the following equation.

$$P_{CA} = C \times N \times A$$

where:

C = Probability per square mile of a significant crash per aircraft movement
N = Number (per year) of movements by aircraft in vicinity of plant
A = Effective plant area (in square miles). For PFP this value is approximately 200 ft x 300 ft (60,000 ft^2 or 0.00215 mi^2)

$$P_{CA} = (1.2 \times 10^{-8} \text{ crash/mi}^2\text{-aircraft movement}) \times (50 \text{ aircraft movements/yr}) \times (0.00215 \text{ mi}^2)$$

$$= 1.29 \times 10^{-9} \text{ crashes/yr.}$$

9.2.7.1.7 Aircraft Hazard Analysis of Standard Review Plan Criteria. The criteria for the analysis of the probability of an aircraft accident at a nuclear plant were utilized for this section. Regulatory Guide 3.39, *Standard Format and Content of License Applications for Plutonium Processing and Fuel Fabrication Plants* (NRC 1976) does not specify an analysis technique, rather it identifies that a specific analysis is required if primary and secondary confinement can be "credibly breached." The criteria of the referenced NUREG-75/087, *Standard Review Plan* (NRC 1975) were used as a basis for analysis of the probability of an aircraft accident and the determination that it was, conservatively, an incredible event.

Criterion 1. Section 3.5.1.6, Subsection II.1. states that "The plant is considered adequately designed against aircraft hazards if the probability of aircraft accidents resulting in radiological consequences greater than 10 CFR Part 100 exposure guidelines is less than about 10^{-7}/yr."

Response.

Type of air traffic	Route	Probability
Commercial air carrier	V187	2.85 E-10
Commercial air carrier	V497	1.42 E-10
Commercial air carrier	V204	3.42 E-10
General aviation	V187	3.75 E-09
General aviation	V497	1.87 E-09
General aviation	V204	4.49 E-09
Military	VR1350	6.44 E-10
Contract chemical applicators	200 West Area	1.29 E-09
Total		1.28 E-08

Criterion 2. Section 3.5.1.6, Subsection II.2. states that "The probability is considered acceptable by inspection if the level of aircraft activity near the site falls below the criteria given in Section 2.2.3 of Regulatory Guide 1.70... for analysis of hazards due to commercial, experimental, and general aviation aircraft." (Section 2.2.3.1 states: "Design basis events... are those accidents that have a probability of occurrence on the order of about 10^{-7}/yr or greater...").

Response. See response to Criterion 1 above.

Criterion 3. Section 3.5.1.6, Subsection II.2. states that "For military airspace, a minimum distance of 5 mi from the reactor is adequate for low level training routes except those associated with usage greater than 1,000 flights per year or activities (such as practice bombing) where an unusual stress situation exists."

Response. Military low level training route VR1350 passes above the western edge of the Hanford Site, 9 mi west of the PFP. The traffic over VR1350 is approximately 1,800 sorties per year (according to the military authority responsible for the route). The R-6714 B&E Restricted Area (Yakima Firing Center) closest boundary to the PFP is 14.3 smi. Military air operations may occasionally overfly the PFP area (675 ft MSL), but due to the proximity of Rattlesnake Mountain (3,629 ft MSL), a low approach is generally not routine. Aircraft tend to maintain significant vertical separation in the Hanford area either due to the FAA request or for safety considerations around the mountain.

Criterion 4. Section 3.5.1.6, Subsection III.1. states that "Data describing aviation uses in the airspace near the proposed site, including airports and their approach paths, federal airways, FAA restricted areas, and military uses is obtained from Section 2.2 of the SAR. For many cases, no detailed analysis need be made as the probability can be judged adequately low based on a comparison with analyses previously performed."

Response. See Criteria 1 and 3 above.

Criterion 5. Section 3.5.1.6, Subsection III.2. states that "For situations where federal airways or aviation corridors pass through the

vicinity of the site, the probability per year of an aircraft crashing into the plant (P_{FA}) should be estimated. This probability will depend on a number of factors such as the altitude and frequency of the flights, the width of the corridor, and the corresponding distribution of past accidents.

One way of calculating P_{FA} is by using the following expression:

$$P_{FA} = C \times N \times A/w$$

where:

C = Inflight crash rate per mile for aircraft using airway
w = Width of airway (plus twice the distance from the airway edge to the site when the site is outside the airway) in miles
N = Number of flights per year along the airway
A = Effective area of plant in square miles."

Response. The value of A for the PFP is approximately 200 ft by 300 ft (60,000 ft^2 or 0.00215 mi^2).

w = 8 mi + 2 x 2.5 mi = 13 smi factor PFP to V187 (6.5 smi to airway centerline).

Airway ID#	PFP to Airway centerline	Airway width	w =
V187	6.5 smi	8 smi	13 smi
V204	10.5 smi	8 smi	21 smi
V497	6.5 smi	8 smi	13 smi
VR1350	9.0 smi	8 smi	18 smi

(The PFP facility is outside of all federal low-level airways: V187, V204, and V497 airways are 8 nmi wide, 4 nmi either side of airway centerline.)

Air traffic type	C[b]	N	Route	P_{FA}
Commercial air carrier	0.12 E-08	1,438	V187	2.85 E-10
General aviation	1.20 E-08	1,892	V187	3.75 E-09
Commercial air carrier	0.12 E-08	719[a]	V497	1.42 E-10
General aviation	1.20 E-08	946[a]	V497	1.87 E-09
Commercial air carrier	0.12 E-08	1,726[a]	V204	3.42 E-10
General aviation	1.20 E-08	2,270[a]	V204	4.49 E-09
Military aviation	0.30 E-08	1,800	VR1350	6.44 E-10
Contract aerial applicators	Analysis applicable to federal airway usage only			

[a]Assumptions: V204 N = 1.2 times V187 N; V497 N = 0.5 times V187 N; based on FAA Telcon.
[b]Source: NRC (1975).

Criterion 6. Section 3.5.1.6, Subsection III.3. states that "The probability of an aircraft crashing into the site should be estimated for cases where either of the following apply:

a. An airport is located within 5 mi of the site.

b. An airport with projected operations greater than 500 d^2 movements per year is located within 10 mi of the site, or an airport with projected operations greater than 1,000 d^2 movements per year is located beyond 10 mi from the site, where "d" is the distance in miles from the site."

Response.

a. Does not apply; nearest airport is 22.5 mi away.

b. Does not apply; Pasco Airport is the highest volume airport in the vicinity of the Hanford Site and it is 33 mi away from the PFP. Pasco Airport had only 88,459 operations (departures and arrivals) in all of 1988. This is far below the required 1.089M operations required by the "1,000 d^2 movements per year" criterion above.

$$P_{CA} = i\sum_{(1-L)} j\sum_{(1-M)} (C_j x N_{ij} x A_j)$$

where: $i\Sigma_{(1-L)}$ = Summation over all flight trajectories, for i = 1 to L, affecting the site
$j\Sigma_{(1-M)}$ = Summation over all different types of aircraft, for j = 1 to M, using the airport.

9.2.7.2 Radiological Survey Helicopter Overflights. This analysis evaluates the probability of a helicopter malfunction and subsequent crash into the PFP during the performance of an aerial radiological survey. A helicopter crash into the PFP is considered to be an incredible event as long as the helicopter does not operate in the near proximity of the PFP (i.e. a 2,300 ft square centered on the 291-Z-1 stack). A single helicopter is able to map and record data for an aerial radiological survey. During surveys, the helicopter typically flies at an elevation of 200 ft and a speed of 80 knots (approximately 90 mph).

For this analysis, it is assumed that a failure results in autorotation. The average sink rate of a helicopter with autorotation is 1,700 ft/min as given in *Hanford Aviation Safety Assessment* (WHC 1992b). Using a flight elevation of 200 ft, the time to reach the ground is approximately 7 s. Given a forward speed of 90 mph, the helicopter could travel approximately 900 ft horizontally before striking the ground.

Based on the dimensions of the buildings comprising the PFP, a simplifying assumption is made that the area of concern wherein a crash would release radiological materials is represented by a 500 ft square building centered on the 291-Z-1 stack. Accordingly, a failure within 1150 ft (i.e., 900 ft plus 250 ft) from the center could potentially impact the building. Stated another way, a failure anywhere within a 2,300 ft square centered on the 291-Z-1 stack could potentially impact the building.

Given that a helicopter flies in parallel paths 400 ft apart, and a width of 2,300 ft, it would take approximately 7 flights to cover the area of concern. This is equivalent to a total distance of 16,100 ft, or 3 mi. Given a speed of 90 mph, the helicopter would spend approximately 0.034 h (2 min) within the area of concern.

Helicopter failure rate data are available from several sources:

- Hanford aviation operations: 1×10^{-3} to 10^{-4}/hr (WHC 1992b)
- NTBS data: 6.8 to 13.4 x 10^{-5}/hr (WHC 1992b)
- U.S. Army Safety Center: 15.4 x 10^{-5}/hr (WHC 1992b)
- NTBS\FAA: 1.6 x 10^{-5}/hr.

These values are presumed to include all causes (e.g., equipment failure, human error, and maintenance errors). For this analysis, the 15.4 x 10^{-5}/hr failure rate was selected for conservatism and because the helicopter is similar to military aircraft. Applying the failure rate and a mission time of 0.034 hr, the probability of failure during the mission is 5.2 x 10^{-6}. Assuming the failure occurred within the area of influence, the helicopter would have an equal probability of crashing in the direction of the PFP as in the opposite direction, and the probability of heading toward the PFP after a malfunction is 2.6 x 10^{-6}.

To determine the likelihood of striking the PFP if the malfunctioning helicopter is heading towards the PFP, the fraction of area represented by the PFP versus the total area of influence must be determined. The hazard area represented by the PFP is 250,000 ft^2 (i.e., 500 x 500). The total area of influence is 5,290,000 ft^2 (i.e., 2,300 x 2,300). Therefore, the hazard area represents 5% of the total area. Because of the potential for flying debris from a nearby crash impacting the PFP, the hazard area is assumed to be 10% of the total area. This yields a probability of the crash affecting the PFP of 2.6 x 10^{-7} (i.e., 0.10 x 2.6 x 10^{-6}).

The failure rate data used above is for routine helicopter operation. The radiological survey flights differ greatly from routine operations, thus the data for routine operation does not correlate directly. The probability of a crash during the mission is believed to be increased by several considerations as follow:

1. Pilots unfamiliar with the Hanford Area - factor of 2
2. Flying at a low altitude - factor of 2
3. Multiple tall stacks and towers - factor of 2
4. Complexity of survey operation - factor of 2.

The above considerations result in an increase by a factor of 16, yielding a probability of 4.2 x 10^{-6} (i.e., 16 x 2.6 x 10^{-7}). If any two of the above four factors were judged appropriate, the probability would be 1 x 10^{-6}

(i.e., $4 \times 2.6 \times 10^{-7}$). It is estimated that the analysis has an uncertainty of 10^{-1} to 10^{+1} associated with this probability.

The above analysis shows a helicopter crash into the PFP during the performance of an aerial radiological survey, within the area of the PFP, is a credible (although extremely unlikely) event. However, analysis shows that a helicopter crash into the PFP is an incredible event when helicopter operation is not permitted in the near proximity of the PFP, which is defined by a 2,300 ft square centered on the 291-Z-1 stack. Therefore, flight restrictions prohibit helicopter operation in the near proximity of the PFP. These restrictions are documented in the USQ Evaluation performed for the helicopter overflights.

No radiological or toxicological consequences were calculated since a helicopter accident involving the PFP is an incredible event.

9.2.8 Toxic Chemical Release

This section considers the release of toxic chemicals due to improper handling. Chemical releases obey the laws of physics as radioactive releases do, in regard to release mechanisms and air transport. Chemical release limits, however, are stated in terms of concentration rather than dose. Therefore, only those chemicals with substantial potential for becoming airborne need to be considered. Most of the chemicals used at the PFP are delivered as crystalline substances, which are then dissolved in water, or as aqueous solutions. However, some materials are delivered as gases.

The potential onsite exposure for chemicals used at the PFP is bounded by an analysis done for the HNO_3 storage tank. The HNO_3 storage tank has been drained and is not in service. Nitric acid is now supplied in 55-gal drums. The analysis of the 7,000 gal tank has been retained as the bounding case for a toxic chemical release. The HNO_3 is a candidate for consideration partly because the 57% material that is stored in the 7,000-gal tank has a moderately high vapor pressure, and produces oxides of nitrogen following a spill as it reacts with its surroundings. In addition, the volume available for release is large compared to other chemicals used at the PFP. The most likely cause for a large spill and for lack of mitigating actions would be a seismic event. A large HNO_3 release is also discussed in Section 9.2.5, "Strong Wind."

A total release of the 7,000-gal capacity HNO_3 tank in 2735-Z results in HNO_3 vapor concentrations, using conservatively stable weather conditions, at the maximum onsite and offsite receptor locations that are well below the Toxicological Risk Acceptance Guidelines for an event with frequency of 1/yr.

It is assumed that the outside HNO_3 storage tank fails and releases HNO_3 to the retention basin. The basin is large enough to retain the entire capacity of both the HNO_3 and ANN storage tanks. ANN is a hydrated aluminum salt solution with a very low vapor pressure. While a small amount could be aerosolized due to the dynamics of a spill, the solution water would preferentially evaporate, leaving hydrated aluminum nitrate salt crystals. Thus, an ANN spill should be bounded by the HNO_3 spill and will not be analyzed. The area of the retention basin which is irregularly shaped, is 976 ft^2 (90.7 m^2) (see Drawing H-2-77439). The HNO_3 storage tank is conservatively assumed to contain the maximum 7,000 gal of 57% HNO_3 and to fail in such a way that the entire 7,000-gal capacity drains into the retention basin. The temperature of the surrounding air is assumed to be 40 °C, corresponding to a very warm day for the Hanford Site. The temperature of the liquid HNO_3 is also assumed to be 40 °C (104 °F). The effects of evaporative cooling will act to lower the pool temperature and are conservatively neglected. As will be verified in the conclusions of the following analysis, the effects of solar radiation and conduction from the ground when the surface temperature is higher than the air temperature are small, so these heat transfer modes will also be neglected. In addition, it is assumed that aerosolization effects due to the ambient wind and the dynamics of the spill are small enough (a small percentage of the total volume should participate in such effects) that the conservatism built into the evaporation analysis provide a sufficient margin of safety.

The evaporation rate is based on the method described by Clewell, 1983. This method uses the following empirical formula:

$$Q = 0.08u^{0.75}AZ[1 + [4.3\times10^{-3}T_p^2]]$$

where: Q = Evaporation rate, kg/hr
u = Wind speed, m/s
A = Spill area, m^2
Z = Volatility factor
T_p = Temperature of liquid, °C

Note that the above equation is empirical and not dimensionally consistent. For the accident considered here:

u = 4.47 m/s (10 mi/h), this speed corresponds to the wind speed for the 99.5% meteorology $\overline{\chi}/Q$ values calculated for the seismic event in Section 9.3
A = 90.7 m^2 (976 ft^2)
T_p = 40 °C (104 °F), the pool temperature is assumed to be equal to the air temperature

Z is the volatility factor of HNO_3 in relation to hydrazine and is calculated using

$$Z = \frac{P_{vb}M_b}{P_{vh}M_h}$$

where: P_{vb} = 3.1 mm Hg, partial pressure of HNO_3 at 40 °C
P_{vh} = 34.7 mm Hg, partial pressure of hydrazine at 40 °C
M_b = 63 g/gmole, molecular weight of HNO_3
M_h = 32 g/gmole, molecular weight of hydrazine.

Thus,

$$Z = \frac{(3.1 \text{ mm Hg})\left(63\frac{g}{gmole}\right)}{(34.7 \text{ mm Hg})\left(32\frac{g}{gmole}\right)} = 0.18$$

Finally, a conservative value for the evaporation rate is given by

$$Q = 0.08(4.47)^{0.75}(90.7)(0.18)[1 + [4.3\times10^{-3}(40°C)^2]]$$

$$= 30.9\frac{kg}{hr}$$

$$= 8.6 \times 10^{-3}\frac{kg}{s}$$

Since the HNO_3 is stored as a 57% solution, the mass release rate of HNO_3 is 4.9×10^{-3} kg/s.

The preceding calculation neglected the effects of solar radiation, ground conduction, and evaporative cooling. The neglect of evaporative cooling is clearly conservative. Approximating the thermal conductivity and heat capacity of the pool of 57% HNO_3 with water properties, conservatively using the maximum solar radiation flux on the 45th parallel of 1,070 W/m^2 (NRC 1991, Table 2.1), and assuming the ground temperature is 20 C° higher than the air temperature, the HNO_3 pool temperature will increase by only 2 C° per hour. This temperature difference will then drive convective heat transfer from the pool to the air, which would act to reduce the pool temperature.

The density of HNO_3 is roughly twice the density of air, so dense gas effects may be important in the dispersion calculation.

This is determined by calculating the Richardson number for a continuous release.

$$Ri_o = \frac{g(\rho_{rel} - \rho_a)\dot{V}}{\rho_a u^3 d}$$

where: g = acceleration of gravity, $9.81\frac{m}{s^2}$

ρ_{rel} = density of the released vapor, $\frac{kg}{m^3}$

ρ_a = density of the ambient air, $\frac{kg}{m^3}$

$\dot{V}$ = volumetric release rate of vapor ($=Q/\rho_{rel}$), $\frac{m^3}{s}$

u = wind speed, 4.47 $\frac{m}{s}$

d = initial length scale of release (i.e. diameter of pool), 10.7 m

Using the perfect gas law, the density (at 40 °C) of the released HNO_3 vapor can be calculated as 2.454 $\frac{kg}{m^3}$. Using this density and the previously

calculated mass flow rate due to evaporation along with the density of air at 40° C, the Richardson number is calculated as

$$Ri_o = \frac{9.81(2.454 - 1.225).000349}{(1.225)(4.47^3)(10.7)} = 3.3 \times 10^{-5}$$

Since the Richardson number is quite small (<0.003), the HNO_3 vapor is considered a passive tracer, and the normal Gaussian dispersion model is appropriate.

To determine the onsite and offsite HNO_3 concentration resulting from the spill, the rate at which the acid evaporates from the pool formed in the basin is multiplied by the appropriate $\overline{\chi}/Q$ values from Tables 9-39 and 9-40. Even though the HNO_3 tank is surrounded by buildings and piping, the concentration at the location of the maximum onsite and offsite individuals will be conservatively based on a point source ground level release with no consideration for building wake effects.

The onsite $\overline{\chi}/Q$ (point-source ground-level release) is 8.72×10^{-4} s/m^3. The concentration at the location of the maximally exposed onsite individual is therefore 4.3×10^{-3} g/m^3.

$$C = \left(4.9 \frac{g}{sec}\right)\left(8.72\times10^{-4} \frac{sec}{m^3}\right) = 4.3\times10^{-3} \frac{g}{m^3}$$

The offsite $\overline{\chi}/Q$ (point-source ground-level release) is 1.62×10^{-5} s/m^3. The concentration at the location of the maximally exposed offsite individual is therefore 7.9×10^{-5} g/m^3.

$$C = \left(4.9 \frac{g}{sec}\right)\left(1.62\times10^{-5} \frac{sec}{m^3}\right) = 7.9\times10^{-5} \frac{g}{m^3}$$

For comparison to the Toxicological Risk Acceptance Guidelines shown in Table 9-53, the above concentrations must be converted to ppm. The conversion formula is taken from AICHE (1989) p. 93.

$$C_{ppm} = C\frac{RT_a}{PM_0}\times10^6$$

where: R = 0.082 atm-m^3/K/kgmole, gas constant
P = 1 atm, ambient pressure
M_0 = 63 kg/kgmole, molecular weight of HNO_3
T_a = 313 K (= 40 °C), assumed ambient temperature

Thus, the onsite individual is exposed to

$$C_{ppm} = 4.3\times10^{-6}\frac{kg}{m^3}\frac{\left(0.082\frac{atm\text{-}m^3}{K\text{-}kgmole}\right)(313\ K)}{(1\ atm)\left(63\frac{kg}{kgmole}\right)}\times10^{6} = 1.8\ ppm$$

Similarly, for the offsite individual,

$$C_{ppm} = 7.9\times10^{-8}\frac{kg}{m^3}\frac{\left(0.082\frac{atm\text{-}m^3}{K\text{-}kgmole}\right)(313\ K)}{(1\ atm)\left(63\frac{kg}{kgmole}\right)}\times10^{6} = 0.032\ ppm$$

Both onsite and offsite concentrations are well below the respective Toxicological Risk Acceptance Guidelines shown in Table 9-53 for a seismic event with a frequency of 1 x 10^{-4}/yr (i.e., 24 ppm and 7.7 ppm, respectively) and even meet the guidelines for an event with a frequency of 1 (i.e., 15 ppm onsite and 2 ppm offsite). Thus, the above conservative analysis demonstrates that the onsite and offsite consequences of a HNO_3 spill are acceptable.

9.2.9 Accidents for the Plutonium-Bearing Solution Stabilization Process Using the Production Vertical Denitration Calciner

The following sections develop the bounding accident scenarios postulated for the plutonium-bearing solution stabilization process using the Production Vertical Denitration Calciner (VDC) in Glovebox HC-230C-2. The accident scenarios for analysis were identified based on categorization and screening of the HazOp analysis contained in Appendix 9D. The accident categories (bins) identified for the plutonium-bearing solution stabilization process are summarized in Appendix 9D, Table 9D-3. The accident categories were screened from the HazOp analysis contained in Table 9D-4 (also see Section 9.0.2.1A). The accident categories represent types of events associated with the Production VDC operations in Glovebox HC-230C-2 that have the potential to breach confinement barriers, resulting in significant spread of radiological or toxicological contamination to Zone 3 or Zone 4 areas within Building 234-5Z and the potential to cause a significant release of radiological or toxicological material from the building to the atmosphere. Each of the accident categories from Table 9D-3 are discussed in turn below.

Each accident category has also been compared and evaluated against the original accident analyses contained in Sections 9.2.1 through 9.2.8. New detailed accident analyses are provided in Sections 9.2.9.1 through 9.2.9.4 for accident categories found not to be adequately represented by the prior analyses contained in Sections 9.2.1 through 9.2.8.

Release from Transfer Line: This accident category involves leaks from the encased transfer lines that run between the HC-227S and HC-230C-2

gloveboxes. For the majority of leaks that could occur from primary transfer lines, the leaked fluid will drain back to the glovebox at either end, collect in the sump and be detected by the glovebox sump level detectors. The release remains confined because of the glovebox structure and ventilation system. The more significant accident scenario is less likely and would require the failure of the encasement pipe along with the primary transfer line failure. Such an event could result in a leak of radioactive liquid to Zone 3 areas on the first floor or to the floor of the duct level where facility workers could be exposed (e.g, to aerosols generated by splatter of the solution off the floor). As normal transfers between Glovebox HC-227S and Glovebox HC-230C-2 occur in relatively small 9 to 10 L draws, the exposure potential is limited. Except in a DBE, the airborne release to Zone 3 from a failed transfer line and encasement pipe would be filtered by the E-3 exhaust system and the consequences outside the plant would be insignificant. The consequences of a leak from the encased transfer line (non-seismic initiated) are considered to be adequately represented by the radioisotope bearing liquid spill analyzed in Section 9.1.1. The release from the transfer line in a seismic event is considered to be adequately covered in seismic accident analysis in Section 9.2.4, as that accident analysis assumes a fountain-like liquid release from a sheared transfer line within Glovebox HC-227S. No separate analysis was found to be warranted for this accident category.

Flammable Gas Deflagration in the Production Vertical Denitration Calciner: Should feed containing a significant quantity of separable organic be pumped into the calciner, a deflagration could occur in the Production VDC vessel or in the vessel offgas system. The deflagration would pressurize the calciner and force a fraction of its PuO_2 powder bed to become airborne. The heat and offgases produced in the deflagration could also pressurize the glovebox, causing a spread of radiological material to Room 230C. This accident cannot be easily compared to a pre-existing accident analysis and is therefore analyzed as a new accident in detail in Section 9.2.9.1.

Criticality: Glovebox HC-230C-2 processes and is allowed to store up to approximately 27 kg of Pu material at any given time. The Criticality Safety Evaluation Report (CSER) for the Production VDC (Hillesland 1997) establishes mass limits and separation requirements to minimize the likelihood of a criticality in Glovebox HC-230C-2. The glovebox is equipped with a criticality drain sized to handle credible infiltration of water from the facility fire sprinkler systems. In addition, the glovebox supports are seismically qualified to prevent toppling in the design basis earthquake which might pool liquids and solids together in a corner of the glovebox. In the extremely unlikely event a criticality occurs in Glovebox HC-230C-2, the consequences would be expected to be bounded by the criticality accident presented in Section 9.2.3. An additional criticality accident is not required specifically for Glovebox HC-230C-2 to assess facility risk.

Glovebox HC-230C-2 Fire: Glovebox HC-230C-2 is constructed out of stainless steel, with fire-resistant Lexan™ (polycarbonate) or wire-mesh reinforced glass shield windows. Combustible loading in the glovebox is limited to cartons used to bag cans in and out of the glovebox, rags, gloves, wire insulation, and equipment grease. Due to the high heat load and hot surfaces in the glovebox, small fires are possible in the glovebox, but a large fire that consumes the glovebox and spreads to other portions of the RMC

line is not anticipated. The Glovebox HC-230C-2 fire is evaluated in Section 9.2.9.2.

Glovebox HC-230C-2 Loss of Confinement: This category includes all failure scenarios not covered by other specific accident analyses that can result in the spread of radiological material from Glovebox HC-230C-2 to the Room 230C atmosphere. Postulated scenarios include pressurization of the glovebox due to an imbalance between the ventilation supply and exhaust on the RMC line, pressurization of the glovebox from compressed air line failures within the glovebox or from failure of the compressed air supply regulator, pressurization of the glovebox due to loss of calciner temperature control, diffusion of contamination from a stagnant glovebox caused by loss of both supply and exhaust flow, contamination spread caused by improper transfer of cans and other items into or out of the glovebox through the bag-in port, contamination spread through failed glovebox windows caused by internal or external equipment or tool impacts, and vapor releases back through the chemical addition line due to chemical reactions in the flush tank. (Note: A funnel break has been added between the flush and chemical addition tanks to preclude releases through the chemical addition line into Room 230C. Isolation valves would also have to be left open for such a release to occur).

The pressurized glovebox scenarios would produce the largest release from the glovebox. Scoping calculations indicate that failure of compressed air lines within the glovebox will not significantly pressurize the glovebox. The heat produced by the calciner will only significantly overpressurize the glovebox if ventilation flow through the glovebox is lost. The calciner is provided with a temperature control system and overtemperature alarm. In addition, glovebox air temperature is monitored. The worst-case pressurization scenario is a scenario where the E-4 exhaust system is shutdown but supply air to the RMC line continues. Interlocks are provided between the glovebox supply and exhaust systems to prevent this from occurring. Pressure indication is provided at Glovebox HC-230C-2 to warn operators of an overpressurized glovebox. CAMs strategically located in Room 230C will also alert operators to an airborne contamination hazard.

The potential release of contamination from the pressurized glovebox to Zone 3 could be expected to be similar to the powder spill addressed in Section 9.1.3 or to the conservative pressurized powder release analyzed in Section 9.1.4. The release from the glovebox would be filtered by the E-3 system and the consequences outside the facility would be negligible, as with the events addressed in Sections 9.1.3 and 9.1.4. No further evaluation of this accident category was therefore judged to be necessary to assess facility risk.

Toxic Chemical Release Inside Facility: The solution stabilization process using the Production VDC utilizes NaOH (for offgas scrubbing) and nitric acid (for flushing the VDC feed line). Fifty-five gallon drums used to feed the scrubber can be spilled or pumped through a failed transfer line to the floor of Room 230C. Small quantities of nitric acid transferred to the chem add tank can be similarly spilled. Operator training and procedures are primarily relied on to limit operator exposures. Such spills have the potential to cause burns to facility workers and to expose workers to airborne vapors due to evaporation of the spilled solutions. Outside the facility, however, airborne concentrations would be too low to be of concern due to

dilution with the plant air, release through an elevated stack and atmospheric dispersion. The consequences of a spill of NaOH or nitric acid associated with the Production VDC process are bounded by the toxic material release evaluated in Section 9.2.8. No further evaluation is necessary.

Failure of Compressed Air Supply Bottles: The atomizing air and filter back pulsing air for the Production VDC are supplied from compressed air cylinders. The compressed air cylinders present a significant stored energy source. Should a cylinder rupture or have its supply valve sheared off in a handling accident, it could be propelled as a missile injuring workers and causing damage to the facility. Because of the large number of compressed air cylinders required to support Production VDC operations, the failure of a cylinder due to a handling accident was determined to warrant detailed analysis, which is provided in Section 9.2.9.3.

Storage Canister Rupture: The HazOp analysis identified numerous process upsets and failures that could result in inadequately stabilized PuO_2 being produced by the Production VDC. If the inadequately stabilized oxide is not detected before sealing up the powder in site convenience cans, the cans could rupture in storage due to internal pressurization. A reaction between absorbed water and PuO_2 produces hydrogen gas that can cause overpressurization of the can. This accident is not unique to the Production VDC process as oxides stabilized in furnaces in other PFP gloveboxes have the same potential to overpressure canisters. Instrumentation is provided in the storage vault pedestals to detect bulging cans. Should a canister rupture while being handled within the 234-5Z Building, any released PuO_2 would be drawn through the E-3 ventilation exhaust system and filtered. In the Building 2736-Z storage vaults, the release from a ruptured can would be confined and filtered by the vault ventilation system. The consequences outside the plant would be negligible. The potential consequences of an overpressurized storage container are developed in Section 9.1.4. No further analysis was deemed to be necessary for this accident bin.

Natural Phenomena, Seismic Event: The Pu inventory in Glovebox HC-230C-2 potentially adds to the total facility source term in the seismic event. The potential release from Glovebox HC-230C-2 in the design basis earthquake (DBE) is developed in Section 9.2.9.4.

Natural Phenomena, Ashfall: A volcanic ashfall is considered to be a potentially occurring natural phenomenon in the same category with tornado and earthquake. With an appropriate wind pattern, the cloud of ash from a volcanic eruption could be directed toward the PFP.

Ash causes three immediate concerns to the PFP safety. The ash is extremely abrasive to any exposed mechanical equipment, ash may cause pluggage problems with the ventilation system, and heavy accumulations on top of the facility may exceed roof loading limits. Chapter 5.0, Section 5.2 states that the 234-5Z Building was analyzed and found to acceptably resist combined volcanic ashfall and snowfall (Giller 1990).

In the event of ashfall at the PFP, most exterior equipment that would be exposed to the abrasiveness of the ash would be shut down, including the vehicles such as the process and sample trucks. Normal ventilation may be maintainable during an ashfall, however, it may be necessary to shut down

normal ventilation and utilize emergency ventilation fans. It also may become necessary for the PFP personnel to clear the roof of the ash before excessive buildup occurs. This action is included in the plant emergency planning for response to volcanic eruption.

The PFP FSAR did not develop consequence calculations for an ashfall. This was based on two considerations, first the ability to take corrective action before roof loading became a problem and second, with regard to ventilation, the assumption that some level of ventilation could be maintained during the ashfall event. However, even if all ventilation were lost, the consequences were determined to be acceptable (Chapter 9.0, section 9.1.8). The addition of Glovebox HC-230C-2 does not introduce any new considerations for the loss of ventilation event as compared to existing analysis.

Natural Phenomena, High Wind: The PFP has been evaluated for capability to withstand high winds. It was determined that the facility could withstand the 90 mi/h wind called for in the Hanford Site design criteria document. The analyses referenced in Section 5.2.1.1.2 of the PFP FSAR show that the main load-bearing structure is not over stressed by the extreme wind or adversely impacted by the design criteria specified plank traveling at 50 mi/h. Section 9.2.5 evaluated the effect of high wind on the PFP. It was concluded that only facilities and components exterior to the 234-5Z Building would be vulnerable to high wind effects. The location of Glovebox HC-230C-2 inside Building 234-5Z precludes any affect from the wind or wind driven missiles.

External Event, Facility Wide Loss of Power: The PFP facility power loss can occur from many causes. Loss of power could be caused by lightning strikes, high wind, aircraft striking high voltage power lines, switch gear failure, and human error. A loss of ventilation would occur if both the supply fans and exhaust fans were to simultaneously lose power. This would occur only during a simultaneous loss of two electrical circuits and the backup power supply.

There are two concerns that result from a 234-5Z Building wide loss of power, both of which involve the loss of ventilation. The first is generation of hydrogen gas from tanks containing plutonium solutions. Provided that solutions are present, calculations indicate it would take nearly four weeks to accumulate sufficient hydrogen to result in a structure-threatening deflagration. The second is loss of confinement. Even if all ventilation were lost, the consequences were determined to be acceptable (Chapter 9.0, Section 9.1.8). The addition of Glovebox HC-230C-2 does not introduce any new considerations for the loss of ventilation event as compared to existing analysis.

External Event, Range Fire: Vegetation is removed routinely within and adjacent to the PFP site fencing for security purposes. This creates a large area devoid of material capable of allowing a fire to get within close proximity to the PFP. Also, the nature of the desert vegetation surrounding the 234-5Z Building coupled with the large vegetation control area does not support the presence of airborne embers capable of igniting the roof of the facility.

However, range fires do create conditions where loss of site power can occur. Although the main Hanford Site electrical system that provides power

to the 200 Areas is carried on metal towers, the distribution of that power to various locations in the 200 Areas is on wood poles. These poles are vulnerable to fire damage that could cause failure of the pole structure with resulting line faults and power loss. Therefore, range fires are a way of initiating site power loss and causing a facility ventilation failure. Ventilation failures are discussed under Loss of Power above.

External Event, Aircraft Crash: Aircraft accidents involving the PFP are evaluated in Chapter 9.0, Section 9.2.7. The frequency of a commercial or military aircraft accident involving the PFP was determined for several of the most credible or consequential categories of overflights. Using the available data, the frequency of a commercial or military aircraft accident involving the PFP has been determined to have a total value of less than 1.0×10^{-7}/yr, indicating that the event is not credible. Helicopters are also occasionally used to perform radiological surveys of the Hanford Site. A helicopter crash into the PFP is determined in Section 9.2.7 to not be credible as long as helicopters do not operate in a square 2,300 feet on a side centered on the 291-Z-1 Stack. Therefore this event is not evaluated further for the HC-230C-2 Glovebox.

9.2.9.1 Flammable Gas Deflagration in the Production Vertical Denitration Calciner. The aqueous solutions processed by the Production VDC contain small concentrations of entrained residual organic solvents from processing. It is possible that the immiscible organic material in the feed solution may coalesce and separate out from solution in the feed pump tank prior to being injected into the Production VDC. Because the Production VDC operates at very high temperature (in excess of 1000 °C), the injection of feed solution with a high organic content may result in a flammable gas burn inside the calciner. Thermal stabilization of plutonium-bearing solutions using the Production VDC are not currently authorized. The likelihood and consequences of a flammable gas burn associated with VDC operation will be developed prior to operation of the VDC.

9.2.9.2 Glovebox HC-230C-2 Fire. If combustible loading is not controlled in Glovebox HC-230C-2 and comes into contact with the hot surface of the Production VDC, a fire could result. Operation of the calciner is currently not authorized. The likelihood and consequences of a Glovebox HC-230-2 fire will be evaluated prior to initiation of calciner operations.

9.2.9.3 Compressed Air Cylinder Failure. The atomizing air and filter back-pulsing air for the Production VDC is supplied from compressed air cylinders. The cylinders are connected to the air supply line for the Production VDC from a bottle rack located outside Room 230C in Corridor 6. The layout of 234-5Z Building is provided in Figures 9-1 and 9-2. Four cylinders are contained in the bottle rack at a time. As is shown in Section 9.2.9.3.3 below, approximately 1000 cylinders will be needed to support Production VDC operations during the one-year solution stabilization campaign. The air cylinders, when full, contain 250 standard cubic feet of air at a pressure of approximately 2400 psi. Each cylinder brought into the facility presents a significant stored energy source. With the large number of cylinders needed, there is concern that a cylinder could be damaged and ruptured in a handling accident. In such an event, pressurized air ejected from the gas cylinder could accelerate the cylinder, turning it into a missile that could injure workers and cause damage to the facility.

9.2.9.3.1 Scenario. Compressed gas cylinders can fail in a number of ways. The cylinder itself could spuriously rupture because of a manufacturing flaw or internal corrosion. The cylinder could rupture from overpressure, if exposed to high temperatures in a fire (requires pressure relief valve to also fail). Or the cylinder could be punctured by impact with another object. The most likely way, however, for a compressed gas cylinder to become a missile is for the supply valve on top of the cylinder to be sheared off or otherwise damaged during handling of the cylinder. There have been several cases in the chemical industry where this has occurred. Within the DOE complex, at the Oak Ridge Site in 1995, a 100-pound-capacity cylinder containing carbon dioxide discharged its contents and became airborne after workers incorrectly manipulated a discharge-valve, hand-lever attachment. The cylinder narrowly missed the workers as it was propelled out of the storage enclosure. The cylinder hit a paved parking area and travelled an additional 30 feet before striking an inclined concrete ramp (ORPS Report ORO--MMES-Y12SITE-1995-0025).

For this accident analysis, it is assumed that one of the numerous compressed air cylinders brought into the plant to support Production VDC operations is mishandled and dropped in such a manner that the supply valve contacts the wall or another piece of equipment and is sheared off.

9.2.9.3.2 Mitigation. In DOE Facilities, compressed gases are handled, stored and used in compliance with Compressed Gas Association CGA P-1-1991, "Safe Handling of Compressed Gases in Containers." The compressed air cylinders are stored and used in an area that is dry, well ventilated, and of fire resistant construction. When not being moved, the cylinders are secured to prevent falling. Recycled cylinders are retested in accordance with the requirements of Code of Federal Regulations 49 CFR 173.304, *Qualification, Maintenance and Use of Cylinders.*

The likelihood of spurious cylinder failures is minimized by the safety factors built into the design of the cylinders, initial pressure testing of the cylinders, and periodic inspection by the supplier. The cylinders are provided with a pressure relief device to protect against high temperature exposure.

The likelihood of a handling accident resulting in failure of a compressed air cylinder is minimized by operator training and procedures. The air cylinders are transported on a cylinder hand truck. Rolling or "walking" of cylinders is prohibited. By procedure, when the cylinders are not in use, a cover (cap) is required to be installed over the cylinder supply valve. When installed, this cover protects the cylinder supply valve in most handling accidents.

9.2.9.3.3 Probability. Blanton and Eide (1993) recommends a failure rate for rupture of pressurized gas cylinders of 5.0×10^{-9}/cylinder-h. It is unknown whether this failure rate includes cylinder ruptures caused by handling errors, or if it applies only to passive storage and use of canisters restrained in bottle racks. Use of the Blanton and Eide failure rate is therefore potentially nonconservative for representing handling accidents. A second method of estimating the accident frequency is therefore provided below. For determining the annual probability of a cylinder rupture inside the PFP using the Blanton and Eide failure rate, it is necessary to determine the total cylinder-hours of exposure inside the facility. There are 8760

hours in a year. At any given time, four pressurized cylinders can be expected to be in the plant (assuming gas cylinders are normally stored outside the plant). Multiplying the Blanton and Eide failure rate (5.0×10^{-9}/cylinder-h) by the number of cylinder hours (8760 x 4) gives an annual probability for a cylinder accident inside the plant of 1.8×10^{-4}. Note that this annual probability does not include potential ruptures in the storage location outside the plant.

Assuming handling errors result in the majority of catastrophic cylinder failures, an alternate way to estimate the annual probability of an accident inside the facility is to use typical human error rates and engineering judgment. Typical human errors of commission or omission range from one in ten to one in one hundred operations, depending on training, the complexity of the task, and the stress involved in performing the task (Swain and Guttmann 1983). If the midrange human error value is used, roughly one in a hundred cylinders could be expected to be dropped or toppled during handling. It can also be assumed that human error results in roughly one in 100 cylinders being handled without the protective cover installed over the supply valve. Based on engineering judgement, it is assumed that one in ten cylinders that are mishandled falls or topples with the supply valve contacting a wall or another piece of equipment with enough force to be sheared off, provided the protective cover is not in place. It is estimated that approximately 1000 cylinders will be needed to complete the solution stabilization campaign. This number was arrived at as follows: The calciner is planned to be operated 24 h per day, 5 days per week. The total capacity of air in each cylinder is 250 scf, and the nominal flowrate of air to the calciner when it is operating is 40 scfh (Stubbs 1997). Dividing the cylinder capacity by the air flowrate gives 6.25 hours of operation per cylinder or approximately 3.8 cylinders per day. Multiplying the number of cylinders per day (3.8) by the number of days per week of calciner operation (5) and by 52 weeks per year gives a total of 990 cylinders used each year. This number is rounded up to 1000. Multiplying the drop probability (1/100) by the probability the protective cap is off (1/100), by the conditional probability that the drop occurs in such a manner that the exposed supply valve is impacted (1/10), and by the total number of cylinders handled (1000), gives a point probability estimate for the accident of 1.0×10^{-2}.

Based on the two approaches discussed above, and acknowledging uncertainties, the likelihood of the cylinder failure accident inside the facility is estimated to be in the "unlikely" frequency range (between 1.0×10^{-2}/yr and 1.0×10^{-4}/yr).

9.2.9.3.4 Consequence Analysis. In an event where the supply valve on a compressed gas cylinder is sheared off, the cylinder will be accelerated due to the expulsion of compressed gas from the cylinder. The acceleration of the cylinder is proportional to the mass expulsion rate and the velocity of the expelled gases, and is inversely proportional to the mass of the cylinder and its contents. The mass flowrate of air expelled from the cylinder is proportional to the pressure in the cylinder. However, the pressure in the cylinder drops as the gas is expelled per the ideal gas law. Likewise the mass of the cylinder drops as the air is expelled. The momentum and material balance equations for the cylinder are developed in Appendix 9E.

The model in Appendix 9E assumes that the sheared-off supply valve leaves a one-inch diameter hole in the top of the cylinder. The leak path is assumed to have flow characteristics similar to a square-edged orifice. Appendix 9E shows that the flow of air from the cylinder is choked (e.g., limited to sonic velocity) until the pressure in the cylinder drops to 28 psia. The model assumes the cylinder is unconstrained and unconfined (e.g., the cylinder does not lose energy bouncing off or penetrating through objects). Aerodynamic drag forces on the cylinder are ignored.

The key results of the analysis in Appendix 9E are provided in Figure 9-36. Figure 9-36 shows that acceleration of the cylinder is initially very high (266 ft/s^2) and decays in an exponential manner as the air in the cylinder is expended. Figure 9-36 also shows that the cylinder approaches an asymptotic velocity of approximately 166 ft/s 2.8 s after the supply valve is sheared off. At 2.8 s the flow of gas ejected through the orifice drops below sonic velocity. The cylinder is predicted to travel a total of 366 ft over the 2.8 s time frame. The model was not carried beyond 2.8 s due to the diminishing mass ejection rate, gas ejection velocity, and cylinder acceleration.

A compressed air cylinder weighs approximately 138 lb when fully charged and 119 lb empty. A ruptured cylinder can clearly cause serious injuries or fatalities to individuals in the path of the cylinder. From the perspective of the onsite and offsite receptors, however, a significant consequence occurs only if the failed cylinder causes a release of radioactive material to the atmosphere. As discussed previously, the cylinders are connected to the VDC air supply line at a bottle rack located outside room 230C in Corridor 6. The bottle rack holds four cylinders. The cylinders are brought into Corridor 6 through room 171 from the loading dock on the South side of Building 234-5Z or potentially through the loading dock door at the west end of the corridor. Excess cylinders are stored outside the facility.

The most likely scenario is that the cylinder handling accident would occur in room 171 or in corridor 6. The areas of the facility that contain large quantities of radioactive material are protected by reinforced concrete walls with a minimum thickness of 8 inches. The relevant areas for the cylinder accident are the RMC line and the PR-can storage areas. The following calculations show that the failed cylinder will not achieve enough momentum to penetrate into these areas.

The penetration distance of a non-deforming projectile into an infinitely thick concrete wall can be estimated using the following equation developed by the National Defense Research Committee (ASCE 1988):

$$x = \sqrt{4\,K\,N\,W\,d\,b_1}$$

where: x = penetration distance, inches
K = $180/(fc)^{1/2}$
fc = compressive strength of concrete, in psi
N = nose factor
= 0.72 for flat nose

= 0.84 for blunt nose
= 1.0 for spherical nose
= 1.14 for pointed nose
W = weight of projectile, lbs
d = diameter of projectile, inches
$b_1 = (v/(1000*d))^{1.8}$
v = velocity at impact, ft/s

This equation is valid when $x/d < 2$. It will be shown that $x/d < 2$ in this case.

The penetration depth for the infinitely thick wall, estimated using the above equation, can in turn be used to estimate the maximum perforation thickness and scabbing thickness. The perforation thickness is the maximum target thickness that the projectile at the given velocity will completely penetrate. The scabbing thickness is the thickness required to prevent spalling of material from the rear face of the target.

The following equations for estimating the perforation and scabbing thicknesses have been proposed (ASCE 1988):

$$e/d = 3.19(x/d) - 0.718(x/d)^2, \text{ for } x/d < 1.35$$

$$s/d = 7.19(x/d) - 5.06(x/d)^2, \text{ for } x/d < 0.65$$

where: e = perforation thickness, inches
s = scabbing thickness, inches

Figure 9-36 shows that the cylinder requires room to build up momentum. To reach a velocity of 80 ft/s (approximately 50% of the cylinder's maximum velocity), the cylinder has to travel, unimpeded, a distance of approximately 16 ft. To reach a velocity of 123 ft/s (approximately 75% of the cylinder's maximum velocity), the cylinder must travel, unimpeded, a distance of approximately 56 ft (from Appendix 9E, Table 9E-1). Because of the tight spaces in which the accident is likely to occur (room 171 and corridor 6 are less than 15 ft wide and tall), the cylinder would be expected to impact and reflect off the walls, floor, or ceiling a short distance from where the missile originated. Multiple, glancing blows are likely with each impact limiting the missile's momentum. For this analysis, the cylinder is conservatively assumed to reach a speed of 123 ft/s (75% of its maximum speed) before striking a wall. The compressive strength of concrete, fc, ranges from 3000 to 4000 psi. The lower value of 3000 psi is conservatively applied here. The cylinder has a flat bottom so a value of 0.72 is used for N. The weight of the cylinder (conservatively ignoring its contained air) is 119 lbs. The diameter of the cylinder is 9 in. The penetration distance (x), perforation thickness (e), and scabbing thickness (s) are therefore calculated as follows:

$$K = 180/(3000)^{1/2} = 3.29$$

$$b_1 = [(123 \text{ ft/s})/((1000)(9))]^{1.8} = 4.41 \times 10^{-4}$$

$$x = [(4)(3.29)(0.72)(119)(9)(4.41 \times 10^{-4})]^{1/2} = 2.12 \text{ in.}$$

$$x/d = 2.12/9 = 0.235$$

$$e = [3.19(2.12/9) - 0.718(2.12/9)^2](9) = 6.4 \text{ in.}$$

$$s = [7.91(2.12/9) - 5.06(2.12/9)^2](9) = 14.2 \text{ in.}$$

The above equations are based on impact tests with non-deformable missiles (armor-piercing projectiles). Being hollow, the gas cylinder would be expected to deform considerably in impacts at high speed. The minimum thickness of the concrete walls protecting the RMC line and PR-can storage areas is 8 in. Given the conservatisms in the above analysis, it is concluded that the cylinder will not perforate the walls, although back face scabbing can be expected.

The dense metal doors on the south wall of the RMC line area and on the north wall of the PR-can storage rooms 174 and 175 are expected to also provide adequate resistance to perforation. The doors are subject only to glancing impacts at limited speeds due to the factors discussed previously. The doors open out into the corridor and are thus well supported against impacts from the corridor side. There is no door in the RMC line south wall that is lined up with room 171 that could be subjected to a head-on impact.

Based on the above assessments, it is concluded that the most likely outcome should a compressed gas cylinder become a missile in corridor 6 is for the cylinder to ricochet down the corridor in either an east or west direction. Depending on direction, the cylinder is likely to penetrate through the doors separating corridor 6 from corridor 5 or corridor 7. Worker injuries in the corridors or adjacent offices not protected by thick concrete walls are possible. Because the gloveboxes and Pu storage areas in the plant are protected behind thick concrete walls that can withstand the maximum cylinder velocity, no significant radiological release within the facility is expected. Penetration of the doors separating corridors 5 and 7 from corridor 6 will cause only minor ventilation imbalances within the facility.

The potential for the cylinder to penetrate through the ceiling and cause damage in the duct level has not yet been evaluated. Use of the Production VDC to stabilize Pu-bearing solutions, however, is not currently authorized. An evaluation of the damage potential in the duct level will be added to the FSAR before use of the Production VDC is authorized.

9.2.9.3.5 Conclusions. Cylinder ruptures or handling accidents that result in the cylinders being propelled as missiles can cause severe worker injuries or fatalities. Strict adherence to the Compressed Gas Association guidelines and plant procedures regarding the storage, handling, and use of compressed air cylinders is vital to minimize facility worker risk.

Significant releases of radiological material outside the plant are not expected in a compressed air cylinder missile accident.

9.2.9.4 Glovebox HC-230C-2 Seismic Release. The plutonium-bearing solution stabilization equipment (known as the Production VDC) and Glovebox HC-230C-2

were added to the RMC Line after the seismic analysis contained in Section 9.2.4 was developed. Glovebox HC-230C-2 contains considerable quantities of $Pu(NO_3)_4$ and PuO_2 when in use and has the potential to add significantly to the total release from the facility in a seismic event. The analysis presented in this section estimates the potential release from Glovebox HC-230C-2 in a seismic event and compares this release with the releases estimated for the remainder of the PFP facility in Section 9.2.4. The estimated release for Glovebox HC-230C-2 has been factored into the dispersion and dose analyses in Section 9.2.4.

9.2.9.4.1 Scenario. The equipment in Glovebox HC-230C-2 and the solution stabilization process using the Production VDC are described in detail in Chapter 5.0, Section 5.2.1.2 and Chapter 6.0, Section 6.4.1, respectively. Glovebox HC-230C-2 contains the Production VDC, storage tanks for plutonium nitrate feed solution and nitric acid flush solution, a scrubber to treat the offgas stream from the calciner, a phase separator tank, and spent scrub solution receiver tanks. The calciner, scrubber, and phase separator are connected to the plant process vacuum system. The process vacuum system is supplied with a vacuum trap inside the glovebox to prevent carryover of liquid into the E-4 exhaust system. Treated offgases from the Production VDC pass through the process vacuum system into the E-4 exhaust system. With the exception of the Production VDC, the vessels inside the glovebox are made out of glass pipe to allow visual monitoring of tank liquid and solids levels. Glovebox air is supplied through conveyor Glovebox HC-3. Conveyor Glovebox HC-3 connects the glovebox to the rest of the RMC line. Glovebox air is exhausted through the E-4 ventilation system.

The potential combination of failures possible in a large earthquake are numerous. The seismic event can cause failure of some vessels and transfer lines while other vessels and lines can remain intact. The seismic event can fail some utilities (e.g., plant vacuum system) while leaving other utilities running (e.g., compressed process air). Active components like pumps can fail or can continue to operate. Partial or total loss of power is possible. To determine the potential combination of failures that are likely in a seismic event, it is first necessary to examine the seismic qualification of the items of concern.

The Glovebox HC-230C-2 structure is qualified to withstand the effects of a 0.2 g seismic event (DBE) without toppling. The primary benefit of seismically qualifying the glovebox is that it ensures the glovebox does not fall on a corner or edge and provide a potential collection volume for spilled solutions, powders and fire water (that may infiltrate into the glovebox in an earthquake). The seismically qualified glovebox design and the glovebox's criticality drain preclude the potential for a DBE-induced criticality. The E-4 ductwork connection to the glovebox is designed to shear in a 0.2 g seismic event to prevent loads from being transmitted to the glovebox. Similarly, the HC-3 Conveyor Glovebox is not qualified for an earthquake larger than UBC size and may fail providing a leakage path to Room 230C for Pu material released inside the glovebox. The interface between Glovebox HC-230C-2 and the HC-3 Conveyor Glovebox has been evaluated to verify that movement of the HC-3 Conveyor Glovebox will not compromise the seismic qualification of Glovebox HC-230C-2.

The tank supports and piping inside the glovebox are designed to UBC seismic requirements. The glass tanks are not specifically qualified to withstand seismic forces. It is therefore assumed in this analysis that the glass tanks are vulnerable to rupture due either to the direct loads imparted in the seismic event or due to pipe whip interaction.

None of the utilities feeding Glovebox HC-230C-2 (i.e., plant process vacuum, plant process air, compressed instrument air, and electrical power) are specifically qualified for the 0.2 g DBE. It is possible for these to fail or to continue operating after the seismic event.

The most important item in Glovebox HC-230C-2, from an accidental release perspective, is the Production VDC. By design it produces fine PuO_2 powder. Normally, the powder is confined to the calciner vessel. In the seismic event, the worst-case scenario for the calciner is that it loses process vacuum but continues to receive feed from an intact feed pump tank and continues to receive atomizing air feed through the injector nozzle. The water vapor flashed from the oxide bed in the calciner and the flow of atomizing air will result in pressurization of the calciner and the release of PuO_2 powder through the calciner relief port into the glovebox air. If software interlocks designed to shut down the calciner on high pressure fail in the seismic event, PuO_2 powder could be lofted continually through the relief path. Continuous feed of atomizing air to the calciner could sparge the PuO_2 bed in the calciner resulting in continuous release of powder through the relief port even after the feed pump tank was pumped dry. Continuous operation of the calciner agitator would contribute to the release of powder through the relief port.

A calciner pressurization event caused by a loss of calciner vacuum is evaluated in Section 9.1.10.1. The release in that abnormal event is postulated to occur over a 30 minute time frame before being shut down by operators. Because operators will evacuate the PFP in a seismic event and may not reenter for some time, the continuous release from the calciner after a seismic event could occur over a much longer time frame (e.g., 24 hours). At the nominal feed rate of 2.5 L/h, the 10 L feed pump tank would take 4 hours to drain. Hence, the potential release from a pressurized calciner in the seismic event could be at least eight times higher than estimated in Section 9.1.10.1, with continued flow of atomizing air and continued operation burning contaminated rags, polyjars, etc., would be expected to be very small in comparison to the conservatively estimated splatter and resuspension releases in this analysis and is therefore not specifically modelled.

Regarding potential chemical releases, two chemical sources are relevant to the plutonium-bearing solution stabilization process using the Production VDC: the 55-gal drum of NaOH used to feed the caustic scrubber, and the nitric acid that could be contained in the chem add and flush tanks (combined volume of 14 L) at the time of the accident. Both sources could be spilled and resuspended in a similar manner to the $Pu(NO_3)_4$ solution spilled in Glovebox HC-230C-2. However, the airborne release quantities from resuspension would be very small and would not pose a significant health threat to persons outside the plant, especially after being diluted with other air from the plant before being released through the 291-Z-1 exhaust stack or building doors. The consequences outside the plant from a spill of 55 gal of caustic or 14 L of nitric acid would clearly be negligible in comparison to the

receptor exposures estimated for the postulated spill of the 5000 gal outdoor nitric acid tank in a seismic event in Section 9.2.8. That spill is shown to have airborne concentrations below guidelines even for an event with an annual frequency of 1. The consequences of seismic-induced spill of the NaOH and nitric acid supplies to Glovebox HC-230C-2 are therefore not addressed further in this analysis.

9.2.9.4.2 Mitigation. The 234-5Z Building has been shown by analysis to survive the loads of a 0.25 g seismic event with minimal damage (see Section 9.2.4.1). The RMC line concrete walls and vault-like doors experience limited bending (URS 1987) and will not fail in the seismic event. The seismic qualification of the 234-5Z Building and the RMC line walls and doors ensures that releases inside the RMC line rooms remain confined to those rooms in the "no ventilation" case, as discussed in Section 9.2.4.7.1. The seismic shutdown interlock on the building supply fans prevents the pressurization of the RMC line rooms (such as Room 230C containing Glovebox HC-230C-2) and prevents the spread of contamination from those rooms to other areas of the plant.

The potential release from the Production VDC is limited by its seismic shutdown system. As discussed above, the calciner seismic shutdown shuts off liquid feed, atomizing air, and filter back pulsing air. This eliminates driving mechanisms which could continually force PuO_2 powder through the calciner relief path following a seismic event.

The Glovebox HC-230C-2 supports are bolted to the floor and designed to withstand DBE forces. This ensures the glovebox will not topple in the DBE. The interface between the qualified glovebox and the unqualified HC-3 Conveyor has been assessed to ensure the response of the HC-3 Conveyor in the seismic event will not compromise the seismic qualification of Glovebox HC-230C-2. Glovebox HC-230C-2 is provided with a criticality drain sized to handle potential infiltration of water from the building fire suppression system in the seismic event. DBE-induced criticalities are precluded in Glovebox HC-230C-2 because of the seismic qualification of the glovebox, the presence of the criticality drain, and administrative controls on fissile inventory in the glovebox.

The potential magnitude of a post-DBE fire in glovebox HC-230C-2 is limited by the metal design of the glovebox, the use of fire resistant Lexan™ and wire reinforced glass windows in the glovebox and the limited quantity of transient combustibles needed in the glovebox to perform calciner operations.

9.2.9.4.3 Probability. The annual probability of the 0.20 g earthquake is shown in Section 9.2.4 to be 1.0×10^{-4} (see Table 9-29). The tank and calciner vessel failures postulated in this analysis are conservatively assumed to occur with a conditional probability of 1, given the occurrence of a 0.2 g level earthquake.

Failure of the calciner seismic shutdown interlock system concurrent with a 0.2 g seismic event is considered to be incredible (i.e. to have a combined annual probability $< 1.0 \times 10^{-6}$). Seismic switches and electrical relays are highly reliable, with failure rates of 6.7×10^{-7}/h (IEEE 1984) and 7.6×10^{-5}/demand (SAIC 1989), respectively. The most likely way for the seismic interlock system to fail is for the air supplies to the calciner to

remain flowing due to failure of the solenoid operated valves on the atomizing air and back pulsing air lines. The failure rate for solenoid valves (failure to close on demand) is 2.8×10^{-3}/demand (SAIC 1989). Combined with the 1.0×10^{-4} annual probability of the earthquake, the probability of failure to shut off the two air supplies in the large seismic event is $(5.6 \times 10^{-7}) \times [(1.0 \times 10^{-4})(2 \text{ valves})(2.8 \times 10^{-3} \text{ valve failure/demand})]$. The seismic shutdown interlock system is therefore credited to work as intended in this analysis.

9.2.9.4.4 Source Term Analysis. The airborne releases from spilled $Pu(NO_3)_4$ solutions and exposed PuO_2 powders within the compromised glovebox HC-230C-2 are quantified separately below. The total release from glovebox HC-230C-2 is then compared to the sum of the estimated releases for the remainder of the 234-5Z building from Section 9.2.4.

Airborne Releases from Spilled Solutions. Should the glass tanks in glovebox HC-230C-2 rupture in the seismic event, the spilled solutions from the tanks will produce an initial "puff" release caused by splatter of liquid off of equipment in the glovebox and the glovebox floor. The splatter release will be followed by a long term resuspension release due to air flowing over the surface of the spilled solution.

For the splatter release, an airborne respirable release fraction (ARRF) of 2.0×10^{-5} is used. This is the bounding ARRF recommended in DOE-HDBK-3010-94, (DOE 1994), *Airborne Release Fractions/Rates and Respirable Fractions For Nonreactor Nuclear Facilities*, Section 3.0 for free-fall spills of concentrated heavy metal solutions. This release fraction is very conservative because it is based on free-fall spills of solution from 3 m, a height that is much higher than is possible for spills from tanks inside glovebox HC-230C-2. The total capacity of the feed receipt and the feed pump tanks is 20 L (10 L apiece). It is conservatively assumed that each tank contains the maximum allowed concentration of 450 g/L. The total Pu splatter release from the two tanks is therefore:

Release from Open Slip-Lid Can. For the open slip-lid can, there is short-term release due to sliding and impacting of the can with other objects in the glovebox, followed by a longer term resuspension release. To estimate the short-term release, the 1 m free-fall powder release fraction of 4.0×10^{-5} is once again utilized. As with resuspension of the powder spilled from the calciner, only the top layer of powder contained in the can (assume 10%) is subject to release from seismic motion. Applying the free fall spill release fraction to the top 10 % of the powder in the open can should give very conservative results as the shearing forces on a slug of fine powder free falling over a distance of 1 m would seem to be much greater than the deagglomeration forces exerted on the top layer of powder in an open can sliding around in the bottom of the glovebox for a short period of time associated with a seismic event. For resuspension in the glovebox air after cessation of seismic motion, the resuspension release rate of 4×10^{-5}/h from above is once again used.

The capacity of the slip-lid can is 0.5 L. The maximum plutonium density in the calcined product allowed by the CSER for the Production VDC (Hillesland 1997) is 5.5 kg/L. The Pu inventory in the can is therefore 2.75 kg.

Applying the free fall and resuspension release fractions to the top 10% of the powder in the can gives a total release over 24 hours of:

$$\text{Release, open can} = (2750\ \text{g})(0.1)[4 \times 10^{-5} + (4 \times 10^{-5}/\text{h})(24\ \text{h})]$$

$$= 0.28\ \text{g}$$

Release from Broken Collection Jar. This release is estimated in the same way as the open slip-lid can case. The capacity of the jar is approximately 0.75 L. At the maximum plutonium density allowed for the calcined powder in the CSER of 5.5 kg/L, the total inventory of Pu in the jar is 4.125 kg. The total release over 24 hours is:

$$\text{Release, broken jar} = (4125\ \text{g})(0.1)[4 \times 10^{-5} + (4 \times 10^{-5}/\text{h})(24\ \text{h})]$$

$$= 0.41\ \text{g}$$

Total Airborne Seismic Release from Glovebox HC-230C-2. The total of the respirable airborne releases from $Pu(NO_3)_4$ solutions and exposed PuO_2 powders in Glovebox HC-230C-2 is 1.64 g (0.27 g + 0.68 g + 0.28 g + 0.41 g). This compares to the total release estimated in Section 9.2.4 for all the PFP facilities of 15.3 g (see Table 9-31).

9.2.9.4.5 Dose Analysis. The release from Glovebox HC-230C-2 does not factor into the "no ventilation" case seismic release discussed in Section 9.2.4.7.1, as the release would remain confined within the RMC line walls and would not be available to be swept from the building in wind blowing through the facility through open evacuation doors. The release from Glovebox HC-230C-2 would, however, add to the release in the "ventilation" case discussed in Section 9.2.4.7.2 because the release, along with releases from the other RMC line gloveboxes, would be drawn through the E-3 and E-4 exhaust systems and expelled, unfiltered, through the 291-Z-1 exhaust stack. The E-3 and E-4 filters are assumed to fail in the seismic event.

The release model in the ventilation case analysis (Section 9.2.4.7.2) includes gravitational settling of material within the building before release out the 291-Z-1 exhaust stack. Assuming the same particle size distribution for the material released from Glovebox HC-230C-2 as for the releases from the other RMC line gloveboxes, the percentage of the Glovebox HC-230C-2 release deposited in the facility due to gravity settling will be the same as for the releases from the remainder of Building 234-5Z. Section 9.2.4.7.2 shows that 16% of the material released within the facility will gravity settle out before discharge through the 291-Z-1 exhaust stack. Therefore of the 1.64 g released from Glovebox HC-230C-2, 1.38 g will be emitted from the stack to the environment.

The onsite and offsite receptor doses are estimated using the atmospheric dispersion and dose models presented in Section 9.3. The release from Glovebox HC-230C-2 is conservatively assumed to be composed of an isotopic mixture containing >10% ^{240}Pu. This is conservative because the majority of

the Pu to be processed by the vertical denitration calciner contains <10% ^{240}Pu, which has a lower unit dose factor. A discussion on the isotopic composition of Pu contained in the PFP is contained in Section 9.3.5. Of the 1.38 g released from the facility 0.23 g originates from $Pu(NO_3)_4$ solutions. The unit dose factors corresponding to class W lung retention from Table 9-46 are used to estimate inhalation doses for this portion of the release. The unit dose factors from Table 9-46 corresponding to class Y lung retention are used to estimate the inhalation doses associated with the remaining oxide portion of the release.

The onsite and offsite receptor EDE dose estimates corresponding to the seismic release from Glovebox HC-230C-2 are summarized in Table 9-58 and are 0.67 and 0.24 rem, respectively. The onsite and offsite receptor dose estimates for the base case seismic event (ventilation case) from Section 9.2.4 are summarized in Table 9-33. Adding the Glovebox HC-230C-2 dose estimates to the base case estimates gives onsite and offsite EDE exposures of 7.5 and 2.0 rem, respectively. The combined doses are below the previously approved onsite and offsite doses reported in prior revisions of the FSAR. The total seismic dose estimates, with the Glovebox HC-230C-2 release included, are below the previously approved estimates due to reductions in maximum dispersible inventory limits in several gloveboxes.

9.2.9.5 Changes to the RMC Line Fire Analysis from Glovebox HC-230C-2. Glovebox HC-230C-2 is located at the West end of the RMC line. The hazards analysis for the Pu-bearing solution stabilization process postulates that the RMC line fire evaluated in Section 9.2.2A possibly spread to Glovebox HC-230C-2 by consuming the plastic panels in the HC-2 and HC-3 conveyors. An airlock, however, is located in the between the HC-2 and HC-3 conveyors in Room 230B. The airlock doors are kept closed except during short time periods when materials are being transferred from the HC-2 to HC-3 conveyors. The airlock doors are kept closed to ensure proper operation of the glovebox dry fire suppression systems in the RMC line. The airlock doors and the walls of the conveyor between both airlock doors are constructed of metal. The RMC line fire analyzed in Section 9.2.2A has a duration of 40 minutes. The time frame over which the airlock would be subjected to the heat of the fire would be much less. The airlock is thus assumed to remain intact during the fire, preventing spread of the fire to Glovebox HC-230C-2. This assumption is consistent with the PFP Fire Hazards Analysis (McKinnis 1998) that credits the airlock with preventing the spread of fire. It is concluded that Glovebox HC-230C-2 will not add source term to the RMC line fire accident.

9.2.10 Accidents for Reactive Plutonium-Bearing Material Stabilization Operations.

The following sections develop the bounding accident scenarios postulated for the thermal stabilization of plutonium oxide process in glove boxes HC-21A, HC-2, HC-21C, HC-3, HC-4, HA-21I, HC-18BS, and HC-18M. The accident scenarios for analysis were identified based on categorization and screening of the PHAs contained in Appendices 9F and 9G. The accident categories were screened from the PHAs shown in Tables 9F.23, 9G.4, 9G.8, 9G.9, 9G.13, and 9G.20 and are discussed in Appendices 9F, Section 9F.4.3.3, and 9G, Section 9G.4.2, respectively. The same catgories also apply to seal-in/seal-out operations in glovebox HC-13MD and thermal stabilization operations in

gloveboxes HA-28 and HA-22B. The hazard analysis and accident categories for stabilization of plutonium metals are presented in HNF-4823, Hazards Evalauation of Plutonium Metal Opening and Stabilization (FDH 1999). The accident categories represent types of events associated with the thermal stabilization operations that have the potential to breach confinement barriers, resulting in significant spread of radiological or toxicological material from the building to the atmosphere. Each of the accident categories from Tables 9F.23, 9G.4, 9G.8, 9G.9, 9G.13, and 9G.20 are discussed below in alphabetical order of accident category. New detailed accident analyses are provided in Sections 9.2.10.1 through 9.2.10.5 for accident categories not found to be adequately represented by the prior analyses contained in Sections 9.2.1 through 9.2.9.

Criticality:

Relatively large masses of plutonium are handled during thermal stabilization activities. Placing enough material in a glovebox or having sufficient material in a non-safe geometry due to human error could result in a criticality. Therefore, without controls, criticalities are possible within Gloveboxes HC-21A, HC-21C, HC-1, HC-2, HC-13MD, HC-3, HC-4, HA-21I, HC-18BS, HA-28, HA-22B, and HC-18M. Controls to prevent criticalities include administratively controlled mass and spacing limits within the gloveboxes, hardware to physically separate containers of Pu oxide, exclusion of water in the gloveboxes, and limiting the number and size of containers allowed in each glovebox. The specific controls that provide double-contingency protection against criticalities in the various gloveboxes used for thermal stabilization are specified in the following CSERs (listed by gloveboxes):

- HC-1, HC-2, HA-22B — CSAR 81-007 (RHO 1981)
- HC-4 and HA-28 — CSAR 80-022 (RHO 1980)
- HC-13MD — CSAR 79-015 (RHO 1979)
- HC-18M — CSER 98-005 (HNF-1998c)
- HC-18BS — CSER 98-004 (HNF 1998b)
- HC-21A — CSERs 98-003 (HNF 1998a), 99-002 (HNF 1999), 99-007 (HNF 1999a), and 00-002 (HNF 2000)
- HC-21C — CSERs 94-007 (WHC 1994), 99-002 (HNF 1999), and 99-007 (HNF 1999a)
- HA-21I — CSER 99-007 (HNF 1999a).

It is assumed that the Criticality Prevention Program requirements for PFP (including the above referenced CSERs) are adequate to ensure criticality safety.

External Events - Aircraft Crash, Facility Wide Power Loss, and Range Fire:

Aircraft Crash: Aircraft accidents involving the PFP are evaluated in Section 9.2.7. The frequency of a commercial or military aircraft accident involving the PFP was determined for several of the most credible or consequential categories of overflights. Using available data, the frequency of a commercial or military aircraft accident involving the PFP has been

determined to have a total value of less than 1.0×10^{-7}/yr, indicating that the event is not credible. Helicopters are also occasionally used to perform radiological surveys of the Hanford Site. A helicopter crash into the PFP is determined in Section 9.2.7 to not be credible as long as helicopters do not operate in a square 2,300 feet on a side centered on the 291-Z-1 stack. Therefore this event is not evaluated further for the thermal stabilization process.

Facility Wide Loss of Power: The PFP facility power loss can occur from many causes. Loss of power could be caused by grid collapses, lightning strikes, ice storms, high wind, range fires (see below), aircraft striking high voltage power lines, switch gear failure, and human error. A loss of ventilation would occur if both the supply fans and exhaust fans were to simultaneously lose power. This would occur only during a simultaneous loss of two electrical circuits and the backup power supply.

There are two concerns that result from a 234-5Z facility wide loss of power, both of which involve the loss of ventilation. The first is loss of confinement. Even if all ventilation were lost, the consequences were determined to be acceptable (Chapter 9.0, Section 9.1.8). The addition of the plutonium oxide thermal stabilization process does not introduce any new considerations for the loss of confinement caused by a ventilation failure event as compared to existing analysis. The second concern is the potential for accumulation of flammable gasses (ethylene) if plastic material is present in a furnace boat being thermally stabilized in a furnace in either glovebox HC-21C or glovebox HA-21I and ventilation flow is lost due to a facility wide loss of power. Analysis of deflagrations are presented in section 9.2.10.2.

Range Fire: Vegetation is removed routinely within and adjacent to the PFP site fencing for security purposes. This creates a large area devoid of material capable of allowing a fire to get within close proximity to the PFP. Also, the nature of the desert vegetation surrounding the 234-5Z coupled with the large vegetation control area does not support the presence of airborne embers capable of igniting the roof of the facility.

However, range fires do create conditions where loss of site power can occur. Although the main Hanford Site electrical system that provides power to the 200 Areas is carried on metal towers, the distribution of that power to various locations in the 200 areas is on wood poles. These poles are vulnerable to fire damage that could cause failure of the pole structure with resulting line faults and power loss. In addition, electrically conductive smoke can cause power lines to short to ground even if the wooden poles or metal towers are not significantly damaged in the fire. Therefore, range fires are a way of initiating failures discussed under Loss of Power above.

Flammable Gas Deflagration In Glove Box:

Deflagrations are postulated to occur in gloveboxes from several causes. The magnitude of the deflagration is postulated to be sufficient to cause releases that could severely impact the facility worker. In glovebox HC-21A there is a potential for a radiolysis created hydrogen gas release and subsequent burn when a plutonium oxide containing can is opened. Opening a can containing organics caused by an incorrect container being selected as a result of erroneous labeling or human error can also result in hydrogen

release and ignition. A burn of flammable gas upon opening Pu containers in Glovebox HC-21A is evaluated in detail in Section 9.2.10.1. In glovebox HC-21C or HA-21I, flammable gas can be generated and ignited if plastic contaminants are allowed to be heated in the thermal stabilization furnace because they are not identified and removed from the plutonium oxide feed. Loss of offgas flow through the stabilization furnace during heat up is required for flammable gases to build up in the furnace. Loss of offgas flow is possible during normal operation or during a seismic event. A flammable gas deflagration in the Glovebox HC-21C or HA-21I furnaces during normal operation is evaluated in detail in Section 9.2.10.2. A seismically induced flammable gas deflagration is analyzed in Section 9.2.10.3.

Loss of Glovebox Confinement Due To Ventilation Failure:

This category includes all failure scenarios not covered by other specific accident analyses that can result in the spread of radiological material from the gloveboxes associated with the plutonium oxide thermal stabilization process. Postulated scenarios include pressurization of the glovebox due to an imbalance between the ventilation supply and exhaust on the RMS line, stagnation of the gloveboxes due to complete ventilation failure (not associated with power loss), and overheating the HC-21C or HA-21I glovebox due to a lack of heat removal caused by inadequate ventilation flow. The worst-case pressurization scenario is a scenario where the E-4 exhaust system is shutdown but the supply air to the RMC continues to be present. Interlocks are provided between the glovebox supply and exhaust systems to prevent this from occurring. Pressure indication is provided to warn operators of an overpressurized glovebox. CAMs strategically located in rooms 230C and 235B will also alert operators to an airborne contamination hazard.

The potential release of contamination from the pressurized glovebox to Zone 3 could be expected to be similar to the powder spill addressed in Section 9.1.3 or to the conservative pressurized powder release analyzed in Section 9.1.4. The release from the glovebox would be filtered by the E-3 system and the consequences outside the facility would be negligible, as with the events addressed in Sections 9.1.3 and 9.1.4. No further evaluation of this accident category was therefore judged to be necessary. The pressurized glovebox case bounds the stagnant glovebox case.

Overheating the glovebox can result in loss of confinement from several different causes. Port bags, gloves, and viewing windows can be failed due to overheating which have the potential for creating large openings through which radioactive material can escape. Activation of the glovebox dry fire suppression system in a glovebox overheating scenario could contribute to expulsion of radiological material from the compromised glovebox. The glovebox (E-4) ventilation is designated safety significant in Chapter 4, (Table 4-7). This system is connected to backup power and is considered sufficiently reliable to protect glovebox HC-21C or HA-21I from overheat damage. An interlock is also provided to shut down the furnaces on detection of high temperature in the glovebox.

Natural Phenomena - Seismic, Ashfall, And High Wind:

Seismic: The Pu inventory in the glove boxes used for thermal stabilization potentially adds to the total facility source term in the seismic event.

Ashfall: A volcanic ashfall is considered to be a potentially occurring natural phenomenon in the same category with tornado and earthquake. With an appropriate wind pattern, the cloud of ash form a volcanic eruption could be directed toward the PFP.

Ash causes three immediate concerns to the PFP safety. The ash is extremely abrasive to any exposed mechanical equipment, ash may cause pluggage problems with the ventilation system, and heavy accumulations on top of the facility may exceed roof loading limits. Chapter 5.0, Section 5.2 states that the 234-5Z Building was analyzed and found to acceptably resist combined volcanic ashfall and snowfall (Giller 1990).

In the event of ashfall at the PFP, most exterior equipment that would be exposed to the abrasiveness of the ash would be shut down, including the vehicles such as the process and sample trucks. Normal ventilation may be maintainable during an ashfall, however, it may be necessary to shut down normal ventilation and utilize emergency ventilation fans. It also may become necessary for the PFP personnel to clear the roof of the ash before excessive buildup occurs. This action is included in the plant emergency planning for response to volcanic eruption.

The PFP FSAR did not develop consequence calculations for an ashfall. This was based on two considerations, first the ability to take corrective action before roof loading became a problem and second, with regard to ventilation, the assumption that some level of ventilation could be maintained during the ashfall event. However, even if all ventilation were lost, the consequences were determined to be acceptable (Chapter 9.0, Section 9.1.8). The addition of the thermal stabilization process does not introduce any new considerations for the loss of ventilation event as compared to existing analysis.

An ashfall event can also cause a loss of power which has the potential to lead to a loss of offgas flow through the thermal stabilization furnaces. Loss of offgas flow has been postulated as a cause of a flammable gas deflagration in the furnace. The loss of offgas flow accident is covered in Section 9.2.10.2. An ashfall event is characteristically a slow developing event at any appreciable distance from the volcanic eruption that causes it. Emergency response as a result of an ashfall event would result in processes in PFP being shutdown and placed in a safe condition. Sufficient time would be available to shutdown the thermal stabilization furnaces so that the likelihood of glovebox overheating and potential flammable gas deflagrations would be minimized. The availability of backup power for ventilation would reduce even further the likelihood of ashfall induced ventilation failures resulting in glovebox overheating or flammable gas deflagration.

High Wind: The PFP has been evaluated for capability to withstand high winds. It was determined that the facility could withstand the 90 mi/h wind called for in the Hanford Site design criteria document. The analyses referenced in Section 5.2.1.1.2 of the PFP FSAR show that the main load-bearing structure is not over stressed by the extreme wind or adversely

impacted by the design criteria specified plank traveling at 50 mi/h. Section 9.2.5 evaluated the effect of high wind on the PFP. It was concluded that only facilities and components exterior to the 234-5Z facility would be vulnerable to high wind effects. The location of glove boxes for thermal stabilization activities precludes any affect from the wind or wind driven missiles. High wind is also a potential initiator for loss of facility power. Loss of power has the potential to lead to a loss of glovebox ventilation and stabilization furnace offgas flow with subsequent glovebox overheating or flammable gas deflagration. The loss of offgas flow accident is covered in Section 9.2.10.2.

Pyrophoric Reaction in Glove Box:

The PHA analyses identified one event involving pyrophoric reaction causing slight pressurization of the glovebox. This could only occur if significant hydride contamination was present in the Pu oxide material being processed. The glovebox ventilation system (E-4) would have to fail for significant quantities of material to escape from the glovebox. This event is considered to be bounded by the loss of glovebox confinement event.

Rupture of Container In Storage Vault:

The PHA analyses identified numerous process upsets and failures that could result in inadequately stabilized plutonium oxide. If the inadequately stabilized oxide is not detected before sealing up the powder in Hanford Site convenience cans, the cans could rupture in storage due to internal pressurization. A reaction between absorbed water and plutonium oxide produces hydrogen gas that can cause overpressurization of the can. This accident is not unique to the thermal stabilization process as oxides that have been dried in furnaces in other PFP glove boxes have the same potential to overpressurize canisters. Instrumentation is provided in the storage vault pedestals to detect bulging cans. Should a canister rupture while being handled within the 234-5Z Building, any released plutonium oxide would be drawn through the E-3 ventilation exhaust system and filtered. In the Building 2736-Z storage vaults, the release from a ruptured can would be confined and filtered by the vault ventilation system. The consequences outside the plant would be negligible. The potential consequences of an overpressurized storage container are developed in Section 9.1.4. No further analysis was deemed to be necessary for this accident bin.

Uncontrolled Fire In Glove Box:

An uncontrolled fire in a glovebox associated with the thermal stabilization of plutonium oxide process can occur only if an ignition source is combined with a combustible material supply. These ignition sources would normally be associated with the thermal stabilization furnaces located in gloveboxes HC-21C and HA-21I. The amount of combustible material available determines the potential severity of such a fire. Combustible loading in the gloveboxes is limited to cartons used to bag cans in and out, rags, gloves, wire insulation, and equipment grease. However, portions of the RMC line have large Lucite (PMMA) viewing panels, which represent a significant quantity of combustible material. Two general types of events could result in glovebox fires. The first is errors that bring combustible materials in contact with the hot furnace surfaces. The second is combustible materials being brought

into contact with hot furnace surfaces by seismic events. Both of these scenarios are developed in Sections 9.2.10.4 and 9.2.10.5 respectively.

9.2.10.1 Hydrogen Deflagration in Glovebox HC-21A from Opening Pressurized Containers. Plutonium storage containers are opened in Glovebox HC-21A. Flammable gases, primarily hydrogen, may be present in these containers due to the thermal and radiolytic decomposition of plastic packaging materials and moisture. As shown in the following analysis, the release and subsequent ignition of the hydrogen potentially present in the specific plutonium storage containers to be processed in Glovebox HC-21A does not result in a breach of the glovebox.

9.2.10.1.1 Scenario. Plutonium is stored in multiple overpack containers using standard food-pack cans. Stored plutonium oxide may be contained in two, three, or four nested containers. In all cases, the outer container is a crimp-sealed, 7-Inch Can (see Figure 6-10).

The generation of hydrogen can result in pressurized containers. Pressurization criteria have been developed that correlate storage can deformation to internal can pressure, as shown in Figure 9-37. For the thermal stabilization of reactive plutonium-bearing material, only Type A or B Cans will processed and, therefore, opened in Glovebox HC-21A.

For the purposes of this analysis, it is assumed that a Type D Can pressurized to 30 psig is inadvertently placed in glovebox HC-21A and opened. Type D Cans are defined as having a pressure in the range of 20 to 40 psig. In terms of physical appearance, a Type D Can has either a lid that protrudes outward showing severe signs of stress or has several ripples in the lid. A value of 30 psig was chosen for analysis because containers may vent at their seams beginning at a pressure of 30 psig.

Given a pressure of 30 psig, the quantity of gas in a container can be calculated using the Ideal Gas Law:

$$PV = nRT$$

where: P = pressure, atm
V = volume, L
T = absolute temperature, K
n = number of moles
R = universal gas constant, 0.0825 atm liter/mol K

The volume of a 7-Inch Can is 1.5 L. Some fraction of this volume will be filled by the plutonium oxide, inner can or cans, and packaging materials. Accounting for these items, it is estimated that the free volume within the 7-Inch Can is 1.25 L.

Given a free volume of 1.25 L and assuming a temperature of 300 K, the number of moles of gas present at a pressure of 30 psig is:

$n = [(44.7 \text{ psia})(1 \text{ atm}/14.7 \text{ psia})](1.25 \text{ L})/(0.0825 \text{ atm-L/mol-k})(300 \text{ K})$

$n = 0.15$ moles

The 0.15 moles of gas in the 7-Inch Can at 30 psig is comprised of the hydrogen generated by thermal and radiolytic decomposition of plastic packaging materials and moisture and the air initially present in the container. Applying the Ideal Gas Law, the quantity of air in the can before pressurization can be shown to be 0.05 moles. Therefore, the 7-Inch Can contains 0.05 moles of air and 0.10 moles of hydrogen at the time it is opened.

Plutonium storage containers are opened in Glovebox HC-21A by use of an electric can opener. As the can opener punctures and begins to open the 7-Inch Can, a flammable mixture of hydrogen and air will be released. Because of its low ignition energy, nominally small heat producing sources (e.g., friction and static generation) can result in the prompt ignition of hydrogen. Should this occur, the hydrogen would burn as a jet or flare. This short duration, unconfined burn would not pressurize the glovebox.

If the hydrogen does not burn as it exits the 7-Inch Can, it will, given its high diffusivity, rapidly mix with the glovebox atmosphere. Glovebox HC-21A, with dimensions of 10 ft 8 in. by 3 ft 6 in. by 3 ft, has a volume of 3,150 L. Subtracting the 680 L volume of the Inert Atmosphere Confinement portion of the glovebox yields a volume of 2,470 L. Applying the Ideal Gas Law, this volume can contain 100 moles of gas. If the 0.10 moles of hydrogen released from the 7-Inch Can were to mix uniformly within the volume of the glovebox, the resultant concentration would be 0.10%, which is significantly below the lower flammability limit of 4%. Accordingly, the hydrogen would not burn but would be swept from the glovebox via the E-4 ventilation system and further diluted.

As the hydrogen is released from the 7-Inch Can and mixes with the glovebox atmosphere, localized concentrations within the flammability range will exist for a short period of time. Assuming that all of the hydrogen is released as a puff and is ignited before mixing below the lower flammability limit, the instantaneous energy release would be:

$$Q = (240 \text{ kJ/g-mole})(0.10 \text{ moles}) = 24 \text{ kJ}$$

where: Q = heat generated
kJ/g-mole = heat of combustion of hydrogen.

Conservatively assuming 100% of the heat from the hydrogen burn is transferred to the air in the glovebox, the increase in temperature can be calculated by:

$$\Delta T = Q/mC_p$$

where: ΔT = change in temperature (K)
Q = heat generated (kJ)
m = mass of air in glovebox (kg)
C_p = specific heat of air (kJ/kg-K).

The mass of air in Glovebox HC-21A is equal to the volume of air multiplied by its density:

$$m = (\text{volume})(\text{density}) = (2.47\ \text{m3})(1.16\ \text{kg/m3}) = 2.86\ \text{kg}$$

Solving for ΔT yields a temperature increase of:

$$\Delta T = 24\ \text{kJ}/(2.86\ \text{kg})(1.007\ \text{kJ/kg-K}) = 8.33\ \text{K}$$

Applying the Ideal Gas Law, the pressure in the glovebox given a temperature rise of 8.33 K is calculated as follows:

$$(P_{final}/P_{initial}) = (T_{final}/T_{initial})$$

$$P_{final} = (14.7\ \text{psia})(300\ \text{K} + 8.33\ \text{K})/(300\ \text{K}) = 15.1\ \text{psia}$$

The increase in pressure is therefore 0.4 psig.

A pressure increase of 0.4 psi is not expected to fail the glovebox gloves. Walden (1980) suggests gloves fail at an overpressure of 0.6 psi. A pressure increase of 0.4 psig could breach the glovebox via failed seal-in ports. Although a pressure increase of 0.4 psig can be conservatively calculated, such an increase would not be realized for three principal reasons. First, 100% of the hydrogen released in a puff would not burn as assumed. A stoichiometric mixture of 0.10 moles of hydrogen and air has a volume of 8.4 L, which would fill approximately 0.4% of the glovebox. Accordingly, the hydrogen would burn as an unconfined cloud, the efficiency of which can be significantly less than 100%. As stated in *Evaluation of Unconfined Vapor Cloud Explosion Hazards* (Pugh 1987), when small unconfined vapor clouds are ignited, the vapors usually burn without pressure effects and with a low flame speed. Second, 100% of the heat from the hydrogen burn would not be transferred to the air as assumed above, i.e., the system is not adiabatic. Third, Glovebox HC-21A is not a sealed vessel. A 3 ft. by 17 in. opening in the north end of Glovebox HC-21A provides access to Conveyor Glovebox HC-2. Qualitatively considering these factors, it is concluded that the release and subsequent ignition of hydrogen from a pressurized Type D Can will not breach Glovebox HC-21A since there would be little or no pressure increase. This conclusion is consistent with operating experience at PFP and throughout the DOE complex.

9.2.10.1.2 Mitigation. Mitigation is provided by administratively limiting the introduction of pressurized plutonium storage containers to Type

A or B criteria as defined in Figure 9-37. This control limits the quantity of hydrogen and other flammable gases potentially released into Glovebox HC-21A.

9.2.10.1.3 Probability. The burning of flammable gas released from Type A and B Cans is an anticipated event, defined in Table 9-49 as having an annual probability in the range of 1 to 1 x 10^{-2} per year. This probability is based on the planned introduction and opening of Type A and B Cans in Glovebox HC-21A and the low ignition energy of hydrogen.

The burning of flammable gas released from a Type D Can is an unlikely event, defined in Table 9-49 as having an annual probability of occurrence in the range of 1 x 10^{-2} to 1 x 10^{-4} per year. This probability is based on the relatively small number of Type D Cans at PFP and the fact that Type D Cans are readily discernable from Type A or B Cans based on physical appearance.

9.2.10.1.4 Consequence Analysis. The analyzed scenario does not result in a breach of the glovebox. The quantity of plutonium potentially suspended inside Glovebox HC-21A by burning hydrogen is judged to be small relative to that suspended by normal operations (e.g., pouring oxide through a sieve, use of mortar and pestle).

9.2.10.1.5 Conclusions. The release and ignition of hydrogen from Type D plutonium storage containers is an unlikely event. The small pressure increase, if any, due to the burning hydrogen would not be sufficient to breach the glovebox. Accordingly, from a pressurization event perspective, the hydrogen does not pose a risk to workers, the public, or the environment. The burning hydrogen does represent an ignition source for a glovebox fire that, if not prevented or mitigated, could potentially breach the glovebox. The probability and consequences of a fire in thermal stabilization gloveboxes is presented in Section 9.2.10.4 below.

9.2.10.2 Deflagration in Glovebox HC-21C or HA-21I. Thermal stabilization of plutonium-bearing compounds will take place within the two muffle furnaces in Glovebox HC-21C or the three muffle furnaces in Glovebox HA-21I. Thermal stabilization is accomplished by heating the plutonium bearing materials to 1000 °C driving off components that affect long-term storage.

The analysis discussion for a deflagration in either Glovebox HC-21C or Glovebox HA-21I is presented in two sections. Section 9.2.10.2.1 will address deflagrations resulting from decomposition of polymeric compounds. Section 9.2.10.2.2 will address deflagrations resulting from decomposition of tributylphosphate (TBP) in Plutonium Reclamation Facility (PRF) sludge.

Glovebox HC-21C contains two furnaces. Each furnace is equipped with a temperature controller and two interior air space gas flows; one from the CO_2 system and one from the 26-in.-Hg vacuum system. Glovebox HA-21I contains three furnaces. The temperatures in the three HA-21I furnaces are fedback through a programmable logic controller (PLC), and the only gas flow through these furnaces is from a dedicated 5-in. mercury process vacuum system. Therefore the three furnaces in Glovebox HA-21I can not be used to process PRF sludges or any feed containing organic materials. (Section 6.4.1.4.2) The air flow from the 26-in.-Hg vacuum system or the dedicated 5-in. mercury process vaccuum system is used for processing feed types other than PRF sludge only

during the cool-down portion of the cycle (Section 6.4.1.5.1). For processing PRF sludge, which can only be performed in Glovebox HC-21C furnaces, both the CO_2 purge flow and air flow from the 26-in.-Hg vacuum system are needed. The air flow rate is 1.0 ft^3/min. The flow rate is calculated to be sufficient for complete combustion of the contaminants and removal of the off-gas (water and CO_2). The temperature controller or PLC limits the heat up rate of the furnace to 5 °C/min from room temperature to 500 °C, 3.3 °C/min from 500 °C to 700 °C, 2 °C/min from 700 °C to 900 °C and 1.25 °C/min from 900 °C to 1000 °C. The "full-on" ramp rate is about 7 °C/min. The "full-on" ramp rate can result in coil failure, hence the need for a more controlled ramp rate. The time for heat-up to 1000 °C is 5.7 hours. The oxide remains at 1000 °C for two hours and then the power to the furnace is cut off. It takes about five hours to cool to 200 °C when the furnace boats can be removed.

The plutonium-bearing material covered by this analysis is plutonium oxide (both "clean" and non-product quality) and other non-product quality feed materials. Non-product quality feed materials include non-product quality (impure) plutonium oxides, mixed uranium and plutonium oxides (MOX), floor sweepings, plutonium oxalate, and PRF sludges.

Flammable gases are generated by the thermal decomposition of organic contaminants potentially present in non-product feed materials (impure oxide, MOX, floor sweeps, and oxalates) or by the thermal decomposition of TBP and its degradation products known to be present in PRF sludges. Organic contaminants of concern potentially present in the feed materials include polymeric compounds (e.g., plastics), hydraulic oil, and sealants (e.g., elastomers). These materials behave similarly when heated to high temperatures.

9.2.10.2.1 Deflagration in Glovebox HC-21C or Glovebox HA-21I Due to Decomposition of Polymeric Compounds. The deflagration analysis related to polymeric compounds (primarily plastics) is presented in the following sequence. First it is shown that it is possible for plastics to be in the oxide as a contaminant. Following this, the types of plastics present and their thermal degradation products are discussed. The degradation products are flammable gases. Then, sensitivity calculations are performed to determine if a flammable concentration could be formed from the degradation products and furnace air. The sensitivity analysis included the quantity of plastic and plastic type. Large and small quantities of plastic are considered since large quantities probably yield flammable gas concentrations above the upper flammability limit while small quantities may result in quantities of flammable gas with excessive diluent. This is generally what was found.

There are cases, however, in which a deflagration could occur after the furnace gases are cooled and if a spark source is present. The probability of this condition is addressed next, followed by the consequence. The probability range is 10^{-3} to 10^{-5} depending on the type of plastic in the oxide. Plastic type is important because some plastics degrade below the auto-ignition temperature of the flammable gases given off. In this case, normal furnace operation can provide the spark source. When the deflagration occurs, oxide is resuspended into the furnace and blown out into the glove. The glove bursts and aerosol is blown into the room. The building HEPA filters are not affected by the deflagration so the release leaves the

building filtered. As a result, the onsite and offsite doses are quite small ($<10^{-3}$ rem).

The polymeric contaminants are bounded by one of the following four materials

- polyethylene (PE) - $(CH_2)_n$

  - Where the subscript "n" indicates that the molecule is made up of repeating groups.

- polystyrene (PS) - $(RCH\text{-}CH_2)_n$

  - Where "R" denotes benzene ring

- polycarbonate (PC) - $(HO\text{-}R\text{-}C_3H_3\text{-}R\text{-}CO\text{-}Cl)_n$

- polyvinyl chloride (PVC) - $(CH_2\text{-}CHCl)_n$

From these four plastic materials are made bags, bottles, bottle caps, sample containers, wire insulation, packaging, molded items, tool handles and brush bristles (Hilado 1982). The types of polymeric compounds most likely present in non-product quality feed material are plastics used for plutonium packaging (e.g., plastic bags), or small pieces of plastic from broken equipment (e.g., tool handles, polyjars). There are a number of hydraulic oil formulations (e.g., phosphate esters, siloxane). Over the years, various formulations have likely been used at PFP. The principal sealant used at PFP is a vulcanizing silicone elastomer (RTV). Table 9-62 summarizes thermal decomposition information for hydraulic oil and RTV. The flammable constituents (e.g., methyl and ethyl groups) of these compounds are such that they can be adequately represented by an analysis of polymeric compounds. Some glovebox windows are made from polymethyl methacrylate. This polymer is similar to polyethylene except that there are side groups of acetic acid. However, the decomposition products or mechanism is not significantly different from PE. The glovebox gloves are made of Hypalon which is a chlorosulfonated polyethylene. This material is different than the four bounding polymers in that heating can give off SO_2 and CS_2 (Polymer Science 1986). Bits or pieces of glove are not expected to be in the glovebox or added to the oxide. Unattached gloves are not left in gloveboxes as are plastic bottles and tools. The failure mode of gloves is cuts or holes. Cuts or pin holes in gloves do not leave pieces within the glovebox that could be placed into oxide containers. Therefore hypalon can be left out of the bounding polymers.

Heating of oxide containing these polymers can result in products that are flammable if insufficient oxygen is present during heating. The phenomena in which polymers degrade into component pieces in inert atmospheres is called pyrolysis. The term combustion refers to the phenomena where these polymers are heated in air forming CO_2 and H_2O. Testing of the thermal degradation of these polymers in air and in argon is documented in Barney (1998). Barney shows that with air flow providing oxygen for combustion, the off-gas is primarily carbon dioxide and water. If the atmosphere is argon, the off-gas products are various hydrocarbons (Barney 1998 and Landrock 1983). However,

PVC and polystyrene (as resin beads) produced low molecular weight hydrocarbon gases during combustion in air.

The thermal degradation products of the 4 plastics are described in Landrock (1983) and are summarized below. Landrock uses the term thermal degradation which is the common term for pyrolysis.

Polyethylene - Polyethylene is a member of the category "polyolefins." Polyolefins burn readily in air and produce virtually no soot. The polyolefins pyrolyze under heating into volatile fragments by random chain scission. In a limited oxygen environment, the products of pyrolysis are carbon monoxide (CO), carbon dioxide (CO_2), ethylene, butene, hexene, propane and pentane.

Polystyrene - Polystyrene burns readily in air with the production of dense smoke. Polystyrene volatilizes rapidly at 300 °C and is completely volatilized at 450 °C. In a limited oxygen environment, the products of pyrolysis are predominantly styrene with some small amounts of toluene and benzene.

Polyvinyl chloride - Polyvinyl chloride (PVC) itself does not burn under most conditions. When exposed to heat, PVC releases HCl at relatively low temperatures. The release is highly endothermic. As a result thermal degradation slows as heat is absorbed in the liberation of HCl. However, PVC is usually compounded with large amounts of plasticizers many of which are flammable. Depending on the plasticizer used, the thermal decomposition products may include the same components as that from polyethylene in addition to benzene.

Polycarbonates - In a limited oxygen environment, the products of pyrolysis of polycarbonate include large amounts of methane and lesser amounts of benzene and toluene.

The flammable pyrolysis products of the four bounding polymers are:

benzene	toluene
carbon monoxide	alkenes (e.,g., butene, hexene, ethylene)
styrene	alkanes (e.g., methane, propane)

Barney (1998) determined the pyrolysis products to be toluene, ethylene, tetramethylammonium (he used resin beads as his PS where Landrock discussed pure PS) and phenol (chemical form is R--OH). These are similar to the list taken from Landrock.

In some cases, Barney (1998) shows that hydrogen is also a constituent of the off-gas. Hydrogen can be a pyrolysis product or as one of the products of a catalyzed reaction of water vapor with hydrocarbons over a metal oxide bed. Examples of this are from Sneed (1957) who describes a reaction of alkane (C_nH_{2n+2}) over a bed containing 25% nickel, 25% zirconium sulfate and 50% magnesium oxide which produced hydrogen and a catalytic conversion of methane (CH_4) to hydrogen over a bed of barium oxide or calcium oxide at a similar temperature.

Table 9-59 summarizes the information on ignition and decomposition from Landrock (and Barney) and the Chemical Engineers Handbook.

The operators will sieve the oxide and visually inspect the oxide in the furnace boat for contaminants. It is assumed that up to 10 g of plastic can escape the sieving and visual inspection process. To show the likelihood of that occurring, consider the following. The density of most plastics is about 1 g/cm^3. Therefore, 10 g represents a total volume of 10 cm^3. To get an idea of how much plastic this is, consider the following. A 10 g piece of a 12 mil plastic bag would have an area of 328 cm^2 (e.g., a square 7 inches on a side). A 10 g cube would be 0.85 inches on a side. However, a "4-mesh" screen has a square opening 0.185 inches on a side. A cube of this dimension weighs 0.1 g. One hundred of these very small cubes equates to 10 g. It is this material that escapes the sieving and inspection process. Failure to sieve and inspect could result in quantities greater than 10 g.

9.2.10.2.1.1 Scenario. From the discussions above, a deflagration could occur if oxide containing plastics is heated in the furnace having insufficient or no air flow to support full combustion. It is assumed that both furnaces are operational. A 2500 g (Pu weight) charge is sieved and the sieved material is placed in each furnace boat. The material in the boat is visually inspected for contaminants. One of the charges is also assumed to contain 10 g of plastics in the form of very small pieces. Both boats are placed in the furnaces and heated normally. It is assumed that there is a failure such that there is no purge air flow through either furnace. Note that the sensitivity of the analysis to both smaller (i.e., 1 g) and larger (i.e., 50 g) quantities of plastic is subsequently addressed.

Whether or not a deflagration can occur or not is dependent on many factors. The pyrolysis products are flammable gases. For flammable gases to deflagrate, an oxidizer must be present (e.g., oxygen in the air) as well as an ignition source. Likely ignition sources are the heat from the furnace coils (if the coil temperature exceeds the auto-ignition temperature) or short circuits in the electrical power circuit to the coils. If the flammable gases are not pre-mixed with air initially but mix with air as a result of the scenario, and if the ignition source is present at the beginning of air entrainment, a flash fire, not a deflagration will occur (AIChE 1994). If the air is entrained first then ignited, a deflagration will occur (AIChE 1994).

The combustion and pyrolysis of various types and quantities of plastic materials, during the heat-up and cool-down cycles of the furnace, are modelled in the following paragraphs. This allows identification of scenarios that can result in flammable gas concentrations in the furnace.

The feed material containing plastic (or contaminant that reacts like plastic on heating) is placed into a furnace boat. The furnace boat is placed into the furnace and heated. It is assumed that there is no offgas air flow through the furnace. As the temperature increases, the oxygen in the furnace atmosphere reacts with the plastic. Combustion is assumed to occur. Combustion is defined as the following:

$$C_nH_m + (n + m/4)\ O_2 + 3.8\ (n + m/4)\ N_2 \rightarrow nCO_2 + (m/2)H_2O + 3.8\ (n + m/4)\ N_2$$

where "m" ranges from "n" to "2n" for the plastics under consideration.

It is seen that there are more moles of products than gaseous reactants. Because the furnace is so small, there is only enough oxygen to combust a little of the plastic. Therefore combustion results in an oxygen deficient atmosphere and a pressurized furnace. The increased pressure results in flow of these gases out of the furnace until atmospheric pressure is reached.

The furnace interior dimensions are 5 inches by 5.5 inches by 13 inches for a volume of 0.2 ft^3 or 6 L. Initially there is 0.24 moles of air in the furnace (assuming 1 atmosphere and 300 °K). During combustion the 0.05 moles of O_2 in the air will react with 0.017 moles of plastic as ethylene. The 0.017 moles of plastic is 0.5 g. This is the quantity that is burnt (combustion) early. This initial combustion is ignored in the following calculations.

As the furnace temperature increases there is gas flow out of the furnace due to the expansion of the gases. At the decomposition temperature, the remaining plastic under goes pyrolysis and is transformed into an alkene, or benzene, etc., depending on the plastic. Since the most likely plastic found is polyethylene, ethylene (C_2H_4) is chosen to be the representative off-gas.

Ten grams of ethylene case

Ten grams of plastic equates to 0.36 moles of ethylene. The pyrolysis is complete at about 450 °C [Barney (1988) and Landrock (1983)]. At this temperature and atmospheric pressure, there are 0.1 moles of gas in the furnace. Prior to pyrolysis, the gas is mostly N_2 with a small quantity of CO_2 and H_2O from combustion. The combustion products will be ignored.

The generation of ethylene from pyrolysis, coupled with lack of air flow creates a positive pressure in the furnace which results in the flow of ethylene and N_2 out of the furnace. This occurs throughout the time of pyrolysis. If the furnace temperature exceeds the auto ignition temperature of ethylene, the gas could burn when it reaches the air exterior to the furnace (if it hasn't cooled to below the auto ignition temperature).

At 1000 °C, there are 0.057 moles of gas in the furnace in a ratio of 0.36 moles of ethylene to 0.1 moles of N_2. As a result there are 0.045 moles of ethylene and 0.012 moles of N_2.

As the furnace cools, air enters the furnace due to the contraction of the gas inside. At 485 °C, the auto ignition temperature of ethylene, the furnace can hold 0.096 moles of gas. It already has 0.045 moles of ethylene and 0.012 moles of N_2. To this will be added 0.039 moles of air of which 0.008 moles is O_2. The furnace now contains:

0.045 moles ethylene
0.039 moles air
0.012 moles N_2

Ethylene makes up about 47% of the air space by volume. The flammability limits for ethylene are 2.7% to 36% at room temperature. The lower flammability limit decreases to about 1.5% at 485 °C (Zabetakis 1965). The upper flammability limit increases but a value is not provided. It is known however that the gas will burn in air at the auto ignition temperature.

As air enters the furnace as it cools. At 1000 °C the air entering reacts with the flammable gas. The upper limits of flammability for ethylene is 36% at room temperature (Zebatikis 1965). At 1000 °C it is much greater. The air is drawn in slowly so the burn occurs slowly. A deflagration will not occur as the flammable gas is not premixed with air at this point (AIChE 1994). The addition of 0.008 moles of O_2 above the auto-ignition temperature will result in a reaction with the ethylene present. The 0.008 moles of O_2 will react with 0.003 moles of C_2H_4 to create 0.006 moles of CO_2 and 0.006 moles of H_2O.

Therefore at conditions just below the auto-ignition temperature (i.e., after all the burning is completed) there is:

(0.045 - 0.003) = 0.042 moles ethylene
(0.012 + 0.039 - 0.008) = 0.043 moles N_2
0.006 moles CO_2
0.006 moles H_2O

The moles of CO_2 and H_2O are added to the moles N_2 to simplify the math. This addition yields 0.055 moles N_2.

At 100 °C the furnace can hold 0.196 moles of air. Therefore 0.1 moles of air was drawn in resulting in a mixture of:

0.042 moles ethylene
0.055 moles N_2
0.1 mole air

<u>One gram of ethylene case</u>

If instead of 10 g there were 1.0 g of plastic (0.036 moles ethylene), there would be 0.015 moles of ethylene and 0.042 moles N_2 at 1000 °C. After cooling to 485 °C and reacting with the 0.008 moles O_2 coming in, there would be:

0.012 moles ethylene
0.084 moles N_2

After cooling to 100 °C, there is:

0.012 moles ethylene
0.084 moles N_2
0.1 moles air

Ten grams of ethylene case with partial decomposition to hydrogen

One of the decomposition products is hydrogen. Assume that there is 10 g plastic present. Since H_2 comprises 15% of the ethylene molecule assume the pyrolysis gases are 15% H_2 and 85% C_2H_4 (mole percent) (Barney 1998 shows 14% H_2). Now ten grams of plastic pyrolyzes to 0.353 moles ethylene and 0.062 moles H_2. For a total of 0.415 moles of gas. This is in the furnace with 0.1 moles N_2 at 450 °C.

At 1000 °C there is 0.057 moles of gas total in the furnace. The total is comprised of:

0.007 moles H_2
0.039 moles ethylene
0.011 moles N_2

After cooling to 485 °C and reacting the H_2 with the oxygen first, as H_2 is more reactive then C_2H_4, there is:

0.038 moles ethylene
0.058 moles N_2 (adding the 0.007 H_2O from the reaction of H_2 with O_2 and the products of the reaction with ethylene)

After cooling to 100 °C, there is:

0.038 moles ethylene
0.058 moles N_2
0.1 moles air

Ten grams of ethylene case with pyrolysis to benzene

If the plastic pyrolyzed to benzene, 10 g would equal 0.128 moles. At 1000 °C there would be 0.033 moles benzene and 0.026 moles of N_2. The auto-ignition temperature of benzene is 592 °C. The following calculation is done at 485 °C to provide a comparison to the other calculations. After cooling to 485 °C and burning some of the benzene in air, there would be:

0.032 moles of benzene
0.066 moles N_2 (adding 0.01 moles of the reaction products of benzene and air)

At 100 °C there is:

0.032 moles of benzene
0.066 moles of N_2
0.1 moles of air

One gram of ethylene case with pyrolysis to benzene

If there were 1 g of plastic and the pyrolysis product were benzene, 1.0 g would equal 0.032 moles. At 1000 °C there would be 0.007 moles of benzene and 0.050 moles of N_2. After cooling to 485 °C and reacting with the O_2, there would be:

0.006 moles of benzene
0.09 moles N_2 (including 0.01 moles of reaction products)

After cooling to 100 °C, there is:

0.006 moles of benzene
0.09 moles of N_2
0.1 moles of air

Fifty grams of ethylene case

Now assume 50 g of plastic all as ethylene. This assumption is made to determine the sensitivity of the results to the assumption of 10 g of plastic. At 450 °C there is 0.1 moles N_2 and 1.79 moles ethylene. At 1000 °C there is 0.054 moles ethylene and 0.003 moles N_2.

After cooling to 485 °C and reacting some of the ethylene with air, we have:

0.051 moles ethylene
0.044 moles N_2

After cooling to 100 °C, there is:

0.051 moles ethylene
0.044 moles N_2
0.1 moles air

The summary of the above is shown in Table 9-60.

The flammability limits for ethylene in air is 2.7 to 35 volume %. Zebatakis (1965) shows that with N_2 as a diluent, the lower flammability does not change appreciably with the addition of N_2. The upper flammability limit decreases from 37% with 0% N_2, to 20% with 20% N_2, to 10% with 35% N_2 to "non-

flammable" at about 50% N_2. The flammability limit for benzene is 1% to 9% in air.

Table 9-60 shows that the 10 g ethylene (15% H_2, 85% C_2H_4) and the 1 g cases are within the flammability limits at 100 °C, as is the 1 g benzene case. The other cases have too much N_2 as a diluent.

At 100 °C ethylene is within the flammability limits even with the N_2 diluent. Should a spark occur at this time, a deflagration in the furnace would result. Should a reheating cycle inadvertently occur, the gas could deflagrate at the auto ignition point. A deflagration during reheating will, however, only involve only a fraction of the ethylene contained in the furnace at 100 °C because the air expands as it is reheated, forcing some of the ethylene out. The air temperature when the furnace coils reach 485 °C is unknown.

Potential Gas Burn Outside of the Furnace

As pyrolysis occurs, some of the flammable gas is forced out of the furnace. The ratio of the moles of gas in the furnace at 1000 °C divided by the moles of gas at 450 °C is 0.57. This means that 43% of the flammable gas was forced out of the furnace or 4.3 g from the 10 g case. Since there is a gap all the way around the door, the gas will escape in all directions. The gas is initially hot and could burn as a flame out of the doors when the gas meets the air. Section 9.2.10.3 shows the results of a fire ball containing more than the 4.3 g of gas released through the door. Neither the panel nor the gloves are adversely affected.

If the gas does not burn, it mixes with the air in the glovebox. The glovebox ventilation flow is 30 ft^3/min. The inlet flow comes from the HC-2 conveyor, flows across the furnaces (which are quite close to the conveyor) into the open portion of the glovebox and out the top. The volume of the area in front of the furnaces is 2 ft wide, 6 ft long and 1.5 ft tall. The volume is 18 ft^3.

The gas will mix with the glovebox ventilation flow in front of the furnaces. If perfect mixing of the blown out furnace gas with the air in front of the furnace occurs, the mass of gas in this volume with time is found by the following:

$$\frac{dM}{dt} = m_{in} - \frac{M\ (30\ ft^3/min)}{18\ ft^3}$$

where: M = mass of furnace gas, g
m_{in} = flow rate of furnace gas into glovebox, g/min.

Solving for "M" when at time equal to zero, "M"equals zero yields:

$$M = \frac{m_{in}}{30/18} \quad [1\text{-exp-}(30/18)t]$$

Assume the gas comes out in 1 min, then m_{in} equals 4.3 g/min.

Solving for "M" for various values of "t" yields the following:

T, min	M
0	0
1	2.1 g of the 4.3 g total

The rest of the gas is swept into the remainder of the glovebox.

If the gas comes out over 5 min, then:

T, min	M
0	0
5	0.52 g of the 4.3 g total

The calculation shows that even with ventilation flow, most of the gas is mixed with the rest of the glovebox air.

The glovebox ventilation system inlet being very close to the furnaces and having a high flow rate removes and mixes the gas efficiently. Even if the glovebox ventilation system should fail at the point where gas is coming out, the gas flow rate and its temperature and the fact that gas is released in four directions (up, down, right and left) is judged to mix it well. In the case of no purge air or glovebox vent flow, there is likely no electricity to the building and therefore no ignition source even if the gas does not mix. Once the gas is in the glovebox (volume of 105 ft^3), the equation for removal is:

$$\frac{dM}{dt} = m_{in} - \frac{M\ (30\ ft^3/min)}{105\ ft^3}$$

Solving yields:

$$M = M_o \exp\ (-30t/105)$$

The results of solving this equation are as follows:

m/m_o	T, min
1.0	0

So the glovebox is effectively purged in about 7 to 10 minutes.

In summary there are two scenarios to be considered. All involve a loss of purge air and the presence of plastics. The two scenario's are:

- Ignition of flammable gas in the furnace after cooling,
- Flash fire if the door is opened after the furnace has reached the auto-ignition temperature.

The flash fire case is analyzed in Section 9.2.10.3 and is shown to produce minimal damage.

9.2.10.2.1.2 Mitigation. Adequate purge air flow ensures the plastic contaminant is combusted in a controlled manner during ramp up in the furnace. The purge air flow is assured by procedural controls. Purge air flow is set by the operator during the phases of furnace operation. Proper purge air flow is initiated by the operator prior to furnace heating. By procedure the operator first checks to assure that the 26-in.-Hg vacuum system is operational by reading the vacuum off a gauge. From this reading, the operator consults a chart to determine the purge air flow rotameter reading necessary to produce 1 to 1.5 standard cubic feet per minute (scfm). The operator adjusts a valve to obtain that reading. The operator logs both the rotameter reading and the purge air line differential pressure reading at 1 to 1.5 scfm. The rotameter is then valved out (i.e., bypassed). By procedure, the differential pressure gauge is read every 15-20 minutes to check that the purge air flow is at the set value.

The oxide is sieved prior to placement in the furnace boat in Glovebox HC-21A. The plastic is likely in the form of pieces of noticeable size as it was added to the pure oxide prior to packaging. Sieving is very effective for pieces of this size.

Most of the oxide to be processed will likely not contain plastics. Adding contaminants to containers of clean oxide is not performed per procedure and is not a routine occurrence. The plastics are much more likely to be found in floor sweepings which are typically kept in a separate container.

By procedure, the operator pulls the gloves out of the glovebox and secures them with a bungie cord before operating the furnaces. The operator also visually checks the glovebox interior to verify the no combustible material is in contact with the heated surfaces. The operator checks to

assure that the temperature recorder is running and periodically observes the furnace temperature. Only when the furnace temperature is below 200 °C is the operator instructed to open the furnace door. The furnace door is kept closed when the furnace is hot to preclude flash fires in the furnace.

The glovebox ventilation system sweeps away those gases that came out of the furnace door, thus precluding a deflagration outside the furnace.

9.2.10.2.1.3 Probability. The probability of the deflagration in the furnace given PE or PC as the plastic (Scenario 1) is in the middle of the Extremely Unlikely category (or about 10^{-5}) for processing "clean" oxides. This is because it requires three independent failures. The first is a failure such that purge air flow is not occurring at any time during the heating and cooling cycle. This has a probability of 10^{-2}, based on requiring an operator failing to follow procedure for setting up the most important support system in the operation, the purge air. Per Swain and Guttmann (1980), Table 20-20 and 20-27, the human error probability (HEP) for the failure to follow an established procedure is 10^{-2} and the failure to properly use written procedures under normal conditions is 10^{-2}. Failure of purge air flow could also be due to a system failure. The system failure probability is no greater than the HEP and likely less.

The second failure is having plastics in the oxide when there is not supposed to be any present. The likelihood of this is about 10^{-1} as it requires deliberately putting plastic into a "non-glovebox sweeps" container. The plastic considered here is not part of the process but debris. Debris is placed in different containers than is product.

The third failure is an ignition source when the furnace door is opened or inadvertent reheat cycle prior to opening the door. The likelihood of either of these is about 10^{-2}. The furnace door interlock is an electrical switch that very likely sparks each time it is actuated. However the spark energy is small and located away from the location of the furnace gas. The furnace gas is hydrocarbons not hydrogen. Ignition of hydrocarbons requires more energy than that of hydrogen. In addition, the hydrocarbon concentration is far from stoichiometric and nitrogen is present as the diluent. As a result, ignition requires a large spark which is judged to occur only under off-normal conditions. An inadvertent reheat has a low probability as this requires either two operator failures to pay attention to detail (failure to remove the boat after cooling and failure to insert a boat prior to starting the furnace) or a system failure.

The probability of the deflagration in the furnace given PE or PC as the plastic is 10^{-4} for non-product quality feed material. This is because it requires two independent failures (the first and third failures described above for the "clean" oxides).

The probability of the deflagration if PVC or PS is the plastic is 10^{-2}. This is because these plastics decompose at a low temperature. At this low temperature oxygen may still be present when the flammable gases appear. They are ignited when the furnace coils cycle on. Therefore, a separate failure is not required for ignition. The probabilities discussed above are per boat processed. Depending on the number of boats processed per year, the annual

probability of a deflagration could easily be in the anticipated category for either type of deflagration considered.

As an example; assume PVC decomposes into ethylene (C_2H_4) at 260 °C. At 260 °C, the number of moles of air in the furnace is 0.137. Ten grams of plastic (as C_2H_4) equates to 0.36 moles. Adding this to the air and normalizing the mole quantities back to 0.137 (equivalent to depressurizing the mixed gases to attain atmospheric pressure) yields:

C_2H_4 - 0.10 moles
air - 0.038 moles

Of this mix, C_2H_4 comprises 72% which is above the upper flammability limit. If 2 g of plastic (0.07 moles) were involved, not 10 g, the normalized quantity would be:

C_2H_4 - 0.046 moles
air - 0.091 moles

Of this mix, C_2H_4 comprises 34% which is just within the flammability limits at room temperature. The flammability limits expand as the temperature increases.

In this case, the furnace cycling on causing the furnace coils to exceed the auto-ignition temperature would result in a deflagration.

The above conditions require that the oxygen not react with the plastic prior to the flammable gas evolving and that the furnace coils remain below the auto-ignition temperature for a period of time that is long as compared to the flammable gas evolution time. Otherwise the furnace coils will burn the gas as it evolves.

In addition, almost any air flow at all will purge the furnace. Using the purge equations set up for glovebox flow above, one finds:

$$M = M_o \exp [-(cfm/V)t]$$

where: cfm = flow rate through the furnace, ft^3/min
V = furnace volume, ft^3
V = 0.2 ft^3
t = time, min.

With "cfm" equal to 1.0 ft^3/min, the furnace is purged (m/m_0 of 0.05) in 0.6 min. With "cfm" equal to 0.2 ft^3/min, the furnace is purged in 3 min. A deflagration under these conditions (i.e., no separate spark source needed) is less likely with PE and PC as the decomposition does not occur until the gas is above or at the auto-ignition temperature. This allows more time and for favorable conditions for oxygen reaction with the plastic prior to

decomposition. In addition, with the temperatures above the auto-ignition temperature and oxygen present, the gas will burn off as it is generated.

The probability of a flammable gas deflagration occurring outside the furnace due to pyrolysis gases being expelled from the furnace is much less likely than a deflagration in the furnace. This is due to the fact that the gases flow out of the furnace over time. This allows ample time for mixing and dilution afforded by the glovebox ventilation flow. There is also a lack of an ignition source in front of the furnace.

The probability of the flash fire (Scenario 2) is 10^{-4} as it requires a failure of purge air flow throughout the heating and cooling cycle, presence of the plastics and the operator opening the furnace door when the temperature is above the auto-ignition temperature. The probability discussed above is per boat processed. Depending on the number of boats processed per year, the annual probability of a deflagration could be in the anticipated category for a flash fire.

9.2.10.2.1.4 Consequences. A deflagration could occur if a flammable concentration of gas exists within the furnace in the presence of an ignition source.

It is believed that the most likely plastic is PE. The discussion to follow assumes the plastic is PE. The consequences of a deflagration with PVC are quite similar to that from PE.

A review of the gas concentration versus furnace temperature data shows that a flammable mixture could exist in the furnace after cooling is complete if the plastic contaminant pyrolyses in the furnace due to the failure of purge air flow. This mixture can be ignited if an ignition source should appear after cooling is completed. Should this occur, a deflagration would result as the gas is pre-mixed. To cause a deflagration, following are required:

- Presence of plastics in the oxide feed material,
- No purge air flow for an entire heating and cooling cycle,
- No opening of the furnace door after cooling,
- Ignition of the gas.

Ignition could be as a result of one of three possible failures. A potential ignition source is the limit switch on the door. A spark, as the door is being opened, could ignite the gas inside. A less likely ignition source is mechanical sparks when the boat is dragged across the furnace floor or static charge set up by the operator using the gloves to move the boat out of the furnace. The spark from the limit switch could ignite gas within the furnace or ignite the heavier-than-air gases (the benzene pyrolysis case) as they flow out of the glovebox as the door is opened. The static spark or mechanical spark case would ignite the gas left in the furnace after the door was opened. The gas within the furnace in this case will be to some extent diluted by the communication with air outside the furnace as well as flowing out of the furnace and being replaced by outside air.

Another unlikely source is inadvertent or spontaneous restart of a furnace heating cycle. The restart will cause the coils to go full on which will increase their temperature beyond the auto-ignition temperature of the gas in the furnace.

The 10 g, 15% hydrogen - 85% ethylene case is analyzed as the potential quantity of energy released is a little larger than that of the 10 g ethylene case. This is because the concentration is less near the upper flammability limit resulting in more gas burning. The 10 g benzene case is above the upper flammability limit.

The chemical formula for the reaction is as follows.

$$0.038\ C_2H_4 + 0.137\ N_2 + 0.021\ O_2 \rightarrow 0.014\ H_2O + 0.014\ CO_2 + 0.031\ C_2H_4 + 0.137\ N_2$$

The heat of formation for the components are:

H_2	0.0
C_2H_4	-20.2 k cal/mole
N_2	0.0
O_2	0.0
$H_2O(v)$	-57.8 k cal/mole
CO_2	-94.0 k cal/mole

The heat of reaction is 1.98 k cal. It is found by summing the product of the heats of formation of the products with the moles of each product and subtracting that from the product of the heats of formation of the reactants with the moles of each reactant.

The energy is used to heat the reactants. It is assumed that the average temperature over the reaction is 430 °C (703 °K). The specific heats are (from Perry 1951):

Product	Formula	cal/mole -C
H_2O	$6.93 + 8.3 \times 10^{-4} (T)$	7.5
CO_2	$10.34 + 2.7 \times 10^{-4} (T)$	10.5
N_2	$6.5 + 10^{-3} (T)$	7.2
H_2	4.97	4.97
C_2H_4	graph	26

The value of "cal/C" for the products is found by multiplying the number of moles of products by the specific heat. The value is 2.04 cal/C.

The temperature rise is found by:

Heat of reaction = (cal/C)(dT)

The temperature rise is found to be 970 °C. The final temperature is 1000 °C. So use of 430 °C, as the average, is reasonable.

The pressure inside the furnace is found by the ideal gas law:

$$PV = nRT$$

where: V = 6 L
N = 0.194 g-moles of gas in the furnace after reaction
R = 0.082 L-atm/g-mole-K
T = 970 °C + 273 + 30 °C
= 1273 K

Solving for "P" yields 3.4 atm, absolute or 2.4 atm, gauge (35 psig).

The gas comes out of the furnace as a turbulent free jet for a very short period of time. Turbulent free jets entrain air and expand which lessens the center line velocity. Daily (1966) shows that for a jet coming from a slot of width "2b" or a circular jet of diameter "d", the velocity does not decrease significantly until:

$$x/2b \quad \text{or} \quad x/d > 8 \text{ to } 10$$

where "x" is the downwind distance.

In our case the value of "d" or "2b" is the furnace width or 5 inches. The gloves are located about 24 inches away (i.e., "x" equals 24 inches). Since "x/d" is not greater than 8 to 10, the jet velocity remains the same. As a result, the gas from the furnace does not lose much energy due to entrainment before impacting the gloves and plastic panel.

The effect of the jet on the panel is assessed first. The energy of the reaction is 1.98 kcal or 1980 cal. The energy of explosion of TNT is 1050 cal/g (AIChE 1994). Therefore the reaction is equivalent to 1.9 g TNT or 0.004 lb. AIChE (1994) discusses using equivalency factors for vapor cloud explosions. The factors range from 1% to 30% depending on the study. In all of these studies, the exploding gas was largely unconfined. In this case the gas is fully confined or mostly confined within the furnace if the scenario is the "door opening" case or the "spontaneous reheat" case. An efficiency of 100% will be used because of the confinement.

The effect on the panel comes from Baker (1983), Figure 4-31. First, the TNT curves are used to determine impulse and pressure at the location of the panel. The TNT curves require a value for:

$$Z = R/W^{1/3}$$

where: Z = scaled distance, $ft/lb^{1/3}$
R = distance to panel, ft
= 2 ft
W = weight of TNT, lb
= 0.004

Solving for "Z" yields 12.6. From the TNT curves, the value of Z equal to 12.6 gives the following values of "P" and "$i_r/W^{1/3}$".

$$P_r = 17 \text{ psig}$$

$$i_r/W^{1/3} = 20 \text{ psi-ms/lb}^{1/3}$$

where: P_r = peak positive normal refected pressure

$i_r/W^{1/3}$ = scaled unit positive normal reflected impluse

Multiplying $i_r/W^{1/3}$ by the cube root of the TNT weight ($W^{1/3}$) yields a value for i_r of 0.003 psi-s.

Baker (1983), Figure 4-31, is a graphical solution to the question of whether a plate deforms. Deformation occurs in all cases if the value of the following parameter exceeds 1.0:

$$(E^{0.5}\ i_r)/(A\ \sigma_y\ \rho^{0.5}\ h)$$

where: E = modulus of Elasticity, psi
= 5×10^5 for poly-methyl methacrylate (Avallone 1978, pg 13-4)
i_r = 0.003 psi -s
A = a shape factor
= 0.25 for brittle clamped plates
σ_y = yield stress, psi
= 9000 psi (Avallone 1978)
ρ = density in lb/in^3 divided by acceleration due to gravity in in/sec^2.
= 8.9×10^{-5} based on a specific gravity of 0.95 for methyl methacrylate
h = thickness, in.
= 0.375

Solving yields 0.27. Since this value is less than 1.0, the panel will not deform. In Baker's terminology deform means deform to the point of yield. In addition, the furnaces are oriented at a 45 degree angle to the panels. This will lessen the effect of the pressure pulse.

Now consider the gloves. The gloves fail at an over pressure of 0.6 psi (Walden 1980). The gloves are a little more than twice the volume of the furnace. The furnace pressure was 35 psig. It is assumed that the entire furnace volume (at 35 psig and 1273 K) enters the glove and expands to fill

the volume of the glove. The instantaneous glove pressure will be about half that of the furnace or 17 psig. Rhude (1962) describes a test in which a 17.7 ft^3 glovebox was filled so that it contained a 10% by volume hydrogen - air mixture. The peak pressure in this burn is found by using the same methods as above. The volume of H_2 is 1.77 ft^3 which equates to 2 moles at 30 °C. The air volume is 15.9 ft^3 or 451 L. This equates to 18.1 moles of air. The balanced equation is as follows:

$$H_2 + 3.8O_2 + 14.3\ N_2 \rightarrow 2H_2O + 2.8\ O_2 + 14.3\ N_2.$$

The heat of this H_2-air reaction is 115,400 cal. The temperature increase is found using a specific heat for oxygen of 8.27 cal/mole -C. This value, like nitrogen, is relatively insensitive to temperature. The temperature increase is 748 °C. The final temperature is 778 °C or 1051 °K. The final pressure is 51 psia or 36 psig. Rhude showed that under these conditions one glove was blown off intact and the other three were completely shattered. In our case, the glove pressure is initially 17 psig with no back pressure (i.e., glovebox pressure of 0.0 psig allowing expansion back into the glovebox). In Rhude's case, the back pressure was also 36 psig. Since the pressure in this case is close to that of Rhude's and since the gloves in his test failed catastrophically, the gloves in this case are assumed to fail as well.

Plutonium Release - The amount of plutonium suspended is determined next. For the case of a deflagration in the furnace, DOE (1994), Section 4.4.2.3, is applicable. The volume of flammable gas in the furnace is 24% of the total (at 100 C), however, only about 1/4 of the gas is burnt. Therefore the situation is covered by Section 4.4.2.3 ("vapor < 25% of container volume"). Given these conditions, DOE (1994) suggests that the pressurized venting experiments bound the release. Given the peak pressure of 35 psig (0.24 MPa), DOE (1994), Table 4-12, gives a value for ARF*RF of 0.0064 for UO_2 powder vented from 0.34 MPa and 7 x 10^{-4} for powder vented at 0.17 MPa. A value of 2 x 10^{-3} is used (the logarithmic average).

Applying this to the furnace boat within the furnace yields a respirable quantity (RQ) of

$$RQ = 2 \times 10^{-3}(2500\ g) = 5\ g.$$

In the discussion on jets above, it was argued that there is little air entrainment in the jet coming from the furnace. As a result, the jet is approximated by the furnace length and cross-section. The furnace volume is 6 L or 0.006 m^3. The aerosol loading in this volume is 5/0.006 or 833g/m^3.

The jet is more accurately modelled as a fast moving puff. The puff will slow and expand as it travels due to air entrainment and expansion due to energy dissipation. The release will be into the room. The concentration in the puff will still be large as the puff leaves the glovebox but very likely not as large due to agglomeration and settling. The puff goes into the glove. The glove either breaks loose or shatters (Rhude 1962). If it shatters, the

powder is dispersed throughout the room. If the glove breaks loose, the puff travels to the wall across from the glovebox where it stops. Much of the material will rebound back into the room and disperse in a much more quiescent manner (ignoring capture of the powder within the glove). The net effect of both cases is judged to be aerosol loading within the entire room of 10 mg/m^3. This is a conservative value for the following reasons. The "glove breaks loose" case is considered first. The dimensions of the room volume in front of the HC-21C glovebox is 16 ft long, 20 ft wide and 16 ft tall. Considering the room layout of which glovebox HA-21I is a part, the nearby glovebox HA-23S would act as wall similar to the discussion above related to a glove breaking loose from HC-21C hitting the wall across from the glovebox. Thus the room volume in front of the HA-21I glovebox is considered to be similar to the volume related to the HC-21C glovebox and the remainder of the release calculations are representative of the releases for the HA-21I glovebox. The puff from the furnace expands only to about 2 ft in radius (Daily and Harleman 1966). The effect of the rebound off the wall will be felt in a much smaller volume than the entire room. Sutter (1982), Section 2.4.9 shows that the airborne aerosol concentration is less than 33 mg/m^3 a few minutes after an accident. The initial aerosol loading was much larger. The concentration decreased due to settling, impaction and agglomeration which enhances settling. It is judged that use of 10 mg/m^3 over the entire portion of the room in front of the glovebox envelopes 33 mg/m^3 over a smaller volume. Using 10 mg/m^3 over this volume results in a respirable quantity of 1.5 g. For the situation in which the powder disperses (glove "shatters"), the release is spread over the entire volume in front of the glovebox. The concentration is 34 mg/m^3 initially. Some of this release will settle out over time. While 5 g respirable are carried over, there are larger particles carried over as well. This will settle much faster. As they settle, they will intercept (i.e., agglomerate) smaller particles and remove them. It is judged that the 10 mg/m^3 value used in the "glove blown out" case is a reasonable value here as well. The consideration that two furnaces (in HC-21C) or three furnaces (in HA-21I) might have deflagrations within a short time period of one another due to common cause events, leads to tripling (for HA-21I) the respirable quantity to 4.5 g (1.5 g per furnace times 3 deflagrations separated by a short period of time = 4.5 g respirable release to the room).

The Criticality Specifications state that only 5 kg of Pu can be in the HC-21C glovebox at one time and that there must be 10 inches separation between containers. The Criticality Specifications state that only 8 kg of Pu can be in the HA-21I glovebox at one time. Since each boat is to contain 2500 g and Glovebox HA-21I could have three boats in its three furnaces, then this leaves 500 g of Pu that could be in Glovebox HA-21I either fixed on the furnace or in cracks or crevices.

Both furnaces in HC-21C and all three furnaces in HA-21I could be operating and in fact that may be the preferred mode of operation. It is unlikely that more than one furnace boat in either glovebox (HC-21C or HA-21I) will contain 10 g of plastic. It is possible that air flow could be lost to all furnaces at the same time but not likely that the door interlock for each will spark at the same time. It is therefore not likely that more than one furnace will deflagrate at the same time. If this occurs, the release out of the room of Pu from the furnace deflagrations will be by the conservative release of the 4.5 g Pu in Glovebox HA-21I that was in the furnaces. For the releases from the 500 g plutonium fixed on the furnace or located in cracks or

crevices, a value for ARF*RF of 4×10^{-5}/hr for aerodynamic entrainment and resuspension (DOE 1994) is used. Based on a conservative 1 hour release from the glovebox for pressurized venting, 0.02 grams plutonium (500 g x 4×10^{-5}/hr) would be released. Thus 4.52 g of respirable Pu (4.5 g from within the furnaces and 0.02 g from outside the furnaces but within the glovebox) will be assumed to be released to the room.

There is unburned ethylene as one of the products of the deflagration. It is assumed that the ethylene is heated as it is part of the hot deflagration gases. The jet models show that there is little air entrained during the time that the gas travels from the furnace to the gloves. This means that a second, but now unconfined, deflagration will not occur as the product ethylene does not mix with air. However, the ethylene could burn as a flash fire or a flame. Flash fires are discussed in Section 9.2.10.3. The consequences of this flash fire are insignificant as compared to the deflagration. The flash fire, while in the glovebox, could further heat the deflagration gas but this effect would be small as the time spent in the glovebox is quite short. The flash fire, if it occurs at all, will occur in the room where there will be little effect.

The dose consequence of a 4.52 g release into the room uses the methodology in Section 9.3. The release will be filtered by at least one stage of HEPA filtration. The quantity remaining after filtration is:

$$RQ = 4.5\ g\ (5 \times 10^{-4}) = 2.3 \times 10^{-3}\ g$$

The release will be elevated. The dose is determined by:

$$D(rem) = Q(g) \times X/Q'(s/m^3) \times R(m^3/s) \times C(rem/g)$$

Where: D = dose
Q = respirable quantity released, g
= 2.3×10^{-3}
X/Q' = atmospheric dispersion factor for elevated releases, s/m^3
= 1.62×10^{-5} onsite (Table 9-39)
= 5.7×10^{-6} offsite (Table 9-40)
R = breathing rate, m^3/s
= 3.3×10^{-4} (Table 9-48)
C = dose conversion factor, rem/g inhaled
= for EDE the value is 1.7×10^{8} per Table 9-46, ">10% ^{240}Pu, Class Y".
= for Bone Surface Dose the value is 2.7×10^{9} per table 9-47, ">10% ^{240}Pu, Class Y."

Solving for "Dose" yields:

Onsite = 2.1×10^{-3} rem EDE, 0.03 rem Bone Surface
Offsite = 7.4×10^{-4} rem EDE, 0.01 rem Bone Surface

9.2.10.2.1.5 Conclusions. These doses are well below the Guidelines for any frequency category. The reason for this is the ability of the HEPA filters to remain functional after the deflagration. Thus a deflagration in either Glovebox HC-21C or HA-21I due to thermal decomposition of polymeric contaminants would result in doses below the Guidelines for any frequency category.

9.2.10.2.2 Deflagration in Glovebox HC-21C or Glovebox HA-21I Due to TBP in PRF Sludges. PRF sludges are non-thermal stabilized plutonium-bearing material that appears wet. The wet appearance is due to the presence of nitric acid and possibly TBP. When thermally stabilized, sludges can give off oxides of nitrogen (NO_x), butene, and butanol. The butene evolution rates are documented in a report by Barney and Cooper (1994). Table 3 of that reference is reproduced in Table 9-63.

9.2.10.2.2.1 Scenario. PRF sludges are usually processed in an inert environment. This is because flammable gas is evolved from the TBP in the sludge. Flammable gas may also evolve from contaminants potentially present in the sludge (e.g., plastics), but the quantity of gas would be less than evolved from the TBP in the sludge. A 2,500 g (Pu weight) charge is placed in a furnace boat. The material in the boat is visually inspected for contaminants. The charge is assumed to contain 10 g of TBP.

TBP is an organic compound that was used in the solvent extraction process. Upon heating, TBP releases butene gas. When sludges are processed, the vacuum is set so that 2-3 ft^3/min of air and CO_2 are drawn through the furnace. The CO_2 purge flow is set at 0.5 ft^3/min. The controller on the furnace allows the temperature to rise slowly to 175 °C. The temperature is held there for two hours. Over that time the butene is completely released. The release rate is 0.0084 g of butene/min-g of TBP at 172 °C (Table 9-63). Given 10 g of TBP in the charge, the release rate is 0.084 g of butene/min at 172 °C (Table 9-64). The 10 g of TBP (0.038 moles) releases over time 0.113 moles of butene (6.3 g of C_4H_8). At 0.084 g/min, the butene will be completely released in 75 minutes. During this time the furnace atmosphere is purged with CO_2.

If the CO_2 purge fails, air will be drawn by the vacuum system. The volumetric flow rate of butene is 0.055 L/min. at 175 °C. The CO_2 flow is 0.5 ft^3/min (14.2 L/min). If the CO_2 fails, the vacuum will cause air to be drawn through the doors. It is assumed that the airflow is drawn in at a flow rate equal to the CO_2 purge rate, as the furnace doors are not air tight. Under these conditions, the butene concentration is 0.4%. This is well below the lower flammability limit. The vacuum is typically adjusted to draw in 2-3 ft^3/min. (with the CO_2 flow included). There is additional air flow not accounted for in the butene concentration calculation above and results in even lower concentrations.

If there were no vacuum or CO_2 flow, butene would accumulate in the furnace. The furnace volume is 6 L. The volumetric flow rate of butene at 175 °C is 0.055 L/min. The flammability limits of butene at room conditions are 2% to 13% (Kanury 1975).

If the vacuum fails, the furnace will be purged of air as more and more butene is evolved and butene-air mixtures are pushed out of the furnace.

Assume that the furnace temperature is held at 175 °C with no purge flow. The butene generation rate is 0.1 g/min by interpolation to 175 °C of Table 9-64 values. The furnace volume is 6 L. At 175 °C, the furnace contains 0.16 moles of air. The butene generation rate is 0.1 g/min or 0.0018 moles/min. The amount of butene in the furnace at any time is found by the following equation:

$$(dM/dt) = m_{in} - M(V_{in}/V) \quad (1)$$

where

M = mass of butene in the furnace, g
m_{in} = butene mass generation rate
m_{in} = 0.1 g/min per Table 9-64 with 10 g TBP
V_{in} = butene volumetric generation rate
V_{in} = 0.066 L/min per the ideal gas law with T=448 K
V = volume of furnace, L = 6 L
V_{in}/V = 0.011
$m_{in}/(V_{in}/V)$ = 9.09, g

Solving yields

$$M = [m_{in}/(V_{in}/V)][1 - \exp(-V_{in}\, t/V)] \quad (2)$$

The mass and volume of butene in the furnace at various times is found in Table 9-65. Table 9-65 shows that the concentration is above the lower flammability limit within a few minutes and above the upper flammability limit at about 20 minutes. The auto-ignition temperature for butene is 443 °C (Kanury 1975). The air temperature is 175 °C but the furnace coil temperature is much greater. The furnace coils ignite the gas. If the upper flammability expands to 20% by volume, the flammable condition exists for about 20 minutes at a temperature below the auto-ignition temperature. If the furnace coils cycle off and on during this period the gas may ignite. Since the butene flow rate is small, the gas will not have time to adequately mix with the furnace air. As a result, a small flash fire will occur. There will likely be a continuing small fire as the butene evolves and burns. It is assumed that air can be drawn in fast enough to support combustion. The combustion reaction is

$$C_4H_8 + 6\ O_2 \rightarrow 4\ CO_2 + 4\ H_2O \quad (3)$$

The butene flow rate is 0.0015 moles/min (using 0.055 L/min at 175 °C). The air flow needed is 0.043 moles/min. The heat of combustion for butene is 10.8 kcal/g (Perry 1963, page 3-143). The heat rate is 907 cal/min (0.06 kw). The heat of combustion will heat the air and pressurize the furnace. This will force burning gases out the door and could potentially blow the door open. The heat rate is small enough that no damage should occur.

The temperature controller could fail or not be set on the correct program. Under these conditions, the furnace temperature could ramp up at 300 °C/hr until a temperature of 500 °C is reached. Butene begins to evolve at 112 °C and evolves at an ever increasing rate up to 268 °C. Table 9-64 shows

the butene evolution rate and total evolved assuming 10 g TBP initially. Table 9-64 shows that the last portion of the butene comes out at 3.3 g/min. at 252 °C (525 K). Using the ideal gas law, the volumetric flow rate is 2.5 L/min. At a purge flow of 0.5 ft^3/min, (14 L/min) the butene concentration is 18% by volume. At 3 ft^3/min (84.9 L/min) the concentration is 3%. So the mixture is within the flammability range even with purge flow and CO_2 for a short time when the temperature is below the auto-ignition temperature. So even under conditions, in which there is both air and CO_2 flow, a flammable concentration of gas exists for about 5 minutes (time during which the furnace temperature is between 232 °C and 252 °C).

A volumetric flow rate of 2.5 L butene/min will result in a well mixed volume during the time the furnace coils are off. When the furnace coils come back on a deflagration may occur. The deflagration will pressurize the furnace and blow open the door. The rest of the butene given off will likely burn in and outside the furnace as the expanding furnace air will transport the butene out. The heat rate of the burn is found from the following equation:

$$\text{Heat Rate} = (3.3 \text{ g/min})(10.8 \text{ kcal/g}) = 35.6 \text{ kcal/min}$$

$$= 2.5 \text{ kw}$$

The heat will continue for 2 minutes when the butene is fully evolved.

Now consider the case with no air or CO_2 flow and the temperature controller does not stop the heating ramp rate at 175 °C (i.e, furnace heats at 300 °C/hr), assume the quantity of TBP as 10 g, and that the butene generation rate is 0.5 g/min. Using equation 2 above with a temperature of 222 °C (495 °K), an approximate average generation rate over the last 12 minutes, per Table 9-64, results in the following:

- M = 1.66 g
- M_{in} = 0.5 g/min
- V_{in} = 0.36 L/min with T = 495 °K
- V_{in}/V = 0.06
- $M_{in}/(V_{in}/V)$ = 8.33
- time to reach the lower flammability limit - very short
- time to reach a volume fraction of 0.2 the assumed upper flammability limit at 250 °C - 3.7 min.

The accident analysis will be performed assuming a stoichiometric quantity of butene in the furnace and assuming no purge or CO_2 flow. At the auto-ignition point of 443 °C, the stoichiometric quantity of butene is 0.22 g. The air-butene mixture expands as it is heated, removing some of each out the door. It is interesting to note that to be left with 0.22 g of butene in the furnace at 443 °C only requires 0.35 g TBP to be present initially for the case where the controller holds heating at 175 °C.

A summary of flammability conditions for sludges are as follows:

1. Purge air or CO_2 at 0.5 ft^3/min, furnace temperature remains at 175 °C - concentration never within the flammable range

2. Purge air alone or with CO_2 at 0.5 ft^3/min, furnace temperature increases at 300 °C/hr, 10 g TBP - concentration within the flammable range for 5 minutes - deflagration occurs.

3. No purge air or CO_2, 10 g TBP, temperature controller stops increase at 175 °C- concentration is within flammable range for 20 minutes. Then it is above the upper flammability limit - flash fire occurs followed by burn.

4. No purge air or CO_2, 10 g TBP, furnace temperature increases at 300 °C/hr, flammable concentration for about 4 min - deflagration occurs.

5. No purge air or CO_2, 0.35 g TBP - stoichiometric conditions at the auto-ignition temperature. Larger quantities would also be within the flammability limits.

9.2.10.2.2.2 Mitigation. Important features to preventing fires and deflagrations include:

- Purge air (prevents flammable concentrations)
- CO_2 purge (prevents flammable concentrations at high butene release rates should the temperature program be incorrect if the flow rate is at least 25 volume percent CO_2 in air flow - present flow rate is 16 volume percent)
- Temperature controller (if CO_2 purge is too unreliable or as a secondary safety feature).

Adequate purge air and CO_2 flow ensures that the contaminant is exhausted during ramp up in the furnace such that conditions in which deflagrations or fires could occur do not exist. In addition the operator pulls the gloves out of the glovebox before operating the furnace. This is discussed in Section 9.2.10.2.1.2.

Glovebox ventilation is discussed in Section 9.2.10.2.1.2.

The feed is sampled for TBP content. Any feeds with greater than 10 g TBP will not be stabilized in this manner.

9.2.10.2.2.3 Probability. The accident scenario in Section 9.2.10.2.2.1 is based on a CO_2 flow rate of 0.5 ft^3/min. At this flow rate, a deflagration could occur with TBP if both the vacuum offgas and temperature controller fail. If the CO_2 is set at a flow rate that yields at least 25% CO_2 in the furnace, then an additional failure, i.e., loss of CO_2, is required.

For this analysis, it is assumed that the CO_2 flow rate is set such that there is at least 25% CO_2 in the furnace. Using the rationale developed for plastic contaminants, the annual probability is 10^{-3} to 10^{-4}. Both the CO_2 and vacuum offgas flowrates could be erroneously set by a single operator. This is a more likely failure mode than the concurrent failure of both systems.

Another consideration is the operator error of sending boats with PRF sludge to HA-21I, which does not have the CO_2 cover gas, by mistake. Thus the additional error of sending boats to HA-21I with PRF sludge, which lowers the

chance of a deflagration, is approximately offset by the probability of deflagration in HA-21I with PRF sludge and no CO_2 cover gas. The probabilities discussed above are per boat processed. Depending on the number of boats processed per year, the annual probability of a deflagration could easily be in the anticipated category for a deflagration while processing PRF sludge.

9.2.10.2.2.4 Accident Analysis and Dose. To develop a flammable concentration of butene in the furnace requires 0.35 g of TBP. This results in the presence of 0.0039 moles (0.22 g) of butene at the auto-ignition temperature. The reaction is

$$0.0039\ C_4H_8 + 0.023\ O_2 \rightarrow 0.016\ CO_2 + 0.016\ H_2O \qquad (4)$$

The heats of formation are

CO_2 -94.0 kcal/mole, at 25 °C (Perry 1963, page 3-135)
H_2O -57.8 kcal/mole, at 25 °C (Perry 1963, page 3-137)
C_4H_8 0.3 kcal/mole, at 25 °C (Perry 1963, page 3-135)

The heat of reaction is 2.4 kcal.

The temperature increase is found by using the reaction products above and 0.075 moles N_2 present initially. The average temperature is taken to be 1,500 °C. The specific heat is found in the same way it was for plastics. The specific heat is found to be 0.9 cal/C. The temperature rise is found to be 2,666 °C. The final temperature is 3,110 °C. So use of 1,500 °C is a reasonable average. The pressure is found to be 4.9 atm, using a total of 0.107 moles and a temperature of 3,110 °C (3,383 K). The peak pressure 4.9 atm and the energy of reaction of 2,400 cal are similar to the peak pressure for plastics of 3.4 atm and energy of reaction of 1,980 cal. Given all of the uncertainties, the structural results for butene deflagration will be similar if not slightly more severe then those for plastics described in Section 9.2.10.2.1.4.

Since sludge containing TBP is guaranteed to contain organics (from the TBP), it is very likely that more than one furnace could have the flammability conditions necessary for a deflagration. Thus deflagrations could occur in three furnaces (in HA-21I by operator error) and it is assumed that deflagrations will be separated by a short period of time such that 4.5 g of respirable material from the furnaces and 500 g of respirable material from outside the furnaces but inside the glovebox will be assumed to be released to the glovebox room.

As a result the dose consequences will be similar to those calculated in Section 9.2.10.2.1.4.

9.2.10.2.2.5 Conclusion. These doses are well below the risk guidelines for any frequency category. The reason for this is the ability of the HEPA filters to remain functional after the deflagration.

9.2.10.3 Seismically Induced Deflagration in Glovebox HC-21C or HA-21I. Section 9.2.10.2 provides a discussion of the conditions necessary to result in a deflagration as a result of Glovebox HC-21C or HA-21I operation. It is shown in this section that a seismically induced deflagration is not credible. However, a flash fire scenario is shown to be credible and is analyzed in detail.

9.2.10.3.1 Scenario. Section 9.2.10.2 showed that a deflagration could only occur if the following conditions were met:

1. Organic contaminants in the feed material.
2. The air purge is off prior to the point where the assumed organic contaminants within the oxide pyrolyzes.
3. The door remains closed allowing flammable gases to remain relatively undiluted.
4. A spark source occurs after the point when sufficient air has been drawn in during cooling to result in a flammable mixture.

Barney (1998) showed that plastic will pyrolyze at 260 °C to 450 °C, depending on the plastic, if no air is present. With a furnace heat-up rate of 5 °C/min, these temperatures are reached at between 46 and 84 minutes. In the analysis that follows, a heat-up time to pyrolysis of about 90 minutes is used for conservatism.

Therefore in order for a deflagration to occur as a result of a seismic event, one of the following condition sets is necessary.

Condition Set 1

Organic contaminants in the feed material being heated.

Seismic event occurs prior to the time that the organic contaminants have combusted resulting in loss of purge air flow only. Glovebox and equipment remain in-place. The duration of this condition is just under 1.5 hours twice per day as the furnace is heated from room temperature to 450 °C in just under 1.5 hours.

Power remains on and temperature controller functions normally or fails so as not to result in power loss.

Operator fails to shut power off as he/she evacuates. A seismic event mild enough that evacuation is not necessary is not considered a seismic event for this analysis.

Spark occurs when door opens either due to aftershock or when operator opens door on return to the building. A deflagration will not occur if the door opens prior to cooldown as a flammable concentration does not exist per Section 9.2.10.2. A flash fire will occur under these conditions.

Condition Set 2

Organic contaminants in the feed material being heated.

Operator error in starting furnaces with no purge air flow. Airflow loss is either due to operator error during pre-heating activities or system failure. The furnace operates as normal.

Seismic event occurs after cooling is complete. Seismic event results in door opening and spark but not glovebox toppling or significant equipment movement. Seismic event before cooling is complete does not result in a deflagration but a flash fire. The window is about 2 hours twice per day at the end of the cool down time.

9.2.10.3.2 Probability. The seismic deflagration is not considered credible because the four following situations must occur:

1. A seismic event capable of causing damage must occur (10^{-3} to 10^{-4} event),
2. Organic contaminants must be present in the oxide being heated (10^{-1}),
3. The window during which the seismic event can satisfy the pyrolysis condition is about 10-15% of the time,
4. Either a pre-existing failure must be present prior to the seismic event (Condition Set 2) or the seismic event must fail specific equipment yet allow certain equipment to survive (10^{-1} to 10^{-3}).

The failures above describe the conditions necessary for a seismically induced deflagration for polyethylene (the most likely plastic contaminant) or polycarbonate. As was discussed in Section 9.2.10.2, the spark source may not be needed if the plastic is polyvinyl chloride. This results in Condition Set 1 requiring the first three failures, not all four. The event is still not considered to be credible for the reasons given.

If the plastic is PVC, Condition Set 2 is not applicable as the gas will deflagrate prior to the seismic event that occurs at cool conditions.

The phenomena that could occur in a seismic event is a flash fire. A flash fire occurs when air and an ignition source are brought together with a flammable gas at a concentration that is above its flammability limit. Fireballs are a type of flash fire. This can occur from Condition Set 1 or 2 conditions if the door opens prior to the furnace being cool. The annual probability of this event is still quite low (on the order of 10^{-5} or 10^{-6}) as it requires a seismic event, and either specific seismically induced failures but survival of other components or pre-existing failures. The window for this event is 20 hours/day if the furnaces are operated on a 12 hours/boat cycle.

9.2.10.3.3 Consequences. The flash fire can result in radiant heat applied to the panels and glovebox air. The first calculation shows the

effect of radiant heat. The conservatisms are chosen to maximize the radiant heat. The second calculation shows the effects of heating the air.

SFPE (1988), pg 2-78, provides a method for calculating the damage due to a fireball (or flash fire). The diameter of the fireball as a function of time is given by:

$$D = 0.81n^{1.12}V^{1/3} + d_o$$

where: V = vapor volume, m^3
= $6 \times 10^{-3} m^3$ (6L) in our case
$n = 3.13t/V^{1/6}$
D = diameter of fireball, m
t = time after ignition, s
d_o = initial diameter based on fuel volume, m, $(6V/\pi)^{1/3}$

The maximum duration of the fireball is given by:

$$t = 2.8\ V^{1/6}\ \text{sec.} = 1.2\ \text{sec.}$$

The thermal flux generated by the fireball varies with time. The variance is shown in Fig 2-4.35 of SFPE 1988. A number of points of that figure are shown below.

Normalized Heat Transfer rate, v	Nondimensional Time, n	Actual Time, (from nondimensional time) sec (Note 1)
		0
0.01	0	0.27
0.07	2	0.54
0.10	4	0.68
0.16(peak)	5	1.09
0.10	8	1.36
0.04	10	1.91
0.01	14	3.00
0.0	22	

Note 1 - actual time = (nondimensional time)$(V^{(1/6)})/(g^{0.5})$

The actual heat flux in kW/m^2 is given by:

$$q = vf\tau g^{0.5}\rho h_f V^{5/6}/4\pi r^2$$

where: r = distance from the center of the fireball at the time of interest.

What is assumed is that the seismic event causes the door to open, and fresh air to rush in. This is assumed to displace the flammable gas in the furnace. The gas, air and spark meet in front of the furnace at the door creating a fireball. It is assumed that the furnace is filled with the flammable gas at room temperature and that there is no air mixed in. This maximizes the amount of gas.

The table above shows that the normalized heat flux is a maximum of 0.16 at a nondimensional time, n, of 5. The fireball diameter as a function of V and nondimensional time is given by:

$$D = 0.81n^{1.12}V^{1/3} + d_o$$

At a value of "n" of 5 and "V" of 0.006 m^3, "D" is found to be 1.12 m. Therefore, the value of 0.56 m will be used for "r" above.

To solve for "q" the following is needed:

v = 0.16
f = fraction of heat that is radiated to the environment assumed to be 1.0
τ = atmospheric transmissivity
Taken to be 1.0 per Fig 2-4.20 of SFPE 1988 which show values of 0.95 at low relative humidity and small fireballs.
g = 9.8 m/s^2
ρ = density of flammable gas at ambient conditions, kg/m^3
= 1.13 for ethylene
h = heat of combustion, kJ/kg
= 51500 for ethylene

Solving for "q" yields 105 kW/m^2.

Glovebox windows are made out of either polycarbonate or PMMA. Polycarbonate windows are more heat resistant than PMMA. The Fire Hazards Analysis (McKinnis 1998) shows that at a heat flux of 40 kW/m^2 it takes 182 s to ignite polycarbonate and at 70 kW/m^2 it takes 75 s (see also Section 9.2.10.4.1). Extrapolating (using a log-log graph) to 105 kW/m^2 shows the duration must be 40 s. The maximum duration of the fireball was found to be 1.2 s. It is also noted that from Figure 2-4.35 of SFPE (1988) the time of significant heat transfer is only about 1/4 to 1/3 of the duration or 0.4 s in this case. As a result the windows do not fail. Even with PMMA windows the duration must be 2.5 s (log-log extrapolation) for failure to occur. The FHA states that even small fires result in failure of PMMA panels. The hypalon glovebox gloves are judged to be no more readily ignitable than PMMA panels. It is therefore concluded that the gloves will also survive the fireball. Since the glovebox is not breached as a result of the fireball, there is no

release out of the glovebox for this condition. Release due to toppling is found in Section 9.2.4.

If the seismic event fails the panel, the fireball might be able to carry the resuspended material out of the glovebox.

The fireball travels across the powder pan and could resuspend some of the powder. Mishima (1973) describes a test in which a 15 inch diameter, 2 inch deep stainless steel pan was placed in a wind tunnel. Twenty-five grams of ball milled UO_2 powder was sprinkled on the horizontal surface of the pan. Wind was blown over the pan and the amount of powder suspended was measured. The results for a 1 m/s wind was that 0.09 wt% of the powder was suspended over 4.8 hrs. Of this, 83% was respirable. The release rate vs time is an inverse exponential function; large at the start of the experiment and small at the end. Data on the release rate was not provided for the "1m/s wind over stainless steel" case. So the rate will be inferred from other cases discussed in Mishima (1973). For the "9 m/s wind over stainless steel" case, 50% of the release occurred over the first 30 minutes with the remainder occurring over the next 23 hours. The "1 m/s wind over sandy soil" case showed 50% of the release occurred over 2 hours for a 1m/s wind. It will be assumed that 50% of the release occurs over 1 hour. The vertical flux is therefore:

$$\text{Flux} = \frac{Q(0.09/100)(0.83)}{2(dt)(A)}$$

where: Q = initial quantity in the pan
= 25 g
dt = duration of 50% release
= 1 hour
A = area, m^2
= 0.114 m^2 based on 15 in. diameter
Flux = g/m^2 -hr

Solving for "Flux" yields 0.08 $g/hr\text{-}m^2$. Applying this to the fireball case:

$$RQ = (0.08\ g/hr\text{-}m^2)(1.2\ s/3600)(A)$$

where: A = area of boat, m^2
= $(5.5)(13)/144\ (3.28\ ft/m)^2$
= 0.046 m^2
RQ = respirable quantity released

Solving for "RQ" yields 1.2×10^{-6}g.

Iverson (1984) was used as a check. Iverson placed various heavy powders in pans distributed along a bed. Wind was blown over the top of the pans. The bed was 183 cm long (72 in) and 14 cm wide (5.5 in). The amount resuspended was measured. He calculated resuspension fluxes (g/cm^2-s) from 2×10^{-7} to 6×10^{-6}. The wind speeds used were 7 to 10 m/s. Using these values

for the fireball case (duration of 1.2 s, area of 461 cm^2) yields 1 x 10^{-4} to 3 x 10^{-3} g. These resuspension values are greater than those calculated from Mishima, of 1.2 x 10^{-6}, because of the greater wind speed.

Iverson also presents the results of suspension off of a coal pile. The empirical relationship is

$$Q = \frac{336\ u^3\ \rho^2\ A^{0.345}}{(PE)^2}$$

where: u = wind speed, m/s
= use 1 m/s
ρ = bulk density, g/cm^3
= 5 g/cm^3 for PuO_2
A = area m^2
= 0.046 m^2 for this boat
PE = moisture index which ranges from 7 to 180. Use 10 as 7 is extremely dry coal.
Q = resuspension rate mg/s.

Solving for "Q" yields 29 mg/s. Over 1.2 s the release is 0.035 g. If a value of 50 had been used for "PE", the release would have been 10^{-3} g. The release is therefore insignificant.

The ignition of the flammable gas could increase the glovebox temperature and cause pressurization. Section 9.2.10.2 shows the glovebox volume to be 105 ft^3. The total quantity of flammable gas in the furnace is taken from the 10 g benzene case as the energy release is greatest. There is 0.032 moles of benzene in the glovebox or 2.5 g. The heat of combustion for benzene is 9.56 kcal/gm. The energy release from combustion is 23,900 cal. The amount of air in the glovebox at room temperature (30 C) is found by the ideal gas law to be 119.6 g-moles or 3470 g. The specific heat of air is 0.24 cal/g-C. The temperature rise from this energy release assuming all of it goes into heating only the air is 28.7 °C. The glovebox pressure after burning assuming no air flow out of the glovebox is 1.4 psi. To maintain the pressure at atmospheric conditions at this greater temperature means that 10 ft^3 must be removed from the glovebox. The duration of the burn is 1.2 s, so the flow rate must be greater than 10 ft^3/s at pressures much less than 1.4 psig to maintain the glovebox pressure near atmospheric.

There will be flow-out of the glovebox into the conveyor as the glovebox pressure increases. The opening to the conveyor is taken to be 1.5 ft wide (distance from edge of glovebox to the center of the furnace door) and 1.5 ft. high (from the floor of the glovebox to the top of the conveyor).

The gas flow rate under subsonic conditions comes from AIChE (1989). The gas flow rate at a pressure equal to 0.4 psig and 8.2 C increase (the approximate conditions of Section 9.2.10.1) is found by:

$$G = \frac{C\ A\ P\ B}{a}$$

where: G = gas flow rate, kg/s
C = discharge coefficient, taken to be 1.0
A = area of opening, m^2
= $1.5(1.5)/3.28^2$ = 0.21 m^2
P = upstream pressure N/m^2
= 101320 [(14.7 + 0.4)/14.7]
= 104100 N/m^2
a = sonic velocity of gas at T
= $(s\ RT/M)^{0.5}$
s = ratio of specific heats = 1.3 for air
R = gas constant = 8310 J/kg-mole-K
T = upstream temperature, K = 311.2
M = molecular wt of gas = 29 for air
a = 340.5
B = flow factor
= $[(b)(c)(d)]^{0.5}$
b = $2s^2/(s-1)$ = 11.3
c = $(Pa/P)^{2/s}$ = 0.96
Pa = atmospheric pressure, N/m^2
= 101320
d = $[1-(Pa/P)^{(s-1/s)}]$
B = 0.26

Solving for "G" yields 16.7 kg/s.

The density of air at 311.2 and 15.1 psi is 0.04 moles/L or 1.167 g/L. The volumetric flow rate out is 14300 L/s or 505 ft^3/s. This flow rate easily maintains the glovebox pressure below that in Section 9.2.10.1 of 0.4 psi with the indication of high gas flow rates at even lower pressures, the peak glovebox pressure will likely be much less than 0.4 psi.

9.2.10.3.4 Conclusions. The releases are insignificant. As a result, the consequences due to a seismically induced deflagration are very much less than those of a seismic event (Section 9.2.4).

9.2.10.4 Glovebox HC-21C or HA-21I Fire. Reactive-material stabilization operations are conducted in gloveboxes HC-21A, HA-21I, and HC-21C (See Chapter 6.0). Glovebox HC-21C is located in room 230A of the 234-5Z Building. Glovebox HA-21I is located in room 235B of the 234-5Z Building. Glovebox HC-21C uses two muffle furnaces and glovebox HA-21I uses three muffle furnaces to stabilize the reactive plutonium-bearing materials. A fire in either Glovebox HC-21C or HA-21I is possible as either glovebox contains intense heat sources (the muffle furnaces and their exhaust), the potential for electrical sparks and combustible material (e.g. the tape and plastic from the container plus polycarbonate windows).

9.2.10.4.1 Scenario. The potential for a fire exists whenever combustible materials coexist with a source of ignition. The high temperatures associated with operation of the furnaces represent a credible ignition source. Therefore, to reduce the probability and magnitude of potential fires, administrative controls are established to minimize the quantities of combustible materials present in the glovebox. These materials

consist primarily of packaging materials (plastic bags and tape) used for sealing items into or out of the glovebox.

A fire could be initiated if the insulation fails while the furnace is operational or the furnace door is opened when the furnace is at a high temperature. The polycarbonate windows will burn if a heat source of 40 kW/m^2 for 182s (about 3 minutes) or 70 kW/m^2 for 75s (a little more than 1 minute) or the equivalent is applied to the window (McKinnis 1998). A fire involving glovebox windows can also be initiated if trash accumulates and is ignited so as to result in the above heat fluxes and duration. It is assumed that one of these scenarios occurs.

For this analysis, it is assumed that a fire of sufficient magnitude and duration to breach the glovebox via burned-out gloves or failed windows occurs, releasing material to the surrounding room.

9.2.10.4.2 Mitigation. The mitigating factors are as follows:

1. Administrative controls help to minimize the amount of combustible waste kept within the glovebox and keep it located away from hot surfaces.

2. The operation of the Halon system for Glovebox HC-21C and the operation of the dry-chemical fire protection system for HA-21I.

3. The wet-pipe sprinkler system.
4. The response of the Hanford Fire Department.

9.2.10.4.3 Probability. The muffle furnaces are used to thermally stabilize reactive plutonium-bearing compounds. The glovebox has polycarbonate panels (see Hanford drawing H-2-97289 and H-2-95707). The polycarbonate panels were installed in 1985 and 1986. The polycarbonate panels are covered by lead glass panels. To burn through polycarbonate panels requires a heat flux of 30 kW/m^2 (McKinnis 1998). McKinnis 1998 states that in a separate experiment a fire having a heat rate of 18 kW causes ignition of PMMA in 2 minutes. Table 7-1 of McKinnis shows that in general the heat needed to ignite polycarbonate is about double that needed to ignite PMMA. Therefore a 36 kW fire is needed to cause polycarbonate to burn. An example of a heat source of this magnitude is a pile of paper or trash about 1 ft. in diameter containing about 3 kg of trash (McKinnis 1998). It is unlikely that this amount of trash would accumulate, if allowed, as a result of stabilization activities. The ignition source is also unlikely. Possible ignition sources are:

- failure of insulation on exhaust line. The exhaust line insulation touches the plastic panel. This may also require simultaneous prolonged operation of the furnace or a process upset within the furnace in order to deliver the required energy to the window.

- failure of electrical leads into the furnace. This is a very unlikely ignition source as the trash is likely in the front of the glovebox and the power is in the rear.

- prolonged operation with the door open (radiant heating of the front panel). This is unlikely because an interlock on the furnace door interrupts power if the door is opened.

- failure such that the glove contacts a hot furnace surface.

The probability of allowing trash to accumulate is taken to be 10^{-2} (Swain and Guttmann, 1980, Table 20-22, entry on "failure to carryout a plant policy," and "use of written procedures under normal operating conditions).The probability of igniting the trash creating a fire large enough to breach the windows is judged to be on the order of 10^{-2} based on the above. The probability of a propagating fire involving glovebox panels is therefore 10^{-4}.

Should administrative controls fail such that a large quantity of combustible material accumulates and ignites in the gloveboxes, redundant fire suppression measures are in place. Operators are present in rooms 230A and 235B and are trained to extinguish fires in accordance with *Respond to Plutonium Metal/Scrap Fires*, Procedure ZO-200-010. An automatic Halon system is provided in Glovebox HC-21C and an automatic dry-chemical system is provided in Glovebox HA-21I. The wet-pipe sprinkler system servicing rooms 230A and 235B would activate if the magnitude of the fire was large. In addition to these in-plant measures, the HFD is available to respond to onsite emergencies. Section 9.2.2A estimates the annual probability of the failure of fire suppression measures to be about 10^{-4} (i.e., the combined "failure to act" of the Halon system, wet pipe sprinkler system, and HFD response probabilities). The annual probability of a fire that will breach this glovebox and not be extinguished rapidly is less than 10^{-6}. The consequences of this fire is evaluated as a bounding event.

9.2.10.4.4 Accident Analysis and Dose. Criticality Prevention Specifications (CPS) limit the plutonium inventory in Glovebox HC-21C to 5 kg (see Table 9-25). The Criticality Prevention Specifications (CPS) limit the plutonium inventory in Glovebox HA-21I to 8 kg (see Table 9-25). Therefore, the inventory of plutonium available for a bounding, postulated suspension and release in this analysis is limited to 8 kg.

For a given inventory at risk, the amount of plutonium aerosolized by a fire is dependent upon many variables such as the chemical and physical form of the plutonium, the matrix in which it is held, and the direction and velocity of entraining gases. Recommended values of ARF and RF for solids undergoing thermal stress are documented in DOE (1994). The ARF is defined as the coefficient used to estimate the amount of radioactive material that can be suspended in air and available for transport. The RF is defined as the fraction of the airborne radionuclides present as particles that can be transported through air and inhaled into the human respiratory system (commonly assumed to be particles 10-μm AED and less in size).

DOE (1994) presents the recommended bounding ARF*RF for various plutonium compounds (as powders) subjected to thermal stress (temperature <1000 °C; natural convection). It is conservatively assumed that the plutonium inventory involved in this scenario is in the form of a non-reactive oxide compound in open furnace boats.

For this analysis, the ARF*RF per DOE (1994) for non-reactive compounds (i.e, plutonium dioxide) is 6 x 10^{-5} (ARF of 6 x 10^{-3}, RF of 10^{-2}). The quantity of respirable PuO_2 made airborne is therefore:

8000 g x 0.006 x 0.01 = 0.48 g

DOE (1994) stated that the respirable fraction was 0.01. Figure 9-28 shows a respirable fraction of 0.04 for plutonium fluoride as prepared by PFP. It could be argued that the RF for heating is 0.04, not 0.01 making the assumption that oxide powder would have a similar size distribution. DOE (1994) recognizes this question and stated that it was difficult to obtain process powders with RF greater than 1%. DOE (1994) further stated that even if this were possible, the particle size distribution changes with the time over which the container sits. The respirable fraction gets less and less (see Figure 1-41 of DOE 1994). Therefore DOE (1994) believes the value of RF 0.01 to be reasonable and conservative.

For the purpose of this analysis, it is assumed that one-half of the plutonium aerosols generated are exhausted via the E-4 ventilation system servicing Glovebox HA-21I, and one-half is exhausted via the E-3 system that services room 235B. Both the E-3 and E-4 pathways were given credit for one stage of HEPA filtration. The minimum acceptable collection efficiency, as indicated by testing, is 99.95%. Since both paths lead to the stack through HEPA filtration, the flow split between the two paths does not affect the consequences. Applying this value to the 0.48 g of plutonium assumed to be released via the E-3 and E-4 pathways, results in the discharge of 2.40 x 10^{-4} g from the 291-Z-1 stack, all of which is respirable.

The doses due to the release of 2.40 x 10^{-4} g of plutonium can be calculated by using the methodology from Section 9.5.

$$D(rem) = Q(g) \times \chi/Q'(sec/m^3) \times R(m^3/s) \times C(rem/gram)$$

where: D = Dose
Q = Quantity of plutonium released = 2.40 x 10^{-4} grams.
χ/Q = Atmospheric dispersion coefficient for elevated release = 1.62 x 10^{-5} s/m^3 for onsite receptor and 5.73 x 10^{-6} s/m^3 for offsite receptor from Table 9-39 and 9-40 respectively.
R = Breathing rate = 3.3 x 10^{-4} m^3/s.
C = Gram plutonium to dose conversion factor for Class Y >10% ^{240}Pu, 90th percentile = 1.7 x 10^8 rem/gram (EDE) and 2.7 x 10^9 rem/gram (Bone Surface) from Table 9-46 and 9-47, respectively.

Therefore, the EDE doses are:

- onsite = 2.2 x 10^{-4} rem
- offsite = 7.7 x 10^{-5} rem

The bone surface doses are:

- onsite = 3.5×10^{-3} rem
- offsite = 1.2×10^{-3} rem

9.2.10.4.5 Conclusions. The results of the preceding analysis show that the consequences of a bounding release from a large-scale fire are several orders of magnitude below these Risk Acceptance Guidelines (Table 9-49) for even an anticipated event. The reason the doses are so small is the functioning of the HEPA filters during and after the fire.

9.2.10.5 Seismically Induced Fires in Gloveboxes HC-21C and HA-21I.

9.2.10.5.1 Scenario. Fires in these gloveboxes are addressed in Section 9.2.10.4. Fires require an accumulation of flammable material and for this flammable material to come in contact with an ignition source. Administrative controls prevent accumulation of large quantities of flammable material. To produce a fire therefore, a heated surface must contact the glovebox window. This can occur if the glovebox topples. When the glovebox topples, it is likely that the furnace will impact the front window when it hits the floor (i.e., the glovebox, the window and the furnace strike the floor and each other at the same time). Even if the glovebox remains partially upright, the vibratory motions along with the tipping is assumed to cause impact of the furnace and the plastic panel. The impact is assumed to result in a hot surface touching the panel for sufficient duration that the panel begins to burn. It is also possible that the seismic event causes the furnace door to open and causes failure of the vacuum and glovebox ventilation system. It is assumed that radiant heat from the furnace can result in ignition of the panels. The effects of seismically induced fires in these gloveboxes are discussed in Section 9.2.4.2.12.F.

9.2.10.6 Changes to the RMC/RMA Lines Fire Analysis from Gloveboxes HC-21A, HC-21C, and HA-21I. Section 9.2.2A analyzes a worst case glovebox fire which includes gloveboxes HC-21A, HC-21C, and HA-21I. Therefore all changes due to these gloveboxes have been incorporated in the analysis discussed in Section 9.2.2A.

9.2.11 Accidents for the Laboratory Prototype Calciner

The Laboratory Prototype Calciner is not currently authorized for operation. However, the previous accidents analyzed for the laboratory calciner are retained in the FSAR for future evaluation if the calciner is reauthorized for operation in the future.

Accidents which have been postulated to potentially result from operation of the Laboratory Prototype Calciner are as follows:

- Hydrogen deflagration in Room 188 from opening drum
- Hydrogen deflagration in Glovebox 188-1 from opening bagged polybottle

- Flammable gas deflagration in the Laboratory Prototype Calciner
- Glovebox 188-1 fire
- Glovebox 188-1 seismic event.

Each of these accidents is discussed in detail in the Laboratory Prototype Calciner addendum to this FSAR. The accident analysis provides a description of the accident scenario, mitigation, probability, consequences and conclusions for each event analyzed.

9.2.12 Accidents for the Magnesium Hydroxide Precipitation Process.

Accidents associated with operation of the Magnesium Hydroxide Precipitation Process are identified and analyzed in the related addendum (Carson 2000) to this FSAR.

9.2.13 Accidents for the Bagless Transfer System (BTS).

Accidents associated with the operation of the BTS are identified and analyzed in the related calculation notes (FH 2000).

9.3 DOSIMETRY CALCULATIONS

Radiation dose is proportional to the quantity of energy deposited per unit mass of irradiated tissue. The total "absorbed dose" is reported in units of rad (100 ergs/g) or gray (1 J/kg). This is normalized to relative biological effect, depending on the type of radiation, in dose equivalent units of "rem" or "sievert."

All radiological dose calculations for this study were made using the GXQ code in combination with the plutonium inventory appropriate to a specific accident. The following sections summarize the models used in the GXQ code, the primary accident scenarios for which $\overline{\chi}/Q'$ values are calculated, the dose conversion factors for various plutonium isotopic distributions, and provide a sample calculation for a 1 g release from the 61 m stack.

9.3.1 Material Release

The dosimetry calculation begins when the radioactive material is released from the facility into the environment via discharge into the air, a body of water, or the ground. For the PFP analysis all releases were assumed to be into the air. A discharge may be characterized as a total release in Curies, a release rate, or as a concentration in stack effluent. In any case, the specification is made in terms of a detailed radionuclide inventory at the moment of release. In order to be transported for any distance the material must be either gaseous or a fine aerosol. Aerosols are assumed to be in the form of a particulate distribution in the respirable size range (less than 10 μm).

9.3.2 Material Transport Methodology

This section briefly discusses the methodology and models used to estimate $\overline{\chi}/Q'$ in this report. Implementation is performed with the aid of a computer program called GXQ. For more detailed information on the models used and their applicability, refer to the GXQ documentation (Hey 1993a, 1993b).

The atmospheric dispersion coefficient $\overline{\chi}/Q'$ represents the dilution of an airborne contaminant due to atmospheric mixing and turbulence. It is the ratio of the average contaminant air concentration $\overline{\chi}$ at the receptor to the contaminant release rate Q' at the release point. Since atmospheric conditions fluctuate, a bounding atmospheric condition is determined to be that condition that causes a downwind concentration of airborne contaminants that is exceeded only a small fraction of time due to weather fluctuations. The NRC defines this fraction as 0.5% for each sector or 5% for the overall Site, whichever is greater (NRC 1982).

9.3.2.1 Atmospheric Dispersion Coefficient Calculation - $\overline{\chi}/Q'$. The Gaussian straight-line model is employed by GXQ for calculating atmospheric dispersion.

The time integrated atmospheric dispersion coefficient $\overline{\chi}/Q'$ for a continuous point source is given by:

$$\frac{\overline{\chi}}{Q'} = \frac{f(y)g(z)}{2\pi\sigma_y\sigma_z\overline{u}}$$

where: σ_y = Horizontal diffusion coefficient (m)
σ_z = Vertical diffusion coefficient (m)
$f(y)$ = Horizontal correction term
$g(z)$ = Vertical correction term
$\overline{u}$ = Mean wind speed (m/s).

The horizontal correction term is given by:

$$f(y) = \exp\left[-\frac{1}{2}\left(\frac{y}{\sigma_y}\right)^2\right]$$

where: y = Horizontal offset from plume centerline (m).

If the mixing height is large compared to the release height and the vertical diffusion coefficient, then the vertical correction term is given by:

$$g(z) = F_{ref}\exp\left[-\frac{1}{2}\left(\frac{h_e - z}{\sigma_z}\right)^2\right]$$

where: F_{ref} = Reflection factor[1]
h_e = Effective release height (m)
z = Receptor height (m).

Mathematical approximations are used to evaluate the atmospheric diffusion coefficients σ_y & σ_z which are based on the Pasquill-Gifford-Turner curves. These approximations are identical to those used in the GENII Code (Napier 1988).

[1]The reflection factor is based on the virtual image source and assumes 100% ground and mixing layer reflection. The mathematical expression is given in Hey (1993a).

9.3.2.2 Additional Dispersion Models. When appropriate, certain additional effects may be considered in the calculation of $\overline{\chi}/Q'$. The models for these effects are summarized below and are utilized to varying degrees in the consequence calculations discussed in Section 9.2.

9.3.2.2.1 Building Wake Effect. The building wake model is a simple alteration of the Gaussian plume model. It assumes the release point to be at the ground level and in the middle of the downwind face of the building. The plume horizontal and vertical dimensions are initialized such that the plume concentrations at the sides and roofline of the building from which the release occurs are assumed to be 10% of plume centerline concentrations (i.e., building edges are 2.15 σ from the plume centerline). The formulae below were taken from Equation 2.2 of the *MELCOR Accident Consequence Code System (MACCS) Model Description*, NUREG/CR-4691 (NRC 1990).

$$\sigma_y(x=0) = \frac{W_b}{4.3}$$

where: W_b = Building width (m).

$$\sigma_z(x=0) = \frac{H_b}{2.15}$$

where: H_b = Building height (m).

The above adjustment is made using the virtual distance method. The virtual distance method involves calculating the distances corresponding to $\sigma_y(x = 0)$ and $\sigma_z(x = 0)$ and adding these distances to the distance from the release point to receptor (x). These adjusted "virtual distances" are then used to calculate subsequent diffusion coefficients.

9.3.2.2.2 Exhaust Flow Rate Effect. As the release point to receptor distance, x, approaches zero, the values for σ approach zero as well. Thus, the calculated atmospheric dispersion coefficient ($\overline{\chi}/Q'$) using the Gaussian model approaches infinity. In reality, the $\overline{\chi}$ should not exceed the initial effluent concentration at the release point.

To correct this deficiency in the mathematical model, the diffusion coefficients at the point of release are chosen to represent the initial plume dimensions (Rittmann 1984). The initial lateral plume spread, $\sigma_y(x = 0)$, is based on the stack diameter or initial plume width. The initial vertical plume spread, $\sigma_z(x = 0)$, is based on the exhaust flow rate in such a way that the effluent concentration is obtained at $x = 0$. This dimension is essentially the vertical rise of the plume in the time it takes the plume to travel downwind one stack diameter.

This model is applicable to releases having an initial vertical velocity. The above adjustment is accomplished through the following equations.

$$\sigma_y(x=0) = \frac{d}{\sqrt{2\pi}}$$

where: d = Stack diameter (m).

$$\sigma_z(x=0) = \frac{F_{ref}(z=hs)V_0}{\sqrt{2\pi}\,\bar{u}d}$$

where: V_0 = Plume volumetric flow rate (m^3/s)
$F_{ref}(z=hs)$ = Reflection factor evaluated at stack height.

As in the building wake model, the virtual distance method also is used in the exhaust flow rate adjustment. If both the building wake and exhaust flow rate models are selected, then the larger diffusion coefficient of the two is used to calculate $\bar{\chi}/Q'$.

9.3.2.2.3 Plume Meander Effect. The plume meander model (as follows) is based on the fifth power law formula (Hanna 1982, eq. 4.15). When selected, it is applied to the horizontal diffusion coefficient based on the release duration t_A.

$$\frac{\sigma_{yA}}{\sigma_{yB}} = \left[\frac{t_A}{t_B}\right]^{\alpha}$$

where: σ_{yA} = Horizontal diffusion coefficient averaged over time t_A
σ_{yB} = Measured horizontal diffusion coefficient
α = 0.2, when 10 min $\leq t_A <$ 1 h
α = 0.25 when 1 h $\leq t_A \leq$ 100 h
t_A = Release duration
t_B = Measurement averaging time (10 min).[1]

9.3.2.2.4 Plume Rise Effect. The momentum/buoyancy plume rise model used in GXQ is taken from Equations 8.35, 8.36, and 8.57 of *Atmospheric Science and Power Production*, DOE/TIC-27601 (Randerson 1984) for plume rise in a crosswind. Assumptions made are that the effluent is a heated gas with a heat capacity and mean molecular weight close to that of air, and that initial effluent density and vertical velocity within the plume are constant.

[1]The standard Pasquill-Gifford curves represent a sampling time of approximately 10 min (Hanna 1982).

$$z_c' = \left[\frac{3}{\beta_m^2} \frac{F_m}{\bar{u}^2} x + \frac{3}{2\beta_b^2} \frac{F_b}{\bar{u}^3} x^2 \right]^{1/3}$$

where:

z_c' = Centerline rise of plume (m)

$\beta_b = 0.6$

$\beta_m = 0.4 \frac{1.2}{R}$

$\bar{u}$ = Mean ambient wind speed (m/s)

x = Distance downwind (m)

R = Velocity ratio = $\frac{w_0}{\bar{u}}$

w_0 = Initial plume vertical velocity (m/s) = $\frac{4V_0}{\pi d^2}$

d = Stack diameter (m)

F_b = Buoyancy flux

$= 3.7 \times 10^{-5} q_h (m^4/s^3)$

g = Gravitational acceleration (9.82 m/s^2)

q_h = sensible heat emmission rate (cal/s)

$F_m = \frac{\rho_0 w_0 V_0}{\pi \rho_a}$

ρ_0 = Initial plume density (g/cm^3)

V_0 = Initial plume volume flow rate (m^3/s)

ρ_a = Ambient air density (0.00122 g/cm^3 assumed).

The above equation provides a transition from the $x^{1/3}$ law for bent-over jets to the $x^{2/3}$ law for bent-over buoyancy-dominated plumes.

For Pasquill stability conditions E, F, and G, the buoyant rise of the plume is assumed to be limited by

$$\Delta h = 2.6 \left[\frac{F_b}{\bar{u} S} \right]^{1/3}$$

where: S = Stability parameter
$= 5.04 \times 10^{-4}$ for stability class E
$= 1.27 \times 10^{-3}$ for stability class F
$= 1.75 \times 10^{-3}$ for stability class G.

This equation can be found in the MELCOR/Accident Consequence Code System (NRC 1990).

For Pasquill stability conditions A through D, buoyant rise is terminated when any of the following conditions are met (NRC 1990):

- $\Delta h = 300\ (F_b/u^3)$.
- The plume centerline reaches the height of the mixing layer.
- The plume has travelled downwind for 1 h.

Near-surface wind speeds increase with altitude. Because plume rise is a function of wind speed and wind speed is a function of effective release height, iteration is necessary to converge on an effective release height and corresponding wind speed. As the plume experiences a change in elevation, the average of the wind speeds at the release point elevation (assumed to correspond to the meteorological wind data) and the effective release height at the receptor is used. Iteration on effective release height and average wind speed continues until the difference between the last two calculated effective release heights becomes less than 1 m or until five iterations are completed. This procedure is used in GXQ any time an elevation-corrected wind speed is selected and a non-zero stack height or plume height model (i.e., plume rise, stack downwash, or gravitational settling) results in an elevation different than the height corresponding to the wind speed data.

9.3.2.2.5 Liftoff Criterion. When wind speeds are high, a buoyant plume that is released into a strong building wake will be unable to escape from the wake. Escape of a buoyant plume from a building wake is governed by a lift-off criterion. The criterion states that plume rise occurs only when the stack-level wind speed is less than a critical wind speed, u_c, that is calculated using the following formula.

$$u_c = \left[\frac{9.09F_b}{H_b}\right]^{1/3}$$

where: H_b = Building height (m)
F_b = Buoyancy flux (m^4/s^3).

9.3.2.2.6 Wind Speed Variation with Height. The measurement height for meteorological data is provided in the joint frequency file. If the measurement height differs from the effective release height, the wind speed at the effective release height is corrected using a power law function given in Equation 4.9 of the *Handbook on Atmospheric Diffusion*, DOE/TIC-11223 (Hanna et al. 1982).

$$u = u_m\left[\frac{h_e}{h_m}\right]^p$$

where: u = Corrected wind speed for elevated release (m/s)
u_m = Measured wind speed (m/s)
p = Power coefficient for rural roughness
h_m = Height of measured wind speed
h_e = Effective release height.

The corrected wind speed remains constant below 10 m and above 200 m in height. Power coefficients for rural areas also were taken from Hanna (1982). Rural coefficients were chosen to represent Hanford Site surface roughness.

9.3.2.3 Model Integration. The above discussions center on the individual models and approaches used. Control of model application is divided between the user of the code and the code itself. The user specifies which models to implement. The choice is based on the scenario under consideration. The code determines how those models interact with each other. This subsection describes how the various models are combined in GXQ to provide a single calculated $\overline{\chi}/Q'$.

For a release scenario involving a long-duration release from a building with a short stack, application of the plume meander, building wake, and flow correction models may be appropriate. These models, described above, are applied to the Gaussian plume model as an adjustment to the lateral and vertical diffusion coefficients (σ_y,σ_z) to account for the additional dispersion phenomena. The code calculates a corrected coefficient for the process that dominates the initial spreading of the effluent. The code does not attempt to combine the effects of all three models simultaneously.

For a release scenario involving a buoyant plume or vertical jet, application of a momentum buoyancy rise model may be appropriate. The plume rise model described in Section 9.3.2.2.4 raises the centerline of the Gaussian plume to model a vertical offset from the receptor to the plume centerline. If a stack or building is also involved, then stack downwash phenomena and plume trapping can be modeled through application of the downwash model and lift-off criterion. The effective release height, h_e, is determined using the following formula:

$$h_e = h_s + z_c'$$

where: h_s = Stack height (m)
z_c' = Centerline rise of plume (m)

To model the general increase in wind-speed with vertical distance from ground level, the wind speed correction model can be applied. Since wind speed is a function of plume rise and visa versa, GXQ iterates on the two until a converged value is reached.

When calculating a frequency-based $\overline{\chi}/Q'$, GXQ factors in the frequency of the combination of atmospheric stability class, wind speed, and wind

direction. These data are stored in a joint-frequency file. The procedure involves the calculation of a $\overline{\chi}/Q'$ and the selection, through interpolation, of a value that is exceeded only 0.5% of the time (i.e., for a 99.5% $\overline{\chi}/Q'$).

9.3.3 Release Point to Receptor Distances

Both onsite and site-boundary receptors are considered. These are chosen to yield the worst exposure to airborne contaminants. The receptor is assumed to remain at a given location for the duration of the plume passage. A map of the Hanford Site showing the irregular boundary and a map of the 200 West Area showing the location of nearby facilities are presented in Chapter 5.0. Onsite and site-boundary distances are given in Tables 9-37 and 9-38.

Onsite receptors are defined as workers at facilities that are occupied at least 5 d/week. Workers involved in sporadic activity that may occur at lesser distances are not considered. Only five sectors are identified for onsite receptors, since the remaining sectors either do not contain a facility or the nearest facility is several kilometers away (i.e., in the 200 East Area) and so the associated χ/Q would be much lower than for the facilities identified in Table 9-37.

Ground-level distances are from the edge of the 234-5Z Building. Distances from the PFP perimeter fence to the onsite receptor are approximated by subtracting 100 m from the ground-level distances.

9.3.4 Scenario Descriptions and $\overline{\chi}/Q'$ Results

Each of the accident scenarios for which $\overline{\chi}/Q'$ calculations are performed are briefly discussed below. Pertinent parameters for the models discussed above are also stated. Calculated $\overline{\chi}/Q'$s are provided at the end of this section.

9.3.4.1 Elevated Release. This release scenario is applied to postulated glovebox releases into rooms within the PFP that assume that all of the release occurs through the 200-ft (61-m) PFP stack. Scenarios postulated for gloveboxes HC-21C and MT-5 are characteristic of when this scenario is applicable. The stack flow rate is 260,000 std ft^3/min (123 m^3/s). The stack ID is 13.5 ft (4.1 m) (Section 1.2.2). Effluent is assumed to be at ambient temperature. The release occurs over approximately 6 min and is, therefore, essentially instantaneous.

The distance to the onsite receptor is taken to be the stack distance shown in the second column of Table 9-37.

9.3.4.2 Ground Level Release with Building Wake and Plume Meander. This release scenario is applied to a postulated event that assumes a release occurs through openings in the 234-5Z Building structure (i.e., doors, cracks). The release is assumed to occur at ground level with no rise in plume centerline. Building wake is modeled as described in Equations 4 and 5 for a building height and width of 14 m and 46 m, respectively. Additionally,

plume meander is also modeled for a 1-h duration release using the fifth power law model described in Hey (1993a).

The distance to the onsite receptor is taken to be the ground-level distance shown in the third column of Table 9-37.

9.3.4.3 Buoyant Plume Rise. This release scenario is applied to a postulated ground-level fire, such as that from stored combustible waste that assumes an attendant plume rise. The buoyancy of the plume depends upon the sensible heat generated.

A 3-m-dia pan fire of gasoline is assumed with a small fire being conservative. This assumption is based on the premise that combustion of the contaminated solids contained in an array of several sealed drums does not occur unless externally heated, and the most likely means for this to occur is by ignition of spilled fuel. The assumed fuel is gasoline, which has a heat of combustion of 43.7 MJ/kg and a burn rate of 0.055 kg/m^2 s (DiNenno 1988). The radiative heat loss is assumed to be 30%, a conservatively high value. Under these conditions, 60 gal of gasoline would burn in approximately 10 min (a little more considering fire growth and burn-out periods).

Due to the short duration of the fire, no credit is taken for plume meander. Additionally, plume trapping due to building turbulence is invoked using the liftoff criterion. The buildings near enough to cause this effect are single-story structures. A building height and width of 6.1 m (20 ft.) and 10 m (33 ft.) are used, respectively. Credit for building wake is taken if conditions prevent buoyant plume rise (i.e., plume trapping).

The distance to the onsite receptor is measured from the PFP perimeter fence to the nearest occupied onsite facility (see the fourth column of Table 9-37). It is assumed that such a fire occurs in waste drums stored in the southwest corner of the PFP fenced perimeter.

9.3.4.4 Point Source Ground Level Release. This release scenario is described as a point-source release of short duration. It may be applied to a postulated storage drum rupture involving a single drum that is assumed to rupture and release some portion of its contents. Additionally, it may be applied to the release from 232-Z, which is also assumed to release its contents instantaneously. No credit is taken for any plume rise, wake effects, or plume meander. It is modeled as a point-source ground-level release.

For the drum-rupture scenario, the distance to the onsite receptor is measured from the PFP perimeter fence to the nearest occupied onsite facility, as it was for the storage drum fire. For the 232-Z release, the distance to the onsite receptor is taken to be the ground-level distance shown in the third column of Table 9-37.

9.3.4.5 $\overline{\chi}/Q'$ Results. Tables 9-39 and 9-40 list the calculated $\overline{\chi}/Q'$ for each of the accident scenarios described above. The distance and direction listed under the column heading "Release scenario" refers to the location of the maximum receptor. That is, all other receptor locations had a calculated $\overline{\chi}/Q'$ that was smaller and less conservative. It might be observed that the

direction of the maximum onsite boundary does not coincide with the direction of the maximum site-boundary receptor. This is a direct result of the irregular site boundary and wind rose frequency.

9.3.5 Plutonium Inventory Characterization

9.3.5.1 Plutonium Isotopic Composition. Plutonium produced in nuclear reactors is a mixture of plutonium isotopes. The potential radiological hazard of plutonium depends significantly on the abundance of particular isotopes present. Each isotope represents a different hazard due to its specific activity and decay mechanism. Therefore, establishing a source term for the PFP requires appreciating and understanding the variation in plutonium isotopic ratios found in the stored materials. Table 9-41 shows the half-life and specific activity of major plutonium isotopes.

The principal exposure pathway in PFP-postulated accidents is via dispersion in air and subsequent inhalation by individuals. Differences in the magnitude of this radiological hazard for selected plutonium isotopes can be seen by examining doses incurred through inhalation of a given mass of each isotope. The term 'unit dose' describes the dose a person would receive over the next 50 yr if they inhaled 1 g of an isotope. Table 9-42 presents the EDE and bone-surface unit doses for plutonium compounds with two different lung-clearance classes. Plutonium compounds other than oxides, such as plutonium nitrate, that have relatively short clearance times in the lungs are considered Class W compounds (Eckerman et al. 1988). Oxides of plutonium are considered Class Y compounds (Eckerman et al. 1988). Although the differences are significant in dose consequences, they do not affect the determination of the plutonium inventory and isotopic composition. Only Class W material EDE values will be used for illustrative purposes through the remainder of this section until the final section where tables presented summarize the calculations for both Class W and Class Y materials.

Plutonium production in a nuclear reactor begins with a neutron-capture in ^{238}U and subsequent beta decays to form ^{239}Pu, which in turn is followed by successive neutron capture reactions as shown in Figure 9-31 (Wick 1967). Plutonium isotopes 240, 241, 242, and 243 are formed by these successive neutron captures. The sequence of isotopes thus produced ends with ^{242}Pu because of the short half-life of ^{243}Pu (4.95 h). ^{238}Pu is created by (n, 2n) reactions in ^{239}Pu and through decay chains from ^{238}U and ^{236}U.

The isotopic composition of plutonium from a reactor depends on the reactor power level, length of fuel exposure, neutron flux energy spectrum, and other factors that influence the production and removal rates of individual plutonium isotopes. The effective neutron cross sections of the various plutonium isotopes are dependent on the neutron flux energy spectrum. The ratio of fissions to captures in plutonium is expected to be greater in a fast spectrum than in a thermal spectrum. Consequently, the plutonium created in a thermal reactor has a greater percentage of the higher isotopes of plutonium than that produced in a fast reactor. Because the production of the higher isotopes requires multiple neutron captures, the isotopic ratios (relative amounts of higher isotopes) also depend on the length of time the fuel is left in the reactor and on the neutron flux level.

Radioactive decay decreases the quantity of each isotope at different rates because of the different half-lives of each isotope. Table 9-41 presented half-life data for plutonium isotopes. In the case of ^{241}Pu, the decay is principally beta decay that results in a daughter product, ^{241}Am. Alpha decay from this americium isotope contributes to the inhalation doses from plutonium and thus represents a personnel exposure concern. The processing of plutonium removes the americium and lowers the dose from the plutonium on a per gram basis. The production, decay, and processing history of each particular lot of plutonium significantly affects its isotopic composition, and therefore its potential radiological hazard.

9.3.5.2 PFP Plutonium Inventory. The current plutonium inventory is a collection of individual items and not a continuous spectrum of a single product line. The plutonium in each inventory container is unique because of its creation in a particular reactor environment and its chronological history of processing and storage. Individual containers may have similar plutonium isotopic distributions because they have a common history, were a part of a common process blend lot, or purely from coincidence.

Nondestructive analysis of shipments and periodic vault-inventory verifications have been performed at the PFP for more than a decade using gamma spectroscopy to determine isotopic concentrations of plutonium. The vault-verification program includes randomly selecting a number of items from the inventory and nondestructively verifying container contents. The shipping NDA measurements verify the composition of material shipped into and out of the PFP. Additional measurements are made for items created during PFP operations. In all, more than 4,700 items have been measured since 1985. The results of these measurements have been maintained by PFP laboratory analysts in a historical database.

This database, referred to as the NDA Verification Database, assessed the distribution of individual isotopes and their net effect on calculated potential doses in safety analyses. However, because the database is a record of "all" measurements, it includes duplicate measurements and counts of standards made for quality control purposes. These data were deleted from the database before use in this evaluation because they do not represent items in the inventory. Some of the database items were analyzed when shipped in, and again when shipped out. Counting these items in the estimate is not appropriate because these items no longer are in the inventory; therefore they were deleted from the database. Table 9-43 shows the plutonium isotopic distribution of the NDA database. The remaining mass of plutonium and number of items measured are also shown in Table 9-43, columns 2 and 3.

9.3.5.3 Dose Consequences of Current Inventory. Figure 9-32 depicts the plutonium inventory in terms of Class W EDE inhalation dose, based on 2,722 sample points from the NDA verification activity using the conversion factors from Table 9-42. The data points within each column show the range of inhalation doses within the corresponding ^{240}Pu bin. The dramatic difference in the scatter of data points for material with less than 10% ^{240}Pu, compared with that having more than 10% ^{240}Pu can be seen.

The description of the PFP inventory was continued one step further. The seven bins were collapsed into two ranges, one for items with greater than 10% ^{240}Pu and the other for items with <10% ^{240}Pu in Table 9-44.

These ranges are represented by three values each for the inhalation doses, the mass-weighted average, maximum value, and the 90th percentile as seen in Table 9-45. The inhalation dose varies because different isotopic compositions and different ages are presented in these tables. An item in the inventory need only be described as having more or less than 10% ^{240}Pu to have a maximum rem/g inhalation dose specified. The 90th percentile for each bin represents an inhalation-dose value greater than 90% of the inventory in each range. Because each range represents about half of the inventory, the 90th percentile for the upper range is approximately the 95th percentile for the total inventory. Table 9-45 gives the mass-weighted average, the minimum, the maximum, and the 90th percentile value for the two ranges.

The worst case class (Class W) for lung clearance is presented in the above table. This class is generally applicable to all plutonium compounds except for PuO_2. For PuO_2, the unit doses reported above would generally be lower by approximately 25%. The exact difference is a function of the americium content, which has only one lung-clearance class. The next section provides values for both lung-clearance classes.

9.3.5.4 Summary and Conclusions. Enough information has been presented for safety analysts to characterize the PFP inventory on a mass-weighted average basis by the ^{240}Pu content. Table 9-44 gives the plutonium isotopic composition for each of these bins based on the NDA verification sampling for the past 8.5 yr. Table 9-45 provides the maximum consequences as a function of age (Crowe and Szempruch 1994). Any specific isotopic composition concern addressed in a safety analysis can use this information to define a source term.

In addition, the description of the PFP inventory was continued one step further. The seven bins were collapsed into two ranges, one for items with greater than 10% ^{240}Pu and the other for items with less than 10%. These ranges are represented by three values each for the inhalation doses, the mass-weighted average, maximum value and the 90th percentile as seen in Table 9-45. An item in the inventory need only be described as having more or less than 10% ^{240}Pu to have a maximum rem/gram inhalation dose specified.

Tables 9-46 and 9-47 summarize the considerations for various plutonium compounds. These table values are adjusted to account for aging, so from a time standpoint, these computed doses are always conservative (Crowe and Szempruch 1994).

Single items should be described by the appropriate 90th percentile value depending on the ^{240}Pu content (less than or greater than 10% ^{240}Pu) and the plutonium compound (Class W or Class Y). Because the > 10% 90th percentile unit dose is greater than the mass-weighted average from the > 19% bin (by approximately 40%), even the selection of items from the highest exposure bin should not, on the average, exceed the 90th percentile unit dose values.

It can be seen that it is appropriate to use of the 90th percentile data for individual items by examining the Radiological Risk Acceptance Guideline curve (The radiological Risk Acceptance Guideline curve is shown with additional annotation as Figure 9-33). Because only 10%, by mass, of the items have a dose consequence greater than the 90th percentile value, the probability of getting an item with a greater dose consequence than the 90th

percentile is by definition 1/10. When the greatest possible dose consequences are represented by the maximum values shown in Tables 9-46 and 9-47, the largest maximum to 90th percentile ratio is 2.1, coming from the bone-surface Class Y material in the less than 10% ^{240}Pu range. Point A in Figure 9-33 is a hypothetical calculated consequence using a 90th percentile dose value, Point B represents a consequence of 2.1 greater than Point A occurring at 1/10 the probability. Even in this extreme example, the slope of line A-B is not greater than the slope of the Radiological Risk Acceptance Guidelines curve at any point. Thus, the risk stays within the acceptable risk region at all times.

For situations in which multiple inventory items are needed to accumulate sufficient mass for use in a safety analyses (e.g., loading a glovebox to capacity), the weighted-average values are appropriate to use. The Central Limit Theorem in the field of statistics describes mathematically that the distribution of the average of a series of random samples from a given population, no matter what the original probability distribution, tends to be normally distributed with the mean of the averages equal to the mean of the parent population.

Given that the current inventory at PFP is the majority of reprocessed plutonium with > 10% ^{240}Pu in the United States, the data presented in tables have wide applicability and are universally valid within the following context:

- The values account for all plutonium compositions from the DOE ^{239}Pu production programs and for all commercially reprocessed power reactor plutonium to-date. Plutonium from the DOE ^{238}Pu-production programs are not covered by these values. There is significant confidence, based on the several thousand isotopic distributions examined, that any given item of plutonium would exhibit the statistical characteristics used to create the unit doses reported.

- The unit dose values account for current and potential future inventories of plutonium at the PFP, provided there is no concerted effort to selectively transfer large amounts (hundreds of thousands of grams) out of the inventory based on a criterion that results in lower dose materials being moved. This would result in shifting the 90th percentile numbers slightly upward. Transfers of such materials into the inventory would lower the values, which is conservative from a safety analysis perspective.

- The values are valid for plutonium of any age.

9.3.6 Dose Calculation

This section describes how $\overline{\chi}/Q'$ is used to estimate the dose from a release of radioactive materials.

The $\overline{\chi}/Q'$ refers to the concentration of airborne contamination. It is the ratio of contaminant concentration at a specific receptor location to contaminant release rate. The receptor of concern is normally defined as a

human having a standard breathing rate and metabolism. The standard man breathing rates are typically taken from ICRP (1975). Values are provided in Table 9-48.

The product of $\overline{\chi}/Q'$ and breathing rate is a unitless number representing the fraction of contaminant inhaled to contaminant released. Inhalation is by far the most significant, unavoidable, and likely pathway to human exposure. Although ingestion represents an additional theoretical pathway, the ingestion pathway can be avoided through interdiction of food products, if necessary, in the event of an accident. The ground-shine and plume-submersion pathways can, for all practical purposes, be ignored for releases of plutonium.

The dose from the inhalation of radioactive materials, plutonium in particular, can be calculated using the following formula:

$$D\ (rem) = Q\ (g) \times \frac{\overline{\chi}}{Q'}\ (s/m^3) \times R\ (m^3/s) \times C\ (rem/g)$$

where: Q = Quantity plutonium released
$\overline{\chi}/Q'$ = Atmospheric dispersion coefficient
R = Breathing rate
C = Gram plutonium to dose conversion factor.

The quantity released, Q, is specific to the accident scenario. It is a function of several factors, including the inventory at risk, dispersing energy available, release fraction, RF, and mitigation. It is essentially a source term represented in grams. The grams plutonium to dose conversion factor, C, is specific to the isotopic mixture and chemical compound under consideration. Conversion factors for both oxides (Class Y) and non-oxides (Class W) are provided in Section 9.3.5 for both the committed EDE and the maximum-organ committed dose. Thus, to calculate the 50-yrcommitted dose for a given release, one must determine the appropriate isotopic mixture of the plutonium, select the proper breathing rate, and apply the appropriate $\overline{\chi}/Q'$ from Section 9.3.4.

9.3.7 Dose Calculations - Highway 240

Report HNF-6493, *Additional Air Transport Factors of PFP*, documents calculations done to evaluate the impacts to receptors at Highway 240. These impacts are shown in Table 9-1 and in accordance with Hanford procedures are provided for information only. The same accident conditions and modeling assumptions were used to ensure consistency with the FSAR. The consequences were originally evaluated using GXQ Version 3.1D (WHC-SD-GN-SWD-30002, Rev. 0); however, this version is no longer available and, therefore, Version 3.1C of GXQ was used in these calculations. As can be seen in HNF-6493, with the exception of the fire release, Version 3.1C calculated X/Q's are the same as version 3.1D. The calculated X/Q' for the fire using Version 3.1C is approximately 3% greater (1.19×10^{-6} s/m^3 versus 1.16×10^{-6} s/m^3) than the X/Q' calculated using Version 3.1D. It can be concluded that Version 3.1C is

suitable to calculate X/Q's to determine consequences to a receptor located on Highway 240.

The nearest individual on Highway 240 is located 4,210 m in the WSW direction. For the purposes of these dose calculations, the highest X/Q for each scenario was selected. In all instances this X/Q corresponds to a different direction. Four release scenarios are evaluated; 1) elevated stack release, 2) fire or buoyant plume release, 3) seismic ground level release with building wake, and 4) seismic ground level release with no building wake.

The glovebox releases from the 291-Z stack were modeled as a simple elevated stack release. As in the PFP FSAR, no credit was taken for momentum rise or the large flow rate out the stack. The stack flow rate is 123 m3/s, the stack diameter is 4.1 m, and the receptor height is 2 m. The calculated X/Q determining offsite consequences is 5.73×10^{-6} s/m^3 and the calculated X/Q for determining consequences to the nearest individual located on Highway 240 is 1.35×10^{-5} s/m^3. Thus the calculated offsite dose consequences are multiplied by 2.36 to determine consequences to the individual located on Highway 240.

The seismic release was modeled differently for 234-5Z and 232-Z. The 234-5Z building is assumed to have numerous penetrations so that the MACCS building wake model applies. Building 234-5Z width is 46 m and height is 14 m. In addition, the effect of plume meander was included through the fifth power law with a duration of 1 hour. In contrast, the 232-Z building is assumed to be a point source at ground level with no building wake.

The calculated X/Q for a ground level release with building wake (234-5Z Building modeled consequences), is 1.01×10^{-5} s/m^3 and the calculated X/Q for determining consequences to the nearest individual located on Highway 240 is 3.93×10^{-5} s/m^3. Thus the calculated offsite dose consequences, for a ground level release with building wake, are multiplied by 3.89 to determine consequences to the individual located on Highway 240. The calculated X/Q for a ground level release with no building wake (232-Z Building modeled consequences), is 1.62×10^{-5} s/m^3 and the calculated X/Q for determining consequences to the nearest individual located on Highway 240 is 6.58×10^{-5} s/m^3. Thus the calculated offsite dose consequences, for a ground level release with no building wake, are multiplied by 4.06 to determine consequences to the individual located on Highway 240.

The fire release uses a buoyant plume model. In Version 3.1 of GXQ, plume rise was computed using the MACCS formulas and user input was simply the thermal emission rate of the stack, namely, 2.80×10^{6} cal/s. As before, the volumetric flow rate is 7.07 m3/s with a fire diameter of 3 m. Building wake was included with a building width of 10 m and a building height of 6.1 m. The calculated X/Q for a buoyant plume release (fire), is 1.16×10^{-6} s/m^3 and the calculated X/Q for determining consequences to the nearest individual located on Highway 240 is 1.74×10^{-6} s/m^3. Thus the calculated offsite dose consequences, for a buoyant plume release, are multiplied by 1.50 to determine consequences to the individual located on Highway 240.

9.4 RISK ACCEPTANCE GUIDELINES AND EVALUATION

9.4.1 Risk Acceptance Guidelines

The radiological and toxicological Risk Acceptance Guidelines are shown in Tables 9-49 and 9-50, respectively. These guidelines are to be applied as curves, as shown in Figures 9-34 and 9-35. For example, an event with a likelihood of 9×10^{-3}/yr that produces a potential EDE of 1 rem to the maximum offsite individual is not acceptable because it falls above the guideline in Figure 9-34, even though it lies within the stated range in Table 9-49.

The radiological Risk Acceptance Guidelines represents EDEs and corresponding organ dose equivalents from all pathways (inhalation, air submersion, ingestion, and direct exposure). Radiological doses reported in safety analyses should include the contributions from each pathway, and consideration should be given to the fact that action could be taken to control doses from ground contamination, ingestion, and water immersion if necessary. The Environmental Release Analysis Manual provides further guidance on this subject.

9.4.2 Bases for Risk Acceptance Guidelines

Tables 9-49 and 9-50 are based on the philosophy that higher probability events, because they theoretically could occur more often, should have more restrictive consequences guidelines than lower probability events. They are also based on the philosophy that offsite guidelines should be more restrictive than onsite guidelines. This philosophy is consistent with common practice within the nuclear industry (e.g., annual dose limits and radionuclide concentration guides).

ERPG values do not exist for all chemicals. In the event that there is no ERPG-1 concentration, and one cannot be developed by the Hanford Environmental Health Foundation(HEHF), the chemicals Threshold Limit Value - Time Weighted Average (TLV-TWA) should be used in the comparison. When comparing calculated concentrations to a TLV-TWA or ERPG, normalize the average concentration over a period of 8 h and 1 h, respectively, for comparison purposes.

9.4.2.1 Specific Basis for Radiological Guidelines. The 25 rem EDE ceiling for offsite individuals is well established in the nuclear industry as a siting criterion (DOE Order 6430.1A; Elder et al. 1986). The ceiling is also suggested as an offsite risk acceptance criterion for low probability events (Elder et al. 1986).

A 25-rem EDE has been applied as a Risk Acceptance Guideline for offsite consequences. It is recognized that consequences of any given accident may be higher onsite than offsite and the onsite Risk Acceptance Guideline has been set to four times the offsite guideline, or 100 rem EDE. The endpoint for the offsite guidelines is thus established at the point corresponding to an annual probability of 10^{-6} and a dose consequence of 25 rem EDE, or corresponding organ-dose equivalents (i.e., 75 rem to the lens of the eye and 250 rem to all

other organs, in accordance with DOE Order 5480.11, *Radiation Protection for Occupational Workers*, EDE, and organ-dose equivalent limit relationships). The endpoint for the onsite guidelines is similarly established at the point corresponding to an annual probability of 10^{-6} and a dose consequence of 100 rem EDE, or corresponding organ dose equivalents (i.e., 300 rem to the lens of the eye and 1,000 rem to all other organs).

The DOE Order 5400.5, *Radiation Protection of the Public and the Environment*, also specifies an annual limit of 0.1 EDE for continuous exposure of the public. Limits for events with an annual probability approaching one are set an order of magnitude lower, which provides an endpoint for the offsite guideline at an annual probability of one and 0.01 rem EDE, or corresponding organ dose equivalents.

The DOE Order 5480.11 specifies an annual limit of 5 rem EDE for occupational exposure. It is therefore conservative to apply this criterion to events with an annual probability of 10^{-2}. This provides a midpoint for the onsite guideline at an annual probability of 10^{-2} and 5 rem EDE, or corresponding organ dose equivalents. A limit of 1 rem EDE is established for events with an annual probability of occurrence of 0.1. The 1-rem-EDE limit is also applied to events with annual probabilities between 0.1 and 1.

All other dose guidelines are defined by lines on log-log graphs whose endpoints are the onsite or offsite dose guidelines addressed above.

9.4.2.2 Specific Basis for Toxicological Guidelines. The ERPGs (ERPG-1, -2, -3) values are intended as estimates of concentration ranges where there is a reasonable probability of adverse effects from exposure to the specific chemical. The adverse effects are described in the definitions for ERPG-1, ERPG-2 and ERPG-3 below:

> "The ERPG-1 is the maximum airborne concentration below which it is believed that nearly all individuals could be exposed for up the 1 h without experiencing other than mild transient adverse health effects or perceiving a clearly defined objectionable odor.
>
> The ERPG-2 is the maximum airborne concentration below which it is believed that nearly all individuals could be exposed for up to 1 h without experiencing or developing irreversible or other serious health effects or symptoms that could impair their abilities to take protective action.
>
> The ERPG-3 is the maximum airborne concentration below which it is believed that nearly all individuals could be exposed for up to 1 h without experiencing or developing life-threatening health effects." (AIHA 1990)

A TLV-TWA is the TWA concentration for a normal 8-h workday and a 40-h workweek, to which nearly all workers may be repeatedly exposed, day after day, without adverse effect. It is considered conservative to use the TLV-TWA as an acceptable offsite guideline for higher probability events.

9.4.3 Gram Equivalent of Dose Guidelines

This section converts dose guidelines to grams released. During the PHA the analyst needed to understand the significance of an event in order to know whether or not it should be forwarded for more complete analysis. The gram-equivalents were determined from the ratio between the unit doses given in Tables 9-46 and 47 and the Risk Acceptance Guidelines from Table 9-49 follows:

$$\frac{\text{Guide rem}}{\text{Dose rem}} = \text{Equivalent g}$$

The following example shows how the amount of plutonium that would just meet the criterion for EDE following a ground-level release to an onsite individual at a probability of 0.1 is calculated. From Table 9-49, note that the guide dose is 1 rem. From Table 9-46 the maximum unit inhalation dose for Class Y (2.3×10^{8} rem/g) is multiplied by the acute breathing rate from Table 9-48 (3.3×10^{-4} m^3/s) and by the onsite atmospheric dispersion coefficient for a point source ground level release from 232-Z from Table 9-39 (8.72×10^{-4} s/m^3). This result, the acute EDE to an onsite individual from a ground-level release of 1 g, Class Y, gives a dose of 66 rem. Therefore,

$$\frac{1.0 \text{ rem}}{66 \text{ rem}} \times 1 \text{ g} = 0.015 \text{ g}$$

The elements of Table 9-51 and 9-52 were constructed using this procedure.

9.4.4 Gram Release at Stack Alarm Level

The number of grams PuO_2 released at just the stack alarm level at a maximum stack flow for 1 h is calculated for comparison to the stack-release equivalents presented in Tables 9-51 and 9-52. The maximum stack flow recorded between 1979 and 1989 was 270,000 ft^3/min. The stack alarm limit is set at 2×10^{-12} Ci/m^3 of alpha-emitting isotope. From Tables 9-41 and 9-44 the total activity for 1 g of weighted-average, >10% ^{240}Pu inventory is 1.61 Ci. This information is combined as follows:

$$\frac{2 \times 10^{-12} \text{ Ci/m}^3}{1.61 \text{ Ci/g}} = 1.24 \times 10^{-12} \text{ g/m}^3$$

$$1.24 \times 10^{-12} \text{ g/m}^3 \times 2.83 \times 10^{-2} \text{ m}^3/\text{ft}^3 \times 2.7 \times 10^{5} \text{ ft}^3/\text{min} \times 60 \text{ min/h}$$

$$= 5.7 \times 10^{-7} \text{ g/h}$$

Therefore, the amount released during 1 h at the stack-alarm set point is a factor of 3.5×10^{4} lower than the limit value for the most limiting

stack-release event shown in Table 9-51, and a factor of 2.6×10^4 lower than the most limiting stack release event shown in Table 9-52.

9.4.5 Toxicological Risk Acceptance Guidelines for HNO_3.

The Risk Acceptance Guidelines are defined by the accepted ERPGs as provided by the HEHF. The specific concentration limits for the various frequency ranges are presented in Table 9-53 for HNO_3. The ERGP values define the endpoints and the interior points were calculated by interpolation.

Table 9-1. Summary of Accident Analysis Consequences. (4 sheets)

Section	Scenario	Postulated event	Calculated annual probability	Postulated dose consequences (rem)	Risk acceptance guidelines (rem)	Highway 240 Dose (rem)
9.2.1F	Flammable gas deflagration	Flammable gas deflagration resulting from: 1) slow leak of propane gas or 2) catastrophic failure of propane cylinder	Slow leak: 1.0 assumed Catastrophic Failure: Incredible (<1.0 E-06)	The slow leak event was found to have acceptable consequences even with an assumed probability of 1.0. For the event with a <1 E-06 probability, no consequence was calculated since the event is incredible.	The overpressure resulting from the deflagration is not large enough to breach any PFP wall panels.	N/A
9.2.2A	RMC/RMA Lines Fire	Fire in trash igniting RMC/RMA Lines and Adjacent rooms	10^{-4} to 10^{-6}	Onsite EDE = 1.2 E-02 Offsite EDE = 4.3 E-03 Onsite bone = 2.0 E-01 Offsite bone = 7.4 E-02	Onsite EDE: 25 Offsite EDE: 4 Onsite Bone: 250 Offsite Bone: 40	0.01
9.2.2B	Hydraulic oil fire, Room 231 234-52	Roof collapse due to failed structural members	Incredible (<1.0 E-06)	None calculated as probability <1.0 E-06 and low source term	Not applicable	N/A
9.2.2C	Not Used					
9.2.2D	Waste Drum Events	Vehicle crash with ensuing fire	<<1.0 E-02	Onsite EDE = 2.2 Offsite EDE = 0.04 Onsite Bone = 32.8 Offsite Bone = 0.64	(Probability = 1.0 E-02) Onsite EDE: 5 Offsite EDE: 0.5 Onsite Bone: 50 Offsite Bone: 5	0.06
		Mechanical Release	1.0 E-01	Onsite EDE = 0.12 Offsite EDE = 2 E-03 Onsite Bone = 2.2 Offsite Bone = 0.03	Onsite EDE: 1 Offsite EDE: 0.1 Onsite Bone: 10 Offsite Bone: 1.0	8 E-3
		Drum Explosion	<<1.0 E-02	Onsite EDE = 1.65 Offsite EDE = 0.02 Onsite Bone = 28.7 Offsite Bone = 0.38	(Probability = 1.0 E-02) Onsite EDE: 5 Offsite EDE: 0.5 Onsite Bone: 50 Offsite Bone: 5	0.08
9.2.3	Criticality	The generic criticality from Regulatory Guide 3.35 used	2.5 E-02	Ground release: Onsite EDE total = 0.73 Offsite EDE total = 0.053 Onsite thyroid = 2.4 Offsite thyroid = 1.6 Stack release: Onsite EDE total = 0.16 Offsite EDE total = 0.032 Onsite thyroid = 0.27 Offsite thyroid = 0.97	Onsite EDE: 2 Offsite EDE: 0.2 Onsite Thyroid: 20 Offsite Thyroid: 2 Onsite EDE: 2 Offsite EDE: 0.2 Onsite Thyroid: 20 Offsite Thyroid: 2	2.15 E-1 7.55 E-2

Table 9-1. Summary of Accident Analysis Consequences. (4 sheets)

Section	Scenario	Postulated event	Calculated annual probability	Postulated dose consequences (rem)	Risk acceptance guidelines (rem)	Highway 240 Dose (rem)
9.2.4[1]	Seismic Event[1]	no ventilation case	1.0 E-04	Onsite EDE = 17.71 Offsite EDE = 0.37 Onsite Bone = 256 Offsite Bone = 5.26	Onsite EDE: 25 Offsite EDE: 4 Onsite Bone: 250 Offsite Bone: 40	1.44
		ventilation case	1.0 E-04	Onsite EDE = 11.49 Offsite EDE = 2.53 Onsite Bone = 178 Offsite Bone = 38	Onsite EDE: 25 Offsite EDE: 4 Onsite Bone: 250 Offsite Bone: 40	5.97
		Small earthquake with release from Building 232-Z only	2.0 E-03	Onsite EDE = 4.57 Offsite EDE = 0.09 Onsite Bone = 73 Offsite Bone = 1.36	Onsite EDE: 8.5 Offsite EDE: 1.0 Onsite Bone: 85 Offsite Bone: 10	0.37
9.2.5	Strong wind and missile strike	Wind driven missile breaches transfer line at the bottom of the outside HNO_3 storage tank causing a large pool and release of HNO_3 vapors	<1.0 E-02	HNO_3 Onsite = 18 ppm HNO_3 Offsite = 0.29 ppm	HNO_3 Onsite: 19 ppm HNO_3 Offsite: 3.9 ppm	0.92 ppm
9.2.7	Aircraft accident	Airplane crash into building	Incredible (<1.0 E-06)	Not calculated; probability <1.0 E-06	N/A	N/A
9.2.8	Toxic chemical release	7000 gal outside HNO_3 storage tank failure caused by seismic event; HNO_3 vapor release from spilled solution surface	1.0 E-04	Onsite: 1.8 ppm Offsite: 0.032 ppm	Onsite 24 ppm Offsite 7.7 ppm	0.13 ppm
9.2.9	Accidents for the Plutonium-Bearing Solution Stabilization Process using the Production VDC					
9.2.9.1	Flammable Gas Deflagration in the VDC	Injection of organic material into the VDC	To be developed before authorization of Production VDC operations			
9.2.9.2	Glovebox HC-230C-2 Fire	Fire due to failure to control combustibles in glovebox which contact hot surfaces of the calciner	To be developed before authorization of Production VDC operations			

Table 9-1. Summary of Accident Analysis Consequences. (4 sheets)

Section	Scenario	Postulated event	Calculated annual probability	Postulated dose consequences (rem)	Risk acceptance guidelines (rem)	Highway 240 Dose (rem)
9.2.9.3	Compressed Air Cylinder Failure	Hnadling accident results in supply valve being sheared off	1.0 E-2 to 1.0 E-4	Negligible	(Probability = 1.0 E-2) Onsite EDE = 5 Offsite EDE = 0.5 Onsite Bone = 50 Offsite Bone = 5	N/A
9.2.9.4	Glovebox HC-230C-2 Seismic Release	Seismic event	1.0 E-04	Onsite EDE = 0.67 rem Offsite EDE = 0.24 rem Onsite Bone = 10.5 rem Offsite Bone = 3.7 rem	See 9.2.4	0.57
9.2.9.5	Changes to RMC/RMA Lines Fire Analysis from Glovebox HC-230C-2	Spread of RMC Line fire down HC-2 and HC-3 conveyors to Glovebox HC-230C-2	NA Airlock between HC-2 and HC-3 prevents spread of fire	NA Airlock prevents spread of fire to Glovebox HC-230C-2	----	N/A
9.2.10	Accidents for Reactive Plutonium-Bearing Material Stabilization Operations in Gloveboxes HC-21C and HA-21I.					
9.2.10.1	Hydrogen Deflagration in Glovebox HC-21A from Opening Pressurized Containers	Deflagration	1.0 E-02 to 1.0 E-04	Negligible	NA	N/A
9.2.10.2	Deflagration in Glovebox HC-21C or HA-21I	Deflagration	1.0 E-04 to 1.0 E-06 for PE or PC 1.0 E-02 to 1.0 E-04 for PVC and PS	Onsite EDE 2.1 x 10^{-3} Offsite EDE 7.4 x 10^{-4} Onsite Bone 0.03 Offsite Bone 0.01	(Probability 1.0 E-02) Onsite EDE = 5.0 Offsite EDE = 0.5 Onsite Bone = 50 Offsite Bone = 5	1.7 E-03
9.2.10.3	Seismically Induced Deflagration in Glovebox HC-21C or HA-21I	Deflagration Flash Fire	Not credible 1.0 E-04 to 1.0 E-06	NA Negligible	NA	N/A
9.2.10.4	Glovebox HC-21C or HA-21I Fire	Fire	Not credible	Onsite EDE 2.2 E-04 Offsite EDE 7.7 E-05 Onsite Bone 3.5 E-03 Offsite Bone 1.2 E-03 Also included in Section 9.2.2A.	See 9.2.2A	1.82 E-4
9.2.10.5	Seismically Induced Fire in Glovebox HC-21C and HA-21I	Fire	1.0 E-04	See Section 9.2.4.2.12.F Included in total for seismic event, Section 9.2.4.	See Section 9.2.4	0.31

Table 9-1. Summary of Accident Analysis Consequences. (4 sheets)

Section	Scenario	Postulated event	Calculated annual probability	Postulated dose consequences (rem)	Risk acceptance guidelines (rem)	Highway 240 Dose (rem)
9.2.10.6	Changes to the RMC/RMA Lines Fire Analysis from Gloveboxes HC-21A, HC-21C, and HA-21I	All changes have been incorporated into the RMC/RMA Lines fire analysis in Section 9.2.2A.				
9.2.11	Accidents for the Laboratory Prototype Calciner	Refer to the Laboratory Prototype Calciner addendum to this FSAR for information on analyzed accidents (This process is not currently authorized.)				
9.2.12	Accidents for the Magnesium Hydroxide Precipitation Process	Refer to the Magnesium Hydroxide Precipitation Process addendum (Carson 2000) to this FSAR for information on analyzed accidents				
9.2.13	Accidents for the Bagless Transfer System	Refer to the calculation notes for the Bagless Transfer System (FH 2000) for information on analyzed accidents				

EDE = Effective dose equivalent.
LPG = Liquid propane gas.
PFP = Plutonium Finishing Plant.
RMC = Remote Mechanical C.

Note: 1. The consequences for the seismic event exclude the seismic analysis related to the laboratory Prototype Calciner shown in the Laboratory Prototype Calciner addendum to this FSAR since the calciner is not authorized for operation. Similarly, the seismic event consequences do not include the seismic releases associated with the Production Vertical Denitration Calciner since it is not authorized for operation.

Table 9-2. Functions Excluded from Analysis.

Function	Building/glovebox, or room
Electrolytic metal dissolution (Discontinued Operation)	236-Z/MT-3
Incinerator ash calcination (Discontinued Operation)	234-5Z/HA-40F
Incinerator ash dissolution (Discontinued Operation)	234-5Z/HC-46F
Polycube calcination (Future Operation)	236-Z/MT-4
RMA Line button and oxide production gloveboxes	234-5Z/Rooms 235-A1, 2, and 3 (Included for Seismic)
Hydrogen Fluorination (Discontinued Operation)	234-5Z
Laboratory Concentration (Discontinued Operation)	234-5Z
Product Concentration (Discontinued Operation)	236-Z
Filtrate Evaporation (Discontinued Operation)	236-Z
Slag and Crucible Operation (Discontinued Operation)	236-Z

Table 9-3. Synopsis, Abnormal Events. (2 sheets)

Number	Title	Synopsis
9.1.1	Radioisotope-Bearing Liquid Spills	A spill involving a 10-L bottle of plutonium solution is used as a bounding event. Other spills with lower combinations of volume, energy, and concentration give a smaller release. The event is shown to release 0.16 g Pu into the building. Such a release is well below the criteria for a probability one event with the presence of HEPA filters (9.4.3).
9.1.2	Radioisotope-Bearing Pressurized Liquid Container	A pressurized 10-L container is assumed to release half the contents to a room. The airborne release is 0.08 g Pu. Such a release is well below the criteria for a probability one event with HEPA filters (9.4.3).
9.1.3	Radioisotope-Bearing Powder Spills	A powder spill is assumed that requires an incredible number of errors to achieve. The resulting 3 g airborne release is just slightly greater than needed to just equal the limit amount for a probability one stack release event even without HEPA filters (9.4.3).
9.1.4	Radioisotope-Bearing Pressurized Powder Container	Plutonium, when stored in closed containers, has the potential for release to a room when driven by internal gas pressure. Chemical reactions or radiolysis of hydrogenous material can develop such gases. The analysis shows storage room air concentrations to be on the order of 2.5×10^{-10} µCi/mL. This is far lower than would be significant as a stack release.
9.1.5	Stack Release Resulting from Filter Changes	During exchange of final-stage HEPA filters there is a potential for release of plutonium if a filter is handled roughly. This section shows that such an event would have a low consequence.
9.1.7	Ventilation System Upsets (introduction)	Properly functioning ventilation systems provide a vital part of the equipment that makes it possible to handle plutonium safely. The following subsections detail the most important of the failure modes. In no case does upset directly result in a release of radioactive materials. Such events, in conjunction with loss of containment events, could, however, exacerbate the spread of contamination within a building. In most events within Buildings 234-5Z, 242-Z, and 236-Z, no automatic recovery systems would be available. However, the normal operator response in difficult situations is to automatically shut off the electric supply fans, place all dampers in their fail positions, activate either emergency exhaust fan EM-1 or EM-2, and evacuate zone 3 ventilation areas.
9.1.7A	Excessive Building Pressurization-234-5Z	Excessive building pressurization can occur from failure of control dampers. Supply dampers B, C, D, and E each feed air to rooms and corridors within the radiation zones of the 234-5Z Building. A number of separate scenarios are presented under this heading. Pressure differentials of up to 1 in. w.g. between adjacent rooms will occur but gloveboxes remain negative to room atmospheres.
9.1.7B	Excessive Pressurization of 236-Z Building	The 236-Z Building receives air from 234-5Z Building through Supply Damper F. Failure to the open position can cause pressurization of up to 0.5 in. w.g. over normal. As with the damper failures within the 234-5Z Building, the process cell and gloveboxes remain negative to the rooms. No radioactive materials escape from the building.
9.1.7C	Excessive Building Pressurization, 2736-ZB Building	A ventilation control failure could lead to a pressurization of ~2 in. w.g. Such a pressurization is not expected to cause a breach of the building or release of material from the single glovebox located in the building.
9.1.7D	Excessive Building Pressurization, 2736-Z Building	A pressurization of the 2736-Z Building is not expected to cause any release of radioactive material into the building or to the outside as all materials stored in this facility are double or triple canned in metal cans or drums. The building could be pressurized to 2 in. w.g.
9.1.7E	Excessive Building Pressurization, 241-Z Building	No building pressurization would happen as there are no supply fans.

Table 9-3. Synopsis, Abnormal Events. (2 sheets)

9.1.7F	Excessive Building Depressurization, 234-5Z Building	Significant depressurization of the 234-5Z Building is prevented by a pair of gravity-operated supply relief dampers on the supply plenum and by control on the exhaust fans.
	236-Z Building	Accidental closure of Supply Damper F could result in depressurization to -15.2 cm (-6 in.) w.g. Such a depressurization is approximately equal to the 14.7 cm (5.8 in.) w.g. live load of the roof. During such an event the pressure inside and outside gloveboxes would be the same but there would be no force to release radioactive materials to the rooms. There would, of course, be no release to the environment.
	2736-ZB Building	No credible scenario was found.
	2736-Z Building	An actual event once depressurized the building to ≈7.6 cm (≈3 in.) w.g. with no adverse effect.
	241-Z Building	There is no way to significantly depressurize this building.
9.1.8	Loss of Ventilation	This section contains a number of events that result from loss of ventilation--none of which result in a significant spread of plutonium. The topics include air reversals due to convection and weather changes, radiolytic hydrogen accumulation, and spread of contamination in vaults due to container rupture from heat rise.
9.1.9	Glovebox Glove Breach	The most vulnerable part of the plutonium confinement system is the glove system. This section discusses various release mechanisms and concludes that the hazard to operating personnel is not great.
9.1.10.1	Pressurized Production Vertical Denitration Calciner	The VDC is assumed to pressurize due to a loss of vacuum. The pressurized calciner is estimated to release 127 mg of Pu to the HC-230C-2 glovebox atmosphere. Two testable stages of HEPA filtration within the E-4 ventilation system limit the release out the exhaust stack to an insignificant value. (A third testable stage of HEPA filters exists in the exhaust system but was not credited in the analysis).
9.1.11	Reactive Material Thermal Stabilization Process	No unique abnormal operations were identified that were associated with operation of the thermal stabilization process.
9.1.12	Laboratory Prototype Calciner	No unique abnormal operations were identified that were associated with operation of the Laboratory Prototype Calciner.
9.1.13	Loss of Filtration	Loss of filtration events were analyzed for Buildings 232-Z and 241-Z to determine impacts. Based on annual stack emission data, Loss of filtration is at or near current emissions.
9.1.14	Magnesium Hydroxide Precipitation Process	See the Magnesium Hydroxide Precipitation Process addendum (Carson 2000) to this FSAR for identification and evaluation of abnormal operations.
9.1.15	Bagless Transfer System (BTS)	See the calculation notes (FH 2000) for the BTS for identification and evaluation of abnormal operations.

Table 9-4. Room Ventilation Zones.

Zone	Ventilation system	Damper	Set pressure (in. w.g.)
1	S-1	A	+0.14 to +0.16
3*	S-3*	B	-0.14 to -0.17
3	S-3	C	-0.14 to -0.17
3A	S-3A	D	-0.11 to -0.14
3B	S-3B	E	-0.03 to -0.10

*Note that zone 3 includes those rooms formerly balanced as zone 2.

Table 9-18. Plutonium Finishing Plant TRU Mixed Waste Drum Summary.

Time span	Waste drums (55 gal)		
	1978 to 1981*	1982 to 1985*	1986 to 1988*
Total number of containers	4,945	5,258	1,212
Average TRU (g)	21.0	10.6	28.2
Average % combustible	79	85	81

*Based on data presented in Table 4-37 in Anderson et al. (1990) covering production from 1985 to 1988. Historically, the average weight of a 55-gal TRU waste drum was 175 lb (79.4 kg) (Anderson et al. 1990). Currently the maximum weight, without prior approval of PFP management, for a CH-TRU waste package is 1,000 lb (454 kg)/drum (WHC 1993).

Table 9-19. Atmospheric Dispersion Coefficients for Onsite and Site Boundary Maximum Individuals.

Accident Scenario		$\bar{\chi}/Q'_3$ (s/m^3)	Atmospheric Condition
Onsite	Waste Drum Fire (950 m ESE)	5.98×10^{-5}	D @ 9.80 m/s
	Waste Drum Rupture (450 m WNW)	1.22×10^{-3}	G @ 4.70 m/s
Site Boundary	Waste Drum Fire (17,400 m NNW)	1.16×10^{-6}	G @ 2.65 m/s
	Waste Drum Rupture (12,500 m W)	1.62×10^{-5}	G @ 2.65 m/s

Table 9-20. Risk Factors for Potential Accidents for Plutonium Storage Outside Plutonium Finishing Plant.

Accident	Annual frequency	Onsite (rem)		Offsite (rem)	
		EDE * (limit)*	Bone * (limit)*	EDE * (limit)*	Bone * (limit)*
Fire	Much less than 10^{-2}	2.2 (5)	32.8 (50)	0.04 (0.5)	0.64 (5)
Mechanical	10^{-1}	0.12 (1)	2.2 (10)	0.002 (0.1)	0.03 (1.0)
Explosion	Much less than 10^{-2}	1.65 (5)	28.7 (50)	0.02 (0.5)	0.38 (5)

*limits based on annual frequency as described in Section 9.4.

Table 9-25. Criticality Prevention Specification (CPS) Total Plutonium Limits and Seismic Qualification Status of Plutonium Finishing Plant Facilities. (4 sheets) (See Note 3)

Glovebox/room	Room	Building	Maximum plutonium allowed (g) per CPS	Seismic Qualification
Glovebox (repackaging glovebox)	636	2736-ZB	20,000	YES

NOTES: 1. See Table 9-26 for additional limits.

2. This limit does not include containers that may be on the conveyer. Assumed time spent on conveyer is negligible.

3. Does not include the gloveboxes that comprise the Magnesium Hydroxide Precipitation Process or Bagless Transfer System. The inventories are in Carson (2000) and FH (2000), respectively.

Table 9-26. Maximum Dispersible Plutonium Quantities Considered in Accident Analysis.

ROOM/GLOVEBOX	TOTAL DISPERSIBLE PU ALLOWED	COMMENTS
Analytical Laboratory All Gloveboxes and Hoods in Rooms 131, 134, 135, 136, 137, 139, 143, 144, 145, 146, 148, 152, 153, 154, 155, 156, and 157, and Plutonium Process Support Laboratory (PPSL) All Gloveboxes and Hoods in Rooms 179, 180, 183, 187, and 188, and Standards Laboratory All Gloveboxes, Hoods and Storage Cabinets in Rooms 221-C, 221-D, and 221-E	12,450 g Total for all rooms, of which no more than 5,250 g has ^{240}Pu greater than 10%.	The limit applies to the sum of all DISPERSIBLE plutonium quantities in the three laboratory areas combined.
INACTIVE Gloveboxes (in any room)	Introduction of Plutonium containers is prohibited. Residual quantities are allowed. See Criticality Prevention Specification CPS-Z-165-80010 for general limits for inactive gloveboxes and hoods.	Residual quantities have been included in the accident analyses.
Room 235B: Glovebox HA-19	0 g	Only polystyrene cube storage permitted.

Table 9-27. Plutonium Reclamation Facility Solvent Extraction--List of Potential Seismically Induced Accidents. (2 sheets)

Accident	Comment
Criticality	Considered in the bottom of the north end of the W glovebox (location of the criticality drain) as a result of the mixing of concentrated plutonium solution from concentrator failure with other solutions coupled with the assumed pre-existing failure of the 4-in.-dia. criticality drain screen resulting in a plugging of the drain.
$Na2CO_3$ and HNO_3 Reaction	The Na2CO3 is used in the CX column. If this line fails and the valve spuriously opens and HNO_3 lines fail, then the Na2CO3 can mix with the HNO_3 resulting in mass and energy release into the glovebox.
Hydroxylamine and HNO^3 Reaction	If hydroxylamine and HNO_3 are mixed and boiled, when the acid reaches about 6M the hydroxylamine decomposes rapidly. This is not seismically induced as there is no continuous heat source in Solvent Extraction. It is not considered credible for the heat from the criticality or the $Na2CO3$-HNO_3 reaction to boil this mixture down to the point where it will vigorously react.
Red oil explosion	This accident is not possible in solvent extraction due to a seismic event as it requires too many very specific equipment failures as a result of the seismic event.
Pipe or tank failure in canyon	Possible.
Pipe or tank failure in glovebox	Possible.
Overflow of various solution to tanks 51 and 52	Overflows are possible as a result of line breaks or the failure of pumps to shut off.
NaOH to tank may cause a backflow	The TK-17 and TK-18 provide the feed stream CAF. If the chemical addition valve opens (seismically induced valve circuit, etc.), NaOH will be added to the tank and react with the HNO_3. This reaction could also occur in the glovebox.
Red oil explosion in non-heat tanks	Not possible. It is possible to get an organic and HNO_3 mixture in these tanks but since the tanks are open any heat source (like a fire) will either burn off the organic or boil the solution.
Failure of cooling water jackets	While this is possible the consequences are quite small. The cooling water is recirculated in a closed-loop system. Components of the system are geometrically favorable for criticality safety. The cooling water jackets are outside the tank (Gibson 1989).
Failure of the air pulser	Failure of the air pulser can result in a blowback of aerosol if an instrument line is broken as well. The flow may not be very large as the total airflow will be split between the ruptured line and the vent.
Failure of the lines in the "Pipe Chase" outside the CA and CC column glovebox	A number of piping lines are in an enclosed vertical pipe chase outside the CA and CC column glovebox. These lines include column pulse legs, CCP stream, CAIS stream, CAX stream, CCDP stream, and CUX stream. The CCDP, CCP, and CAIS streams are moderately concentrated aqueous plutonium. The CAW stream is an aqueous waste stream, the CUX and CAX contain no plutonium. Failure of these lines could result in the pumping of plutonium solution into the atmosphere of the fourth floor.
Failure of CAS or CCX stream (no flow)	There are a number of these streams within the Solvent Extraction system whose failure may result in plutonium carryover, or column flood, or precipitation. The tanks are geometrically favorable with respect to criticality. There are no energetic chemical reactions which may occur under these conditions. There is only "gummed up" columns. There is no red oil explosion because the pump in the storage tank upstream of the concentrator must be manually actuated and the valves manually aligned to direct solution to the concentrator, the stream line must also become unregulated.

Table 9-27. Plutonium Reclamation Facility Solvent Extraction--List of Potential Seismically Induced Accidents. (2 sheets)

Accident	Comment
Transfer line failure outside of the column glovebox	None.
Failure of drain lines or pipes between the second floor glovebox and the first floor glovebox or between the first floor glovebox and the floor	None.
Reaction of Hydroxylamine nitrate with HNO_3	If the CCX flowrate increases, there is excessive carryover of HN to the CAIS pump tank (same is true if there is low plutonium inventory in the CC column). Concentrated HNO_3 is added to the CAIS tank to keep the molarity high. The reaction between HN and HNO_3 is exothermic and produces NO_2 gas. The CAIS tank is cooled to prevent pressurization. If the cooling fails, the process is upset so CCX flow is increased and CCF flow is decreased then there could be a reaction in TK-36.
Pump MOP-120 discharge line fails or pump MOP-26 CAM pump CAIS out PPCW if line in cooling jacket fails	None.
Pu-HNO_3 solutions generate H_2 which can accumulate if not swept away by ventilation	None.

Table 9-28. Plexiglas™ Panels in Gloveboxes.

Glovebox	Location of Plexiglas™ panels	Approximate percentage of boxes that are Plexiglas™
HC-9B	North side--Bottom third and one-half of top third	15
HC-10	All	100
HC-11	All	100
HC-12S	None	0
HC-13MD	West side (covered by leaded glass)	25
HC-15A, -B, -C	East and west side (covered by leaded glass)	25
HC-16	None	0
HC-17	One-third of south, east, and west side	40
HC-18BS	None	0
HC-1	Sections of small panel interspersed between exam panels on north and south side in room 228-A, on south side only in room 228-B, and on the south side only in room 228-C	20
HC-7	Middle third of south side, all of north side	25

*Most of the top panels (except for HC-9B) are Plexiglas™; this percentage is not included. Plexiglas™ is flammable; its replacement, polycarbonate (Lexan™), is not.

Table 9-29. Best Estimate Values and Uncertainties of Return Period for Earthquake Levels.

"g" Value	Best estimate (yr)	Span of the standard deviations (yr)
0.10	500	300 to 1,700
0.15	3,000	900 to 10,000
0.20	10,000	2,500 to 50,000*
0.25	30,000	6,000 to 120,000*

Source: Coats (1984).
*Values over 10,000 are extrapolated.

Table 9-30. Chemical Storage, 234-5Z, 2nd Floor Chemicals, Amounts and Rooms.

Material	Amount	Room
Activated charcoal	150 lbs	338
Portland cement	100 lbs	338
Sodium carbonate	30 lbs	338

Total into Facilities		15.56[1]		

Notes: 1. The release values for the laboratoriesexclude the Laboratory Prototype Calciner in Room 188 of the PPSL since the calciner is not currently authorized for operation.

2. Denotes solution.

3. The releases from the Magnesium Hydroxide Precipitation Process gloveboxes, HC-230C-3 and HC-230C-4, and the Bagless Transfer System glovebox, HA-53BTS, are not shown in this table. See Sections 9.2.4.10 and 9.2.4.11 for releases from these gloveboxes.

Table 9-32. "No Ventilation Case" Radiological Consequences For Seismic Event: 1×10^{-4} Annual Probability

Facility	Release (g Pu)	Onsite dose (rem)		Offsite dose (rem)	
		EDE	Organ	EDE	Organ
PFP[1]	1.05	7.36	98	0.16	2.08
Building 232-Z	0.20	1.61	18	0.03	0.34
Building 241-Z	0.10	2.96	55	0.06	1.02
Bagless Transfer System Glovebox HA-53BTS	0	0	0	0	0
Magnesium Hydroxide Precipitation Process Gloveboxes HC-230C-3 and HC-230C-4	0	0	0	0	0
Seismic Initiated Fire in Gloveboxes HA-21I and HC-21C	0.42	5.78	85	0.12	1.82
Total	1.77	17.71	256	0.37	5.26
Risk Acceptance Guidelines		25	250	4	40

Note: 1. Includes releases originating from 234-5Z, 2736-Z, 2736-ZA, 2736-ZB, 242-Z, and 291-Z.

2. Values shown represent additional dose contributions resulting from a seismically initiated fire in Gloveboxes HA-21I and HC-21C as shown in Sections 9.2.4.10 and 9.2.4.11, respectively. Releases from Gloveboxes HA-21I and HC-21C due to seismic vibratory motion and assumed glovebox collapse are included in the row labeled "PFP". In the "no ventilation case", the value in row "PFP" is 0 since there are no releases from the RMC and RMA areas where these gloveboxes are located.

Table 9-33. "Ventilation Case" Radiological Consequences For Seismic Event: 1×10^{-4} Annual Probability.

Facility	Release (g Pu)	Onsite dose (rem)		Offsite dose (rem)	
		EDE	Organ	EDE	Organ

Table 9-54. Effect of Production Vertical Denitration Calciner Operations on Prior PFP Abnormal Occurrence and Accident Analyses (4 sheets)

PFP FSAR Section	PFP Abnormal Occurrence or Accident Analysis	Effect on Current Analysis Posed by Calciner Operations	Comments
Abnormal Operations			
9.1.1	Radioisotope-Bearing Liquid Spills	**No effect.** Analysis generically covers spills of plutonium nitrate solution within the facility. The analysis adequately covers potential spills of plutonium nitrate in the load in/load out area (Glovebox HC-227S and Hood HC-227T) and within Glovebox HC-230C-2.	Accident scenario analyzed is a 10-L of plutonium nitrate from a height of 3 m. Analysis credits building ventilation system and a single stage of HEPA filtration with mitigating the release to the atmosphere.
9.1.2	Radioisotope-Bearing Pressurized Liquid Container	**No effect.** Analysis adequately covers pressurized releases from PR cans and polybottles in the LI/LO area (Glovebox HC-227S and Hood HC-227T).	Analysis postulates that 5 L of solution are ejected upon depressurization when opening container; splatter release fraction is for 3 m fall. E-3 ventilation system and single stage HEPA filter is credited with limiting release to the atmosphere.
9.1.3	Radioisotope-Bearing Powder Spills	**No effect.** Analysis covers PuO_2 spills outside of gloveboxes. Analysis adequately covers potential spills of powder inside or outside the product handling glovebox HC-21A.	1 kg powder spill is assumed to occur from height of 3 m, releasing 1.2 g. E-4 and E-3 ventilation systems and single stage HEPA filtration credited with limiting release to atmosphere.
9.1.4	Radioisotope-Bearing Pressurized Powder Container	**No effect.** Analysis covers, generically, pressurized powder releases from cans in gloveboxes, vaults or rooms. Improper calciner operation has the potential to produce insufficiently stabilized PuO_2, with potential canister ruptures during handling or NDA testing in the 2736-ZB Building or potential canister ruptures in the storage vaults in the 2736-Z Building. Ruptured canister releases are considered to be adequately represented by the pressurized powder release evaluated in Section 9.1.4.	Analysis is based on historical facility airborne contamination levels measured following off-normal events. Single stage HEPA filter is credited with limiting release to the atmosphere.
9.1.5	Stack Release Resulting from Filter Changes	**No effect.** Second stage filter source term is insignificantly effected by vertical denitration calciner operations. Changes to analysis not required.	Analysis assumes filter is dropped containing twice the contamination levels ever measured on the secondary filters.
9.1.6	Overpressure of Remote Mechanical C Line Pressure Vessel	**No effect.** The RMC Line pressure vessel is no longer used. Accident no longer relevant.	
9.1.7A	Excessive Building Pressurization–234-5Z	**No significant effect.** Analysis presents qualitative argument that the consequences of building pressurization would be low because the structure remains intact and multiple failures would have to occur for a significant quantity of radiological material to be released from Zone 4 areas into Zone 3 areas.	Potential source term added by calciner operations is small in comparison to the total source term in the plant.
9.1.7B	Excessive Pressurization of 236-Z Building	**No effect.** Calciner operations not relevant to 236-Z.	

Table 9-54. Effect of Production Vertical Denitration Calciner Operations on Prior PFP Abnormal Occurrence and Accident Analyses (4 sheets)

PFP FSAR Section	PFP Abnormal Occurrence or Accident Analysis	Effect on Current Analysis Posed by Calciner Operations	Comments
9.1.7C	Excessive Building Pressurization 2736-ZB Building	**No effect.** The analysis concludes that the building pressurization does not result in a significant release to the environment because the building has no significant levels of contamination and the building structure is not compromised by the overpressure.	
9.1.7D	Excessive Building Pressurization 2736-Z Building	**No effect.** The analysis concludes that building pressurization would not cause the storage packages to rupture or the vault structure to be compromised. The analysis concludes there is no loose radiological material stored in the vaults. Storage of convenience cans filled with stabilized PuO_2 from the VDC presents no new hazards to the storage vaults.	
9.1.7E	Excessive Building Pressurization, 241-Z Building	**No effect.** Calciner operations not relevant to 241-Z.	
9.1.7F	Building Depressurization--All Plutonium Finishing Plant Operations	**No effect.** The analysis in Section 9.1.7F concludes that depressurization of Building 234-5Z will not result in structural failures. The analysis also concludes that the RMC line pressure will remain more negative than room pressure should the building depressurize due to dry air supply regulating valve. Based on the conclusions of the analysis in Section 9.1.7F, the glovebox containing the vertical denitration calciner (Glovebox HC-230C-2) will not contribute to an environmental release.	Any contamination spread from the calciner glovebox (Glovebox HC-230C-2) to the 230C room would pass through the E-3 HEPA filters before discharge to the atmosphere.
9.1.8	Loss of Ventilation	**No significant effect.** An air flow reversal from the exhaust stack is concluded to only result in minor contamination spread from Zone 4 to Zone 3 areas. The plutonium inventory in Glovebox HC-230C-2 is small compared to total inventory in all the gloveboxes in the plant.	
9.1.9	Glovebox Glove Breach	**No effect.** Glovebox glove breach analysis is representative of potential glove breach accident in HC-230C-2.	
Accidents			
9.2.1C	Not Used	**No effect.**	
9.2.1F	Flammable Gas Explosion	**No effect.** The risk associated with flammable gases in PFP is determined to be acceptable in Section 9.2.1F based on the implementation of specific controls on gas bottle purchase, storage and use. Bottled flammable gases are not used in calciner operations.	

Table 9-54. Effect of Production Vertical Denitration Calciner Operations on Prior PFP Abnormal Occurrence and Accident Analyses (4 sheets)

PFP FSAR Section	PFP Abnormal Occurrence or Accident Analysis	Effect on Current Analysis Posed by Calciner Operations	Comments
9.2.2A	Mechanical C Line Fire	**Additional source term potential.** Glovebox HC-230C-2 is located at the west end of the RMC line. The plastic panels in the HC-2 and HC-3 conveyor could allow the RMC line fire to propagate to Glovebox HC-230C-2. Pu material in Glovebox HC-230C-2 could add to the release in a seismic event.	See Section 9.2.9.5.
9.2.2B	Hydraulic Oil fire in Room 321	**No effect.** VDC operations do not effect the likelihood or consequences of a hydraulic fire on the third floor of the facility.	
9.2.2C	Not Used	**No effect.**	
9.2.2D	Waste Drum Fire	**No effect.** Calciner operations not relevant to waste drum accidents.	
9.2.3	Criticality	**No effect.** Glovebox HC-230C-2 handles greater than a critical mass of Pu at any given time. The HC-230C-2 glovebox and vessel supports are seismically qualified, the glovebox is equipped with a criticality drain, and the glovebox vessels are geometrically favorable. These factors preclude criticalities in Glovebox HC-230C-2. In the extremely unlikely event a criticality occurs in Glovebox HC-230C-2, the criticality analysis in Section 9.2.3 is adequately representative. No changes are required to Section 9.2.3 as a result of calciner operations.	
9.2.4	Seismic Event	**Additional source term potential.** The radiological inventory in Glovebox HC-230C-2 adds to the potential source term in the seismic event due to the potential for calciner pressurization and vessel ruptures.	See revisions to the seismic analysis in Section 9.2.4 and seismic delta analysis in Section 9.2.9.4. The HC-230C-2 Glovebox structure is qualified to withstand the DBE. The interconnecting conveyor glovebox and exhaust ductwork are not qualified for the DBE, providing potential leakage paths to Zone 3 for particulates made airborne inside the glovebox. Vessel supports inside Glovebox HC-230C-2 are qualified for only the UBC level earthquake.
9.2.5	Strong Wind	**No effect.** The 234-5Z Building is shown in the analysis to survive the design basis wind. No releases from the RMC Line area are postulated. Calciner operations do not affect the Strong Wind accident analysis.	

Table 9-54. Effect of Production Vertical Denitration Calciner Operations on Prior PFP Abnormal Occurrence and Accident Analyses (4 sheets)

PFP FSAR Section	PFP Abnormal Occurrence or Accident Analysis	Effect on Current Analysis Posed by Calciner Operations	Comments
9.2.6	Flood	**No effect.** External floods are not identified as a safety issue relative to the RMC line in the accident analysis. Water intrusion into gloveboxes as a result of internal floods is a contingency in criticality-control documentation. Like the other RMC Line Gloveboxes, HC-230C-2 is equipped with a criticality drain. Worst-case consequence of internal flooding of HC-230C-2 is bounded by the criticality analysis in Section 9.2.3.	
9.2.7	Aircraft Accident	**No effect.** Aircraft impacts into the PFP facility are shown in the analysis to be incredible given flight restrictions prohibit helicopter operation in proximity to the PFP.	
9.2.8	Toxic Chemical Release	**No effect.** The postulated accident in Section 9.2.8 (failure of the 7000 gal outside HNO_3 storage tank) bounds potential NO_x or nitric acid vapor releases through the plant vacuum system caused by calciner or scrubber upsets within Glovebox HC-230C-2. The accident in Section 9.2.8 also bounds potential accidents involving the nitric acid or NaOH supplies to the VDC process.

SYSTEM DESCRIPTION

Air flow in the facility will be controlled to flow from the less contaminated areas to the more contaminated areas. The facility is divided into the following zones:

Zone	Reference Point	Pressure	Symbol
I	Repackaging Room	(-)1.2 in WG (Glovebox) (-)0.5 in WG (Airlock)	
II	Atmosphere	(-)0.25 in WG	
III	Atmosphere	(-)0.10 in WG	
IV	Atmosphere	(+)0.05 in WG	

ZONE PRESSURE CONTROL

Zone I glovebox pressure is controlled, during normal operation conditions, by manually setting air supply flow rate to the glovebox and modulating the exhaust air flow. PX-4 senses glovebox pressure with respect to the repackaging room, sends a signal to DPC-4 which compares the signal to the set point, (-)1.2 in WG, and modulates D-58 to maintain glovebox pressure. Glovebox pressure can be manually controlled by placing switch MS-4 in the manual position. This activates EV-25 which locks out DPC-4. D-58 can then be controlled from MC-4 to regulate glovebox pressure. To prevent positive pressure in the glovebox, DPS-1 is provided to sense glovebox pressure. Should pressure in the glovebox rise to (-)0.25 in WG, DPS-1 signals EV-23 to close. Also at this condition, an alarm annunciates at the 234-5Z Power Control Room, and the system can then be manually controlled. EV-23 is manually opened (reset) after conditions stabilize. DPS-1A signals EV-23A to close. Glovebox pressure is indicated on MC-4. Glovebox pressure is also indicated on local DPT's that are furnished with the glovebox. Zone pressure is recorded on DPR-4.

Zone II Main Support Area (Room 636) pressure is controlled by modulating the supply air to the zone and maintaining constant exhaust flow. PX-2 senses zone pressure with respect to the atmosphere, sends a signal to DPC-2 which compares the signal to set point, (-)0.25 in WG, and modulates D-3 to maintain zone pressure. Zone pressure can be manually controlled by placing switch MS-2 in the manual position. This activates EV-26 which locks out DPC-2. D-3 can then be controlled from MC-2 to regulate zone pressure. Should zone pressure rise to (-)0.05 in WG, an alarm will annunciate on the 234-5Z Power Control Room panel. The system shall be manually controlled until conditions stabilize. Zone pressure is indicated on MC-2 and is recorded on DPR-2.

Zone II NDA Lab (Room 637) pressure is controlled by synchronizing the return and supply air volumes. The return air volume is maintained at constant value by FC-1 which senses velocity pressure from AFM-2 and modulates either RF-1 or RF-2 inlet dampers. FC-1 also signals FC-2, which will adjust the supply air volume (SF-3, SF-4) to match changes in the exhaust volume and also maintain zone pressure. The zone pressure is sensed by PX-3 which sends a signal to DPC-3, and should zone pressure rise to (-)0.10 in WG, PS-8 sends a signal to EV-24A causing DPC-3 to override FC-2 to reduce supply volume to maintain zone pressure. As zone pressure stabilizes, DPC-3 allows FC-2 to return to normal operation.

Should zone pressure rise to (-)0.10 in WG, an alarm will annunciate in234-5Z Power Control Room Panel. The system shall be manually controlled by placing switch MS-3 in the manual position. This activates EV-24 which locks out DPC-3 and FC-2. SF-3 or SF-4 inlet Dampers can then be controlled from MC-3 to regulate zone pressure. Zone pressure is indicated on MC-3 and is recorded on DPR-3.

Radiation Monitoring Equipment samples the return air from the NDA Lab. When readings exceed allowable limits, the system diverts to a once through system. (See System Interlocks description below for damper opening and closing sequence).

Zone III Mechanical Room exhaust pressure is controlled by manually adjusting D-20 to obtain required zone pressure. Zone pressure is indicated on DPI-34.

Zone IV pressure is controlled by modulating the supply air volume to the zone. PX-1 senses zone pressure with respect to the atmosphere, sends a signal to DPC-1 which compares the signal to set-point, (+)0.05 in WG, and modulates D-5 to maintain zone pressure. Should zone pressure drop to 0.00 in WG, an alarm will annunciate on the 234-5Z Power Control Room Panel. Zone pressure can be manually controlled by placing switch MS-1 in the manual position. This activates EV-27, which locks out DPC-1. Damper D-5 can then be controlled from MC-1 to regulate zone pressure. The system shall be manually controlled until conditions stabilize. Zone pressure is indicated on MC-1 and is recorded on DPR-1.

FAN STATIC PRESSURE CONTROL

Supply and exhaust air flow (SF-1, SF-2, EF-1, EF-2) is controlled by maintaining constant pressure in the Supply or Exhaust Plenums. PC-1A senses Supply Plenum pressure with respect to atmosphere, sends a signal to PC-1 which compares the signal to the set-point, (+)2.0 in WG, and modulates either SF-1 or SF-2 inlet Dampers. Exhaust Plenum pressure is controlled in a similar manner by PC-2A and PC-2. Set-point is (-)4.5 in WG. During manual control modes, the Exhaust Plenum pressure can be changed manually by placing switch MS-5 in the manual position. This activates EV-28 which locks out PC-2. Either EF-1 or EF-2 Inlet Dampers can then be controlled from MC-5 to regulate Exhaust Plenum pressure.

MAIN SUPPORT AREA SYSTEM AUTOMATIC FAN CONTROLS

- Place Selector Switch MS-LL-3 for Exhaust Fans to EF-1 or EF-2.
- Place Selector Switch MS-LL-1 for Supply Fans to SF-1 or SF-2.
- Press Main Support Area Start Button. The selected Exhaust Fan starts. EV-21 will open allowing instrument air to all controls associated with the Main Support Area System. After selected Exhaust Fan produces acceptable Exhaust Plenum pressure (sensed by DPS-2) the selected Supply Fan will automatically start.
- Start up of the selected Exhaust Fan activates EV-12 or EV-14 to allow the Outlet Isolation Damper, D-13 or D-14, to open. Also, EV-11 or EV-13 is activated to allow PC-2 to control the operating fan's Inlet Vane Damper. A similar sequence happens on start up of the Supply Fan with EV-2, EV-3, D-2, D-4, EV-1, EV-4 and PC-1.
- With Exhaust Fan EF-1 operating, EF-2 is on standby. Loss of EF-1 is sensed by FS-5 which alarms at the 234-5Z Power Control Room Panel. The HVAC Computer signals EF-2 to start. EV-14 is activated to allow D-14 to open. EV-13 is activated to allow PC-2 to operate EF-2 Inlet Damper. Shutdown of EF-1 deactivates EV-12 to allow D-13 to close and deactivates EV-11 to prevent EF-1 Inlet Damper operation by PC-2. The interlock sequence is similar if EF-2 is operating and EF-1 is on standby.

SYSTEM INTERLOCKS (See drawings H-2-80141, H-2-80142, H-2-80169 for interfaces to Computerized Control System)

- During failure of the operating Exhaust Fan and startup of the standby Exhaust Fan, the operating Supply Fan continues to operate as long as DPS-2 senses Plenum Static Pressure above it's set-point. Should Exhaust Plenum pressure drop below the DPS-2 set-point, the operating Supply Fan is shut down. When Exhaust Plenum pressure reaches DPS-2 set-point, the Supply Fan will restart.
- With Supply Fan SF-1 operating, SF-2 is on standby. Loss of SF-1 is sensed by FS-1 which alarms at 234-5Z Power Control Room Panel. SF-2 is started automatically by the HVAC Computer. Loss of SF-1 deactivates EV-2 to allow Damper D-2 to close, deactivates EV-1 to prevent SF-1 Inlet Damper operation by PC-1. Startup of SF-2 activates EV-3 to allow Damper D-4 to open and activates EV-4 to allow PC-1 to operate SF-2 Inlet Damper. The interlock sequence is similar if SF-2 is operating and SF-1 is on standby.
- Fans SF-1, SF-2, EF-1 and EF-2 can also be operated in hand control mode.

GLOVEBOX DRY AIR SYSTEM

Compressors AC-1 and/or AC-2 are manually started and they cycle on and off to maintain Receiver Air pressure. Pressure Switches PS-9 and PS-10 start AC-1 or AC-2 at 85 psig and stop the compressions at 105 psig.

EV-23 is interlocked with Exhaust Fans EF-1 and EF-2, and will close on loss of the exhaust fans.

NDA LAB AUTOMATIC FAN CONTROLS

- Place selector switch MS-LL-4 for Return Fans to RF-1 or RF-2. Place selector switch MS-LL-2 for Supply Fans to SF-3 or SF-4.
- Press NDA auto-start button. The selected Return Fan starts, EV-20 will open, allowing instrument air to all controls associated with the NDA Lab system. After the selected Return Fan is running, the selected Supply Fan automatically starts. Start up of the Return and Supply Fans activates EV-15, EV-16, EV-17, EV-18, EV-5, EV-6, EV-7, EV-8 and Dampers D-15, D-16, D-8 and D-9 in a similar manner as described previously for Fans EF-1, EF-2, SF-1, SF-2.
- Radiation Monitoring equipment samples the return air from NDA Lab. When readings exceed allowable limits, an alarm annunciates at the 234-5Z Power Control Room Panel and also activates EV-10 to allow Dampers D-17 to open, D-6 to open and D-10 to close. After radiation levels recede, EV-19 is manually reset to place the system back into a recirculating operation mode.
- RF-1, RF-2, SF-3 and SF-4 are interlocked to start the Standby Fan when the Operating Fan fails (similar to EF-1, EF-2, SF-1 and SF-2) an alarm annunciates at 234-5Z Power Control Room if an operating Supply or Return Fan fails.
- Fans SF-3, SF-4, RF-1 and RF-2 can also be operated in hand control mode.

GENERAL CONDITIONS

- Fans SF-1, SF-2, EF-1, EF-2, SF-3, SF-4, RF-1, RF-2, SF-5 and SF-6 are equipped with manual override start-stop stations located on the 234-5Z Power Control Room Panel board. Hand controls are also located at the Motor Control Center in Mechanical Room 602 of 2736-ZB. Running lights and ammeters are located at the 234-5Z Power Control Room Panel.
- Fans SF-1, SF-2, EF-1, EF-2, SF-3, SF-4, RF-1, RF-2, SF-5 and SF-6 are connected to emergency power. If loss of power to the Operating Fan occurs, emergency power will automatically start the Standby Fan. The Instrument Air Compressor is also connected to emergency power.

ALARMS

- Alarms are provided for the following functions:

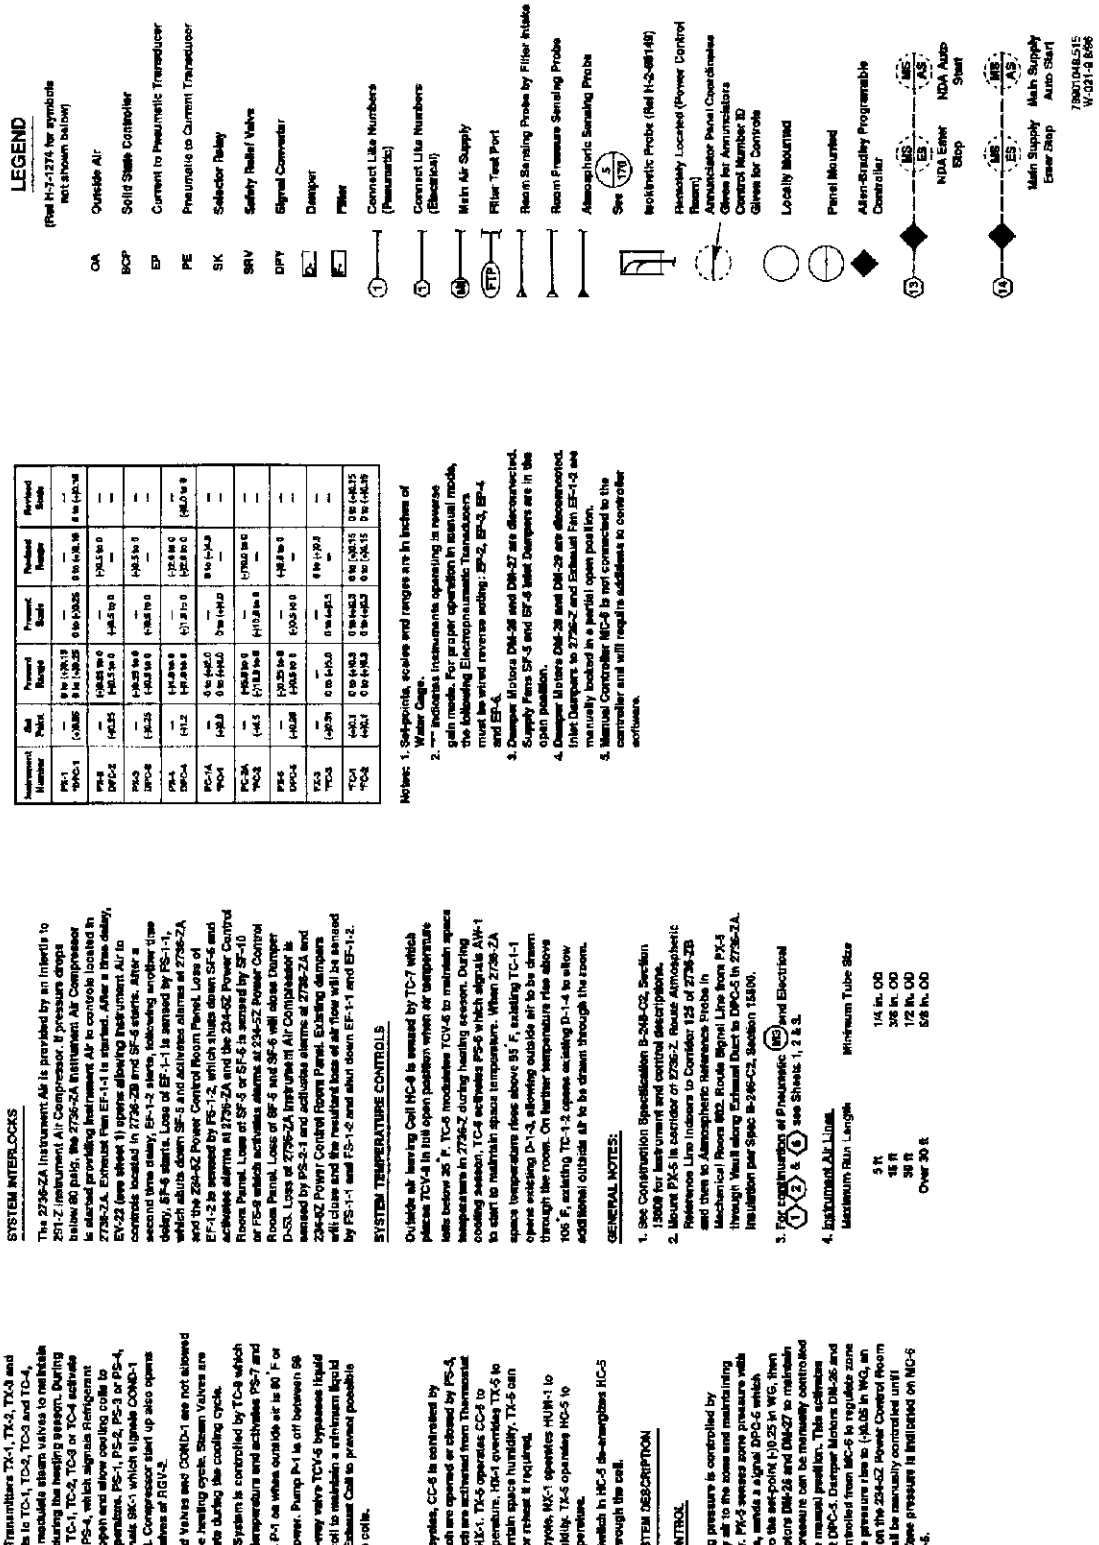
Supply Fan SF-1 loss of pressure
Supply Fan SF-2 loss of pressure
Supply Fan SF-3 loss of pressure
Supply Fan SF-4 loss of pressure
Supply Fan SF-5 loss of pressure
Supply Fan SF-6 loss of pressure
Exhaust Fan EF-1 loss of pressure
Exhaust Fan EF-2 loss of pressure
Exhaust Fan RF-1 loss of pressure
Exhaust Fan RF-2 loss of pressure
Zone I Glovebox pressure off normal
Zone II Process Area pressure off normal
Zone II NDA Lab pressure off normal
Zone IV Administration Area pressure off normal
NDA Lab CAM high alarm
Loss of 2736-ZB instrument air

FIRE ALARM SYSTEM INTERLOCKS

The following table indicates mode of operation for Supply and Exhaust Fans when a fire alarm energizes:

Alarm Location	SF-1 SF-2	SF-3 SF-4	RF-1 RF-2	EF-1 EF-2	Dry Air System
NDA Lab	Off	Off	On	On	Off
Glovebox	Off	Off	Off	On	Off
Zone II Main Support Area	Off	On	Off	On	Off
Zone IV Main Support Area	Off	On	Off	On	Off
Mechanical Room 606	Off	Off	Off	On	Off
Mechanical Room 602	Off	Off	Off	On	Off
Generator Building	On	On	On	On	On

SYSTEM TEMPERATURE CONTROLS



Main Support Area System:

- Outside air leaving HC-7 is sensed by TC-8 which places TCV-7 in full open position when temperature falls below 35°F.

APPENDIX 9A

PLUTONIUM FINISHING PLANT HAZARD EVALUATION

APPENDIX 9A

PLUTONIUM FINISHING PLANT HAZARD EVALUATION

This hazard evaluation systematically identifies and qualitatively assesses all hazards and potential accidents associated with active operations internal to the PFP facility, i.e., those associated with facility operation. The evaluation covers those operations and processes which were active at the time of preparation of the evaluation during Fiscal Year 1996. Subsequent to preparation of the hazard evaluation, two new processes were initiated within the PFP: 1) Plutonium-bearing solution stabilization using the Production Vertical Denitration Calciner (VDC) (operation not yet authorized), and 2) Reactive plutonium-bearing material stabilization (thermal stabilization) of "clean" plutonium oxide. The hazard evaluation for operation of the Production VDC is provided in Appendix 9D and the hazard evaluation for reactive material stabilization is provided in Appendix 9F. In addition to these two new processes, the Laboratory Prototype Calciner has been activated for stabilizing plutonium-bearing solutions. The hazard evaluation for the laboratory calciner is provided in the Laboratory Prototype Calciner addendum to this FSAR. The laboratory calciner sections of Appendix 9A (primarily in Table 9A.1.3) are superseded by the Laboratory Prototype Calciner addendum.

Throughout the hazard evaluation process, preventive and mitigative structures, systems and components (SSCs) and pertinent elements of programmatic and administrative features are identified. The identification establishes functional requirements for SSCs and the essential basis for the development of safety programs. An evaluation of the expected consequences and an estimation of the likelihood of accidents are included to identify abnormal events and accidents, and to facilitate the selection of a limited subset of internal accidents to undergo accident analysis in Section 9.2. This subset of accidents are those accidents that bound the envelope of accident conditions to which the operation would be subjected.

External events (both man-made and natural phenomena) are addressed in Section 9.2. These were determined to have significant impact on the public, therefore requiring quantitative analysis to determine the acceptable safety envelope. External events analyzed arise from two sources: natural phenomena and (seismic events, extreme winds and floods) technological (or man-made) hazards. An aircraft crash is the only man-made external hazard evaluated.

Conventional industrial hazards (i.e., hazards of the type and magnitude encountered and accepted by the public) are addressed through safety management programs as required by DOE Orders and the Occupational Safety and Health Administration (OSHA) and are not addressed in this appendix. The safety programs that mitigate conventional industrial hazards meet the requirements of DOE Orders, federal regulations, and industrial standards.

Methodology

The preliminary step in this evaluation was hazard identification. A hazard is a characteristic or an inherent feature of a system or operation that represents a potential for an uncontrolled release of hazardous material. The hazard evaluation identifies the material, system, process, and plant characteristics that can produce undesirable consequences and assesses the

associated hazards. A qualitative consequence evaluation was performed to determine the adequacy of plant preventive and mitigative features used to control these hazards.

The segmentation and selection of functional areas within the PFP was based on the independent nature of operations and the physical separation of the buildings. The hazards evaluation for the PFP was performed for specific operational hazards associated with the systems/activities within a defined functional area (e.g., analytical laboratories, thermal stabilization, storage vaults).

The hazard evaluation consisted of the following steps:

1) Identify the systems and activities in the functional area

2) Assess the failure modes of the systems and their associated equipment, and activities

3) Determine potential unmitigated consequences

4) Identify features (engineered, administrative, or both) required to prevent or mitigate the consequences of a specific hazard event

5) Qualitatively assess the risk of each event, giving consideration to the effectiveness of the preventive and mitigative features.

The effectiveness of hazard controls will be demonstrated through this hazard evaluation. Absolute risk cannot be determined; however, safety perspective and insights provided by this evaluation can be a basis for determining that the risk associated with operation of the PFP is acceptable. A detailed description of each step of the evaluation is given below.

System Identification. A variety of information was systematically reviewed in order to identify all hazardous and radioactive materials present in the facility and all energy sources associated with the facility. To facilitate the system identification, each facility and/or operation was divided into segments using facility layout drawings. The segment may be a subarea, a subsystem/activity, a function, a piece of equipment, or a step in an operation.

Failure Characterization. The identified system was then subjected to a characterization process that identified the failure modes that directly result in, or contribute significantly to, an abnormal event or an accident. The possible causes of operational deviations and the consequential accident scenarios were then determined.

The consequences of the various failure modes were assessed, assuming no mitigation. The level of detail necessary to sufficiently evaluate a hazard event is dependent upon its severity. If the unmitigated consequence of a hazard event was determined to be minor (see Table 9A-1 for consequence classification), qualitative risk evaluation performed in the hazard evaluation was sufficient. Hazard events with moderate or high unmitigated consequences may need to be analyzed in further detail in subsequent accident analyses.

The consequences were estimated based on the physical and/or chemical behavior of the pertinent process and the plant elements under upset conditions (certain components have malfunctioned and/or certain abnormal process deviations are assumed to have taken place).

TABLE 9A-1. Qualitative Severity Classification (DOE-STD-3009-94).

Descriptive word	Description
No (or none)	Negligible onsite or offsite impact on people or the environs.
Low	Minor onsite and negligible offsite impact on people or the environs.
Moderate	Considerable onsite impact on people or the environs; only minor offsite impact.
High	Considerable onsite and offsite impacts on people or the environs.

Identification of Preventive and Mitigative Features. Preventive features are those that would prevent a hazard event from occurring under normal operating conditions. Preventive features include both engineered safety features and administrative controls. Items such as pressure-relief valves, gloveboxes, circuit breakers, process controls and monitors are considered engineered features. Administrative controls include requirements to physically separate certain chemicals and fissile material for storage, limiting the quantity of chemicals and fissile material in an area, proper handling and segregation procedures for dangerous or toxic materials, and proper procedures for operating equipment.

Mitigative features are those that minimize the impact of a hazard event once it has occurred (e.g., fire protection systems, filters, barriers, and curbs). Mitigative features also include those that are procedural (evacuation of personnel in the event of a release of a toxic substance, instruction in proper use of fire extinguishers, and first aid).

Qualitative Risk Evaluation. Consequence severity and probability of occurrence were qualitatively assessed for each postulated event. A brief qualitative discussion is provided of the probability of the event and the potential consequence if it were it to occur, taking into consideration the PFP preventive and mitigative features. Risk involves both the consequence and the probability of an occurrence (likelihood) of an event. The consequences can be stated as severity of injuries, releases to the environment, etc. The classification of consequences is shown in Table 9A-1.

Each hazard event has a basic frequency of occurrence that reflects how often (on an average) a particular incident may occur to initiate the hazard sequence that causes the identified effect or harm (injury, damage, or exposure). The probability of occurrence for a given event is based, in part, on past plant experience. In other instances, engineering judgment was used to assess the likelihood of event occurrence. The classification of probability of occurrence is given in Table 9A-2.

TABLE 9A-2. Qualitative Likelihood Classification (DOE-STD-3009-94).

Descriptive word	Estimated annual likelihood of occurrence	Description
Anticipated	$10^{-1} \geq p > 10^{-2}$	Incidents that may occur several times during the lifetime of the facility. (Incidents that commonly occur)
Unlikely	$10^{-2} \geq p > 10^{-4}$	Incidents that are not anticipated to occur during the lifetime of the facility. Natural phenomena of this probability class include: Uniform Building Code-level earthquake, 100-yr flood, maximum wind gust, etc.
Extremely unlikely	$10^{-4} \geq p > 10^{-6}$	Incidents that will probably not occur during the life cycle of the facility. This class includes the design basis accidents.
Beyond extremely unlikely (incredible)	$10^{-6} \geq p$	All other incidents.

The initial consequence screening used simplified criteria to determine the magnitude of the potential consequences of a hazard. These criteria provided a consistent method of determining the relative consequences of a hazard event, and addressed both radiological and toxicological effects.

Presentation of Hazard Evaluation. A tabular format is used to present the hazard evaluation results for each identified functional area of the facility. The tables are divided into eleven columns in order to present the results of the hazard evaluation in a systematic and understandable format. A brief description of the information presented in each column of the table is provided below.

Column 1 -- the numeric or alpha-numeric hazard identifier

Column 2 -- the system/equipment being evaluated

Column 3 -- a subsystem/activity of the system being evaluated

Column 4 -- the description of the function of the system/subsystem/activity

Column 5 -- failure mode of the system/subsystem/activity

Column 6 -- description of the potentially unmitigated consequences resulting from the failure

Column 7 -- the preventive/mitigative engineered features that may exist

Column 8 -- the preventive/mitigative administrative features that may exist

Column 9 -- relative risk (qualitative) associated with hazard events, taking into consideration the preventive and mitigative features.

Column 10 -- the location of a representative analysis

Column 11 -- pertinent remarks concerning the hazard evaluated.

The information in these eleven columns is organized into five top-level columns according to purpose. Columns 1-4 identify the system being evaluated, columns 5 and 6 characterize the failure, columns 7 and 8 present the preventive/mitigative features for the hazard event, columns 9 and 10 present the qualitative screening of the event, and column 11 provides pertinent remarks concerning the event. Figure 9A-1 presents the format of the hazard evaluation tables.

The hazard evaluations performed for the PFP are grouped into major PFP buildings as follows:

Appendix 9A.7--The 291-Z Building; Exhaust fan house

Appendix 9A.8--The 242-Z Building.

The Hazard Evaluation tables for the PFP follow. Each Hazard Evaluation table is preceded by a short description of the building operations. The barriers in the building to contain hazardous materials are discussed, as is the confinement system (if the building has one) designed to mitigate the release of hazardous material should a barrier faliure occur. The confinement system discussion includes a description of the building ventilation system(s). In addition, areas of the building not evaluated within the tables and services/utilities to the building are discussed.

APPENDIX 9A.1

HAZARD EVALUATION

The 234-5Z Building

Appendix 9A.1 provides the hazards evaluation performed for the various processes/operations within the 234-5Z Building. The radiological processes authorized for the 234-5Z Building are reactive material stabilization (by thermal processes) in gloveboxes HC-21C and HA-21I, with gloveboxes HC-18M, HC-18BS, HC-21A, HC-2, HA-28, HC-4, HC-3, and 235-B-5 supporting this process; laboratory functions; and SNM shipping, receiving, sorting, and storage. Other production gloveboxes are used for storage and handling operations.

The 234-5Z Building and its internal walls and equipment function as barriers that provide containment of hazardous materials. The primary barrier in the 234-5Z Building is a process enclosure (e.g., glovebox HA-21I), a process vessel within an enclosure, or a SNM storage or transportation container. The secondary barrier serves to enclose the area containing the primary barrier. An example is the internal building walls defining room 235B, which contains glovebox HA-21I. The 234-5Z Building structure in combination with the building ventilation systems forms a confinement system designed to mitigate the release of hazardous materials upon barrier failure.

The ventilation systems complete the confinement system by providing a controlled, continuous flow of air from the environment into the various building areas and process enclosures, and then back to the environment after HEPA filtration. The ventilation supply air is provided by supply fans located within the 234-5Z Building. The flow of supply air within the building is from uncontaminated areas to potentially contaminated areas (zone 3), and then to normally contaminated areas (zone 4). The air pressure in both zone 3 and zone 4 is normally negative relative to the atmosphere to prevent the movement of airborne material out of the building. The ventilation exhaust systems, designated as E-3 and E-4 for zones 3 and 4, respectively, route the exhaust air to rooms containing banks of HEPA filters. The E-3 exhaust is routed to rooms 311 through 316 and room 318, while the E-4 exhaust is routed to rooms 309 and 310. The E-3 and E-4 systems provide single- and two-stage filtration, respectively. The ventilation system exhaust is discharged to the atmosphere via the 291-Z stack by the 291-Z exhaust fans.

The hazard evaluation for the 234-5Z Building has been divided into seven segments as follows:

9A.1.1 RMA/RMC Process Line
9A.1.2 PFP AL
9A.1.3 PPSL
9A.1.4 Radiochemical standards laboratory
9A.1.5 LI/LO
9A.1.6 Storage vaults
9A.1.7 Miscellaneous areas.

No hazard evaluation was performed for offices, corridors, or maintenance shops as these areas are considered to have hazards that are

normally encountered and accepted by the general public. No hazard evaluation was performed for those operations that are inactive and not authorized for production operations (rooms 166, 169, and 170). These operations are not expected to be placed in operation again and will eventually undergo D&D.

A summary of the active processes/operations within the 234-5Z Building is provided below.

Remote Mechanical A and Remote Mechanical C Lines. The RMA and RMC Lines were used for the plutonium conversion of chemical process systems. This process is inactive and is not authorized for operation. However, all gloveboxes are authorized for interim storage of plutonium-bearing material. In addition, some of the gloveboxes within the RMA and RMC Lines have been converted for use in the thermal stabilization process. The thermal stabilization process is used to reduce the inventory of unstable plutonium-bearing materials that do not meet the criteria for secure, interim storage. Thermal stabilization will be performed in gloveboxes HC-21C and HA-21I in rooms 230A and 235B, respectively. Other gloveboxes, as discussed previously, will be used to support this process.

PFP Analytical Laboratory. The PFP AL, located in rooms 131 through 157A of the 234-5Z Building, is provided for analytical and physical test analyses of plutonium samples to support process control, product quality verification, and nuclear material accountability.

Plutonium Process Support Laboratories. The PPSL is located in the southwest corner of the 234-5Z Building in rooms 179 through 191 and room 202. The laboratory is chartered to operate chemical demonstration facilities involving both nonradioactive and radioactive materials.

Standards Laboratory. The standards laboratory in rooms 221C, 221D, and 221E is devoted to the formulation, verification, packaging, and distribution of actinide-containing standards needed in the laboratories for destructive and nondestructive analysis.

Load-In/Load-Out. Room 227 houses hood HC-227T and glovebox HC-227S. The hood and glovebox are used in the LI/LO and SNM-bearing nitrate solutions blending processes. The hood can accommodate either PR cans or L-10 polyethylene bottles transported in their outer containers. This room may also be used to load feed-grade nitrate into PR cans. Chemicals used for LI/LO are supplied by rooms 336 and 337.

Storage Vaults. The function of the storage vaults is to provide safe and secure storage for SNM. The activities associated with the storage vault operations are the storage, handling, and inspection of SNM containers.

Miscellaneous Areas. The miscellaneous areas include waste drum storage, radioactive mixed waste storage, trash compactor, NDA drum counting and the chemical preparation room. Facilities in rooms 336 and 337 were used to prepare and supply chemicals to the RMC Line and may be used to prepare chemical solutions needed for PFP operations.

A summary of all the rooms within the 234-5Z Building and the general usage of each room is given below.

Room number	Room function/usage
80-90	PPSL Offices
100 - 126	Office areas
127 - 130	Room numbers not used
131 - 157[2]	PFP AL[2]
158 - 164	Office areas/ instrument shop
165, 167, 168	Office areas
166, 169, 170	To undergo D&D
171	Corridor
172[6]	PR can storage[6]
173 - 175[6]	SNM storage vaults[6]
176 - 178	Room numbers not used
179 - 191[3]	PPSL[3]
192, 193[6]	SNM storage vaults[6]
194	Nonradioactive storage
195	Room number not used
196[7]	Waste drum storage[7]
197[7]	Radioactive mixed[7] waste storage
198 - 200	Maintenance shops
201	Nonradioactive storage
202[3]	PPSL[3]

Appendix 9A.1.1

RMA/RMC LINE PROCESS

The RMA and RMC Lines were used for the plutonium conversion chemical process systems. This process is inactive and is not authorized for operation. However, gloveboxes not designated as inactive (see table 9.2.4-1) are authorized for interim storage of plutonium-bearing material. The RMC Line is located approximately in the center of the first floor of the 234-5Z Building. The RMA Line, used in the past for converting plutonium nitrate to shippable plutonium metal and oxide powder, is also located in the 234-5Z Building (in the vicinity of the RMC Line). The line is inactive, but some of the equipment is used for other processes. The thermal stabilization process uses some of the gloveboxes located in rooms 230A, 230B, 235B, and 235C that were formerly used for RMA and RMC Line operations. The primary mission of this process is to reduce the inventory of unstable plutonium bearing materials that do not meet the criteria for safe and secure long-term storage.

Plutonium bearing materials are sealed into glovebox HC-21A, removed from the package, weighed, placed into a container called a boat, and then transferred via the conveyor system to glovebox HC-21C or HA-21I. The boat is placed into a muffle furnace and the appropriate temperature controller program is started. The controller ramps and holds the furnace temperature specifically for the type of material being processed. The material is cooled, ground, blended, and sampled to verify that < 1% of the volatiles remain. The processed material is then packaged for long-term storage.

There are three categories of SNM that are thermally stabilized in gloveboxes HC-21C and HA-21I. The furnaces in HC-21C stabilize chemically reactive plutonium sludge residues (which include centrifuge, PRF glovebox, and canyon sludges), oxides (which include plutonium fluoride, plutonium oxide, plutonium oxalate, and plutonium oxycarbonate), and incinerator ash (ash from the RFP incinerator and the 232-Z incinerator). The furnaces in HA-21I will primarily be used to thermally stabilize low fired oxide materials from the 2736-Z Building vault inventories.

The following Hazard Evaluation table identifies stack CAMs as a preventive/mitigative feature for several postulated failure events. The CAMs perform a passive function, which is to detect airborne radioactive material and to activate alarms should the alarm set-point on the CAM be exceeded. They do not provide an active function which would actuate equipment or systems to prevent or mitigate an accident. In most cases the CAMs do not serve to reduce the consequences associated with a release of airborne radioactive material because most accidents involve a sudden release of material over a short period of time. Therefore, by the time the stack CAM detects the release there would be insufficient time to mitigate the event. In addition, the CAM's location in the ventilation discharge stack precludes any preventive/mitigative action since the release would have already occurred. Potentially chronic releases from process operations, or due to equipment failures (e.g., failed HEPA filters), tend to be small in nature. If these releases are sufficient to actuate the CAM alarm, operator action is generally adequate to limit the release so there is no significant consequence. It should be noted that accidents evaluated in the Chapter 9.0 analyses did not rely on the CAMs to serve a preventive/mitigative function.

Table 9A.1.1
The 234-5Z Building
RMA and RMC Lines
(Rooms 228, 230, 232, and 235).

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
1	RMA/RMC Line areas, general	A. Container handling inside of rooms, but outside of gloveboxes.	To safely handle SNM containers as necessary to support operations.	(1) Dropped container	Potential release of SNM to the room. Potential entrainment in the E-3 ventilation exhaust system and release to the environment.	SNM containers resistant to gross failures as a result of a drop. CAMs to detect airborne contamination and to activate alarms. Single-stage HEPA-filtered E-3 exhaust system.	Packaging requirement for double containment. Procedure governing operator response to a spill. Procedure governing operator response to a CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to sections 9.1.1, "Radioisotope-Bearing Liquid Spills," and 9.1.3 "Radioisotope-Bearing Powder Spills."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
				(2) Inadequate container spacing	Loss of a single contingency for criticality safety. Potential criticality if there is a loss of an additional contingency.	Lard cans and food pack cans are transported in fixed array wagons. Drums are moved one at a time using drum barrel hand trucks. CAS to detect a criticality and to activate criticality alarms.	Procedure governing the transportation of SNM. Procedure governing operator response to a criticality alarm.	Inadequate spacing is an anticipated event. There is judged to be no consequence.	Refer to section 9.2.3, "Criticality."	Potentially severe consequences to workers in proximity to a criticality. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005
		B. Ventilation supply system	In conjunction with the E-3 exhaust system, provides airflow to maintain the correct DP between zones.	(1) Insufficient supply airflow	Potential increased DP between zones 3 and 1.	Five operating and three backup supply fans. Pressure sensors/alarms and dampers monitor and control the supply airflow to each zone. Safety interlocks between supply and exhaust fans.	Procedure governing operator response to ventilation system upset.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.7F, "Building Depressurization - All PFP Operating Buildings."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
				(2) Excessive supply airflow	Potential loss of DP between zones 3 and 1. Potential release of SNM to zone 1 areas and to the environment.	Pressure sensors/alarms and dampers monitor and control the airflow to each zone. E-3 exhaust to maintain DP. CAMs to detect airborne contamination and to activate alarms.	Procedure governing operator response to ventilation system upset. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.7A, "Excessive Building Pressurization - 234-5Z."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		C. E-3 exhaust system	In conjunction with ventilation supply system, provides airflow to maintain the correct DP between zones.	(1) Insufficient exhaust flow	Potential loss of DP between zones 3 and 1. Potential spread of contamination to zone 1 areas.	Four operating and three backup exhaust fans. Pressure sensors/alarms and dampers monitor and control the exhaust flow from each zone. CAMs to detect airborne contamination and to activate alarms.	Procedure governing operator response to ventilation system upset. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.7A, "Excessive Building Pressurization - 234-5Z."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011

This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	The hazard analyses for "Gloveboxes, General" are typical for all gloveboxes. WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		B. Ventilation supply system (inleakage through inlet HEPA filters)	In conjunction with the E-4 exhaust system, provides airflow to maintain the correct negative DP between zones 3 and 4.	(1) Insufficient supply airflow	Potential excessive negative pressure. Potential loss of confinement, release of SNM to the room, and entrainment in the ventilation exhaust system.	Dry air system provides supply airflow to glovebox. Glovebox DP gauge. CAMs to detect airborne contamination and to activate alarms. Single-stage HEPA-filtered exhaust system.	Procedure governing operator response to glovebox DP outside of operating limits. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
				(2) Excessive supply airflow	Potential pressurization of the glovebox and loss of confinement. Potential release of SNM to the room and entrainment in the exhaust ventilation system. Potential release to the environment.	Two-stage HEPA-filtered E-4 exhaust system. CAMs to detect airborne contamination and to activate alarms.	Procedure governing operator response to CAM alarm.	This event is very unlikely. The consequence is judged to be low.	Refer to section 9.1.4, "Radioisotope-Bearing Pressurized Powder Spill."	Interconnection of RMA/RMC line gloveboxes minimizes the effects of pressure excursions. WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		C. Ventilation supply system, glovebox inlet HEPA filters	To filter glovebox exhaust in the event of a flow reversal in order to mitigate the release of SNM.	Loss of filtration	Potential release of SNM to the room. Potential entrainment in the exhaust ventilation system and release to the environment.	Glovebox DP gauge. CAMs to detect airborne contamination and to activate alarms. Single-stage HEPA-filtered exhaust system (E-3).	Procedure governing operator response to CAM alarm. Procedure governing operator response to glovebox DP outside of operating limits.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011

RMA and RMC Lines
(Rooms 228, 230, 232, and 235).

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
	RMA/RMC Line gloveboxes, general (continued)	D. Dry air system (note: dryers are not functional)	In conjunction with the E-4 exhaust system, provides airflow to maintain the correct negative DP between zones 3 and 4.	(1) Insufficient supply airflow	Potential excessive negative DP. Potential loss of confinement and release to the room. Potential entrainment in the ventilation system and release to the environment.	Two-staged HEPA-filtered E-4 exhaust system. Glovebox outlet HEPA filter. Air flows through a self-governing regulating valve rated at 250 $stdft^3$/min. Glovebox DP gauge. CAMs to detect airborne contamination and to activate alarms.	Procedure governing operator response to CAM alarm. Procedure governing operator response to glovebox DP outside of operating limits.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	Gloveboxes HC-7, HC-60 and HC-235-B-2 are not supplied by the dry air system. WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
				(2) Excessive supply airflow	Potential glovebox pressurization. Potential loss of confinement and release of SNM into the room. Potential entrainment in the ventilation exhaust system and release to the environment.	CAMs to detect airborne contamination and to activate alarms. Two-staged HEPA-filtered E-4 exhaust system. Sufficient exhaust flow to remove full-open supply air. Glovebox pressure monitored in power control room and alarms if pressure exceeds -0.3 in w.g. PRV on glovebox air supply.	Procedure governing operator response to glovebox DP outside of operating limits. Procedure governing operator response to CAM alarm.	This event is anticipated. Dry air gloveboxes are equipped with self-actuating supply valves that reduce the supply air flow to maintain the proper glovebox pressure. The consequence is judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		E. Glovebox exhaust HEPA filters	To filter the glovebox exhaust in order to mitigate the release of SNM.	Loss of filtration.	Potential entrainment of SNM in the exhaust ventilation system. Potential release to the environment.	HEPA filter DP gauge on glovebox outlet HEPA filters. Two-stage HEPA-filtered E-4 exhaust system. 291-Z-1 stack CAMs to detect airborne contamination and to activate alarms.	Procedure governing operator response to HEPA filter DP outside of operating limits. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Not specifically analyzed.	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006
		F. E-4 exhaust system	In conjunction with the supply systems, provides airflow to maintain the correct negative DP between zones 3 and 4.	(1) Excessive exhaust flow	Potential excessive negative DP. Potential loss of confinement and release to the room. Potential entrainment in exhaust system and release to the environment.	Glovebox outlet HEPA filter. Glovebox DP gauge. HEPA-filtered ventilation exhaust system. CAMs to detect airborne contamination and to activate alarms.	Procedure governing operator response to glovebox DP outside of operating limits. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
				(2) Insufficient exhaust airflow	Potential glovebox pressurization and loss of confinement. Potential release of SNM to the room and entrainment in the exhaust system.	Glovebox DP gauge. CAMs to detect airborne contamination and to activate alarms. Single-stage HEPA-filtered ventilation exhaust system.	Procedure governing operator response to glovebox DP outside of operating limits. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.4, "Radioisotope-Bearing Pressurized Powder Container."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011

Table 9A.1.1

RMA and RMC Lines
(Rooms 228, 230, 232, and 235).

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
	RMA/RMC Line gloveboxes, general (continued)	G. E-4 exhaust system HEPA filters.	To filter the glovebox exhaust through two stages of HEPA filtration before it is discharged to the environment.	Loss of filtration.	Potential release of SNM to the environment.	Glovebox outlet HEPA filters. E-4 exhaust system has one operating and one standby filter bank room (each containing 128 filters). 291-Z-1 stack CAM to detect airborne contamination and to activate alarms.	Procedure governing maintenance and testing of HEPA filters. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Not specifically analyzed.	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006
3	Room 228, glovebox HC-1 (houses the conveyor system).	A. Conveyor	Automated transport of materials between RMA and RMC Line gloveboxes.	(1) Loss of automated transport.	Material must be transferred by hand using the HC-1 gloveports, resulting in increased extremity and whole body exposures to operators.	–	–	This event is anticipated. The consequence is judged to be low.	Not specifically analyzed.	
		B. Handling and storage of SNM-bearing containers.	To safely handle containers as necessary to support operations.	(1) Inadequate container spacing.	Potential criticality resulting in high levels of radiation within the room and a release of fission products to the atmosphere. Potential release of SNM to the room and entrainment in the exhaust system.	CAS to detect a criticality and to activate criticality alarms. HEPA-filtered ventilation exhaust system. CAMs to detect airborne contamination and to activate alarms.	Double-contingency principle. CPS posted on glovebox specifies allowable spacing. Procedure governing operator response to a criticality alarm. Procedure governing operator response to a CAM alarm.	Inadequate spacing is an anticipated event. The consequences are judged to be low.	Refer to section 9.2.3, "Criticality."	Potentially severe consequences to workers in proximity to a criticality. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
				(2) Dropped container/ container failure	Potential spill of SNM within the glovebox. Potential airborne release and entrainment of plutonium in glovebox ventilation system.	Glovebox confinement. Two-stage HEPA-filtered exhaust system. 291-Z-1 stack CAM to detect airborne contamination and to activate alarms.	Procedure governing operator response to a spill of SNM. Procedure governing operator response to a CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.3, "Radioisotope-Bearing Powder Spills."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006
4	Room 228A, gloveboxes HC-7, HC-9B, HC-10, and HC-11.	Repackaging and storage of SNM-bearing containers.	To safely handle containers as necessary to support operations.	Refer to item 3B.	Refer to item 3B.	Refer to item 3B.	Refer to item 3B.	Refer to items 3B.	Refer to item 3B.	Glovebox HC-7 is not supplied by the dry air system. Supply air is from room through two inlet HEPA filters. The glovebox is authorized for interim storage and repackaging of SNM. WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
5	**Room 228A, gloveboxes HC-7 and HC-9B.**	Criticality drain	To drain liquid from the glovebox in order to prevent the accumulation of a critical volume of solution.	Failure to adequately drain liquid.	Potential criticality that results in high levels of radiation within the room and a release of fission products to the atmosphere.	Drains are protected from plugging by large mesh screens. CAS to detect a criticality and to activate criticality alarms.	Double-contingency principle. Procedure governing operator response to nonfunctional criticality drain. Procedure governing operator response to criticality alarm.	This event is unlikely. The consequences are judged to be low.	Refer to section 9.2.3, "Criticality."	Potentially severe consequences to workers in proximity to a criticality. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-008
6	**Room 228B, gloveboxes HC-12S, HC-13MD, HC-15ABC, HC-16CC**	Repackaging and storage SNM-bearing containers	To safely handle containers as necessary to support operations.	Refer to item 3B.	Refer to item 3B.	Refer to item 3B.	Refer to item 3B.	Refer to item 3B.	Refer to item 3B.	Refer to item 3B.
7	**Room 228C, gloveboxes HC-5, HC-17-SBB, HC-17DC, HC-17P, HC-18BS, and HC-18M.**	Repackaging and storage of plutonium-bearing containers	To safely handle containers as necessary to support operations.	Refer to item 3B.	Refer to item 3B.	Refer to item 3B.	Refer to item 3B.	Refer to item 3B.	Refer to item 3B.	Refer to item 3B.
8	**Room 228C, glovebox HC-5 (houses conveyor system).**	Conveyor	Automated transport of materials between RMA and RMC Line gloveboxes.	Refer to item 3A.	Refer to item 3A.	Refer to item 3A.	Refer to item 3A.	Refer to item 3A.	Refer to item 3A.	
9	**Room 228C, glovebox HC-18M (contains TGA)**	A. E-4 exhaust	To remove the heat generated by the TGA.	Buildup of heat.	Potential loss of glovebox confinement. Potential release of SNM to the room and entrainment in the ventilation exhaust system.	Four operating and three backup exhaust fans. Pressure sensors and dampers monitor and control the exhaust flow from each zone. Two exhaust fans connected to backup power. CAMs to detect airborne contamination and to activate alarms. HEPA-filtered exhaust.	Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		B. TGA	Used in Loss-on-ignition (LOI) analysis to determine the amount of volatiles remaining in the product.	(1) Excessive temperature	Potential loss of the TGA.	The TGA high-temperature alarm switch and associated thermocouple. The alarm switch is designed to cut TGA power when the high temperature limit is exceeded.	Procedure governing operator response to TGA high-temperature alarm.	This event is anticipated. The consequence is judged to be low.	Not specifically analyzed.	

Table 9A.1.1

RMA and RMC Lines
(Rooms 228, 230, 232, and 235).

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
	Room 228C, glovebox HC-18M (contains TGA) (continued)	B. TGA (continued)	Used in Loss-on-ignition (LOI) analysis to determine the amount of volatiles remaining in the product. (continued)	(2) Low temperature	Potential incomplete removal of volatiles resulting in potentially invalid LOI results. Potential storage of reactive material in the vaults.	Temperature/time regimes are computer-controlled.	Procedure governing LOI analysis. Procedure governing maintenance and calibration of TGA system.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.4, "Radioisotope-Bearing Pressurized Powder Container."	Refer Appendix 9A.2.1 "2736-Z -- Vault storage of SNM" and Appendix 9A.2.2 "2736-ZA -- Exhaust ventilation and filtration of 2736-Z."
				(3) Temperature ramps up too quickly	Potential loss of the TGA.	Temperature/time regimes are computer-controlled.	Procedure governing LOI analysis. Procedure governing maintenance and calibration of TGA system.	This event is anticipated. The consequence is judged to be low.	Not specifically analyzed.	
				(4) Insufficient time at temperature	Potential incomplete removal of volatiles resulting in potentially invalid LOI results. Potential storage of reactive material in the vaults.	Temperature/time regimes are computer-controlled.	Procedure governing LOI analysis. Procedure governing maintenance and calibration of TGA system.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.4, "Radioisotope-Bearing Pressurized Powder Container."	Refer to Appendix 9A.2.1 "2736-Z -- Vault storage of SNM" and Appendix 9A.2.2 "2736-ZA -- Exhaust ventilation and filtration of 2736-Z"
		C. Hydraulic fluid reservoir (basement level of glovebox)	Supplies hydraulic fluid to pump that operated several rams in the RMC Line (hydraulic rams are no longer used).	Leak from reservoir or pressurized leak from hydraulic lines in the basement level or beneath other RMC Line gloveboxes (if hydraulic pump inadvertently operated).	Operational upset (glovebox activity halted until spill cleaned up). - Non-fire case. Fire in Glovebox HC-18M basement if hydraulic fluid spill heated above its flashpoint and an ignition source is present. Potential loss of glovebox confinement with minor contamination spread to Room 228C.	Glovebox HC-18M basement airspace is not common with RMC Line airspace. Separate Halon fire suppression system in Glovebox HC-18M basement. E-3 ventilation system filters mitigate release to environment of radiological material released from glovebox. CAMs to detect airborne contamination and to activate alarms.	Spill response procedure. Procedure governing operator response to CAM alarm. RMC Line process is in standby status. No reason for hydraulic pump to be operated. Hanford fire department response.	Spill/leak without fire is anticipated. Spill with subsequent fire is extremely unlikely. The consequence is judged to be low.	Refer to section 9.2.2A "Remote Mechanical C Line Fire" as bounding case.	Actuators are outside gloveboxes. Hydraulic lines do not penetrate into RMC Line gloveboxes. The hydraulic fluid is in lines and equipment below the areas where it could contact radioactive materials or other residues; therefore, a leak would not cause a reactive chemical hazard. WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-010 WHC-SD-CP-SDD-011
10	**Room 228C, glovebox HC-18BS**	Storage rack	To maintain container separation for the purpose of criticality safety.	Loss of container separation.	Potential criticality and release of fission products to the atmosphere. Potential entrainment of SNM in the exhaust system and release to the environment.	CAS to detect a criticality and to activate criticality alarms. Two-staged HEPA-filtered exhaust system.	Double-contingency principle. Procedure governing operator response to a criticality alarm.	This event is unlikely. The consequences are judged to be low.	Refer to section 9.2.3, "Criticality."	WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
	Room 230A, glovebox HC-21C (continued)	A. Material handling (continued)	To safely handle material as necessary to support operations. (continued)	(3) Overfill or dropped boat during insertion in or removal from furnace.	Potential spill within the glovebox. Potential entrainment of SNM in the exhaust ventilation system.	Glovebox confinement. Two-stage HEPA-filtered E-4 exhaust system. 291-Z-1 stack CAM to detect airborne contamination and to activate alarms.	Procedure governing operator response to a spill of SNM within the glovebox. Procedure governing operator response to a CAM alarm.	This event is anticipated. The consequence is judged to be low.	Not specifically analyzed.	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006
		B. Halon system	To contain Halon until necessary to suppress a fire within the glovebox.	(1) Failure to suppress the fire.	Potential loss of confinement. Potential release of SNM to the room and entrainment in the ventilation system. Potential release to the environment.	Portable fire extinguishers. Halon system interlocked with the RMC Line emergency exhaust fire damper. HEPA-filtered exhaust ventilation systems (E-3 and E-4). CAMs to detect airborne contamination and to activate alarms.	Procedure governing inspection of the Halon system. Procedure governing operator response to a fire. Procedure governing operator response to a CAM alarm. Response of the HFD.	This event is unlikely. The consequences are judged to be low.	Refer to section 9.2.2C, "Glovebox HA-21I Fire."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-010 WHC-SD-CP-SDD-011
				(2) Accidental discharge of the Halon fire system.	Potential pressurization of the glovebox relative to the room. Potential loss of confinement and a release of SNM into the room. Potential entrainment in the ventilation exhaust system and release to the environment.	E-4 ventilation system designed to maintain negative DP of glovebox during discharge of Halon system.	Procedure governing inspection of the Halon system. Procedure governing operator response to Halon system discharge.	This event is unlikely. The consequence is judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-010
		C. Glovebox muffle furnace	Controlled heating of reactive SNM in order to stabilize it for long-term storage.	(1) Excessive temperature	Potential loss of the furnace. Potential generation of a ceramic-like product.	High-temperature alarm switch and associated thermocouple to monitor furnace temperature. The alarm switch is designed to cut power to the furnace if the high temperature limit is exceeded.	Procedure governing operator response to high temperature alarm.	This event is anticipated. The consequence is judged to be low.	Not specifically analyzed	
				(2) Low temperature	Potential incomplete removal of volatiles. Potential storage of reactive material in the vaults. Potential loss of containment event in the vaults.	Temperature regime is computer-controlled.	Procedure governing the LOI analysis used to verify volatiles have been removed.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.4, "Radioisotope-Bearing Pressurized Powder Container."	Refer to Appendix 9A.2.1 "2736-Z -- Vault storage of SNM" and Appendix 9A.2.2 "2736-ZA -- Exhaust ventilation and filtration of 2736-Z."

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
	Room 230A, glovebox HC-21C (continued)	E. Muffle furnace CO_2 system (used only during the processing of PRF sludge)	Provides CO_2 covergas to the furnace.	(1) Insufficient CO_2 cover gas.	Potential concentration of butene gas or CO in excess of the LFL. Potential ignition and breach of the glovebox. Potential release of SNM to the room and entrainment in the exhaust system.	Two 384-lb CO_2 bottles are manifolded such that the system automatically switches to the second bottle when the first one empties. Liquid level indicators. An audible alarm activates when the manifold switches. CAMs to detect airborne contamination. HEPA-filtered exhaust system.	Procedure governing operator verification of the offgas/CO_2 flow rate settings. Procedure governing operator response to CAM alarm.	This is an anticipated event. The consequences are judged to be moderate.	Refer to section 9.2.1C, "Deflagration in Glovebox HA-21I."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
				(2) Excess CO_2	Potential entrainment of flighty material in offgas and plugging of the filters. Potential pressurization of the furnace and the glovebox with a release of SNM into the room. Potential entrainment in the exhaust system.	CO_2 flow is controlled by a rotameter that acts as an orifice to limit the maximum flow into the glovebox. 26-in. mercury vacuum system. E-4 ventilation exhaust system. Screen on top of boat containing SNM.	Procedure governing operator verification of the offgas/CO_2 flow rate settings.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005
		F. CO_2 gas cylinders	To safely store liquid CO_2.	Leak or cylinder damage due to handling accident.	Potential cryogenic burns to operators. Potential asphyxiation hazard to operators. Pressurization of Room 230A from vaporized gas released from cylinder.	Cylinder restrained within storage cabinet. Cylinders vent approximately 2 lb of CO_2 per day to reduce buildup of pressure. Ring at top of cylinder protects supply valve from damage. Room ventilation flow dilutes carbon dioxide evaporating off spill. Room vents from near floor. Safety relief valve prevents cylinder from failing due to overpressurization.	Procedure governing transportation of gas cylinders. Special liquid cylinder hand trucks used to transport cylinders.	This event is unlikely. The consequences are judged to be low.	Refer to section 9.1.7A, "Excessive Building Pressurization - 234-5Z"	Carbon dioxide is in liquid phase and not under high pressure. Heat transfer limits evaporation rate. WHC-SD-CP-SDD-005
		G. Line containing CO_2 gas.	To transport CO_2 from the cylinder to the HC-21C glovebox muffle furnaces.	Line break in one of the flexible hoses.	Potential breach of the glovebox and a release of SNM into the room. Potential entrainment in the exhaust system and release to the environment.	Pressure-reducing valve at CO_2 cyliner. Two-stage HEPA-filtered E-4 exhaust system. CAMs to detect airborne contamination and to activate alarms.	Procedure governing operator response to a CAM alarm.	This event is unlikely. The consequence is judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	Flowrate into glovebox through breached hose is limited to sonic velocity. WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011

[a]Hazard identifier.
[b]The consequence, as given here, assumes none of the active preventive/mitigative features are in place.
[c]The probability/consequence, as given here, assumes that the preventive/mitigative features are operative.
[d]Gives the section number in the chapter where additional accident analysis is performed.

Appendix 9A.1.2

PFP ANALYTICAL LABORATORY

The PFP AL, located in the southeast corner of the 234-5Z Building in rooms 131 through 157, is used to perform analytical and physical test analyses on plutonium samples supporting process control, product quality verification, and nuclear material accountability. The samples come from the plant operations within the PFP, the research laboratory within the PFP, and a few special test samples from other locations.

Laboratory analysis is performed in rooms 131 through 157 on samples received from the PFP Operations, or others. Measurements include fissile material content, impurities, isotopic content, specific gravity, density, and LOI for oxide powders. Some of the gloveboxes contain argon, thus there is a potential for an argon release to the room and throughout the laboratory. There are fire suppression systems in the laboratory, therefore an earthquake could result in a release of water to the laboratory.

To ensure the safe storage of plutonium bearing materials, it is important to determine the amount of volatiles within the oxide material. By weighing the sample before and after heating, the weight loss or LOI can be calculated. This method was adopted for measuring the weight loss of any solid material. The muffle furnace used can be programmed for heating at any temperature up to 1000 °C for several hours. A controlled rate of heating will allow the temperature to increase at a constant rate (degrees per minute) until the desired setting is reached. A standard is used to provide a check against improper weighing. If the volatile content of a sample is high (1.0% or higher), the sample is reheated to ensure the volatiles are driven off.

The PFP AL contains 33 gloveboxes (two of which are inactive) and 38 hoods. An administrative limit of 5.25 kg of plutonium, of which not more than 2.25 kg is >10% ^{240}Pu, has been established. This material, in the form of a powder or a solution, could be located within gloveboxes, hoods, or both.

The samples received and analyzed in the PFP AL represent process control, material accountability, and product analysis. Both chemical analyses and physical tests are performed. The samples may be liquids, solids (metal and oxide), or substrate captured (filter media).

The PFP AL is located in rooms 131 through 157 of the 234-5Z Building, with quality control standards being formulated and dispensed from rooms 221-C, -D, and -E. The NDA drum counting activities in rooms 192 and 234A are also part of the PFP AL operations.

All laboratory activities are governed by appropriate procedures. The activities are performed by trained personnel and their performance is monitored by a quality control program that includes analysis of standards, compliance overchecks, and audits.

The PFP AL uses common scientific instruments and equipment in an approved manner. The samples analyzed are highly radioactive and have the potential for impacting the safety of personnel.

The following Hazard Evaluation table identifies stack CAMs as a preventive/mitigative feature for several postulated failure events. The CAMs perform a passive function, which is to detect airborne radioactive material and to activate alarms should the alarm set-point on the CAM be exceeded. They do not provide an active function which would actuate equipment or systems to prevent or mitigate an accident. In most cases the CAMs do not serve to reduce the consequences associated with a release of airborne radioactive material because most accidents involve a sudden release of material over a short period of time. Therefore, by the time the stack CAM detects the release there would be insufficient time to mitigate the event. In addition, the CAM's location in the ventilation discharge stack precludes any preventive/mitigative action since the release would have already occurred. Potentially chronic releases from process operations, or due to equipment failures (e.g., failed HEPA filters), tend to be small in nature. If these releases are sufficient to actuate the CAM alarm, operator action is generally adequate to limit the release so there is no significant consequence. It should be noted that accidents evaluated in the Chapter 9.0 analyses did not rely on the CAMs to serve a preventive/mitigative function.

Table 9A.1.2
The 234-5Z Building
PFP AL
(Rooms 131-137, 139, and 141-157).

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
1	PFP AL, general	A. Transportation of SNM	To safely move SNM within the PFP AL.	(1) Inadequate container spacing	Loss of a single contingency for criticality safety. Potential criticality should an additional contingency be lost.	Lard cans and food-pack cans are transported in fixed array wagons. 30- to 55-gal drums are moved one at a time using drum barrel hand trucks. CAS to detect criticality and to activate criticality alarms.	Double-contingency principle precludes the potential for a criticality as a result of a single failure. Procedure governing transportation of SNM. Procedure governing operator response to criticality alarm.	Inadequate spacing is an anticipated event. The consequences are judged to be low.	Refer to section 9.2.3 "Criticality."	Potentially severe consequences to workers in proximity to a criticality. WHC-SD-CP-SDD-003
				(2) Dropped container	Potential breach of SNM container. Potential release of respirable plutonium to the room and environment through the room ventilation system.	Carriers (drum barrel hand truck, fixed array wagon, lard can wagon) are designed for specific operation. CAMs to detect airborne contamination and to activate alarms. Single-stage HEPA-filtered ventilation exhaust system (E-3).	Procedure governing transportation of SNM. Packaging requirements call for double containment. Procedure governing operator response to a spill. Procedure governing operator response to a CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to sections 9.1.1 and 9.1.3 on radioisotope-bearing spills (liquid and powder).	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
		B. Ventilation supply system	In conjunction with E-3 exhaust system, provides airflow to maintain the DP between zones.	(1) Insufficient supply airflow	Potential increased DP between zones 3 and 1.	Five supply fans normally operating, three fans provide backup. Pressure sensors/alarms and dampers monitor and control the supply airflow to each zone. Single-stage HEPA filtered ventilation exhaust system (E-3).	Procedure governing operator response to a ventilation system upset.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.7F "Building Depressurization - All PFP Operating Buildings."	WHC-SD-CP-SDD-005
				(2) Excessive supply airflow	Potential loss of DP between zones 3 and 1. Potential spread of contamination to zone 1 areas and release to the environment.	Pressure sensors/alarms and dampers monitor and control the supply airflow to each zone. CAMs to detect airborne contamination and to activate alarms.	Procedure governing operator response to a ventilation system upset. Procedure governing operator response to a CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.7A, "Excessive Building Pressurization - 234-5Z."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011

Table 9A.1.2

PFP AL
(Rooms 131-137, 139, and 141-157).

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
	PFP AL, general (continued)	C. E-3 ventilation exhaust system	In conjunction with the ventilation supply system, provides airflow to maintain the DP between zones.	(1) Insufficient exhaust airflow	Potential loss of DP between zones 3 and 1. Potential spread of contamination to zone 1 areas and release to the environment.	Four exhaust fans normally operating, three fans provide backup. Pressure sensors and dampers monitor and control the exhaust airflow from each zone. Two electric exhaust fans connected to backup power. Supply fans to the facility are automatically shutdown on high pressure in the exhaust plenum. Zone 1 exhaust fans shutdown or shutdown of the Zone 3 supply fans. CAMs to detect airborne contamination and to activate alarms.	Procedure governing operator response to a ventilation system upset. Procedure governing operator response to a CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.7A, "Excessive Building Pressurization - 234-5Z."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
				(2) Excessive exhaust airflow	Potential increased DP between zones 3 and 1.	Pressure sensors and dampers monitor and control the exhaust airflow from each zone.	Procedure governing operator response to a ventilation system upset.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.7F "Building Depressurization - All PFP Operating Buildings."	WHC-SD-CP-SDD-005
		D. E-3 ventilation exhaust system HEPA filters.	To filter the room exhaust air through a single-stage of HEPA filtration before it is discharged to the environment.	Loss of HEPA filtration.	Potential release of SNM to the environment.	Seven parallel HEPA filter banks located in seven filter rooms; any three are in use simultaneously with the remaining on stand-by. Testable HEPA filters. 291-Z-1 stack CAM to detect airborne contamination and to activate alarms.	Procedure governing HEPA filter maintenance and testing. Procedure governing operator response to a CAM alarm.	This event is anticipated. The consequences are judged to be low.	Not specifically analyzed.	WHC-SD-CP-SDD-005
2	PFP AL, gloveboxes: general	A. Glovebox enclosure	Confinement of SNM.	Loss of confinement.	Potential release of SNM to the room. Potential entrainment in the ventilation exhaust system and release to the environment.	Glovebox is of steel construction with Lexan™ windows. Lexan™ will not shatter upon strong impact. E-4 exhaust ventilation system maintains glovebox at a negative DP relative to the room. CAMs to detect airborne contamination and to activate alarms.	Procedure governing operator response to CAM alarm. Procedure governing glovebox maintenance.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	The hazard analyses for "Gloveboxes, general" are typical for all gloveboxes. WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011

PFP AL
(Rooms 131-137, 139, and 141-157).

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
	PFP AL, gloveboxes: general (continued)	B. Ventilation supply system (inleakage through inlet HEPA filters)	In conjunction with the E-4 exhaust system, provides airflow to maintain the correct negative DP between zones 3 and 4.	(1) Insufficient supply airflow	Potential excessive negative DP. Potential breach of confinement. Potential release of SNM to the room and entrainment in the ventilation exhaust system.	Glovebox DP gauge. Five operating and two backup supply fans. HEPA-filtered ventilation exhaust system. CAMs to detect airborne contamination and to activate alarms.	Procedure governing operator response to glovebox DP outside of operating limits. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
				(2) Excessive supply airflow	Potential pressurization of the glovebox. Potential release of SNM to the room and entrainment in the E-3 ventilation exhaust system. Potential release to the environment.	E-4 exhaust system will maintain glovebox DP negative relative to the room. CAMs to detect airborne contamination and to activate alarms.	Procedure governing operator response to a CAM alarm.	This event is incredible because supply air is provided by inleakage from the room through inlet HEPA filters.	Refer to section 9.1.9, Glovebox Glove Breach."	WHC-SD-CP-SDD-005
		C. Ventilation supply system inlet HEPA filters	To filter the glovebox exhaust in the event of a flow reversal in order to mitigate the release of SNM from the glovebox.	Loss of filtration.	Potential release of SNM to the room. Potential entrainment in the ventilation exhaust system and release to the environment.	Glovebox DP gauge. CAMs to detect airborne contamination and to activate alarms. Single-stage HEPA-filtered exhaust ventilation system.	Procedure governing operator response to glovebox DP outside of operating limits. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		D. Glovebox exhaust HEPA filters	To filter the glovebox exhaust to mitigate the release of SNM from the glovebox.	Loss of filtration	Potential increased ventilation exhaust system contamination. Potential release of SNM from the ventilation exhaust system to the environment.	HEPA filter DP gauge. Two-stage HEPA-filtered ventilation exhaust system. 291-Z-1 stack CAM to detect airborne contamination and to activate alarms.	Procedure governing operator response to HEPA filter DP outside of operating limits. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Not specifically analyzed.	WHC-SD-CP-SDD-005
		E. E-4 ventilation exhaust system	In conjunction with the supply system, provides airflow to maintain the correct negative DP between zones 3 and 4.	(1) Excessive exhaust airflow	Potential excessive negative DP. Potential loss of confinement and entrainment of any loose SNM into the ventilation exhaust system.	Glovebox outlet HEPA filter. Glovebox DP gauge. HEPA-filtered ventilation exhaust system.	Procedure governing operator response to glovebox DP outside of operating limits.	This event is incredible because the E-4 exhaust fans draw air into the glovebox from the room.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
				(2) Insufficient exhaust airflow	Potential glovebox pressurization, loss of confinement, release of SNM into the room, and entrainment in the E-3 exhaust system.	Glovebox DP gauge. CAMs to detect airborne contamination and to activate alarms. Single-stage HEPA-filtered exhaust ventilation system.	Procedure governing operator response to glovebox DP outside of operating limits. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011

Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
	PFP AL, gloveboxes: general (continued)	F. E-4 exhaust system HEPA filters	To filter the E-4 ventilation exhaust before it is discharged to the environment.	Loss of filtration.	Potential release of SNM to the environment.	Glovebox outlet HEPA filters. Two E-4 ventilation exhaust system filter bank rooms (one in operation and the other on standby) containing 128 filters each. 291-Z-1 stack CAM to detect airborne contamination and to activate alarms.	Procedure governing testing and maintenance of HEPA filters. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Not specifically analyzed.	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006
3	**Room 131 chemical assay laboratory, glovebox (three sections used for dissolution and analysis of product quality plutonium).**	A. Handling of SNM	To safely handle SNM as necessary to support operations.	Inadequate container spacing.	Loss of a single contingency for criticality safety. Potential criticality if there is a loss of an additional criticality.	CAS to detect a criticality and to activate criticality alarms.	Double-contingency principle. CPS posted on glovebox specifies the mass, volume, and spacing limits. Procedure governing operator response to a criticality alarm.	Inadequate spacing is an anticipated event. The consequences are judged to be low.	Refer to section 9.2.3 "Criticality."	Potentially severe consequences to workers in proximity to a criticality. WHC-SD-CP-SDD-003
4	**Room 131 (continued), glovebox section 1 (contains a muffle furnace).**	A. Glovebox enclosure	Confinement of SNM and serves as airlock.	Loss of confinement	Potential release of SNM to the room. Potential entrainment in the ventilation exhaust system and release to the environment.	Glovebox DP gauge. Single-stage HEPA-filtered E-3 ventilation exhaust system. CAMs to detect airborne contamination and to activate alarms.	Procedure governing operator response to glovebox DP outside of operating limits. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		B. Material handling	--	(1) Contact with hot surfaces	Potential loss of confinement (glove breach). Potential release of SNM to the room and entrainment in the exhaust ventilation system.	Furnace door interlock cuts power when the door is opened. CAMs to detect airborne contamination and to activate alarms. High temperature interlock cuts power to the furnace when the glovebox temperature exceeds the allowable limit. Glovebox high temperature alarm. HEPA-filtered ventilation exhaust system. Fire suppression system.	Procedure governing required protective equipment (i.e., heat-resistant gloves). Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[1]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[2]	Engineered	Administrative	Relative probability/consequence discussion[3]	Representative analysis location[4]	
	Room 131, glovebox section 1 (continued)	B. Material handling (continued)	--	(2) Dropped or overfilled container.	Potential spill of SNM within the glovebox. Potential airborne release and entrainment of SNM in the exhaust ventilation system.	Glovebox confinement. Two-stage HEPA-filtered E-4 exhaust ventilation system. 291-Z-1 stack CAM to detect airborne contamination and to activate alarms.	Procedure governing operator response to spill. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.3, "Radioisotope-Bearing Powder Spills".	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006
		C. E-4 exhaust ventilation system	To remove the heat generated by the furnace.	No heat removal.	Potential heat rise within the glovebox. Potential loss of confinement and release of SNM to the room. Potential entrainment in the E-3 exhaust ventilation system.	Four operating and three backup exhaust fans. Pressure sensors and dampers monitor and control the exhaust flow from each zone. Two exhaust fans connected to backup power. CAMs to detect airborne contamination and to activate alarms. Single-stage HEPA-filtered exhaust ventilation system.	Procedure governing operator response to ventilation system upset. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		D. Glovebox muffle furnace	Provides controlled heat for fusing PuO_2 samples.	(1) Excessive temperature	Potential furnace failure. Potential generation of ceramic-like product.	Furnace is equipped with a thermocouple to monitor furnace temperature and an alarm switch that cuts power to the furnace should the temperature exceed 1050 °C.	Procedure governing operator response to temperature alarm switch activation.	This event is anticipated. The consequence is judged to be low.	Not specifically analyzed.	
				(2) Low temperature	Potentially invalid LOI results. Potential storage of reactive material within storage vaults.	Temperature control is computer-controlled.	Procedure governing LOI analysis. Procedure governing maintenance and calibration of the furnace.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.4, "Radioisotope-Bearing Pressurized Powder Container."	Refer to hazard tables in Appendix 9A.2.1 "2736-Z – Vault storage of SNM" and Appendix 9A.2.2 "2736-ZA – Exhaust ventilation and filtration of 2736-Z"
				(3) Temperature ramps up too quickly	Potential furnace failure.	Temperature control is computer-controlled.	Procedure governing maintenance and calibration of the furnace.	This event is anticipated. The consequence is judged to be low.	Not specifically analyzed.

PFP AL
(Rooms 131-137, 139, and 141-157).

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
	Room 131, glovebox section 1 (continued)	D. Glovebox muffle furnace (continued)	Provides controlled heat for fusing PuO_2 samples.	(4) Insufficient time at temperature	Potentially invalid LOI results. Potential storage of reactive material within storage vaults.	Temperature control is computer-controlled.	Procedure governing LOI analysis. Procedure governing maintenance and calibration of the furnace.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.4, "Radioisotope-Bearing Pressurized Powder Container."	Refer to Appendix 9A.2.1 "2736-Z -- Vault storage of SNM" and Appendix 9A.2.2 "2736-ZA -- Exhaust ventilation and filtration of 2736-Z"
5	**Room 131, glovebox section 2**	Dissolving, heating, and titration of samples.	--	(1) Spill	Potential airborne release and entrainment in the E-4 ventilation exhaust system.	Glovebox enclosure. Two-stage HEPA-filtered E-4 ventilation exhaust system. Glovebox exhaust HEPA filter. CAMs to detect airborne contamination and to activate alarms.	Procedure governing operator response to spill. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.1, "Radioisotope-Bearing Liquid Spills."	WHC-SD-CP-SDD-005
				(2) Excessive temperature	Potential glovebox glove breach. Potential release of SNM to the room. Potential entrainment in the E-3 exhaust system and release to the environment.	CAMs to detect airborne contamination and to activate alarms. Single-stage HEPA-filtered ventilation exhaust system (E-3). Glovebox fire suppression system.	Procedure governing use of hot plate. Combustibles in the glovebox are kept to a minimum. Procedure governing operator response to a CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
6	**Room 131, glovebox section 3 (contains a argon-purged balance).**	A. Reagents	Safe concentrations are used in analytical procedures involving plutonium.	Detonable reagent concentration.	Potential detonation. Potential loss of confinement and release of SNM to the room. Potential entrainment of SNM in the E-3 exhaust system.	The E-4 exhaust ventilation system. CAMs to detect airborne contamination and to activate alarms. Single-stage HEPA-filtered E-3 exhaust system.	Procedure governing allowable quantity of reagent. Procedure governing operator response to CAM alarm.	This event extremely unlikely. The consequences are judged to be low.	Not specifically analyzed.	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		B. Argon supply	Used to purge balance.		Potential asphyxiation of operators.	Rotameter on argon supply acts as an orifice to limit flow. E-3 and E-4 ventilation exhaust systems.	Procedure governing operation and maintenance of argon supply equipment.	This event is unlikely. The consequences are judged to be low.	Not specifically analyzed.	WHC-SD-CP-SDD-005.
7	**Room 132, mass spectrometer laboratory.**	Nitrogen supply for mass spectrometer.	Used to cool the spectrometer.	(1) Leak	Potential asphyxiation of operators.	E-3 and E-4 ventilation exhaust system. Nitrogen supply control system.	Procedure governing operation and maintenance of nitrogen supply equipment.	This event is unlikely. The consequences are judged to be low.	Not specifically analyzed.	WHC-SD-CP-SDD-005
				(2) No flow.	Potential overheating of mass spectrometer.	--	Procedure governing operation and maintenance of nitrogen supply equipment.	This event is unlikely. The consequence is judged to be low.	Not specifically analyzed.	
8	**Room 133, dark room**		Used to develop film.	--						No radioactive materials are allowed in the room.

Table 9A.1.2

9	**Rooms 134 and 135, mass spectrometry sample preparation: hoods 1 through 4**	A. E-4 ventilation exhaust system	To provides exhaust airflow for the removal of the fumes generated by operations in the hood.	(1) Insufficient exhaust airflow	Potential release of hazardous fumes into the room.	Four operating and three backup exhaust fans. Pressure sensors and dampers monitor and control the exhaust flow from each zone. Hood DP gauge.	Procedure governing verification of adequate exhaust flow rate.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.2.8, "Toxic Chemical Release."	WHC-SD-CP-SDD-005
				(2) Excessive exhaust airflow	Potential entrainment of loose material into the ventilation exhaust system and release to the environment.	Hood exhaust HEPA filters. Two-stage HEPA-filtered exhaust ventilation system.	--	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.3, "Radioisotope-Bearing Powder Spill."	WHC-SD-CP-SDD-005
		B. Hood exhaust HEPA filters	To filter exhaust air from the hood before it is discharged to the E-4 exhaust system.	Loss of filtration.	Potential release of SNM to the E-4 ventilation exhaust system. Potential release to the environment.	HEPA filter DP gauge. Two-stage HEPA-filtered E-4 exhaust system. 291-Z-1 stack CAM to detect airborne contamination and to activate alarms.	Procedure governing operator response to HEPA filter DP outside of operating limits.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.3, "Radioisotope-Bearing Powder Spill."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006
		C. Preparation of samples for mass spectrometer.	To safely prepare samples for analysis.	Spill	Potential generation of airborne contaminants. Potential entrainment in the exhaust system and release to the environment.	Hood enclosure. Hood exhaust HEPA filters. Two-stage HEPA-filtered E-4 exhaust system.	Procedure governing operator response to a spill.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.1, "Radioisotope-Bearing Liquid Spills."	WHC-SD-CP-SDD-005
10	**Rooms 136 and 137, glovebox (one per room). Glovebox is divided into three sections. Section 1 contains a muffle furnace**	A. Material handling	To safely handle material as necessary to support operations.	Refer to item 4B.	Refer to item 4B.	Refer to item 4B.	Refer to item 4B.	Refer to item 4B.	Refer to item 4B. [a]Event category and hazard identifier.
[b]The consequence, as given here, assumes none of the active preventive/mitigative features are in place.
[c]The probability/consequence, as given here, assumes that the preventive/mitigative features are operative.
[d]Gives the section number in the chapter where additional accident analysis is performed.

Appendix 9A.1.3

PLUTONIUM PROCESS SUPPORT LABORATORIES

The PPSL are located in the southwest corner of the 234-5Z Building in rooms 179 through 191 and room 202. These laboratories provide flowsheet verification, flowsheet enhancement, and prototype development studies for the PFP, other Hanford Site facilities, and offsite customers.

The PPSL are chartered to operate nonradioactive and radioactive chemical-oriented demonstration laboratories and equipment to support numerous programs across the Hanford Site and, on occasion, other DOE sites. The PPSL facilities include necessary connections to essential building services, including ventilation, drains, vacuum, electricity, water, distilled water, and compressed air. The PPSL support processing facilities flowsheet evaluation, troubleshooting, new technology implementation, and process demonstration. The above activities are performed on both bench- and pilot-plant scales. The PPSL also perform analyses of nonroutine samples for process support and develop new methods that are transferred to other organizations when the methodology is well established and the need becomes routine. The PPSL also process limited quantities of SNM to demonstrate processes whenever the PPSL have exclusive expertise.

The PPSL contain eight gloveboxes (two of which are inactive) and eight hoods (three of which are inactive). An administrative limit of 6.0 kg of plutonium, of which not more than 2,250 g is >10% ^{240}Pu, has been established. This material, in the form of a powder or a solution, could be located within gloveboxes, hoods, or both.

The gloveboxes in the rooms are used to support bench-scale (mostly wet) chemical procedures to support process development. Examples of these procedures are dissolution, reclamation of plutonium from scrap, extraction, and small scale plutonium work.

Rooms 179 through 188 contain gloveboxes operated by the PPSL. There are no processes in these gloveboxes having a potential for an explosion hazard. These gloveboxes (like the PFP AL gloveboxes) are always open to the introduction of a wide variety of chemicals. The type of support work performed tends to use larger quantities of material than is used in the PFP AL, but less than is used in the production gloveboxes. Room 202 is the nonradioactive pilot-plant laboratory and contains one walk-in hood and two large countertop areas for general chemistry projects. Rooms 81 through 90, 205, 250, and 251-A are used as offices. Room 80 and vault 201 are used for equipment storage.

The following Hazard Evaluation table identifies stack CAMs as a preventive/mitigative feature for several postulated failure events. The CAMs perform a passive function, which is to detect airborne radioactive material and to activate alarms should the alarm set-point on the CAM be exceeded. They do not provide an active function which would actuate equipment or systems to prevent or mitigate an accident. In most cases the CAMs do not serve to reduce the consequences associated with a release of airborne radioactive material because most accidents involve a sudden release of material over a short period of time. Therefore, by the time the stack CAM

detects the release there would be insufficient time to mitigate the event. In addition, the CAM's location in the ventilation discharge stack precludes any preventive/mitigative action since the release would have already occurred. Potentially chronic releases from process operations, or due to equipment failures (e.g., failed HEPA filters), tend to be small in nature. If these releases are sufficient to actuate the CAM alarm, operator action is generally adequate to limit the release so there is no significant consequence. It should be noted that accidents evaluated in the Chapter 9.0 analyses did not rely on the CAMs to serve a preventive/mitigative function.

Table 9A.1.3
The 234-5Z Building: PPSL
(Rooms 179, 180, 182, 183)
(187-191, and 202).

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
1	PPSL, general	A. Handling of SNM containers	To safely handle SNM within the PPSL as necessary to support operations.	(1) Inadequate container spacing	Potential criticality which results in high levels of radiation in room. Potential release of fission products to the atmosphere.	Lard cans and food pack cans are transported in fixed array wagons. 30- to 55-gal drums are moved one at a time using drum barrel hand trucks. CAS to detect criticality and to activate alarms. Single-stage HEPA-filtered ventilation exhaust system.	Procedure governing movement of SNM. Double contingency principle precludes the potential for a criticality as a result of a single failure. Procedure governing operator response to criticality alarm.	Inadequate spacing of containers is an anticipated event. The consequences are judged to be low.	Refer to section 9.2.3 "Criticality"	Potentially severe consequences to workers in proximity of a criticality. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005
				(2) Dropped container	Potential release of SNM to the room. Potential entrainment of SNM in the ventilation system and release to the environment.	Carriers (drum barrel hand truck, fixed array wagon, lard can wagon) are designed for specific operation. CAMs to detect airborne contamination and to activate alarms. Single-stage HEPA-filtered exhaust system.	Procedure governing movement of SNM. Packaging requirements call for double containment. Procedure governing operator response to a spill. Procedure governing operator response to a CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.1,"Radioisotope-Bearing Liquid Spills", and section 9.1.3, "Radioisotope-Bearing Powder Spills."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
		B. Ventilation supply system	To provide airflow to maintain the correct DP between zones.	(1) Insufficient supply airflow	Potential increased DP between zones 3 and 1 and decreased DP between zones 3 and 4.	Five supply fans normally operating, three fans provide backup. Pressure sensors and dampers used to monitor and control the supply airflow to each zone.	Procedure governing operator response to ventilation system upset.	This event is anticipated. Flow will be from areas of no contamination (zone 1) to areas of potential contamination (zone 3). The consequence is judged to be low.	Refer to section 9.1.7F "Building Depressurization-All PFP Operating Buildings."	WHC-SD-CP-SDD-005
				(2) Excessive supply airflow	Potential loss of DP between zones 3 and 1. Potential release of SNM to zone 1 areas and entrainment in the ventilation exhaust system.	Pressure sensors and dampers used to monitor and control the supply airflow to each zone. CAMs to detect airborne contamination and to activate alarms. Single-stage HEPA-filtered ventilation exhaust.	Procedure governing operator response to ventilation system upset. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.7A, "Excessive Building Pressurization--234-5Z."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011

Table 9A.1.3

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
	PPSL, general (continued).	C. E-3 ventilation exhaust system	To provide airflow to maintain the correct DP between zones.	(1) Insufficient exhaust airflow	Potential loss of DP between zones 3 and 1. Potential release of SNM to zone 1 areas and entrainment in the ventilation exhaust system.	Four exhaust fans normally operating, three fans provide backup. Pressure sensors and dampers used to monitor and control the exhaust airflow from each zone. Two exhaust fans connected to backup power. Supply fans to the facility automatically shut down on high pressure reading in the exhaust plenum. CAMs to detect airborne contamination and to activate alarms. Single-stage HEPA-filtered ventilation exhaust system.	Procedure governing operator response to ventilation system upset. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.7A, "Excessive Building Pressurization--234-5Z."	WHC-SD-CP-SDD-005
				(2) Excessive exhaust airflow	Increased DP between zones 3 and 1.	Pressure sensors and dampers used to monitor and control the exhaust airflow from each zone.	Procedure governing operator response to ventilation system upset.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.7F, "Building Depressurization - All PFP Operating Buildings."	WHC-SD-CP-SDD-005
		D. E-3 ventilation exhaust HEPA filters.	To provide single-stage HEPA filtration of room exhaust.	Loss of HEPA filtration	Potential release of SNM to the environment.	Single-stage HEPA filtration provided by filters in seven filter rooms; any three rooms are in use simultaneously with the remaining on standby. 291-Z-1 stack CAM to detect airborne contamination and to activate alarms.	Procedure governing maintenance and testing of HEPA filters. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Not Specifically Analyzed.	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006
2	PPSL, gloveboxes (general)	A. Glovebox enclosure	Confinement of SNM	Loss of confinement	Potential release of SNM to the room. Potential entrainment of SNM in the ventilation system and release to the environment.	Glovebox is of steel construction with Lexan™ windows. Lexan will not shatter upon strong impact. E-4 exhaust ventilation system maintains negative DP in glovebox relative to the room. CAMs to detect airborne contamination and to activate alarms.	Procedure governing operator response to CAM alarm. Procedure governing glovebox inspection and maintenance.	This event is anticipated. Historical events have resulted in minor worker uptake. Thus, the consequence is judged to be low.	Refer to section 9.1.9 "Glovebox Glove Breach."	The hazards analysis for "Gloveboxes, general" are typical for all gloveboxes. Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
	PPSL, gloveboxes; general (continued)	B. Ventilation supply system (inleakage via inlet HEPA filters)	To provide airflow to maintain correct DP between zones 3 and 4.	(1) Insufficient supply airflow	Potential excessive negative DP in glovebox relative to room. Potential breach of confinement.	Glovebox DP gauge. CAMs to detect airborne contamination and to activate alarms. Single-stage HEPA-filtered exhaust system.	Procedure governing operator response to glovebox DP outside of operating limits. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
				(2) Excessive supply airflow	Potential pressurization of glovebox relative to the room. Potential release of SNM to the room and entrainment in the E-3 ventilation system.	E-4 exhaust system will maintain negative DP of glovebox relative to the room. CAMs to detect airborne contamination and to activate alarms. HEPA-filtered ventilation exhaust system.	Procedure governing operator response to glovebox DP outside of operating limits. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.4, "Radioisotope-Bearing Pressurized Powder Container."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
		C. Inlet HEPA filters	To filter glovebox exhaust air should a flow reversal occur.	Loss of filtration	Potential release of SNM to the room. Potential entrainment in the ventilation system and release to the environment.	E-4 exhaust system will maintain glovebox at negative DP relative to the room. Room CAMs provided to detect airborne contamination and to activate alarms. HEPA-filtered exhaust ventilation system.	Procedure governing operator response to ventilation system upset. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
		D. E-4 ventilation exhaust system	To provide airflow to maintain correct DP between zones 3 and 4.	(1) Excessive exhaust airflow	Potential excessive negative DP in glovebox. Potential breach of containment. Potential entrainment of loose material into ventilation duct.	Glovebox DP gauge. Glovebox outlet HEPA filter. Two-stage HEPA-filtered exhaust ventilation system.	Procedure governing operator response to glovebox DP outside of operating limits.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
				(2) Insufficient exhaust airflow	Potential glovebox pressurization. Potential loss of confinement. Potential release of SNM to the room and entrainment in the exhaust ventilation system.	Glovebox DP gauge. Room CAMs to detect airborne contamination and to activate alarms. HEPA-filtered exhaust ventilation system.	Procedure governing operator response to glovebox DP outside operating limits. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.9, "Radioisotope-Bearing Pressurized Powder Container."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011

Table 9A.1.3

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
	PPSL, gloveboxes; general (continued)	E. E-4 exhaust system HEPA filters.	To filter exhaust ventilation air prior to atmospheric discharge in order to mitigate the release of SNM to the environment.	Loss of filtration.	Potential release of SNM to the environment.	Glovebox outlet filters. Testable E-4 exhaust HEPA filters. 291-Z-1 stack CAM to detect airborne contamination and to activate alarms.	Procedure governing testing of HEPA filters. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Not specifically analyzed.	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006
3	**Room 179, process support lab (the room is used for working with plutonium and other TRU isotopes).**	Gas cylinders (helium and air)	To provide safe storage of pressurized gases.	High-velocity cylinder projectile due to high-pressure release.	Potential equipment damage from cylinder impact. Potential minor to severe injury to operators. Potential breach of glovebox and release of SNM to the room.	Restraints used on gas bottles. CAMs to detect airborne contamination and to activate alarms. HEPA-filtered ventilation exhaust system.	Procedure governing transport of pressurized gas bottles. Procedure governing operator response to CAM alarm.	This event is extremely unlikely. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
4	**Room 179, glovebox 1 (houses the TGA system).**	A. E-4 exhaust system	To remove the heat generated by the TGA.	Failure to remove heat.	Potential increased temperature within glovebox. Potential loss of glovebox confinement and release of SNM to the room. Potential entrainment of SNM in the ventilation system and release to the environment.	Four exhaust fans normally operating; three fans provide backup. Pressure sensors and dampers monitor and control the exhaust airflow from each zone. Two exhaust fans are provided with backup power.	Procedure governing operator response to ventilation system upset.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005
		B. TGA system	Used in LOI analysis to determine the amount of volatiles remaining in the SNM.	(1) High temperature	Potential damage to the heating elements of the TGA. Potentially invalid LOI results.	The TGA is equipped with a thermocouple and a high temperature alarm switch. The alarm switch is designed to cut power to the furnace. Audible and visible alarms.	Procedure governing operator response to high temperature alarm.	This event is anticipated. The consequence is considered low.	Not specifically analyzed.	
				(2) Low temperature	Potentially invalid LOI results. Potential storage of reactive material in vaults.	TGA is computer-controlled.	Procedure governing LOI analysis.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.4, "Radioisotope-Bearing Pressurized Powder Container."

	Room 179, glovebox 1 (continued)	B. TGA system (continued)	Used in LOI analysis to determine the amount of volatiles remaining in the SNM.	(3) Temperature ramps up too quickly	Potential damage to the TGA heating elements resulting in the loss of the TGA.	TGA is computer-controlled.	Procedure governing LOI analysis.	This event is anticipated. The consequence is judged to be low.	Not specifically analyzed.	
				(4) Insufficient time at temperature	Potentially invalid LOI results. Potential storage of reactive material in vaults.	TGA is computer-controlled.	Procedure governing LOI analysis.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.4, "Radioisotope-Bearing Pressurized Powder Container."	
5	Room 179, gloveboxes 4, 6, 9, 10, and 12.	A. E-4 exhaust system	To remove the heat generated by hot plates/furnaces.	Failure to remove heat.	Refer to item 2D.	Refer to item 2D.	Refer to item 2D.	Refer to item 2D.	Refer to item 2D.	Refer to item 2D.
		B. Hot plates/furnaces	To safely heat samples as necessary to support operations.	Excessive temperature.	Potential ignition and melting of glovebox gloves. Potential release of SNM to the room. Potential entrainment in the ventilation system and release to the environment.	Glovebox temperature monitored by thermocouples. Fire suppression system activation. CAMs to detect airborne contamination and to activate alarms. HEPA-filtered ventilation system.	Procedure governing protective clothing (i.e., heat-resistant gloves) requirements. Procedure governing allowable amount of combustibles in glovebox.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
6	Room 179, gloveboxes 10 and 12	Criticality drain	To drain liquid from the glovebox in order to prevent it from accumulating to a depth sufficient for a criticality.	Liquid accumulation sufficient for a criticality.	Loss of a single contingency for criticality safety. Potential criticality should there be the loss of an additional contingency.	The CAS to detect a criticality and to activate alarms.	Double-contingecny principle. Procedure governing functionality of criticality drains. Procedure governing operator response to criticality alarm.	This event is unlikely. The consequences are judged to be low.	Refer to section 9.2.3, "Criticality."	Potentially severe consequences to workers in proximity to a criticality. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-008
7	Room 179, hoods 2 and 3	A. Airlock access leading into the glovebox.	To capture contaminated air and direct it into the E-4 exhaust ventilation system.	Loss of exhaust ventilation.	Potential release of contamination from the glovebox to the room. Potential entrainment in the E-3 ventilation exhaust system.	Four exhaust fans normally operating, three fans provide backup. Pressure sensors and dampers to monitor and control the exhaust airflow from each zone. CAMs to detect airborne contamination and to activate alarms. HEPA-filtered exhaust system.	Procedure governing operation of airlock. Procedure governing operator response to CAM alarm.	This is an anticipated event. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
	Room 179, hoods 2 and 3 (continued)	B. Handling of SNM containers.	--	Inadequate container spacing or too many containers.	Loss of a single contingency for criticality safety. Potential criticality if there is a loss of an additional contingency.	CAS to detect a criticality and to activate alarms.	CPS posted on the hood limits the mass, volume, and spacing. Double-contingency principle precludes the potential for a criticality as a result of a single failure. Procedure governing operator response to a criticality alarm.	Inadequate spacing is an anticipated event. The consequences are judged to be low.	Refer to section 9.2.3, "Criticality."	Potentially severe consequences to workers in proximity to a criticality. WHC-SD-CP-SDD-003
8	Room 179, hood 11	Airlock access leading into gloveboxes 10 and 12.	To capture contaminated air and direct it into the E-4 exhaust ventilation system.	Loss of exhaust ventilation	Refer to item 7A.	Refer to item 7A.	Refer to item 7A.	Refer to item 7A.	Refer to item 7A.	Refer to item 7A.
9	Room 180, glovebox (houses the TGA system).	A. E-4 exhaust system	To remove the heat generated by the TGA.	Failure to remove heat.	Potential temperature rise within glovebox. Potential loss of confinement. Potential release of SNM to the room and entrainment in the ventilation system.	Four exhaust fans normally operating, three fans provide backup. Pressure sensors and dampers monitor and control the exhaust airflow from each zone. CAMs to detect airborne contamination and to activate alarms. HEPA-filtered exhaust ventilation system.	Procedure governing operator response to ventilation system upset. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
		B. TGA system	To perform LOI analysis in order to determine the percentage of volatiles within the SNM.	(1) High temperature	Potential failure of the TGA.	Thermocouple to monitor TGA temperature and a alarm switch to cut power upon excessive temperature.	Procedure governing operator response to TGA high temperature alarm.	This event is anticipated. The consequences are judged to be low.	Not specifically analyzed.	WHC-SD-CP-SDD-005
				(2) Low temperature	Potentially invalid LOI results. Potential storage of reactive SNM within vaults.	The TGA is computer-controlled.	Procedure governing LOI analysis.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.4, "Radioisotope-Bearing Pressurized Powder Container."	WHC-SD-CP-SDD-005
				(3) Temperature ramps up too quickly	Potential failure of the TGA.	The TGA is computer-controlled.	Procedure governing LOI analysis.	This event is anticipated. The consequences are judged to be low.	Not specifically analyzed.	WHC-SD-CP-SDD-005

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
	Room 180, glovebox (continued)	B. TGA system (continued)	To perform LOI analysis of SNM.	(4) Insufficient time at temperature	Potentially invalid LOI results. Potential storage of reactive SNM within vaults.	The TGA is computer-controlled.	Procedure governing LOI analysis.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.4, "Radioisotope-Bearing Pressurized Powder Container."	WHC-SD-CP-SDD-005
10	**Room 180, argon cylinder**	Pressurized argon and nitrogen cylinders (cylinders located in 2734-ZA).	To provide containment for pressurized gases.	(1) High-velocity cylinder projectile due to high-pressure release.	Potential equipment damage. Potential minor to severe injury to operators. Potential rupture of glovebox and release of SNM. Potential release of SNM to the environment.	Gas bottles moved on hand trucks. Restraints used on stored gas bottles.	Procedure governing transport and storage of pressurized gas bottles.	This event is extremely unlikely. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
				(2) Loss of containment.	Potential release of argon/nitrogen into the room. Potential asphyxiation of personnel.	High pressure is physically limited by pressure-relief valves on supply system. E-4 exhaust ventilation system.	Procedure governing equipment maintenance.	This event is unlikely. The consequences are judged to be low.	Not Specifically Analyzed.	
11	**Room 182, process support lab microscope**	–	Houses the scanning electron microscope	–						
12	**Room 183, specialized processing**	–	Used for liquid scintillation counting and storage of waste drums prior to removal from the building.	Spill	Potential release of SNM to the room. Potential entrainment in the ventilation exhaust system.	CAMs to detect airborne contamination and to activate alarms. HEPA-filtered exhaust ventilation system.	Procedure governing transportation of waste drums. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.3, "Radioisotope-Bearing Powder Spills."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
13	**Room 186, laboratory chemical storage**	–	To safely store chemicals used in the PPSL.	Spill	Potential release of chemicals to sanitary sewer. Potential exposure of operators to hazardous chemicals.	Exhaust ventilation system.	Procedure governing operator response to chemical leak.	This event is anticipated. The consequences are judged to be low.	Not specifically analyzed.	WHC-SD-CP-SDD-005
14	**Room 187, laboratory open-faced hoods, 1 through 5**	A. E-4 exhaust ventilation system	To remove fumes generated by operations conducted within the hood.	(1) Insufficient exhaust airflow	Potential operator exposure to toxic fumes.	Four exhaust fans normally operating; three fans provide backup. Two exhaust fans are connected to backup power (1 of 2 operates on loss of normal power). Hood flowmeter.	Procedure governing operator response to exhaust flowrate outside of operating limits. Procedure governing operator response to release of toxic fumes.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.2.8, "Toxic Chemical Release."	WHC-SD-CP-SDD-005

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
	Room 187, hoods 1 through 5 (continued).	A. E-4 exhaust ventilation system (continued)	To remove fumes generated by operations conducted within the hood.	(2) Excessive exhaust flow	Potential entrainment of loose material into E-4 ventilation exhaust system.	Hood exhaust HEPA filter prevents loose material from entering the ventilation duct.	Procedure governing operator response to ventilation system upset.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.3, "Radioisotope-Bearing Powder Spills."	WHC-SD-CP-SDD-005
		B. Hood exhaust HEPA filters	To remove particulates from the hood exhaust flow.	Loss of filtration.	Potential entrainment of SNM in the E-4 ventilation system. Potential release of SNM to the environment.	291-Z-1 exhaust stack CAM. HEPA filter DP gauge. Two-stage HEPA-filtered exhaust ventilation system (E-4).	Procedure governing operator response to HEPA filter DP outside of operating limits.	This event is anticipated. The consequences are judged to be low.	Not specifically analyzed.	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
15	**Room 188, glovebox 188-1 (houses the calciner system).**	A. Handling and storage of plutonium-bearing containers	–	(1) Inadequate container spacing	Loss of a single contingency for criticality safety. Potential criticality if there is a loss of an additional contingency.	CAS to detect a criticality and to activate alarms.	Double-contingency principle. Gloveboxes are labeled per CPSs as to the allowable limits on plutonium quantities, container volumes and minimum spacing. Procedure governing operator response to criticality alarms.	Inadequate spacing of containers is an anticipated event. The consequences are judged to be low.	Refer to section 9.2.3, "Criticality."	Potentially severe consequences to workers in proximity to a criticality. WHC-SD-CP-SDD-003
16	**Room 188 glovebox 188-1 (continued)**	A. Material Handling (continued)	–	(2) Contact with hot surfaces	Potential loss of confinement. Potential release of plutonium-bearing materials to the room.	Thermocouples to monitor glovebox temperature. Power to the calciner is cut automatically when the glovebox temperature exceeds the operating limit. Fire suppression system. CAMs to detect airborne contamination and to activate alarms. HEPA-filtered ventilation exhaust system.	Procedure governing protective clothing requirements (i.e., heat-resistant gloves). Procedure governing combustible loading of glovebox.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		B. E-4 ventilation exhaust system	To remove the heat generated by the calciner.	Failure to remove heat.	Refer to item 2D.	Refer to item 2D.	Refer to item 2D.	Refer to item 2D.	Refer to item 2D.	Refer to item 2D.
		C. Criticality drain	To drain liquid from the glovebox in order to prevent it from accumulating to a depth sufficient for a criticality.	Liquid accumulation sufficient for a criticality.	Potential criticality resulting in high levels of radiation within the room. Potential release of fission products to the room and to the atmosphere.	Drains are protected from plugging by large mesh screens. CAS to detect criticality and to activate criticality alarms.	Double-contingency principle. Procedure governing operator verification of drain functionality. Procedure governing operator response to criticality alarm.	This event is unlikely. The consequences are judged to be low.	Refer to section 9.2.3, "Criticality."	Potentially severe consequences to workers in proximity to a criticality. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-008

(187-191, and 202).

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
17	Room 188, calciner	--	To contain and stabilize plutonium nitrate solutions via controlled heating.	(1) Excessive temperature	Potential failure of the calciner. Potential loss of confinement and entrainment of SNM in the ventilation system.	Thermocouple probe measures calciner temperature and activates interlock to cut off power to the calciner upon excessive temperature. Local high temperature alarm. HEPA-filtered ventilation exhaust system.	Procedure governing operator response to high temperature alarm.	This is an anticipated event. The consequences are judged to be low.	Refer to section 9.1.2, "Radioisotope-Bearing Pressurized Liquid Container."	WHC-SD-CP-SDD-005
				(2) Low temperature	Potential incomplete removal of volatiles. Potential flooding of the calciner and the formation of paste in the material bed.	Temperature is computer controlled. Interlock prevents feed pump from operating when temperature is < 700 °C. Calciner contained within glovebox.	An LOI analysis is used to verify volatiles have been removed.	This is an anticipated event. The consequences are judged to be low.	Refer to section 9.1.3, "Radioisotope-Bearing Pressurized Liquid Container."	WHC-SD-CP-SDD-005
				(3) Insufficient time at temperature	Potential incomplete removal of volatiles. Potential storage of reactive material in vaults.	Temperature/time are computer controlled.	An LOI analysis is used to verify volatiles have been removed.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.4, "Radioisotope-Bearing Pressurized Powder Container."	WHC-SD-CP-SDD-005
				(4) Temperature ramps up too quickly	Potential failure of the calciner due to excessive thermal stress.	Temperature/time are computer controlled. Calciner contained within glovebox.	--	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.2, "Radioisotope-Bearing Pressurized Liquid Container."	WHC-SD-CP-SDD-005
				(5) Insufficient mixing	Potential incomplete removal of volatiles. Potential storage of reactive material in vaults.	Calciner equipped with an agitator.	An LOI analysis is used to verify volatiles have been removed.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.4, "Radioisotope-Bearing Pressurized Powder Container."	WHC-SD-CP-SDD-005
		A. Calciner $PuNO_3$ feed	To introduce $PuNO_3$ into the vertical calciner in a controlled process.	(1) Excessive flow	Potential pressurization of the calciner. Potential violation of criticality limit. Potential incomplete removal of volatiles and storage of reactive material in the vaults.	Feed pumps are interlocked with a master stop switch. Feed pump is disabled by the temperature controller when the temperature in the calciner is < 700 °C.	An LOI analysis is used to verify that all of the volatiles have been removed.	This is an anticipated event. The consequences are judged to be low.	Refer to section 9.1.2, "Radioisotope-Bearing Pressurized Liquid Container."	WHC-SD-CP-SDD-005

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
	Room 188, calciner (continued)	A. Calciner $PuNO_3$ feed (continued)	To introduce $PuNO_3$ into the vertical calciner in a controlled process.	(2) Inadequate flow	No product or insufficient product produced by calciner. Potential plugging of the feed tube.	Feed tube designed to be easily replaced. Cleanout rod to clear blockage.	Procedure governing operation and maintenance of calciner.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.2, "Radioisotope-Bearing Pressurized Liquid Container."	WHC-SD-CP-SDD-005
				(3) High organic feed solution	Potential filter blockage and pressurization of the calciner.	Filter blow-back system designed to dislodge any accumulated material from the filter surface.	Procedure governing sampling of feed solution for organics before calcination.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.2, "Radioisotope-Bearing Pressurized Liquid Container."	WHC-SD-CP-SDD-005
				(4) High plutonium content feed solution	Potential criticality resulting in high levels of radiation in the room and a potential release of fission products to the atmosphere.	The calciner is engineered to be inherently critically favorable under any conditions. CAS to detect criticality and to activate alarms.	Double-contingency principle. Procedure governing operator response to criticality alarm.	High plutonium content feed solution is an anticipated event. The consequences are judged to be low.	Refer to section 9.2.3, "Criticality."	Potentially severe consequences to workers in proximity to a criticality. WHC-SD-CP-003
		B. Calciner $PuNO_3$ feed pump transfer line	To provide containment of $PuNo_3$ as it is transferred from the feed tank to the calciner.	Loss of containment.	Potential excessive $PuNO_3$ solution in glovebox. Potential criticality and resulting high levels of radiation within the room. Potential release of fission products to the atmosphere.	Glovebox 188-1 is equipped with a criticality drain. CAS to detect criticality and to activate alarms.	Procedure governing operator response to leak from feed line. Double contingency principle. Procedure governing operator response to criticality alarm.	A line leak is an anticipated event. The consequences are judged to be low.	Refer to section 9.2.3, "Criticality."	Potentially severe consequences to workers in proximity to a criticality. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-008
		C. Calciner process air supply	To insulate the liquid feed from the hot baseplate and to provide some cooling.	Inadequate airflow	Potential boiling of feed solution. Potential degradation of the feed port. Potential flow of plutonium nitrate solution through air line and into the process air system.	Interlock installed to shut down feed pump when air pressure falls below 60 lb/in^2. The feed tube is designed to be easily replaced.	Procedure governing operator response to feed pump shut down.	This event is anticipated. The consequences are judged to be low.	Not specifically analyzed.	WHC-SD-CP-SDD-005

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
	Room 188, calciner (continued)	D. Calciner offgas filter sintered ceramic filter elements	To remove particulates from the calciner offgas.	Failure to remove particulates.	Potential release of plutonium into offgas system and contamination of scrubber solution. Potential contamination of cooling water. Potential criticality and release of fission products to the atmosphere.	High filter DP indicator light. Two-stage HEPA-filtered E-4 ventilation system. Cooling water is pressurized and the scrubber shell is under vacuum, reducing the potential for contamination of the cooling water. Scrubber designed to operate with constant overflow, thus limiting plutonium buildup. CAS to detect a criticality and to activate criticality alarms.	Procedure governing operator response to HEPA filter DP high pressure warning light. Procedure governing operator response to criticality alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.2.3, "Criticality."	Potentially severe consequences to workers in proximity to a criticality. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005
		E. Calciner offgas scrubber	To cool the calciner offgas and to neutralize the acidic vapors.	(1) Insufficient cooling.	Potential entrainment of hot acidic gases into the 26-in mercury vacuum and offgas systems. Potential failure of equipment.	Caustic solution is metered continuously into the scrubber to maintain the desired caustic concentration.	Procedure governing addition of caustic solution to maintain the proper pH.	This event is anticipated. The consequences are judged to be low.	Not specifically analyzed.	In the production version, a pH analyzer/controller will maintain scrubber pH.
				(2) No neutralization of acidic vapors.	Potential failure of vacuum system line due to corrosion.	The pH is manually maintained by adjusting the caustic makeup feed pump flow rate to match feed acidity, salt nitrate, and feed rate.	Procedure governing maintenance of proper solution pH.	This event is anticipated. The consequences are judged to be low.	Not specifically analyzed.	Refer to above.
				(3) Loss of scrubber confinement.	Potential flow of sodium hydroxide solution and hot acidic offgas into the glovebox. Potential breach of glovebox and release of SNM to the room. Potential release of SNM to the environment.	Two-stage HEPA-filtered E-4 ventilation exhaust system to remove acidic offgas. CAMs to detect airborne contamination and to activate alarms.	Procedure governing operator response to loss of scrubber confinement.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		F. 26-in. mercury vacuum system	To provide the motive force necessary for removing the calciner offgas.	(1) Insufficient vacuum	Potential buildup of gases inside the calciner. Potential exhaust of excess gases through the pressure relief valve into the glovebox.	Glovebox enclosure. Two-stage HEPA-filtered E-4 ventilation exhaust system removes gases from the glovebox.	Procedure governing operator response to actuation of calciner pressure relief valve.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.2, "Radioisotope-Bearing Pressurized Liquid Container."	WHC-SD-CP-SDD-005.

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
	Room 190, radioactive material storage vault (continued).	B. E-3 ventilation supply system.	Provides airflow for removal of heat generated by decay of the SNM within the vault and for maintaining correct negative DP control of the vault.	(1) Insufficient supply airflow	Potential excessive negative pressure within the vault if the exhaust system continues to operate. Additional thermal loading of containers and resultant potential loss of containment.	Pressure sensors and dampers monitor and control the flow of supply air. Five supply fans normally operating; three are on standby. SNM contained within sealed storage containers. CAMs to detect airborne contamination and to activate alarms. Two-stage HEPA-filtered ventilation system to mitigate the release of SNM to the environment.	OSD requires SNM stored in the vault to be packaged with a minimum of two containment barriers. Procedure governing operator response to CAM alarm. Procedure governing operator response to a ventilation system upset.	This is an anticipated event. The consequences are judged to be low.	Refer to section 9.1.7F, "Building Depressurization--All PFP Operating Buildings."	WHC-SD-CP-SDD-005 Whc-SD-CP-SDD-011
				(2) Excessive flow of supply air.	Potential pressurization of vault relative to corridor and release of SNM to corridor if there is any loose SNM within the vault.	Pressure sensors and dampers monitor and control the flow of supply air. Supply dampers are designed to fail closed. SNM contained within sealed storage containers. CAMs to detect airborne contamination and to activate alarms. Two-stage HEPA-filtered ventilation system to mitigate the release of SNM to the environment.	OSD requires SNM stored in the vault to be packaged with a minimum of two containment barriers. Procedure governing operator response to CAM alarm.	This is an anticipated event. The consequences are judged to be low.	Refer to section 9.1.7A, "Excessive Building Pressurization, 234-5Z Building."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		C. E-3 ventilation exhaust system.	Refer to above.	(1) Insufficient exhaust airflow.	Additional thermal loading of SNM containers and resulting container pressurization could potentially result in loss of SNM from storage container(s). Potential pressurization of vault with respect to corridor if supply fans continue to operate could result in a release of SNM to the corridor.	Four operating exhaust fans and three on standby. SNM storage containers designed to withstand 100 lb/in^2 internal pressure before gross failure (Szempruch 1984). CAMs to detect airborne contamination and to activate alarm(s) should the alarm set point be exceeded. Two-stage HEPA-filtered ventilation system to mitigate the release of SNM to the environment.	Refer to above.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.7A, "Excessive Building Pressurization, 234-5Z Building."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011

		B. --	Captures contaminated air and directs it into the exhaust duct system.	Loss of ventilation	Possible exposure to toxic fumes causing dizziness, headache, breathing difficulty.	Exhaust system removes fumes from work area. Ventilation system exhaust to the atmosphere through exhaust fan EM-15.	Chemicals are mixed in the hood with adequate exhaust ventilation to outside environment.	This event is anticipated. The consequence is low.	Not specifically analyzed.	WHC-SD-CP-SDD-005
		C. EM-15 fans	Provides hood exhaust and removes fumes generated by operations in hood.	Insufficient exhaust flow	Potential release of toxic fumes into the room.	--	Procedure governing operator response to loss of exhaust flow.	This event is anticipated. The consequences are judged to be low.	Not specifically analyzed.	WHC-SD-CP-SDD-005

[a]Hazard identifier.
[b]The consequence, as given here, assumes none of the active preventive/mitigative features are in place.
[c]The probability/consequence, as given here, assumes that the preventive/mitigative features are operative.
[d]Gives the section number in the chapter where additional accident analysis is performed.

Appendix 9A.1.4

RADIOCHEMICAL STANDARDS LABORATORY

The radiochemical standards laboratory provided in rooms 221-C, 221-D, and 221-E is devoted to the formulation, verification, packaging, and distribution of the plutonium-containing standards needed in the PFP AL.

The standards laboratory contains NDA equipment, balances, blenders, etc. for the fabrication of standards. The plutonium is in liquid or oxide form, and is normally doubly contained (except for material in use).

The standards laboratory contains ten combination glovebox/hoods. An administrative limit of 1.2 kg of plutonium has been established for the laboratory. This material, in the form of a powder or solution, could be located within gloveboxes, hoods, or both.

- Room 221-C contains the fissile standards storage, PuO_2, and decontamination hoods plus a glovebox. Sheet standards for NDA are produced in this laboratory. The laboratory documentation center is also located in a walled-off area in the northeast corner.

- Room 221-D contains four hoods and a glovebox. The wet standard makeup is performed here. Standards containing uranium, neptunium, thorium, and plutonium are formulated and packaged. The analysis of plutonium stock solutions is performed. In-use acids and bases are stored in this room.

- Room 221-E contains three hoods that support the ampulization of low-level standards. The room is also used for preparation of low (radiation) level standards and as the storage area for the small amount of uranium and neptunium used in laboratory standards.

The following Hazard Evaluation table identifies stack CAMs as a preventive/mitigative feature for several postulated failure events. The CAMs perform a passive function, which is to detect airborne radioactive material and to activate alarms should the alarm set-point on the CAM be exceeded. They do not provide an active function which would actuate equipment or systems to prevent or mitigate an accident. In most cases the CAMs do not serve to reduce the consequences associated with a release of airborne radioactive material because most accidents involve a sudden release of material over a short period of time. Therefore, by the time the stack CAM detects the release there would be insufficient time to mitigate the event. In addition, the CAM's location in the ventilation discharge stack precludes any preventive/mitigative action since the release would have already occurred. Potentially chronic releases from process operations, or due to equipment failures (e.g., failed HEPA filters), tend to be small in nature. If these releases are sufficient to actuate the CAM alarm, operator action is generally adequate to limit the release so there is no significant consequence. It should be noted that accidents evaluated in the Chapter 9.0 analyses did not rely on the CAMs to serve a preventive/mitigative function.

(Rooms 221C, 221D, and 221E).

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
1	**Radiochemical standards laboratory, general**	A. Handling of SNM containers.	To safely handle SNM containers as necessary to support operations within the standards laboratory.	(1) Inadequate container spacing	Loss of a single contingency for criticality safety. Potential criticality if there is a loss of an additional contingency. Potential release of fission products to the atmosphere.	Lard cans and food-pack cans are transported in fixed array wagons. 30- to 55- gal drums are moved one at a time using drum barrel hand trucks. CAS to detect a criticality and to activate criticality alarms.	Procedure governing spacing requirements of transportation arrays. Double contingency principle precludes the potential for a criticality as a result of a single failure. Procedure governing operator response to criticality alarm.	Inadequate spacing is an anticipated event. The consequences are judged to be low.	Refer to section 9.2.3 "Criticality."	Potentially severe consequences to workers in proximity to a criticality. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005
				(2) Dropped container	Potential release of SNM to the room. Potential entrainment in the ventilation exhaust system and release to the environment.	Carriers (drum barrel hand truck, fixed array wagon, lard can wagon) are designed for specific operation. CAMs to detect airborne contamination and to activate alarms. HEPA-filtered exhaust ventilation system (E-3).	Procedure governing movement of SNM. Procedure governing operator response to a spill. Packaging requirements for double containment.	This event is anticipated. The consequences are judged to be low.	Refer to sections 9.1.1, "Radioisotope-Bearing Liquid Spills,", and 9.1.3 Radioisotope-Bearing Powder Spills."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
		B. Ventilation supply system	To provide airflow for maintaining the correct DP between zones.	(1) Insufficient supply airflow	Potential increased negative DP between zones 3 and 1. Potential loss of DP between zones 3 and 4.	Five supply fans normally operating, three fans provide backup. Pressure sensors and dampers monitor and control the supply airflow to each zone.	Procedure governing operator response to a ventilation system upset.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.7F "Building Depressurization - All PFP Operating Buildings."	WHC-SD-CP-SDD-005
				(2) Excessive supply airflow	Potential loss of negative DP between zones 3 and 1. Potential spread of contamination to zone 1 areas.	Pressure sensors and dampers monitor and control the supply airflow to each zone. CAMs to detect airborne contamination and to activate alarms.	Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.7A "Excessive Building Pressurization--234-5Z."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		C. E-3 ventilation exhaust system	To provide airflow for maintaining the correct DP between zones.	(1) Insufficient exhaust airflow	Potential loss of negative DP between zones 3 and 1. Potential spread of contamination to zone 1 areas.	Four exhaust fans normally operating; three fans provide backup. Pressure sensors and dampers monitor and control the exhaust airflow from each zone. Two exhaust fans are connected to backup power. CAMs to detect airborne contamination and to activate alarms.	Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.7A "Excessive Building Pressurization--234-5Z."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011

	Room 221-C, glovebox 1 (continued).	B. Ventilation supply system (continued).	To provide airflow for maintaining the correct negative DP between zones.	(2) Excessive supply airflow	Potential pressurization of the glovebox relative to the room. Potential release of SNM to the room and entrainment in the ventilation system.	E-4 ventilation exhaust system will maintain negative DP of glovebox relative to the room. Glovebox DP gauge. Room CAMs to detect airborne contamination and to activate alarms. HEPA-filtered ventilation exhaust system.	Procedure governing operator response to glovebox DP outside operating limits. Procedure governing operator response to CAM alarm.	This event is unlikely. The consequences are judged to be low.	Refer to section 9.1.4, "Radioisotope-Bearing Pressurized Powder Container."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		C. Inlet HEPA filters	To filter glovebox exhaust air in the event of a flow reversal in order to mitigate the release of SNM.	Loss of filtration.	Potential release of SNM to the room. Potential entrainment in the ventilation system and release to the environment.	Room CAMs to detect airborne contamination and to activate alarms. HEPA-filtered exhaust system (E-3).	Procedure governing operator response to CAM alarm. Procedure governing operator response to ventilation system upset.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		D. Dry air supply system (note: dryers are not functional)	To provide airflow for maintaining the correct DP between zones 3 and 4.	(1) Insufficient supply airflow	Potential excessive negative DP within glovebox relative to the room.	Additional supply air provide by inleakage through inlet HEPA filters. Glovebox DP gauge.	Procedure governing operator response to glovebox DP outside of operating limits.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005
				(2) Excessive supply airflow	Potential pressurization of the glovebox and potential loss of confinement. Potential release of SNM into the room and entrainment in the E-3 ventilation exhaust system.	E-4 exhaust system has sufficient exhaust flow to remove full-open supply air. Glovebox DP gauge. Room CAMs to detect airborne contamination and to activate alarms.	Procedure governing operator response to glovebox DP outside of operating limits. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.4, "Radioisotope-Bearing Pressurized Powder Container."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		E. Glovebox exhaust HEPA filters	To filter glovebox exhaust air in order to mitigate the release of SNM.	Loss of filtration.	Potential increased ventilation system contamination, including E-4 HEPA filters. Potential release to the environment.	HEPA filter DP gauge. Two-stage E-4 exhaust HEPA filters. 291-Z-1 stack CAM to detect airborne contamination and to activate alarms.	Procedure governing operator response to HEPA filter DP outside of operating limits. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Not specifically analyzed.	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		F. E-4 ventilation exhaust system	To provide airflow for maintaining the correct DP between zones 3 and 4.	(1) Excessive exhaust airflow	Potential excessive negative DP within the glovebox. Potential loss of confinement. Potential entrainment of loose SNM in the ventilation exhaust system.	Glovebox DP gauge. Supply air provided by the dry air system and via inleakage through the inlet HEPA filter. Glovebox outlet HEPA filter. CAMs to detect airborne contamination and to activate alarms. Two-stage HEPA-filtered exhaust system.	Procedure governing operator response to glovebox DP outside of operating limits. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011

6	**Room 221-D, hoods 1 through 4**	--	Open-faced hoods used for pipetting of microcurie level quantities of SNM and plutonium nitrate characterization.	Refer to item 4.	Refer to item 4.	Refer to item 4.	Refer to item 4.	Refer to item 4.	Refer to item 4.	Hood exhaust is HEPA-filtered.
7	**Room 221-D, glovebox**	--	Glovebox is inactive. There is no equipment located within it.	--	--	--	--	--	--	Equipped with both inlet and outlet HEPA filters, and is exhausted through the building E-4 exhaust system.
8	**Room 221-E, hoods 1 and 2 (hood 1 contains an ultrasonic cleaner).**	Electric bunsen burners.	Used to seal glass ampules and for heating counting disks.	Excessive temperature.	Potential burn injury to operator.	--	Procedure governing required protective equipment.	This event is anticipated. The consequence is judged to be low.	Not specifically analyzed.	
9	**Room 221-E, hood 3**	Heat lamps	Drying low-level sheet standards used in NDA techniques.	Excessive temperature.	Refer to item 8.	--	Refer to item 8.	Refer to item 8.	Not specifically analyzed.	

[a]Hazard identifier.
[b]The consequence, as given here, assumes none of the active preventive/mitigative features are in place.
[c]The probability/consequence, as given here, assumes that the preventive/mitigative features are operative.
[d]Gives the section number in the chapter where additional accident analysis is performed.

Appendix 9A.1.5

LOAD-IN/LOAD-OUT OPERATIONS

The LI/LO of $Pu(NO_3)_4$ solutions from PR cans and 10-L polyethylene bottles is accomplished in room 227 of the 234-5Z Building, in glovebox HC-227S and hood HC-227T. Highly concentrated plutonium solutions are handled in glovebox HC-227S and present a serious contamination hazard.

The LI/LO operations consist of vacuum transfer of solutions between PR cans and tanks. Hood HC-227T is primarily used for the vacuum transfer of 10-L bottles of solutions to tanks in glovebox HC-227S. Hood HC-227T is also used to load-out material and for venting PR cans. Glovebox HC-227S is used to blend and sample plutonium nitrate solutions and to transfer (via hood HC-227T) solutions to PR cans. The PR cans are then transferred to the PFP AL.

Plutonium nitrate solution from PR cans is transferred to batch tanks in glovebox HC-227S via open-faced hood HC-227T. Plutonium nitrate is loaded into tanks BT-1 and BT-2 from storage or shipping containers. It is then blended as one batch and sampled.

Once the transfer is complete, the batch tanks and load out tanks in glovebox HC-227S are flushed, and the floor of glovebox HC-227S is flushed and slurped. General cleanliness of the glovebox floor is maintained by flushing and slurping. Flushing of the tanks is done to keep solids buildup below CPS limits and for accountability purposes.

Solutions that are being down loaded into PR cans are blended and sampled for accountability reasons. Solutions loaded into glovebox HC-227S are blended and sampled if they are being transferred for processing.

Plutonium nitrate is loaded into tanks BT-1 and BT-2 from storage or shipping containers. It is then blended as one batch and sampled. Blending and sampling may be required after transferring solution to glovebox HC-227S from the PFP AL. Blending and sampling is also required before load-out for accountability purposes. Receiver tanks are used for miscellaneous solution handling.

Plutonium nitrate, chloride, and fluoride solutions are transferred from 10-L storage container polybottles to glovebox HC-227S via open-faced hood HC-227T. Solution is loaded into tank BT-3 from 10-L storage containers using a vacuum transfer. The transferred solutions are then blended as one batch and sampled. When analyses are complete, the solution is loaded into 4.2-L polyjugs and transferred to the PPSL.

Plutonium nitrate solution is loaded out from the loadout tank into PR cans and the PR cans are sealed. The PR cans are then placed in approved shipping or storage containers.

Plutonium-bearing solutions removed from poly-bottles (10-L, L-10, and FL-10 container types) are received only in tank BT-3. This material is blended in tank BT-3 using an air-driven, diaphragm pump. After blending, the homogeneous solution is sampled for material accountability and solution

characterization. Plutonium-bearing solution is loaded into tank BT-3 from poly-bottle storage and shipping containers. Solution and bottle rinse from one or more poly-bottles is blended as one batch (or sub-batch) and sampled. Blending and sampling is also required before solution seal-out/load-out for accountability purposes.

Solutions are transferred from tank BT-3 into 4.2-L polyjugs or 3-L containers depending on the concentration of plutonium. The filled polyjug will then be sealed out and transferred to the facility development labs (PPSL). Only one polyjug at a time may be filled and only in glovebox HC-227S. Sample bottles are sent to the PFP AL.

The following Hazard Evaluation table identifies stack CAMs as a preventive/mitigative feature for several postulated failure events. The CAMs perform a passive function, which is to detect airborne radioactive material and to activate alarms should the alarm set-point on the CAM be exceeded. They do not provide an active function which would actuate equipment or systems to prevent or mitigate an accident. In most cases the CAMs do not serve to reduce the consequences associated with a release of airborne radioactive material because most accidents involve a sudden release of material over a short period of time. Therefore, by the time the stack CAM detects the release there would be insufficient time to mitigate the event. In addition, the CAM's location in the ventilation discharge stack precludes any preventive/mitigative action since the release would have already occurred. Potentially chronic releases from process operations, or due to equipment failures (e.g., failed HEPA filters), tend to be small in nature. If these releases are sufficient to actuate the CAM alarm, operator action is generally adequate to limit the release so there is no significant consequence. It should be noted that accidents evaluated in the Chapter 9.0 analyses did not rely on the CAMs to serve a preventive/mitigative function.

Table 9A.1.5

				(2) Inadequate container spacing or too many containers.	Loss of a single contingency for criticality safety. Potential criticality if there is a loss of an additional contingency. Potential release of fission products to the atmosphere.	CAS to detect criticality and to activate criticality alarms. Single-stage HEPA-filtered ventilation system. CAMs to detect airborne contamination and to activate alarms.	Double-contingency principle precludes the potential for a criticality as a result of a single failure. Procedure governing operator response to criticality alarm. The CPS limits the allowable volume, mass, and spacing of SNM. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.2.3, "Criticality."	Potentially severe consequences to workers in proximity to the criticality. A criticality resulting from inadequate spacing is not a credible event. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
		B. Ventilation supply system.	To provide airflow to maintain the correct DP between zones.	(1) Insufficient supply airflow.	Potential increased DP between zones 3 and 1. Potential loss of DP between zones 3 and 4.	Five supply fans normally operating and three backup fans. Pressure sensors and dampers used to monitor and control the supply airflow to each zone. Single-stage HEPA-filtered ventilation system.	Procedure governing operator response to ventilation system upset.	This event is anticipated. Flow will be from areas of no contamination (zone 1) to areas of potential contamination (zone 3). Thus, the consequence is judged to be low.	Refer to section 9.1.7F, "Building Depressurization–All Plutonium Finishing Plant Operating Buildings."	WHC-SD-CP-SDD-005
				(2) Excessive supply airflow	Potential loss of DP between zones 3 and 1. Potential spread of contamination to zone 1 areas.	Five supply fans normally operating and three backup fans. Pressure sensors and dampers used to monitor and control the supply airflow to each zone. CAMs to detect airborne contamination and to activate alarms.	Procedure governing operator response to ventilation system upset.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.7A, "Excessive Building Pressurization 234-5Z."	WHC-SD-CP-SDD-005

	Room 227, process LI/LO (continued).	C. E-3 Exhaust ventilation system	To provide airflow to maintain the correct DP between zones.	(1) Insufficient exhaust airflow	Loss of DP between zones 3 and 1, possible spread of contamination to zone 1 areas.	Five exhaust fans normally operating, two fans provide backup. Pressure sensors and dampers used to monitor and control exhaust airflow from each zone. Building supply fans shut down when DP upstream of exhaust fans becomes > -3.5 in. w.g.	Procedure governing operator response to ventilation system upset.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.7A, "Excessive Building Pressurization 234-5Z."	Total loss of exhaust is unlikely since there will be a natural draft through the exhaust stack. WHC-SD-CP-SDD-005
				(2) Excessive exhaust airflow	Increased DP between zones 3 and 1.	Pressure sensors and dampers used to monitor and control exhaust airflow from each zone.	Procedure governing operator response to ventilation system upset.	This event is anticipated. Flow will be from areas of no contamination (zone 1) to areas of potential contamination (zone 3). Thus, the consequence is low.	Refer to section 9.1.7F, "Building Depressurization--All Plutonium Finishing Plant Operating Buildings."	WHC-SD-CP-SDD-005
			Provides single-stage HEPA filtration of room exhaust.	Loss of HEPA filtration	Potential release of SNM to the environment if airborne contamination is present.	Single-stage HEPA filtration provided by filters in seven filter rooms; any three rooms are in service simultaneously with the remaining rooms on standby. 291-Z-1 stack CAM to detect airborne contamination and to activate alarms.	Procedure governing maintenance and testing of HEPA filters. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Not specifically analyzed.	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
		D. Fire sprinkler system	To provide containment of water until necessary to suppress a fire.	Accidental discharge of water.	Potential criticality. Criticality results in high levels of radiation in the room with a potential release of fission products to the atmosphere.	Plutonium-bearing solutions contained within sealed containers. CAS to detect criticality and to activate criticality alarm. CAMs to detect airborne contamination and to activate alarms. Single-stage HEPA-filtered ventilation system.	Procedure governing handling of SNM containers. Procedure governing operator response to fire sprinkler system activation. Procedure governing operator response to criticality alarm. Double-contingency principle precludes criticality as a result of a single failure.	The probability of this event occurring is unlikely. The consequence is judged to be low.	Refer to section 9.2.3, "Criticality."	Potentially severe consequences to workers in proximity to a criticality. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
	Room 227, process LI/LO (continued).	E. 26-in. mercury process vacuum.	Provides the motive force used to transfer solutions between glovebox HC-227S and hood HC-227T. Vents tanks during blending and sparging operations.	(1) Excessive vacuum	Potential contamination of 26-in. mercury vacuum system with plutonium-bearing solution. Potential criticality if solution reaches E-4 filter bank.	Vacuum trap conductivity probe activates alarm upon detection of liquid. Liquid detectors on inlet line to vacuum pumps before HEPA filters. Inlet line liquid detection system interlock shuts down vacuum pump, closes HEPA filter isolation valves, and activates alarm upon detection of liquid.	Procedure governing operator verification of vacuum trap liquid detection interlock system functionality. Procedure governing operator response to liquid detection alarm.	This event is anticipated. The consequence is judged to be low.	Not specifically analyzed.	WHC-SD-CP-SDD-008
				(2) Insufficient vacuum	Loss of solution transfer capability and equipment cleanup capability.	Vacuum gauge above vacuum tank.	Procedure governing operator verification that 26-in. mercury vacuum system is operative.	This event is anticipated. The consequence is judged to be low.	Not specifically analyzed.	
		F. Chemical addition tank.	To provide HNO_3 for flushing batch tanks, load-out tanks, and floor of glovebox HC-227S.	Excessive HNO_3	Potential spill of HNO_3 onto room floor. Potential release of HNO_3 fumes to the room and entrainment in the ventilation system.	NO_x monitor alarms when NO_x exceeds 3 ppm. Chemical addition tank high-level alarm. Single-stage HEPA-filtered ventilation exhaust.	Procedure governing operator response to spill of HNO_3.	This event is anticipated. Chemical addition tank only holds 3 L of solution, thus release would be small. The consequence is judged to be low.	Refer to section 9.2.8, "Toxic Chemical Release."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		G. E-4 ventilation exhaust system	Prevents gaseous release from entering room.	Loss of exhaust	Potential release of organic fumes to room. Potential exposure of operators to toxic fumes.	Protective clothing and supplied air. NO_x alarm. Single-stage HEPA-filtered ventilation exhaust system (E-3). Four operating exhaust fans and three on standby.	Procedure governing operator response to appearance of brownish vapors (NO_x).	This event is anticipated. The release would be small and confined within hood. Operators are required to wear protective clothing and supplied air. Thus, the consequence is judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
2	**Room 227, glovebox HC-227S (houses the batch and load out tanks).**	A. Glovebox enclosure	Confinement of plutonium.	Loss of confinement.	Potential release of plutonium-bearing materials to areas occupied by personnel. Potential entrainment in the E-3 ventilation system.	Glovebox is of steel construction with Lexan™ windows. Lexan will not shatter upon strong impact. E-4 exhaust ventilation system maintains a negative DP in the glovebox relative to the room. CAMs to detect airborne contamination and to activate alarms at prescribed activity levels.	Procedure governing operator response to CAM alarm. Procedure governing glovebox maintenance (e.g., glove changeout).	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	Historical events have resulted in minor worker uptake. WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		B. Criticality drain	To drain liquid from the glovebox in order to prevent the accumulation of a critical volume of solution.	Failure to adequately drain liquid.	Potential criticality that results in high levels of radiation in room with a potential release of fission products to the atmosphere.	CAS to detect a criticality and to activate alarms.	Procedure governing functionality of criticality drains. Double-contingency principle precludes the potential for a criticality as a result of a single failure. Procedure governing operator response to criticality alarms.	The probability of this event occurring is unlikely. The consequence is judged to be low.	Refer to section 9.2.3, "Criticality."	Potentially severe consequences to workers in proximity to the criticality. A second contingency (failure) would have to occur for a criticality to be possible. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-008
		C. Handling and storage of SNM containers.	To safely handle containers as necessary to support operations.	(1) Inadequate container spacing	Loss of a single contingency for criticality safety. Potential criticality if there is a loss of an additional contingency. Potential release of fission products to the atmosphere.	CAS to detect a criticality and to activate alarms.	CPS posted on glovebox specifies the allowable limits on plutonium quantities, container volumes, and minimum spacing. Double-contingency principle. Procedure governing operator response to criticality alarms.	The probability of inadequate spacing is anticipated. The consequences are judged to be low.	Refer to section 9.2.3, "Criticality."	Potentially severe consequences to workers in proximity to a criticality. Need failure of additional contingency for a criticality to be possible. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-011
				(2) Dropped container	Potential spill of SNM within glovebox. Potential airborne release and entrainment of plutonium in E-4 ventilation system.	Glovebox confinement. Glovebox outlet HEPA filter. Two-stage HEPA-filtered ventilation exhaust system. 291-Z-1 stack CAM to detect airborne contamination and to activate alarms.	Procedure governing operator response to spill of SNM. Procedure governing operator response to CAM alarm.	This event is anticipated. The release would be small and confined within the glovebox. Thus, the consequence is judged to be low.	Refer to section 9.1.1, "Radioisotope-Bearing Liquid Spills."	Historical events has resulted in minor worker uptake. WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011

	Room 227, glovebox HC-227S (continued).	D. Blending/ sampling tanks	To contain solutions during blending/sampling operations.	(1) Leak/overflow of tanks	Potential criticality that results in high levels of radiation in room with a potential release of fission products to the atmosphere.	CAS to detect a criticality and to activate alarms. Glovebox criticality drain. Glovebox sump probe that alarms when liquid is detected.	CPS posted on glovebox specifies volume, mass, and spacing limits. CPS requires any spill in excess of accumulation limit to be cleaned up before operations. Procedure governing operator response to criticality alarm.	A leak/overflow from a tank is an anticipated event. The consequences are judged to be low.	Refer to section 9.2.3, "Criticality."	Potentially severe consequences to workers in proximity to a criticality. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-008
				(2) Excessive plutonium in tanks	Potential criticality which results in high levels of radiation in room with a potential release of fission products to the atmosphere.	CAS to detect criticality and to activate alarms. The tanks are of a critically safe geometry.	CPS posted on glovebox specifies volume, mass, and spacing limits. Double-contingency principle precludes the potential for a criticality as a result of a single failure.	Excessive plutonium in the tanks is an unlikely event. The consequences are judged to be low.	Refer to section 9.2.3, "Criticality."	A criticality could potentially result in severe consequences to the workers. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-008
				(3) H_2 buildup	Potential explosion with release of plutonium-bearing materials. Potential entrainment of material in the E-3 ventilation exhaust system.	CAMs to detect airborne contamination and to activate alarms. Single-stage HEPA-filtered ventilation exhaust system.	Procedure governing operator response to CAM alarm.	This event is unlikely. The consequences are judged to be moderate.	Refer to section 9.1.8.4, "Hydrogen Accumulation."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
		E. Supplied air	To provide air to the receiver tank sparger for sample blending.	(1) Excessive air	Potential pressurization of glovebox may cause a loss of glovebox confinement. Potential release of SNM to the room and entrainment in the E-3 ventilation exhaust system.	Glovebox E-4 ventilation exhaust system maintains glovebox at negative DP relative to the room. 26-in. mercury vacuum system. CAMs to detect airborne contamination and to activate alarms.	Procedure governing verification of 26-in. mercury vacuum system functionality before sparging operation. procedure governing operator response to CAM alarm.	The probability of the event occurring is anticipated. The consequence is judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
				(2) Insufficient air	Solution not thoroughly mixed. Inadequate blending and sampling of nitrate solution sent to processing.	Two water cooled compressors supply process air.		The probability of the event occurring is anticipated. However, the consequence is low.	Not specifically analyzed.	
		F. E-4 exhaust ventilation system	To provide airflow to maintain correct negative pressure control of glovebox.	(1) Insufficient exhaust airflow	Potential loss of negative DP of glovebox relative to the room. Potential release of SNM into the room and entrainment in the E-3 exhaust system.	Glovebox DP gauge. Room CAMs provided to detect and alarm at prescribed airborne radioactivity levels.	Procedure governing operator response to glovebox DP outside of operating limits.	The probability of this event is anticipated. The consequence is judged to be low.	Refer to section 9.1.4, "Radioisotope-Bearing Pressurized Powder Container."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011

Table 9A.1.5

Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
	Room 227, glovebox HC-227S (continued)	F. E-4 exhaust ventilation system (continued)	To provide airflow to maintain correct negative pressure control of glovebox.	(2) Excessive exhaust airflow	Potential increased negative DP in glovebox relative to the room may result in a loss of glovebox confinement. Potential entrainment of loose SNM in the E-4 exhaust system.	Glovebox outlet HEPA filter. Two-stage HEPA-filtered ventilation exhaust system.	Procedure governing operator response to glovebox DP outside of operating limits.	The probability of this event is anticipated. The consequence is judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		G. Glovebox inlet/outlet HEPA filters.	To provide filtration of glovebox exhaust during normal and reverse flow conditions.	Loss of filtration	Potential release of plutonium-bearing materials to the room. Potential entrainment in the ventilation exhaust system and release to the environment.	Two parallel inlet HEPA filters. Two-stage HEPA-filtered E-4 exhaust system. CAMs provided to detect and alarm at prescribed airborne radioactivity levels. Outlet HEPA filter DP gauge. Glovebox DP gauge.	Procedure governing operator response to outlet HEPA filter or glovebox DP outside of operating limits. Procedure governing operator response to CAM alarm.	The probability of this event is anticipated. The consequence is judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
3	**Room 227, hood HC-227T**	A. Hood enclosure	To capture contaminated air and direct it into the E-4 exhaust system.	Inadequate exhaust	Potential release of contaminants to the room. Potential entrainment in the E-3 ventilation exhaust system.	NO_x monitor located in room.	Procedure governing required protective equipment (e.g., respirators). Procedure governing operator response to NO_x alarm.	This event is anticipated. The consequence is judged to be low.	Not specifically analyzed.	
		B. Container handling	To safely handle containers as necessary to support operations.	(1) H_2 build up	Potential explosion with release of plutonium-bearing materials to the room. Potential entrainment of SNM in the E-3 exhaust ventilation system.	HEPA-filtered exhaust ventilation systems. CAMs to detect airborne contamination and to activate alarms.	Procedure governing handling of containers during LI/LO operation.	This event is unlikely. The consequences are judged to be moderate.	Refer to section 9.1.8.4, "Hydrogen Accumulation."	Potentially severe consequences to workers in the vicinity of explosion. WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
				(2) Dropped container	Potential spill and flooding of the confinement structure. Potential criticality. Potential airborne release of SNM. Potential entrainment of SNM in the E-4 exhaust ventilation system.	HEPA-filtered exhaust ventilation systems. CAMs to detect airborne contamination and to activate alarms. Criticality drain to prevent accumulation of liquids. CAS to detect criticality and to activate criticality alarms. HEPA-filtered exhaust system.	Procedure governing inspection of hoist. Use of yoke or clamping device. Procedure governing operator protective equipment. Procedure governing operator response to a criticality alarm.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.1, "Radioisotope-Bearing Liquid Spills."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011

[a]Hazard identifier.
[b]The consequence, as given here, assumes none of the active preventive/mitigative features are in place.
[c]The probability/consequence, as given here, assumes that the preventive/mitigative features are operative.
[d]Gives the section number in the chapter where additional accident analysis is performed.

Appendix 9A.1.6

Storage Vaults

The function of the storage vaults is to provide safe and secure storage for SNM. The activities associated with the storage vault operations are the storage, handling, and inspection of SNM containers.

Rooms 172 and 173 provide floor storage for PR cans.

Rooms 174 and 175 are storage vaults containing cabinet (room 174) or pedestal (room 175) storage. Analysis shows that the containers in the storage cabinets could be overturned, but would remain in the cabinets on their respective trays. Analysis shows that the pedestals will not fail, the anchors to the wall and floor will not fail, and the container will not come out of the holder (Vollert 1987a, 1987b). Ventilation is needed in these storage areas. Loss of ventilation could result in container pressurization due to heat buildup.

Room 190 contains pedestal storage.

Rooms 192-B and 192-C contain pedestal storage of plutonium compounds, and, as such, are similar to room 175. Room 192-A has floor storage of FFTF fuel pins and bundles in shipping containers which will not be ruptured during a seismic event.

Room 225 is a storage vault. Fixed-array storage in cubicles is allowed for laboratory standards samples.

Table 9A.1.6
The 234-5Z Building: Storage Vaults (Rooms 172-175, 192A, 192B, 192C) (194, 201, 225, 236).

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
1	Storage vaults	A. Vault storage cabinets (room 174) and pedestals.	To maintain container separation distance for the purpose of criticality safety.	Loss of container separation.	Potential criticality and release of fission products to the atmosphere. Potential release of SNM from the storage containers and entrainment in the ventilation system.	Analysis shows that pedestals will survive a DBE (Vollert 1987a, 1987b). CAS to detect a criticality and to activate criticality alarms. CAMs to detect airborne alpha contamination and to activate alarms. Two-stage HEPA-filtered ventilation exhaust system.	The OSD requires SNM stored in the vault to be packaged with a minimum of two containment barriers. Double-contingency principle precludes the potential for a criticality as a result of a single failure. Procedure governing operator response to a criticality alarm. Procedure governing operator response to CAM alarm.	Structural failure of the storage pedestals is not credible.	Refer to section 9.2.4A.2.1, "Accident Scenarios, 234-5Z Building."	There is no credible scenario that could challenge the integrity of the storage rack other than an earthquake. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		B. Vault ventilation supply system.	Provides airflow for the removal of heat generated by decay of the SNM within the vault and for maintaining correct negative DP control of the vault.	(1) Insufficient supply airflow.	Additional thermal loading of SNM containers and resulting container pressurization could potentially result in loss of SNM from storage container(s) and entrainment in the ventilation system.	Supply fan flow monitors activate alarm upon low flow condition. SNM containers designed to withstand 100 lb/in^2 internal pressure before gross failure (Szempruch 1984). CAMs to detect airborne alpha contamination and to activate alarms. Two-stage HEPA-filtered ventilation system.	OSD requires SNM stored in the vaults to be packaged with a minimum of two containment barriers. Procedure governing operator response to ventilation system upset. Procedure governing operator response to CAM alarm.	This is an anticipated event. The consequences are judged to be low.	Refer to section 9.1.8.6, "Vault Temperature Rise."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
					Potential excessive negative DP within the vault if the exhaust system continues to operate.	Five operating and two standby supply fans. Pressure sensors and dampers monitor and control the supply airflow to the vaults.	Procedure governing operator response to ventilation system upset.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.7F, "Building Depressurization--All Plutonium Finishing Plant Operating Buildings."	WHC-SD-CP-SDD-005
				(2) Excessive supply airflow.	Potential pressurization of vault relative to adjacent areas. Potential release of any loose SNM to adjacent areas.	Pressure sensors and dampers monitor and control the supply airflow to the vaults. SNM contained within sealed storage containers. CAMs to detect airborne contamination and to activate alarms. Two-stage HEPA-filtered ventilation system.	Procedure governing operator response to a ventilation system upset. Procedure governing operator response to a CAM alarm.	This is an anticipated event. The consequences are judged to be low.	Refer to section 9.1.7A, "Excessive Building Pressurization, 234-5Z Building."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011

Table 9A.1.6
The 234-5Z Building: Storage Vaults (Rooms 172-175, 192A, 192B, 192C) (194, 201, 225, 236).

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
	Storage vaults (continued).	C. Vault ventilation exhaust system	Provides airflow for the removal of heat generated by the decay of SNM within the vault and for maintaining correct negative DP control of the vault.	(1) Insufficient exhaust airflow.	Potential additional thermal loading of SNM containers. Potential pressurization of SNM containers and release of SNM. Potential pressurization of vault relative to adjacent areas if supply fans continue to operate could result in a release of SNM to these areas.	Four operating exhaust fan and three on standby. Two exhaust fans are provided with backup power. Pressure sensors and dampers monitor and control the exhaust airflow from the vaults. SNM storage containers determined to withstand 100 lb/in^2 internal pressure before gross failure (Szempruch 1984). CAMs to detect airborne contamination and to activate alarms. Two-stage HEPA-filtered ventilation system.	Procedure governing operator response to a ventilation system upset. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.7A, "Excessive Building Pressurization, 234-5Z Building."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
				(2) Excessive exhaust airflow.	Potential excessive negative DP within the vault. Potential entrainment of any loose SNM in the exhaust ventilation system.	Pressure sensors and dampers monitor and control the exhaust flow from the vaults. CAMs to detect airborne alpha contamination and to activate alarms. Two-stage HEPA-filtered ventilation exhaust system.	Procedure governing operator response to ventilation system upset. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.7F.1, "Building Depressurization--All Plutonium Finishing Plant Operating Buildings."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		D. Vault SNM storage containers	To provide primary containment of SNM within the vault.	Loss of containment.	Potential release of SNM into the vault. Potential entrainment of SNM in the ventilation system and release to the environment.	CAMs to detect airborne contamination and to activate alarms. Two-stage HEPA-filtered ventilation system.	OSD requires SNM stored in the vaults to be packaged with a minimum of two containment barriers. Procedure governing operator response to CAM alarm. Procedure governing operator response to detection of SNM container anomaly during required (by OSD) monthly inspection.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.1, "Radioisotope-Bearing Liquid Spills", and section 9.1.3, "Radioisotope-Bearing Powder Spills."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		E. Handling of SNM storage containers.	To safely move SNM containers to/from vault storage location as needed to support operations.	(1) Dropped SNM container.	Potential loss of containment and entrainment of SNM in the ventilation system.	Tests have shown that SNM containers dropped to a hard, unyielding surface do not suffer gross failures. CAMs to detect airborne alpha contamination and to activate alarms. Two-stage HEPA-filtered exhaust.	Procedure governing operator response to dropped container. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to item above.	Refer to item above.

Table 9A.1.6

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
	Storage vaults (continued).	E. Handling of SNM storage containers (continued).	To safely move containers to/from vault storage location as needed to support operations.	(2) Inadequate spacing between container being handled and other containers.	Loss of a single contingency for criticality safety. Potential criticality if there is a loss of an additional contingency.	Same as above, except drop test information is not applicable. CAS to detect criticality and to activate criticality alarms.	Double contingency principle. Procedure governing operator response to criticality alarm. Procedure governing operator response to CAM alarm.	Inadequate spacing is an anticipated event. The consequences are judged to be low.	Refer to section 9.2.3, "Criticality."	Potentially severe consequences to operators in proximity to a criticality. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		F. Inspection of SNM storage containers.	To detect SNM container anomalies (i.e., bulging, corrosion, dents, penetrations).	Failure to detect SNM container anomaly.	Potential loss of containment and entrainment of SNM in the ventilation system.	--	Procedure governing operator response to detection of SNM container anomaly.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.3, "Radioisotope-Bearing Powder Spills."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		G. Shipping containers	To provide containment of SNM.	Loss of containment.	Potential release of SNM to the vault. Potential entrainment of SNM in the ventilation exhaust system and release to the environment.	CAMs to detect airborne alpha contamination and to activate alarms. Two-stage HEPA-filtered ventilation system to mitigate the release of SNM to the environment.	Procedure governing storage of containers on floor of vault. Procedure governing operator response upon detection of container anomaly during required (by OSD) monthly inspection. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.3, "Radioisotope-Bearing Powder Spills."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		H. Handling of shipping containers	To safely move shipping containers to/from the vault.	Refer to item 1E.	Refer to item 1E.	Refer to item 1E.	Refer to item 1E.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.3, "Radioisotope-Bearing Powder Spills", and section 9.2.3, "Criticality."	WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
		I. Inspection of shipping containers	To detect container anomalies (i.e., bulging, corrosion, dents, penetrations.)	Refer to item 1F. [a]Event category and hazard identifier.
[b]The consequence, as given here, assumes none of the active preventive/mitigative features are in place.
[c]The probability/consequence, as given here, assumes that the preventive/mitigative features are operative.
[d]Gives the section number in the chapter where additional accident analysis is performed.

Appendix 9A.1.7

Miscellaneous Areas

Miscellaneous operations include waste drum storage (room 196), PR can storage (room 172), radioactive mixed waste storage (room 197), trash compaction (room 234), NDA drum counting (room 234A), PR/L-10 storage vault (room 236), and the chemical preparation room (rooms 336 and 337).

Waste Drum and Radioactive Mixed Waste Storage.

Storage areas for TRU radioactive solid waste and TRU radioactive mixed waste in 55-gal drums.

Trash Compaction.

A trash compactor used to compact miscellaneous radioactive waste.

NDA Drum Counting.

Used for the NDA of containers of SNM to determine the total weight of isotopes by measuring the radioactive emissions and/or the heat output of plutonium bearing material in the package.

Chemical Prep Room.

Facilities in rooms 336 and 337 were used to prepare and supply chemicals to the RMC Line and are currently used to supply chemicals for glovebox HC-227S/hood HC-227T operations. Room 336 contains tanks stored under a ventilated hood that exhausts through roof exhausters. The room is equipped with safety showers, floor drains, and fire sprinklers. Motor controls for outside chemical pumps are located in room 337.

Dilute HNO_3 solution is made up in tanks located in room 336 by first adding the specified volume of water to the tank. Concentrated HNO_3 (57%) is then added by pump transfer from drums. The solution is agitated, sampled, and analyzed for HNO_3 molarity. The solution is piped by gravity-drain to glovebox HC-227S to be used for adjustment of process solution acidity and as a flush solution. One tank is valved in to the process while the second tank is being refilled or is on standby.

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
1	**Room 196, waste drum storage**	A. Handling of waste drums.	To safely handle drums as necessary to support operations.	(1) Dropped container	Potential release of SNM to the room. Potential entrainment in the ventilation exhaust system and release to the environment.	Drum barrel hand trucks used to move drums. Single-stage HEPA-filtered E-3 exhaust system. CAMs to detect airborne contamination and to activate alarms.	Packaging requirement for double containment. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.3, "Radioisotope-Bearing Powder Spills."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
				(2) Inadequate spacing	Loss of a single contingency for criticality safety. Potential criticality if there is a loss of an additional contingency.	CAS to detect a criticality and to activate criticality alarm.	Double-contingency principle precludes the potential for a criticality as a result of a single failure. Procedure governing operator response to a criticality alarm.	Inadequate spacing is an anticipated event. The consequence is judged to be low.	Refer to section 9.2.3, "Criticality."	Potentially severe consequences to workers in proximity to a criticality. WHC-SD-CP-SDD-003
		B. Fire sprinkler system.	To contain water until necessary to discharge for suppression of a fire.	Accidental discharge of water.	Potential criticality that results in high levels of radiation in room and release of fission products to the atmosphere.	CAS to detect a criticality and to activate criticality alarm. Waste drum designed to resist moisture intrusion.	Double contingency principle. Procedure governing operator response to a criticality alarm. Packaging requirements limit the amount of fissile material.	This event is unlikely. The consequence is judged to be low.	Refer to section 9.2.3, "Criticality."	Potentially severe consequences to workers in proximity to a criticality. Room is normally unoccupied. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-010
2	**Room 197, radioactive mixed waste storage**	Refer to items 1A and 1B.	Refer to items 1A and 1B.	Refer to items 1A and 1B.	Refer to items 1A and 1B.	Refer to items 1A and 1B.	Refer to items 1A and 1B.	Refer to items 1A and 1B.	Refer to items 1A and 1B.	Refer to items 1A and 1B.
3	**Room 234, trash compactor**	A. Trash compactor	Confinement of radioactive materials during compaction process.	Loss of confinement.	Potential release of SNM to the room. Potential entrainment in the exhaust ventilation system and release to the environment.	Trash compactor is fabricated from metal. Exhaust ventilation system maintains a negative DP in the compactor relative to the room. CAMs to detect airborne contamination and to activate alarms. HEPA-filtered exhaust ventilation system.	Procedure governing operator response to a CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.4, "Radioisotope-Bearing Pressurized Powder Container." 	Room 234, trash compactor (continued).	B. E-4 exhaust system	To provide airflow to maintain negative DP of the compactor relative to the room.	(1) Insufficient exhaust airflow	Potential loss of negative DP between the compactor and the room. Potential release of SNM into the room and entrainment in the E-3 exhaust system.	CAMs to detect airborne contamination and to activate alarms. Four operating and three backup exhaust fans.	Procedure governing operator response to CAM alarm. Procedure governing operator response to a ventilation system upset (i.e., cessation of compactor operation).	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.4, "Radioisotope-Bearing Pressurized Powder Container."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
				(2) Excessive exhaust airflow	Potential excessive negative DP between the compactor and the room. Potential entrainment of loose material into the exhaust system.	Two-stage HEPA-filtered E-4 exhaust system.	Procedure governing operator response to a ventilation system upset.	This event is anticipated. The consequence is judged to be low.	Not specifically analyzed.	WHC-SD-CP-SDD-005
4	**Room 234A, NDA drum counting**	NaI package counter	A. To measure the plutonium content of waste or scrap in different package forms.	Dropped container (55 gal drum or 50 lb slip lid cans)	Potential loss of containment. Potential release of SNM to the room and entrainment in the exhaust ventilation system. Potential release to the environment.	Drum barrel hand trucks have hook slides that go over the barrel outer ring to keep it from falling. Raised ring on NaI package counter table. HEPA-filtered exhaust system. CAMs to detect airborne contamination and to activate alarms.	Procedure governing movement of SNM. Procedure governing operator response to a spill. Procedure governing operator response to a CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.3, "Radioisotope-Bearing Powder Spills."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-011
			B. Movement of SNM within the PFP AL.	Inadequate spacing	Loss of a single contingency for criticality safety. Potential criticality if there is a loss of an additional contingency.	CAS to detect a criticality and to activate criticality alarms.	Double contingency principle. Procedure governing operator response to criticality alarm. Procedure governing transportation of SNM.	Inadequate spacing is an anticipated event. The consequences are judged to be low.	Refer to section 9.2.3, "Criticality."	Potentially severe consequences to workers in proximity to a criticality. WHC-SD-CP-SDD-003
5	**Room 336 and 337, chemical preparation room**	--	To prepare and supply chemicals to PFP.	Leak	Potential release of hazardous chemicals to the room. Potential generation of hazardous fumes. Potential entrainment of fumes in the ventilation exhaust system.	Sump around tanks to catch leaks and spills. Sump overflows to outside tank that alarms when full. Tanks in a hooded area and ventilates through roof exhausters.	Procedure governing operator response to a spill.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.2.8, "Toxic Chemical Release."	The rooms are used to provide acid to glovebox HC-227S in room 227. WHC-SD-CP-SDD-005

[a]Hazard identifier.
[b]The consequence, as given here, assumes none of the active preventive/mitigative features are in place.
[c]The probability/consequence, as given here, assumes that the preventive/mitigative features are operative.
[d]Gives the section number in the chapter where additional accident analysis is performed.

Appendix 9A.2

The 2736-Z Support/Storage Complex

The 2736-Z complex is comprised of six separate buildings that conduct several different operations in support of the current PFP mission. The buildings and their functions are listed below:

9A.2.1	2736-Z Building--Vault storage of SNM
9A.2.2	2736-ZA Building--Exhaust ventilation and filtration for the 2736-Z Building
9A.2.3	2736-ZB Building--Shipping/receiving/repackaging/NDA of SNM
9A.2.4	2736-ZC Building--All weather loading dock (attached to the 2736-ZB Building via enclosed corridor)
9A.2.5	2736-ZD Building--Currently stores three experimental breeder reactor (EBR) II casks containing irradiated metallic fuel rods. May store a maximum of seven casks.
9A.2.6	2721-Z Building--Backup electrical power (three diesel generators) for the PFP facilities.

Shipments of SNM are received at the 2736-ZC Building. A jib crane equipped with a chain hoist and drum handler unloads material containers from cargo restraint transporters. The cargo restraint transporters are stored within the 2736-ZC Building, while the material containers are transferred to the 2736-ZB Building. Once inside the 2736-ZB Building, the containers are inspected, weighed, and sorted. The 2736-ZB Building is used to repackage stable/shippable SNM as necessary, and to perform NDA of the fissile material content of material containers. Safe and secure storage of stable/shippable SNM containers in vaults is the function of the 2736-Z Building. The 2736-ZA Building provides exhaust ventilation and HEPA filtration for the 2736-Z Building (supply air is provided by the 2736-ZB Building.) The 2736-ZD Building stores three EBR II storage casks containing irradiated metallic fuel rods. The 2721-Z Building houses three diesel generators and the switching gear used to provide backup electrical power to the PFP facilities.

Appendix 9A.2.1

2736-Z Building

The only function of the 2736-Z Building is to provide safe and secure storage for stable/shippable SNM.

The 2736-Z Building has barriers designed to provide containment of hazardous materials. The primary barrier in the 2736-Z Building is a SNM storage or transportation container. The secondary barrier serves to enclose the area containing the primary barrier. An example is a concrete storage cubicle (within one of the vaults) that holds SNM storage containers. The 2736-Z Building structure and building ventilation system work together to form a confinement system designed to mitigate the release of hazardous material should a barrier fail.

The building ventilation system completes the confinement system by providing a controlled, continuous flow of air from the environment into the various building areas and then back to the environment after HEPA filtration. The ventilation supply air is provided by supply fans located in the 2736-ZB Building via an underground duct between the two buildings. The relative pressure of each building area is controlled independently by supply and exhaust dampers. The air pressure in each area is normally negative relative to the atmosphere to prevent the movement of airborne material out of the building. Ventilation exhaust airflow is provided by fans located in the 2736-ZA Building. The 2736-Z Building ventilation exhaust air moves to the 2736-ZA Building via an aboveground duct assembly. The exhaust air is filtered through two stages of HEPA filtration in the 2736-ZA Building and discharged to the environment through the 296-Z-6 stack.

Two rooms, separated by fire walls, are located on each side of the corridor. The rooms are designated as vault 1, vault 2, vault 3, and vault 4. Vaults 1, 3, and 4 contain storage cubicles having pedestal storage rings for SNM storage containers (two of the storage cubicles in vault 1 have shelf storage). Vault 2 contains metal storage racks having storage shelves for SNM storage containers and open floor storage space for larger items such as shipping containers.

Normal electrical power for the building is provided from the 291-Z Building, while backup power is provided by the three diesel generators in the 2721-Z Building and the diesel generator in the 2736-ZA Building.

The only authorized operations occurring within the 2736-Z Building are the storage, handling, and inspection of SNM containers. SNM containers are stored and inspected in each of the four vaults, while handling of containers occurs in each of the four vaults and the building corridor.

Vault 2, unlike the other three vaults, has water supplied for a sprinkler system.

The following Hazard Evaluation table identifies stack CAMs as a preventive/mitigative feature for several postulated failure events. The CAMs perform a passive function, which is to detect airborne radioactive material and to activate alarms should the alarm set-point on the CAM be exceeded.

They do not provide an active function which would actuate equipment or systems to prevent or mitigate an accident. In most cases the CAMs do not serve to reduce the consequences associated with a release of airborne radioactive material because most accidents involve a sudden release of material over a short period of time. Therefore, by the time the stack CAM detects the release there would be insufficient time to mitigate the event. In addition, the CAM's location in the ventilation discharge stack precludes any preventive/mitigative action since the release would have already occurred. Potentially chronic releases from process operations, or due to equipment failures (e.g., failed HEPA filters), tend to be small in nature. If these releases are sufficient to actuate the CAM alarm, operator action is generally adequate to limit the release so there is no significant consequence. It should be noted that accidents evaluated in the Chapter 9.0 analyses did not rely on the CAMs to serve a preventive/mitigative function.

Table 9A.2.1
2736-Z Complex: 2736-Z Building.

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
1	**Vaults 1, 3, and 4.**	A. Vault storage cubicles/pedestal storage rings.	Provides shielding to reduce neutron interactions between SNM stored in adjacent cubicles and maintains container separation distance for the purpose of criticality safety.	Loss of shielding and container separation.	(1) Potential loss of SNM from storage container(s) and entrainment in the ventilation system.	Storage cubicles/pedestals determined to withstand DBE loads (Ocoma 1994). CAMs to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. Two-stage HEPA-filtered ventilation exhaust system to mitigate the release of SNM to the environment.	The OSD requires SNM stored in the vault to be packaged with a minimum of two containment barriers. Procedure governing operator response to CAM alarm.	Structural failure of the storage cubicles/pedestals is not credible.	Refer to section 9.2.4A.1.1, "Building Response During a Seismic Event."	There is no credible scenario that could challenge the integrity of the cubicles other than an earthquake. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
					(2) Potential criticality with a resultant potential loss of SNM from storage container(s) and entrainment in the ventilation system.	Same as above. CAS to detect criticality and to activate criticality alarm.	Same as above. Double-contingency principle precludes the potential for a criticality as a result of a single failure. Procedure governing operator response to criticality alarm .			
		B. Vault ventilation supply.	Provides air flow for removal of heat generated by decay of SNM within the vault and for maintaining correct negative pressure control of vault.	Insufficient supply air flow.	(1) Additional thermal loading of SNM containers and resulting container pressurization could potentially result in loss of SNM from storage container(s) and entrainment in the ventilation system. Potential release of SNM to the environment.	One operating supply fan and one on standby. Supply fan flow monitors activate alarm upon low flow condition. Cubicle/container temperature monitors. SNM containers designed to withstand 100 lb/in^2 internal pressure before gross failure (Szempruch 1984). CAMs to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. Two-stage HEPA-filtered ventilation system to mitigate the release of SNM to the environment.	Procedure governing operator response to flow alarms and a pressure alarm for the 2736-Z Building. Procedure governing operator response to container temperature(s) outside allowable limits. OSD requires SNM stored in the vaults to be packaged with a minimum of two containment barriers. Procedure governing operator response to CAM alarm.	Short term insufficient supply air is an anticipated event. The consequences are judged to be low. Long term insufficient supply air is an extremely unlikely event. The consequences are judged to be moderate.	Refer to section 9.2.4A.6.3.6.D, "Accident Analysis Calculations, 2736-Z Complex, Container Heatup."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
1	**Vaults 1, 3, and 4 (continued).**	E. Handling of SNM storage containers.	To safely move SNM containers to/from vault storage location.	(1) Dropped SNM container.	Potential loss of containment and entrainment of SNM in the ventilation system.	Tests have shown (Hammond 1976a) that food-pack cans (i.e., SNM containers) can be dropped from a height of 3 m without suffering a loss of containment. CAMs to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. Two-stage HEPA-filtered ventilation exhaust system to mitigate the release of SNM to the environment.	Same as above, except response to VSIS anomalies is not applicable.	This is an anticipated event. The consequences are judged to be low.	Refer to section 9.1.3, "Radioisotope-Bearing Powder Spills."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
				(2) Inadequate spacing between container being handled and other containers.	Loss of a single contingency for criticality safety. Potential criticality if there is a loss of an additional contingency. Potential loss of containment and entrainment of SNM in the ventilation system.	Refer to item above, except drop test information is not applicable. CAS to detect criticality and to activate criticality alarm horns.	Refer to item 1A(2)	Inadequate spacing is an anticipated event. The consequences are judged to be low.		A criticality could potentially result in severe consequences to the worker. A criticality due to inadequate spacing of containers is not a credible event. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
		F. Vault safety and inventory system.	To remotely monitor SNM container temperature, ambient air temperature, dimensional changes of the container, container presence, and container identification number.	Failure to detect SNM container anomaly.	Potential loss of containment and entrainment of SNM in the ventilation system.	Refer to item 1D. VSIS anomalies annunciated in rooms 104 and 306A of the 234-5Z Building.	Refer to item 1D. Procedure governing operator response to VSIS anomalies annunciated in rooms 104 and 306A of the 234-5Z Building.	This event is anticipated. The consequence is judged to be low.	Refer to item 1D.	Refer to item 1D. WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
2	**Vault 2**	A. Vault storage racks	To maintain container separation for the purpose of criticality safety.	Loss of container separation.	Refer to item 1A.	Storage racks determined to withstand seismic event (Ocoma 1994, and WHC-SD-CP-SA-026). Refer to item 1A except for seismic qualification of cubicles, which is not applicable.	Procedure governing operator response to CAM alarm.	Structural failure of the storage racks is not credible.	Refer to item 1A.	No credible scenario that could challenge rack integrity other than the seismic event. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011

Appendix 9A.2.2

2736-ZA Building

The 2736-ZA Building consists of two rooms (designated rooms 649 and 650) and the 296-Z-6 stack. The function of the building is to provide exhaust airflow for the 2736-Z Building, and to provide HEPA filtration of the exhaust air before it is discharged to the environment.

The 2736-ZA Building structure and exhaust ventilation system form a confinement system designed to mitigate the release of hazardous material to the environment in the event of a barrier failure in the 2736-Z Building.

Room 650 contains two exhaust fans that provide ventilation exhaust for the 2736-Z Building, and four HEPA filters arranged in series (two groups of two) that provide two stages of filtration for the ventilation exhaust air before discharge to the atmosphere through the stack. Room 650 also houses a small compressor that provides backup instrument air for the 2736-Z and 2736-ZA Buildings.

Normal electrical power is provided to the building by two separate sources in the 234-5Z Building. Backup power is provided by the diesel-generators in Building 2721-Z.

Instrument air and air sample vacuum are provided to the building by equipment located in the 291-Z Building.

The following Hazard Evaluation table identifies stack CAMs as a preventive/mitigative feature for several postulated failure events. The CAMs perform a passive function, which is to detect airborne radioactive material and to activate alarms should the alarm set-point on the CAM be exceeded. They do not provide an active function which would actuate equipment or systems to prevent or mitigate an accident. In most cases the CAMs do not serve to reduce the consequences associated with a release of airborne radioactive material because most accidents involve a sudden release of material over a short period of time. Therefore, by the time the stack CAM detects the release there would be insufficient time to mitigate the event. In addition, the CAM's location in the ventilation discharge stack precludes any preventive/mitigative action since the release would have already occurred. Potentially chronic releases from process operations, or due to equipment failures (e.g., failed HEPA filters), tend to be small in nature. If these releases are sufficient to actuate the CAM alarm, operator action is generally adequate to limit the release so there is no significant consequence. It should be noted that accidents evaluated in the Chapter 9.0 analyses did not rely on the CAMs to serve a preventive/mitigative function.

Table 9A.2.2
2736-Z Complex: 2736-ZA Building.

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ Activity	Function	Failure Mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
1	**Room 650, ventilation system**	A. Exhaust HEPA filters	To filter exhaust ventilation air from the building and the 2736-Z Building before atmospheric discharge in order to mitigate the release of radioactive particulates to the environment.	Loss of exhaust air filtration.	Potential release of SNM to the building and to the environment.	CAMs (room and stack) to detect airborne alpha contamination and to activate alarm(s) if alarm set point is exceeded. HEPA filter DP gauges. Backup two-stage HEPA filtration system on standby.	Procedure governing operator response to off normal HEPA filter DP value. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Not specifically analyzed.	Normally there is no loose SNM in either the 2736-Z Building or the 2736-ZA Building. Therefore, for a release of SNM to the environment to occur there must also be a loss of containment event in the 2736-Z Building. WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
		B. Ventilation supply system.	Provides airflow for cooling of room as necessary.	Insufficient supply airflow.	Potential for excessive temperature inside of room.	Two supply fans available to provide filtered outside air for room. Two temperature controllers to activate motor-controlled dampers to allow filtered outside air into room.	--	This event is anticipated. The consequences are judged to be low.	Not specifically analyzed.	
		C. Ventilation exhaust system.	Provides exhaust airflow for the 2736-Z Building and the 2736-ZA Building.	Insufficient exhaust airflow.	(1) Potential loss of pressure control for the 2736-Z Building, and (2) potential increased temperature of SNM storage containers in 2736-Z. See Table A.2.1 for the hazard analysis of these events for the 2736-Z Building.	Two exhaust fans; one operating and one on standby. Computer-controlled ventilation system activates alarm upon sensing low flow condition.	Procedure governing operator response to low flow alarm.	This event is anticipated. The consequences in the 2736-ZA Building are low.	Not specifically analyzed.	Insufficient exhaust airflow has minimal impact on the 2736-ZA Building. However, the exhaust system also provides exhaust airflow for the 2736-Z Building. See Table A.2.1 for the hazard analysis of the ventilation exhaust system for the 2736-Z Building. Appendix 9A.2.3

2736-ZB Building

The 2736-ZB Building has facilities that enable it to ship and receive, store, repackage, and NDA containers of SNM.

The 2736-ZB Building and its internal walls and equipment function as barriers to contain hazardous material. The primary barrier in the 2736-ZB Building is a process enclosure (e.g., glovebox 636) or a SNM storage or transportation container. The secondary barrier serves to enclose the area containing the primary barrier. An example is the internal building walls defining room 636, which contains glovebox 636. The 2736-ZB Building structure also functions as a barrier.

The 2736-ZB Building structure operates with the building ventilation systems to form a confinement system that is designed to mitigate the release of hazardous material should a barrier fail. The building ventilation systems complete the confinement system by providing a controlled, continuous flow of air from the environment into the various building areas, through HEPA filters, and then back to the environment. Ventilation supply air is provided for the building by equipment located in room 602. The flow of supply air within the building is from uncontaminated areas to potentially contaminated areas (zone 2). Air is supplied to zone 1 (glovebox 636) by a dedicated dry-air system. The air pressure in both zone 2 and zone 1 is normally negative relative to the atmosphere to prevent the movement of airborne material out of the building. The ventilation exhaust air flows to room 600 where it is filtered through two stages of HEPA filtration before being exhausted to the environment through the 296-Z-5 stack. Room 637, the NDA laboratory, has dedicated supply/exhaust fans and HEPA filters that are also located in rooms 600 and 602. Ventilation of room 637 is separate from the rest of the building until the filtered exhausts are combined in the exhaust plenum leading to the 296-Z-5 stack.

The building includes 49 areas designated as separate rooms and the 296-Z-5 stack. The room designations begin with room 600 and end with room 646. Two additional rooms are designated as rooms 638A and 641A. Many of the rooms simply provide administrative or service facilities used to support the primary operations conducted within the building and have no significant radiological or toxicological hazards associated with them. A listing of these rooms, grouped by general function, is provided below.

- Offices--rooms 603 through 607, 610, 611, 631, and 634
- Airlocks--rooms 608, 615, 621, and 646
- Corridors--rooms 601, 609, 617, and 624
- Janitor closets--rooms 613 and 626
- Water heater--room 612
- Restrooms--rooms 614, 618, 627, and 628

- Changerooms--rooms 616, 619, and 622
- Lunchroom--room 620
- UPS room--room 623
- Mardix--room 629
- Decontamination facility--room 630
- Operator ready room--room 635
- Supply room--room 640
- Personnel entry zone III--room 643
- Material passageway--room 644
- Supply air--room 602
- MUX (security system for the 2736-Z Building)--room 641A
- Applied Technology Chemistry--room 632.

Room 636 contains glovebox 636, which is used for storing, inspecting, and repackaging containers of SNM. Room 637 contains the equipment (e.g., large-table Segmented Gamma Scan Assay System (SGSAS), calorimetry pre-equilibration bath) used for the NDA of various containers of SNM. Room 638 (including rooms 638A, 639 and 640) contains the necessary equipment (e.g., can sealers, storage rack) for the staging, recanning, and storage of SNM. Room 641 provides a storage area for 55-gal drums waiting for analysis or shipment. The equipment necessary (e.g., portable NDA equipment) to support International Atomic Energy Agency (IAEA) surveillance activities of SNM is contained in room 642. In addition, corridors 625 and 633 and room 644 are used for transporting containers of SNM within the building.

The building provides its own normal electrical power from a pad-mounted transformer. Backup power is provided by the 2721-Z Building.

The following Hazard Evaluation table identifies stack CAMs as a preventive/mitigative feature for several postulated failure events. The CAMs perform a passive function, which is to detect airborne radioactive material and to activate alarms should the alarm set-point on the CAM be exceeded. They do not provide an active function which would actuate equipment or systems to prevent or mitigate an accident. In most cases the CAMs do not serve to reduce the consequences associated with a release of airborne radioactive material because most accidents involve a sudden release of material over a short period of time. Therefore, by the time the stack CAM detects the release there would be insufficient time to mitigate the event. In addition, the CAM's location in the ventilation discharge stack precludes any preventive/mitigative action since the release would have already occurred. Potentially chronic releases from process operations, or due to equipment failures (e.g., failed HEPA filters), tend to be small in nature. If these releases are sufficient to actuate the CAM alarm, operator action is

generally adequate to limit the release so there is no significant consequence. It should be noted that accidents evaluated in the Chapter 9.0 analyses did not rely on the CAMs to serve a preventive/mitigative function.

Table 9A.2.3
2736-Z Complex: 2736-ZB Building.

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
1	Rooms 636, 637, 638, 638A, 639, and 642; corridors 625 and 633.	A. Handling of SNM storage containers.	To safely handle SNM containers within the building as necessary to support operations.	(1) Dropped SNM storage container.	Potential release of SNM from storage container to room or corridor. Potential plutonium metal/scrap fire in container. Potential entrainment of SNM in the ventilation system.	SNM is contained within sealed metal containers. Tests have shown (Hammond 1976a) that food pack cans are able to survive a drop of 3 m without a loss of containment. CAMs to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. Two-stage HEPA-filtered ventilation exhaust system to mitigate the release of SNM to the environment.	OSD requires SNM (except polycubes) to be packaged with a minimum of two containment barriers. Procedure governing operator response to CAM alarm. Procedure governing operator response to a plutonium metal/scrap fire outside of a glovebox.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.4, "Radioisotope-Bearing Pressurized Powder Container."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
				(2) Inadequate spacing between SNM containers.	Loss of a single contingency for criticality safety. Potential criticality if there is a loss of an additional contingency. Potential loss of SNM from storage container(s) to room or corridor and entrainment in the ventilation system.	Same as above, except drop test information is not applicable. CAS to detect criticality and to activate criticality alarm horns.	Same as above. Double-contingency principle precludes the potential for a criticality as a result of a single failure. Procedure governing operator response to CAS criticality alarm horns.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.2.3, "Criticality", subsection 9.2.3.4.4, "Transport and Storage, Probability."	A criticality due to inadequate spacing of containers during handling could potentially result in serious consequences to the worker. However, it is not a credible event. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
		B. SNM storage containers.	To provide containment of SNM.	Loss of containment.	Release of SNM from storage container to room or corridor and potential entrainment in the ventilation system.	SNM is contained within sealed metal containers. CAMs to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. Two-stage HEPA-filtered ventilation system to mitigate the release of SNM to the environment.	OSD requires SNM (except polycubes) to be packaged with a minimum of two containment barriers. Procedure governing operator response to CAM alarm.	This is an anticipated event. The consequences are judged to be low.	Refer to section 9.1.4, "Radioisotope-Bearing Pressurized Powder Container." Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
2	Rooms 637, 638, 641, and 644; corridors 625 and 633.	A. Handling waste drums and shipping containers.	To safely handle waste drums/shipping containers within the building as necessary to support operations.	(1) Dropped waste drum/shipping container.	Potential breach of waste drum/shipping container. Potential release of SNM to room or corridor. Potential entrainment of SNM in the ventilation system.	Waste drums designed to withstand drop from 4 ft, shipping container from 30 ft, without loss of containment. CAMs to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. Two-Stage HEPA-filtered ventilation system to mitigate the release of SNM to the environment.	Procedure governing movement of SNM using drum barrel hand truck. Packaging requirement for double containment of waste. SNM in shipping containers typically has four levels of containment. Procedure governing operator response to CAM alarm.	This is an anticipated event. The consequences are judged to be low.	Refer to section 9.1.4, Radioisotope-Bearing Pressurized Powder Container."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
				(2) Inadequate spacing between drums/containers.	Loss of a single contingency for criticality safety. Potential criticality if there is a loss of an additional contingency. Potential release of SNM to the room or corridor. Potential entrainment of SNM in the ventilation system.	Same as above, except drop height information not applicable. CAS to detect criticality and to activate criticality alarm horns.	Double-contingency principle precludes the potential for a criticality as a result of a single failure. Procedure governing operator response to criticality alarm horn. Packaging requirement limiting the amount of fissile material in drum/container. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.2.3, "Criticality", subsection 9.2.3.4.4, "Transport and Storage, Probability."	A criticality could potentially result in severe consequences to the worker, but it is not credible for a criticality to occur as a result of inadequate spacing. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
		B. Waste drums/shipping containers.	To provide containment of SNM.	Loss of containment.	Potential release of SNM to the room or corridor. Potential entrainment in the ventilation system.	Waste drums have vents to relieve internal pressure. CAMs to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. Two-stage HEPA-filtered ventilation system to mitigate the release of SNM to the environment.	Waste drums packaging requirements for double containment, limiting volatile organic compounds, and for incompatible materials. Packaging requirements for shipping containers of SNM. Procedure governing operator response to CAM alarm.	This is an anticipated event. The consequences are judged to be moderate.	Refer to section 9.2.2D, "Waste Drum Fire."	An energetic loss of containment (i.e., waste drum explosion) could potentially result in severe consequences to the worker. WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011

3	Room 636, Glovebox 636	A. Glovebox enclosure.	To provide confinement of SNM for various operations (i.e., repackaging, inspection, storage) conducted within glovebox.	Loss of confinement.	Potential release of SNM from the glovebox to the room. Potential entrainment of SNM in the ventilation system.	Glovebox determined to withstand DBE loads (Ocoma 1994). Glovebox maintained at negative pressure relative to room. CAMs to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. Two-stage HEPA-filtered ventilation system to mitigate the release of SNM to the environment.	Procedure governing operator response to CAM alarm. CPS, which limits the form and quantity of SNM inside the glovebox, is posted on the exterior of the glovebox.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
		B. Glovebox ventilation dry-air supply system.	(1) Provides airflow for maintaining correct negative pressure control of glovebox.	(1) Insufficient supply airflow.	Potential excessive negative pressure within the glovebox. Potential loss of glovebox confinement.	Dry-air system has backup equipment. Magnehelic gauge to verify glovebox pressure is within operating limits. DP (between glovebox and room) monitor activates alarm if pressure is off normal. CAMs to detect airborne alpha contamination and to activate alarms should the alarm set point be exceeded. Two-stage HEPA- filtered ventilation system to mitigate the release of SNM to the environment.	Procedure governing operator response to glovebox pressure outside operating limits. Procedure governing operator response to pressure alarm. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	See item 5. WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
				(2) High flow of supply air.	Potential pressurization of the glovebox relative to the room. Potential release of SNM to the room and entrainment in the ventilation system.	Same as above.	Same as above.	Same as above.	Same as above.	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
			(2) Provides dry air to maintain glovebox dew point more negative than operating limit.	Glovebox dew point more positive than operating limit.	Potential uptake of moisture by the SNM exposed to the glovebox atmosphere, which could potentially result in the storage of unstable SNM within room 638 or in the 2736-Z Building. Storage of unstable SNM could potentially result in a loss of containment.	Dry-air system components have backup units. Glovebox dry-air monitor and alarm light. Dry-air receiver tank stores a 5 min reserve of dry air.	Procedure governing operator verification of dry-air monitor alarm light status. Procedure governing operator response to glovebox dew point more positive than operating limit.	This event is anticipated. Refer to Item 1B. for consequences of loss of containment in room 638.	Refer to section 9.1.4, "Radioisotope Bearing Pressurized Powder Container."	Refer to Item 1D. in Table A.2.1 for hazard analysis of loss of containment event in the 2736-Z Building. WHC-SD-CP-SDD-005

Table 9A.2.3
2736-Z Complex: 2736-ZB Building.

3	**Room 636, glovebox 636 (continued).**	C. Glovebox ventilation exhaust.	Provides airflow for maintaining correct negative pressure control of glovebox.	(1) Insufficient exhaust airflow.	Potential pressurization of the glovebox relative to the room. Potential release of SNM from the glovebox to the room. Potential entrainment of SNM in the ventilation system.	Magnehelic gauge to verify glovebox pressure is within operating limits. DP (between glovebox and room) monitor activates alarm if pressure is off normal. One operating exhaust fan and one on standby. CAMs to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. Two-stage HEPA-filtered ventilation system to mitigate the release of SNM to the environment.	Procedure governing operator response to glovebox pressure outside of operating limits. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
				(2) High exhaust airflow.	Potential excess negative pressure in glovebox relative to the room. Potential loss of glovebox confinement.	Magnehelic gauge to verify glovebox pressure is within operating limits. DP (between glovebox and room) monitor activates alarm if pressure is off normal. CAMs to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. Two-stage HEPA-filtered ventilation system to mitigate the release of SNM to the environment.	Procedure governing operator response to glovebox pressure outside of operating limits. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
		D. Glovebox HEPA filters.	To filter any discharges of air from the glovebox in order to minimize the release of radioactive airborne particulates.	Loss of filtration.	Potential release of SNM from the glovebox. Potential entrainment of SNM in the ventilation system.	Glovebox exhaust HEPA filter DP gauge. Exhaust system designed to maintain glovebox at negative pressure relative to room. CAMs to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. Two-stage HEPA-filtered exhaust ventilation system to mitigate the release of SNM to the environment.	Procedure governing operator verification that glovebox exhaust HEPA filter DP is within operating limit. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Same as above.	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011

Table 9A.2.3
2736-Z Complex: 2736-ZB Building.

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
3	Room 636, glovebox 636 (continued).	E. Glovebox argon supply.	To provide flow of argon for use during repackaging plutonium metal (one form of SNM).	(1) Insufficient flow of argon.	Packaging of plutonium metal in container with non-inert atmosphere. Potential storage of unstable SNM in room 638 or the 2736-Z Building. Storage of unstable material could potentially result in a loss of containment event.	Pressure gauge on argon supply bottle.	Procedure governing operator verification of argon bottle pressure prior to repackaging operation. Procedure governing operator verification of argon flow into glovebox.	This event is anticipated. Refer to Item 1B. for the consequences of a loss of containment in room 638.	Refer to section 9.1.4, "Radioisotope Bearing Pressurized Powder Container."	Refer to Item 1D. in Table A.2.1 for hazard analysis of loss of containment event in the 2736-Z Building.
				(2) Excessive flow of argon.	Potential pressurization of the glovebox relative to the room. Potential release of SNM to the room and entrainment in the ventilation system.	Rotameter orifice limits the maximum flow of argon to the glovebox. CAMs to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. Two-stage HEPA-filtered exhaust ventilation system to mitigate the release of SNM to the environment.	Procedure governing operator verification of argon flow into glovebox. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
		F. Inspection, repackaging and storage of SNM containers.	--	(1) Inadequate spacing of containers within glovebox.	Loss of a single contingency for criticality safety. Potential criticality if there is a loss of an additional contingency. Potential release of SNM from the glovebox to the room. Potential entrainment of SNM in the ventilation system.	CAS to detect criticality and to activate criticality alarm horns. CAMs to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. Two-stage HEPA-filtered ventilation system to mitigate the release of SNM to the environment.	CPS, specifying mass limit of SNM and spacing requirements, is posted on the glovebox. Double-contingency principle precludes the potential for a criticality as a result of a single failure. Procedure governing operator response to CAS horn. Procedure governing operator response to a CAM alarm.	Inadequate spacing is an anticipated event. The consequences are judged to be low.	Refer to section 9.2.3, "Criticality."	A criticality could potentially result in severe consequences to the worker. A criticality due to inadequate spacing is not credible. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
				(2) Dropped SNM storage container.	Potential release of SNM from storage container to the glovebox. Potential plutonium metal/scrap fire. Potential entrainment of SNM in the ventilation system.	Glovebox maintained at negative DP relative to the room. MgO sand, empty metal can/fire cover, and dry chemical fire extinguisher to suppress fire. CAMs to detect airborne contamination and to activate alarm(s). Two-stage HEPA-filtered ventilation exhaust system.	Procedure governing operator response to plutonium metal/scrap fire inside of glovebox. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.2.2C, "Glovebox HA-211 Fire."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011

Table 9A.2.3
2736-Z Complex: 2736-ZB Building.

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
3	**Room 636, glovebox 636 (continued).**	F. Inspection, repackaging and storage of SNM containers (continued).	--	(3) Improper repackaging.	Potential release of SNM from the storage container to the glovebox or to the room. Potential entrainment of SNM in the ventilation system.	Glovebox maintained at negative pressure relative to room. CAMs to detect airborne alpha contamination and to activate alarm(s) if the alarm set point is exceeded. Two-stage HEPA- filtered ventilation system to mitigate the release of SNM to the environment.	Procedure governing operator inspection of can seam. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.3, "Radioisotope-Bearing Powder Spills."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
4	**Room 637, NDA laboratory.**	A. Monorail and manual hoist.	Used to safely move waste drums to/from the large table SGSAS.	Failure to move drum safely.	Potential breach of drum. Potential loss of containment of SNM and release to the room. Potential entrainment of SNM in the ventilation system.	Hoist is physically restricted (by the height of the monorail) from lifting a drum higher than 4 ft. Waste drums are designed to withstand a fall from 4 ft. without a loss of containment. CAMs to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. Two-stage HEPA-filtered ventilation system to mitigate the release of SNM to the environment.	Packaging requirement for double containment. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.3, "Radioisotope-Bearing Powder Spills."	Since the hoist can not lift the drum higher than 4 ft, there is minimal potential for a drum to be breached. Thus, the only hazard would be a dropped load with potentially minor consequences to the worker. WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
		B. Large table SGSAS turntable.	Used to safely elevate and rotate waste drums for SGSAS analysis purposes.	Drum dislodged from turntable while at fully elevated position.	Same as above.	Same as above, except drum can fall greater than 4 ft.	Same as above.	Same as above.	Refer to section 9.1.3, "Radioisotope-Bearing Powder Spills."	When the turntable is fully elevated, the drum is approximately 5 ft above the floor. Thus, there is a potential for the drum to be breached in a fall. WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011

Table 9A.2.3
2736-Z Complex: 2736-ZB Building.

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
4	**Room 637, NDA laboratory (continued).**	C. Calorimetry pre-equilibration bath.	To safely bring containers of SNM to thermal equilibrium before calorimetry assay.	Inadequate spacing of containers in bath.	Loss of a single contingency for criticality safety. Potential criticality if there is a loss of an additional contingency. Potential release of SNM from storage container(s) and entrainment of SNM in the ventilation system.	SNM containers are placed inside measurement adapters having tops loaded with copper shot before insertion in bath. Measurement adapters within bath tubes are separated by thermal spacers. CAS to detect criticality and to activate criticality alarms. CAMs to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. Two-stage HEPA-filtered ventilation system to mitigate the release to the environment.	CPS, which limits container size and mass, is posted on bath. Double-contingency principle precludes the potential for a criticality as a result of a single failure. Procedure governing operator response to criticality alarm horn. Procedure governing operator response to CAM alarm.	This event is extremely unlikely. The consequences are moderate.	Refer to section 9.2.3, "Criticality."	A criticality could potentially result in severe consequences to the worker. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
		D. Ventilation supply system (fans located in room 602).	Provides airflow for maintaining correct negative pressure control of room.	(1) Insufficient supply airflow.	Potential excessive negative DP in room relative to atmosphere.	Ventilation system has backup fan. Flow and pressure control alarms. Computer-controlled ventilation system designed to disable supply and exhaust fans upon sensing off normal condition. SNM is contained within sealed storage containers or waste drums. CAMs to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. Two-stage HEPA-filtered ventilation system to mitigate the release of SNM to the environment.	Procedure governing operator response to flow and pressure alarms. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.8, "Loss of Ventilation", subsection 9.1.8.7, "Buildings 2736-Z and 2736-ZB."	There is normally no loose SNM in room 637. The potential for entrainment of SNM in the ventilation system as a result of insufficient or high supply airflow is minimal. WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
				(2) High flow of supply air.	Potential pressurization of room relative to corridor 633. Potential release of any loose SNM to the corridor and entrainment in the ventilation system.	Same as above.	Same as above.	Same as above.	Same as above.

5	**Room 638 (continued).**	C. Recanning of SNM storage containers (room 638).	To seal SNM storage container within additional container(s).	Failure to properly seal additional container(s).	Potential storage of improperly packaged container in room 638A or in the 2736-Z Building. Potential release of SNM in the event of a loss of containment provided by the inner container. Potential entrainment in the ventilation system.	CAMs to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. Two-stage HEPA-filtered ventilation system to mitigate the release of SNM to the environment.	Procedure governing operator verification of container seal. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to item 1B.	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
6	**Room 642, IAEA surveillance activities.**	Refer to item 1.	--	--	--	--	--	--	--	Refer to item 1.
7	**Building ventilation system.**	A. Exhaust HEPA filters (located in room 600).	To filter exhaust ventilation air before atmospheric discharge (via the 296-Z-5 stack) in order to mitigate the release of SNM to the environment.	Loss of exhaust air filtration.	Potential release of SNM to the environment if a loss of containment event occurs concurrently.	Ventilation exhaust system, including HEPA filter housings, designed to survive DBE loads. HEPA filters have backup units on standby. Room 600 CAM and 296-Z-5 stack CAM to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. HEPA filter DP gauges.	Procedure governing operator response to DP outside of operating limits. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are judged to be low.	Not specifically analyzed.	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
		B. Ventilation supply system (fans located in room 602).	To provide airflow for maintaining correct negative pressure control of all areas of building (room 637 has dedicated supply fans; refer to items 4D and 4E).	(1) Insufficient supply airflow.	Potential excessive negative pressure within building relative to atmosphere.	Ventilation supply system has one operating fan and one on standby. Computer-controlled ventilation system is designed to disable fans upon sensing low flow condition. Loss of pressure alarm for supply fans. CAMs to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded.	Procedure governing operator response to flow and pressure alarms. Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.7F.4, "Building Depressurization–All Plutonium finishing Plant Operating Buildings."	The majority of SNM is sealed in storage containers or waste drums. Loose SNM is normally present only in glovebox 636. WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011

Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
9	**Instrument air system (room 602)**	--	To provide non-oily, clean, dry air for general use in instrument controls for the ventilation system.	Failure to provide air.	Potential loss of ventilation system control which could potentially result in a release of SNM to the environment if a loss of containment occurs concurrently.	Loss of instrument air alarm. Backup instrument air supplied by dry-air compressors located in room 602.	Procedure governing operator response to loss of instrument air alarm.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.8, "Loss of Ventilation."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006
10	**Air sample vacuum system (ASV) (room 602)**	--	To provide the motive force (vacuum) necessary to operate the CAMs and samplers in the building, including the stack sampler and monitor.	Loss of vacuum.	Potential inoperability of CAMs and samplers. Potential failure to detect airborne contamination within the building and within the stack effluent.	One vacuum pump in operation and one on standby. ASV failure alarm system. Backup systems (e.g., portable CAMs) are available for use.	Procedure governing operator response to ASV failure alarm.	This event is unlikely. The consequences are judged to be low.	Not specifically analyzed.	WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
11	**Wet-pipe sprinkler system.**	--	To contain water until it is necessary to be used to suppress a fire within the building.	Flooding of building with water.	Loss of a single contingency for criticality safety in those rooms containing SNM.	Containers are designed to resist moisture intrusion. Containers are restrained to stay within storage location.	Double-contingency principle precludes the potential for a criticality as the result of a single failure. Procedure governing operator response to discharge of water from sprinkler system.	This event is unlikely. The consequences are judged to be low.	Refer to section 9.2.4A.2.11.A, "Accident Scenario-Criticality, Vaults."	WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
12	**Steam supply (provided from a PFP-dedicated diesel-fired boiler via a subheader in the 291-Z Building).**	--	To provide steam to heat the ventilation supply air.	Loss of steam.	Potential freezing of water lines that provide fire suppression and other water services within the building and in the 2736-Z Building.	Two coal-fired boilers on-line. Two coal-fired boilers on standby. One oil-fired boiler available for use should the normal supply be interrupted.	Procedure governing operator response to loss of steam.	This event is anticipated. The consequences are judged to be low.	Not specifically analyzed.	

[a]Hazard identifier.
[b]The consequence, as given here, assumes none of the active preventive/mitigative features are in place.
[c]The probability/consequence, as given here, assumes that the preventive/mitigative features are operative.
[d]Gives the section number in the chapter where additional accident analysis is performed.

Appendix 9A.2.4

2736-ZC Building

The 2736-ZC Building provides an enclosed loading dock for the receipt of SNM, an area designated for the staging/storage of cargo restraint transporters, and a transfer corridor that connects to the 2736-ZB Building. A metal building encloses the loading dock and also a 4,000-lb-capacity, 360° jib crane with a chain hoist and a drum handler. In an emergency, a HEPA-filtered temporary greenhouse may be erected within the 2736-ZC Building to provide confinement for the opening of a material package.

The 2736-ZC Building has multiple barriers providing containment of hazardous material. The primary barrier is the SNM storage containers. The shipping containers used to hold the storage containers during transportation provide several barriers to release. The building structure provides an additional barrier.

Normal operations in the building expose workers to the common industrial hazards of mechanical pinchpoints, electrical shock, and dropped loads. Of these, only a dropped load can contribute to or initiate an accident that could result in significant hazards. Emergency operations (i.e., opening of a material package) could result in significant hazards.

The building has no active ventilation system.

Normal electrical power for the 2736-ZC Building is provided by the 2736-ZB Building. Backup electrical power is provided by the 2721-Z Building via the 2736-ZB Building.

Table 9A.2.4
2736-Z Complex: 2736-ZC Building.

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
1	**Jib Crane**	Chain hoist/drum handler	Used to safely unload DOT 6M shipping containers from cargo-restraint transporters.	Failure to unload shipping container safely.	Potential for a shipping container to drop to the floor of the building. Potential for a release of SNM to the environment.	--	Packaging requirements for a minimum of two containment barriers. Procedure governing operator response to a .	This event is unlikely. The consequence is judged to be low.	Refer to section 9.1.3, "Radioisotope-Bearing Powder Spill."	Currently there are a minimal number of shipments being received at the 2736-ZC Building (approximately 6 to 10/yr). The potential for a DOT 6M shipping container to be breached during unloading is minimal.
2	**HEPA filtered temporary greenhouse**	--	To provide confinement of SNM if it is necessary to open a container in the 2736-ZC Building.	Loss of confinement.	Potential for release of SNM to the building and to the environment if there is airborne contamination present.	Portable CAM to detect airborne alpha contamination and to activate local alarm should the alarm set point be exceeded.	Procedure governing operator response to CAM alarm.	This event is anticipated. The consequence is judged to be low.	Refer to item 1.	
3	**DOT 6M shipping container.**	--	To provide containment of SNM.	Loss of containment.	Potential release of SNM to the building and to the environment.	--	Packaging requirement for a minimum of two containment barriers.	This event is anticipated. The consequences are judged to be low.	Refer to item 1.	Material shipped in DOT 6M containers is typically contained within four containment barriers in addition to that provided by the shipping container.

[a]Hazard identifier.
[b]The consequence, as given here, assumes none of the active preventive/mitigative features are in place.
[c]The probability/consequence, as given here, assumes that the preventive/mitigative features are operative.
[d]Gives the section number in the chapter where additional accident analysis is performed.

Appendix 9A.2.5

2736-ZD Building

The 2736-ZD Building currently stores three EBR II storage casks containing irradiated metallic fuel rods from the Los Alamos Molten Plutonium Reactor Experiment. The CPS for the building limits the storage to a total of seven casks and a total fissile mass limit of 4,000 g. The building is a concrete, cylindrical pipe that is 8 ft in diameter and 6 ft deep and has a 1-ft-thick concrete coverplate. It rests on top of the ground and is located west of the 241-Z Building and south of the 2736-ZC Building. The 2736-ZD Building is impervious to moisture, and all necessary shielding and containment is provided by the storage casks.

The 2736-ZD Building has two barriers designed to contain hazardous material. The primary barrier is the EBR II storage casks. The secondary barrier is the watertight concrete pipe that contains the storage casks.

The 2736-ZD Building has no support equipment (e.g., ventilation system components) and receives neither normal or backup electrical power. Surveillance of the building consists simply of walking near enough to observe any gross failure of the structure. Based on this information, there are no significant radiological or toxicological hazards associated with the operation of this building.

Appendix 9A.2.6

2721-Z Building

The function of the 2721-Z Building is to provide backup electrical power for the PFP facilities. The building does not contain any radiological material. The building is divided into two rooms designated as rooms 647 and 648. Room 647 contains a programmable controller that monitors and controls proper voltage levels for most of the operations at the PFP, a UPS system for the controller, and the switchgear necessary for transferring electrical loads to the diesel generators located in room 648. The only hazard associated with operations performed in room 647 is the common industrial hazard of electric shock.

Room 648 houses three 325-kW diesel generators that provide backup electrical power to the PFP facilities. The operation of the diesel generators has several associated common industrial type hazards. These hazards include mechanical pinchpoints, electrical shock, and potential exposure to diesel exhaust fumes. Since these hazards only have the potential to impact worker safety, they need no further evaluation. The failure of the diesel generators to provide electrical power to the PFP facilities in the event of the loss of normal electrical power would not result in significant radiological hazards within the 2721-Z Building. However, this failure could result in significant radiological hazards at other buildings within the PFP that contain SNM.

Exhaust ventilation for the building is provided by two through-the-wall exhaust fans. The fans normally operate only when cooling of the building is required. When the diesel generators are operating, motorized inlet and exhaust dampers open automatically to provide additional air for combustion and cooling.

Table 9A.2.6
2736-Z Complex: 2721-Z Building.

Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
1	**Backup electrical power supply system.**	--	To provide electrical power to the PFP should the normal electrical power supply system fail.	Failure to provide power.	Potential loss of ventilation control within the various buildings of the PFP. Potential loss of monitoring/alarm/safety systems (e.g., CAMs, CAS, fire detection) within the PFP.	Some systems are equipped with UPS systems. CAS have backup battery-powered systems. 125 Vdc stationary battery system. Backup diesel generators are controlled and monitored by the MICON system.	Procedure governing operator response to loss of backup power. Procedure governing testing and inspection of diesel generators.	This event is extremely unlikely. The consequence is judged to be moderate.	Refer to section 9.1.8, "Loss of Ventilation."	

[a]Hazard identifier.
[b]The consequence, as given here, assumes none of the active preventive/mitigative features are in place.
[c]The probability/consequence, as given here, assumes that the preventive/mitigative features are operative.
[d]Gives the section number in the chapter where additional accident analysis is performed.

Appendix 9A.3

The 236-Z Building.

The 236-Z Building currently conducts only limited operations. The primary functions of the building are as follows: (1) to safely store residual radioactive materials in the process cell, process equipment, and in plutonium recovery gloveboxes, and (2) temporary storage of in-process material within plutonium recovery facilities (i.e., gloveboxes).

The 236-Z Building and its internal walls and equipment function as barriers to prevent an uncontrolled release of hazardous material. The primary barrier in the 236-Z Building is a process enclosure (e.g., glovebox 27), a process vessel within an enclosure, or a SNM storage or transportation container. The secondary barrier serves to enclose the area containing the primary barrier. An example is the internal building walls defining room 27, which contains glovebox 27. The external structure of the 236-Z Building provides an additional barrier.

The structure of the 236-Z Building in union with the building ventilation systems forms a confinement system designed to mitigate the release of hazardous material should a barrier failure occur. The building ventilation systems complete the confinement system by providing a controlled, continuous flow of air from the environment into the various building areas and process enclosures, through HEPA filters, and then back to the environment. The ventilation supply air is provided by supply fans located in the 234-5Z Building via a duct mounted on the roof of the 234-5Z Building. The flow of supply air within the building is from uncontaminated areas to potentially contaminated areas (zone 3), and then to normally contaminated areas (zone 4). The air pressure in both zone 3 and zone 4 is normally negative relative to the atmosphere to prevent the movement of airborne material out of the building. The ventilation exhaust systems, designated as E-3 and E-4 for zones 3 and 4, respectively, route the exhaust air to separate banks of HEPA filters located in room 26 of the 236-Z Building (exhaust air from the process cell passes through HEPA filters located in corridors 10 and 20 before reaching the E-4 system filters in room 26). The E-3 and E-4 systems provide single- and two-stage filtration, respectively. The ventilation system exhaust is discharged to the atmosphere via the 291-Z stack by the 291-Z exhaust fans.

The building is separated into 37 areas having individual room or corridor designations. The designations extend from corridor 10 to room 72. The majority of the areas in the building do not conduct operations having significant radiological or toxicological hazards associated with them. These areas and their function or description are listed below:

- Room 13--Cell maintenance area
- Room 15--Storage
- Room 16--Maintenance shop area
- Room 17--Office

- Room 18--Airlock
- Corridors 30 and 31--Access to water-filled viewing windows
- Corridor 33--Crane control and observation gallery
- Room 34--Electrical switchgear
- Room 36--Storage
- Room 37--Janitor
- Room 38--Restroom
- Room 44--Control room
- Room 45--Office
- Corridors 46 and 47--Access corridors
- Room 46--Office
- Room 70--Process cell airlock changeroom
- Room 71--Airlock access
- Room 72--Process cell airlock.

The process cell, designated as room 12, contains the majority of the process equipment (i.e., tanks and piping), while the access gloveboxes (located in corridors 11, 14, 21, and 25) and column gloveboxes (located in rooms 42, 50, and 60), contain tanks, piping, and valves associated with the process equipment. The plutonium recovery gloveboxes, used for temporary storage of radioactive materials, are located in rooms 41 and 43.

An NDA counting center is located in room 19. The room contains equipment used to analyze the radiological material content of waste drums. A glovebox located in room 27 is used to confine radioactive materials during operations involving the cutting of large sections of contaminated pipe or ductwork in preparation for disposal. An additional operation conducted in the glovebox is the cementation of small quantities of radioactive material. The room also contains storage shelves that are used to temporarily store containers holding contaminated pieces of equipment.

The mechanical equipment for the air sample vacuum system is located in room 35. This equipment is used to supply a vacuum to air monitoring (e.g., room CAMs) equipment within the 236-Z Building.

Equipment located in room 40 may be used to prepare acid solutions to be used for decontamination efforts. Currently, however, the room is not being used. Therefore, this activity will not be analyzed further.

Normal electrical power for the building is provided from a substation in the 291-Z Building. Backup electrical power is provided by the 2721-Z

Building via the 234-5Z Building.

The following Hazard Evaluation table identifies stack CAMs as a preventive/mitigative feature for several postulated failure events. The CAMs perform a passive function, which is to detect airborne radioactive material and to activate alarms should the alarm set-point on the CAM be exceeded. They do not provide an active function which would actuate equipment or systems to prevent or mitigate an accident. In most cases the CAMs do not serve to reduce the consequences associated with a release of airborne radioactive material because most accidents involve a sudden release of material over a short period of time. Therefore, by the time the stack CAM detects the release there would be insufficient time to mitigate the event. In addition, the CAM's location in the ventilation discharge stack precludes any preventive/mitigative action since the release would have already occurred. Potentially chronic releases from process operations, or due to equipment failures (e.g., failed HEPA filters), tend to be small in nature. If these releases are sufficient to actuate the CAM alarm, operator action is generally adequate to limit the release so there is no significant consequence. It should be noted that accidents evaluated in the Chapter 9.0 analyses did not rely on the CAMs to serve a preventive/mitigative function.

Table 9A.3
236-Z Building.

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
1	**Corridors 11, 12, 14, and 21; 1st and 2nd floor (east and west) access gloveboxes; rooms 42, 50, and 60; column gloveboxes.**	A. Glovebox enclosure	To provide confinement of SNM.	Loss of confinement.	Potential release of SNM from the glovebox to the corridor/room and potential entrainment in the ventilation system.	Access gloveboxes are seismically qualified. Gloveboxes maintained at negative pressure relative to the corridor/room. Glovebox DP gauges. CAMs to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. HEPA-filtered ventilation system to mitigate the release of SNM to the environment.	Procedure governing operator response to glovebox DP outside of operating limits. Procedure governing operator response to CAM alarm. CPSs limit the access gloveboxes to negligible dispersible material. CPSs limit the amount of SNM in the column gloveboxes.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
		B. Glovebox supply ventilation.	To provide airflow for maintaining correct negative pressure control of glovebox.	(1) Insufficient supply airflow.	Potential excessive negative pressure in glovebox. Potential loss of glovebox confinement.	Glovebox DP gauges. CAMs to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. Two-stage HEPA-filtered ventilation system to mitigate the release of SNM to the environment.	Refer to item 1A.	Refer to item 1A.	Refer to section 9.1.7F, "Building Depressurization--All Plutonium Finishing Plant Operating Buildings."	Access and column gloveboxes draw air from the canyon, which draws air from the second and third floor corridors. Therefore, internal pressure of gloveboxes follows that of corridors unless leakage paths from the canyon to glovebox are obstructed. WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
				(2) High supply airflow.	Potential pressurization of glovebox relative to the atmosphere.	Supply air is provided via leakage from the canyon. Glovebox DP gauges. CAMs to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. HEPA-filtered ventilation system to mitigate the release of SNM to the environment.	Refer to item 1A.	Refer to item 1A.	Refer to section 9.1.7B, "Excessive Pressurization of 236-Z Building."	Access and column gloveboxes draw air from the canyon that, in turn, draws air from the second and third floor corridors. Therefore, the gloveboxes will not be driven to a positive pressure relative to the corridor/room. WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011

6	**Room 27, maintenance glovebox (continued).**	E. Cutting of pipe and ductwork.	To safely cut pipe/ductwork into sections small enough to be packaged for disposal.	Failure to safely perform cutting operation.	Potential breach of glovebox. Potential release of SNM from glovebox to room. Potential entrainment of SNM in the ventilation system and potential release to the environment.	Glovebox maintained at negative pressure relative to room. CAM to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. HEPA-filtered ventilation system to mitigate the release of SNM to the environment.	Procedure governing operator response to CAM alarm.	This event is anticipated. The consequences are moderate.	Refer to section 9.1.9, "Glovebox Glove Breach."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
		F. Cementation of SNM.	To absorb free liquids and to cement solids together within a polyjar to allow for disposal.	Failure to cement properly.	Potential release of SNM from polyjar. Potential release of SNM to the glovebox. Potential release of SNM to the room and potential entrainment in the ventilation system.	Glovebox enclosure. Vented polyjars used for cementation. Cemented polyjars are stored within 55-gal waste drums. CAMs to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. HEPA-filtered ventilation system to mitigate the release of SNM to the environment.	Procedure governing operator inspection of cemented jar for free liquids. Procedure governing operator response to CAM alarm. Procedure governing allowable quantity of plutonium/jar.	This event is anticipated. The consequences are judged to be low.	Refer to section 9.1.1, "Radioisotope-Bearing Liquid Spills."	WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
7	**Room 27, room storage of contaminated equipment in containers.**	A. Storage shelves	To maintain container separation for the purpose of criticality safety.	Loss of container separation.	Loss of a single contingency for criticality safety. Potential criticality if there is a loss of an additional contingency. Potential release of SNM into the room and entrainment in the ventilation system.	CAS to detect criticality and to activate criticality alarm horns. CAMs to detect airborne alpha contamination and to activate alarm(s) should the alarm set point be exceeded. HEPA-filtered ventilation system to mitigate the release of SNM to the environment.	CPS limits the mass of SNM and the container dimensions. Double-contingency principle precludes the potential for a criticality as a result of a single failure. Procedure governing operator response to criticality alarm horn. Procedure governing operator response to CAM alarm.	This event is unlikely. The consequences are judged to be low.	Refer to section 9.2.4A.6.3.2.C.d, "Accident Analysis-Calculations, 236-Z–Room 27."	A criticality could potentially result in severe consequences to the worker. A criticality as a result of inadequate spacing of storage containers is not a credible event. WHC-SD-CP-SDD-003 WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011

Appendix 9A.4

The 241-Z Complex

The 241-Z Complex includes the 241-Z, 241-ZA, 241-ZB, and 241-ZG Buildings, 296-Z-3 stack, 241-Z-RB Retention Basins, and Tank 241-Z-361. The 241-Z Building and auxiliary buildings 241-ZA and 241-ZB are designed to collect, measure, stage, and treat aqueous liquids collected from the process facilities of the PFP. The treated liquid waste is pumped through double-encased lines to the collection tank in the 244-TX receiving facility.

The 241-Z Building is enclosed in a corrugated metal structure that houses the ventilation exhaust HEPA filter enclosures and a bridge crane used to lift the pit coverblocks. The building and its internal structures and equipment function as barriers to contain hazardous materials. The primary barrier in the 241-Z Building is a process enclosure or a process vessel (e.g., tank TK-D5). The secondary barrier serves to enclose the area containing the primary barrier. For the 241-Z Building, an example is the concrete sump cell (and associated coverblock) which contains tank TK-D5. The building structure also functions as a barrier.

The 241-Z Building structure and the ventilation system work together to provide a confinement system designed to mitigate the release of hazardous material should a barrier fail. The building ventilation system completes the confinement system by providing a controlled, continuous flow of air from the environment into the Building 241-ZA tank sampling glovebox and concrete sump cells, through HEPA filters, and then back to the environment. Supply air is provided to the glovebox and sump cells by in-leakage of outside air. The ventilation system does not have supply fans, therefore the motive power for airflow is provided entirely by the exhaust fans. Exhaust ventilation from each tank headspace, the sampling glovebox, and the TK-D9 caustic supply tank first passes through a demister and then joins the exhaust airflow from the sump cells. The exhaust air is then heated to remove any moisture and is passed through two stages of HEPA filtration before being exhausted to the 296-Z-3 stack.

The 241-Z Building is divided into five below-grade, concrete sump cells with coverblocks, with each cell containing a single stainless steel tank (except for one cell that has a primary tank and an additional smaller tank that receives overflow from all four of the operating primary tanks). The primary tanks are designated as tanks TK-D4 through TK-D8 (tank TK-D6 is a confirmed leaker and is no longer in service), and the smaller tank is designated as the TK-D7 overflow tank. Tank TK-D5 is used to treat the aqueous liquids, while the other tanks are used to collect, measure, and stage the liquids for treatment. The 241-ZA Building contains a glovebox that contains equipment used for sampling and testing the liquid waste. The building also contains an annunciator panel housing alarm indicators associated with tank liquid levels, cell sumps, and the transfer line. The 241-ZB Building is comprised of tank TK-D9 (a caustic storage tank that is inactive and scheduled for removal) and a spill barrier. The caustic stored in tank TK-D9 was used to adjust the pH of liquids in tank TK-D5. The 241-ZG Building is a changeroom for personnel and contains no significant radiological or toxicological hazards. The 241-Z-RB Retention Basin and 241-Z-361 Settling Tank are inactive and scheduled for stabilization.

Normal electrical power is provided by the 291-Z Building. Backup power is provided by the 2721-Z Building via the 234-5Z Building. However, no backup power is provided for the building exhaust fans.

Each of the cells has a leak detection system and has the capability to pump out any liquids that may leak from the tank.

The following Hazard Evaluation table identifies stack CAMs as a preventive/mitigative feature for several postulated failure events. The CAMs perform a passive function, which is to detect airborne radioactive material and to activate alarms should the alarm set-point on the CAM be exceeded. They do not provide an active function which would actuate equipment or systems to prevent or mitigate an accident. In most cases the CAMs do not serve to reduce the consequences associated with a release of airborne radioactive material because most accidents involve a sudden release of material over a short period of time. Therefore, by the time the stack CAM detects the release there would be insufficient time to mitigate the event. In addition, the CAM's location in the ventilation discharge stack precludes any preventive/mitigative action since the release would have already occurred. Potentially chronic releases from process operations, or due to equipment failures (e.g., failed HEPA filters), tend to be small in nature. If these releases are sufficient to actuate the CAM alarm, operator action is generally adequate to limit the release so there is no significant consequence. It should be noted that accidents evaluated in the Chapter 9.0 analyses did not rely on the CAMs to serve a preventive/mitigative function.

[d]Gives the section number in the chapter where additional accident analysis is performed.

Appendix 9A.5

The 232-Z Building.

The only operations being conducted in the 232-Z Building are those involved in preparing it for D&D. The equipment in the building is not used and has undergone bulk plutonium removal. In addition, sections of the ventilation exhaust system have been isolated to allow ducting contaminated with plutonium residues to be removed. The building is separated into six major rooms as follows: (1) process room, (2) electrical room, (3) chemical mix room, (4) airlock, (5) changeroom,
(6) storage room.

The 232-Z Building and its internal walls and equipment function as barriers to contain hazardous materials. The primary barrier in the 232-Z Building is a process enclosure such as the incinerator glovebox. The secondary barrier serves to enclose the area containing the primary barrier. An example is the internal walls that form the process room containing the incinerator glovebox. The 232-Z Building also functions as a barrier.

The 232-Z Building structure operates with the ventilation system to form a confinement system designed to mitigate the release of hazardous material should a barrier failure occur. The building ventilation system completes the confinement system by providing a controlled, continuous flow of air from the environment into the various building areas and process enclosures, through HEPA filters, and then back to the environment. A temporary, independent ventilation system for the building has been installed and is operating (the motive power for airflow through the building is provided by the two exhaust fans). Ventilation supply air is provided to the rooms (zone 3) via infiltration throughout the deactivated supply system, while air is supplied to the glovebox and incinerator (zone 4) via leakage from the rooms through inlet HEPA filters. Therefore, the flow of supply air within the building is from potentially contaminated areas (zone 3) to normally contaminated areas (zone 4). The air pressure in both zone 3 and zone 4 is normally negative relative to the atmosphere to prevent the movement of airborne material out of the building. Exhaust ventilation air from zone 3 passes through in-floor HEPA filters before being discharged to two exhaust ducts below the building floor. Zone 4 exhaust air is exhausted through an installed HEPA filter, routed to a filter box containing HEPA filters, and then discharged to the exhaust ducts. Exhaust air is discharged from the exhaust ducts through two-stage testable HEPA filtration and then to the environment via the 291-Z-14 stack.

The only room in the building that is a radiation area containing sources of radiation is the process room that contains the gloveboxes, hoods, and incinerator previously used for the process of combustible waste incineration. Since there are no significant radiological or toxicological hazards in the other rooms, only the process room will be analyzed further for hazards.

Normal electrical power for the ventilation system (e.g., exhaust fans, monitoring equipment) is provided to the building from the 2736-ZB Building, while power for lighting is provided from the 291-Z Building. Backup electrical power is provided by the 2721-Z Building via the 291-Z Building.

The following Hazard Evaluation table identifies stack CAMs as a preventive/mitigative feature for several postulated failure events. The CAMs perform a passive function, which is to detect airborne radioactive material and to activate alarms should the alarm set-point on the CAM be exceeded. They do not provide an active function which would actuate equipment or systems to prevent or mitigate an accident. In most cases the CAMs do not serve to reduce the consequences associated with a release of airborne radioactive material because most accidents involve a sudden release of material over a short period of time. Therefore, by the time the stack CAM detects the release there would be insufficient time to mitigate the event. In addition, the CAM's location in the ventilation discharge stack precludes any preventive/mitigative action since the release would have already occurred. Potentially chronic releases from process operations, or due to equipment failures (e.g., failed HEPA filters), tend to be small in nature. If these releases are sufficient to actuate the CAM alarm, operator action is generally adequate to limit the release so there is no significant consequence. It should be noted that accidents evaluated in the Chapter 9.0 analyses did not rely on the CAMs to serve a preventive/mitigative function.

Appendix 9A.6

243-Z Low-Level Waste Treatment Facility: 243-Z and 243-ZA Buildings.

The function of the 243-Z LLWTF is to collect and treat potentially radioactive or chemically contaminated water from the process facilities of the PFP. The treated water is routed to the sewer system for disposal at the Treated Effluent Disposal Facility (TEDF).

The facility is comprised of the 243-ZA and 243-Z Buildings. The buildings and their internal walls and equipment function as barriers to contain hazardous materials. The primary barrier is a process enclosure or a container (e.g., a 55-gal drum) designed to hold hazardous material. The secondary barrier encloses an area containing a primary barrier. An example is the internal building walls that define room 405, which contains 55-gal drums holding hazardous material. The building structures also function as barrier.

The 243-Z Building structure combined with the building ventilation system forms a confinement system designed to mitigate the release of hazardous material should a barrier fail. The ventilation system completes the confinement system by providing a controlled, continuous flow of air from the environment into the building, through HEPA filters, and then back to the environment. Supply air to the 243-Z Building is provided by a single manual on/off supply fan. Exhaust ventilation air is provided by a single exhaust fan that maintains the building at a negative pressure relative to the atmosphere to prevent the movement of airborne material out of the building. Ventilation exhaust air is transferred through an open-faced hood, passed through a prefilter and a single-stage HEPA filter bank, and then is discharged to the atmosphere via the 296-Z-15 stack.

The 243-ZA Building contains a sump tank, a surge tank, and associated pumps. The 243-Z Building is separated into five rooms designated as rooms 401 through 405. Room 401 is an airlock providing access to room 402, which is a changeroom for personnel. Neither of these rooms contains significant radiological or toxicological hazards and therefore will not be analyzed further. Room 405 is the process room, and it contains the particulate prefilters, adsorption media treatment trains (each consisting of fifteen 55-gal drum process canisters with adsorption media), samplers, and the associated valving, piping, and instrumentation necessary to treat the potentially contaminated water. Room 403 is used for washing new 55-gal filter media canisters (activated carbon and bone char media) before placement in a media train. Since there are no significant radiological or toxicological hazards in this room, it will not be analyzed further. Room 404 contains the open-faced drum turning hood used for draining liquids from saturated 55-gal process canisters before disposal.

Normal electrical power to the 243-Z Building is provided by the 291-Z Building. Backup power is provided for the 243-ZA Building sump pumps by the 2721-Z Building via the 291-Z Building.

Appendix 9A.7

291-Z Building and 291-Z Stack.

The 291-Z Building and 219-Z stack are primarily used to provide ventilation exhaust for the 234-5Z, 242-Z, 236-Z, and 291-Z Buildings. The building, which is normally unoccupied, is divided into 11 rooms having assigned designations of rooms 500 through 510. Room 500 houses two 1,000 kVa transformers and the electrical switchgear used to provide normal electrical power to the 232-Z, 236-Z, 241-Z (-ZA, -ZB), 243-Z, and 291-Z Buildings. Room 501 contains the ASV system equipment for the 234-5Z, 291-Z, 2736-Z, 2736-ZA, and 232-Z Buildings and the 296-Z-5 and 296-Z-6 stacks. Rooms 502 and 509 house the exhaust fans, including the steam-turbine driven backup exhausters. Rooms 503 and 510 house the exhaust plenums which are combined in a common plenum (room 508) that discharges to the 291-Z stack. The two rooms housing the exhaust fans are connected by two cross passageways (rooms 504 and 506). Room 505 contains the inlet plenum, and room 507 contains air supply units that provide conditioned air for the 291-Z Building.

The 291-Z Building and 291-Z stack contain no significant radiological or toxicological hazards. Operations conducted within the building expose workers to the common industrial hazards of electrical shock and mechanical pinchpoints. If the equipment in the building fails to provide exhaust ventilation for other buildings within the PFP, there is a potential for significant hazards to result within those buildings. The same is true if the equipment in room 500 fails to provide electrical power, instrument/process air, or vacuum (air sample vacuum) to the buildings it serves.

Table 9A.7
291-Z Building.

SYSTEM IDENTIFICATION				FAILURE CHARACTERIZATION		PREVENTIVE/MITIGATIVE FEATURES		QUALITATIVE HAZARD SCREENING		REMARKS
Item[a]	System/ equipment	Subsystem/ activity	Function	Failure mode	Failure consequence[b]	Engineered	Administrative	Relative probability/consequence discussion[c]	Representative analysis location[d]	
1	**Rooms 502 and 509, ventilation exhaust system.**	E-3 and E-4 exhaust system fans for the 234-5Z, 236-Z, and 242-Z Buildings.	To provide exhaust air flow for the 234-5Z, 236-Z, and 242-Z Buildings to maintain correct negative pressure control.	Loss of exhaust air flow.	Potential loss of relative negative DPs between zones 1, 3, and 4 and relative to the atmosphere. Potential pressurization of buildings relative to atmosphere. Potential release of SNM to the environment.	Redundant supply fans. Backup electrical power provided by the 2721-Z Building via the 234-5Z Building. Two exhaust fans are provided with backup power (1 of 2 operates on loss of normal power). Computer controlled ventilation system designed to disable supply fans upon sensing exhaust plenum pressure increase.	Procedure governing operator response to ventilation system upsets.	This event is anticipated. The consequence is judged to be low.	Refer to section 9.1.8, "Loss of Ventilation."	Loss of exhaust ventilation may result in significant hazards in the buildings served by 291-Z. See Appendices A.1, A.3, and A.8 for the hazard analysis of a loss of exhaust ventilation as it pertains to these buildings. WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
2	**Room 500, normal electrical power supply system.**	--	To provide electrical power to the 232-Z, 236-Z, 241-Z (-ZA, -ZB), 243-Z, and 291-Z Buildings.	Failure to provide power.	Potential inoperability of systems and equipment that are electrically powered (e.g., ventilation system, CAMs).	Backup electrical power is provided by the 2721-Z Building.	Procedure governing operator response to loss of power.	This event is anticipated. The consequences are judged to be low.	Not specifically analyzed.	Loss of electrical power would have minimal impact on the 291-Z Building, but may result in significant hazards in buildings served by 291-Z. See Appendices A.3, A.4, A.5, and A.6 for the hazard analysis of a loss of normal power for these buildings. WHC-SD-CP-SDD-005 WHC-SD-CP-SDD-006 WHC-SD-CP-SDD-011
3	**Room 501, process/ instrument air supply system.**	--	To supply non-oily, clean, dry air for use in instrument controls for the ventilation system and for process systems in the 234-5Z, 291-Z, 242-Z, 2736-ZA, 241-Z, 241-ZA, and 236-Z Buildings.	Failure to provide air.	Potential loss of ventilation control for the facilities served by the 291-Z Building system.	Second compressor starts automatically if pressure drops below 65 lb/in^2 (gauge). Diesel-powered backup compressor located outside of 291-Z.	Procedure governing operator response to loss of process/ instrument air.	This event is unlikely. The consequences are judged to be low.	Not specifically analyzed. Appendix 9A.8

242-Z Building.

There are no current operations conducted in the 242-Z Building. The building houses equipment once used for PRF waste treatment and americium extraction. The building is separated into three sections; a tank room, an operations room, and an annex (provided for outside entry into the building). The building has not been used since an accident that released contaminated material from a glovebox in the operations room. Subsequent to the accident, nonessential services were disconnected and contaminated surfaces were treated with a strippable coating. Entry to the building is nonroutine and strictly controlled.

The building and its internal walls and equipment function as barriers to contain hazardous materials. The primary barrier is a process enclosure such as a glovebox, or a process vessel within an enclosure. The secondary barrier serves to enclose the area containing the primary barrier. An example is the internal building walls defining the process room which houses gloveboxes. The building structure also functions as a barrier.

The 242-Z Building structure in conjunction with the ventilation systems forms a confinement system designed to mitigate the release of hazardous material should a barrier fail. The ventilation systems complete the confinement system by providing a controlled, continuous flow of air from the environment into the various building areas, through HEPA filters, and then back to the environment. Supply air is provided to the building rooms (zone 3) through the 234-5Z Building supply plenum, while air is supplied to the gloveboxes and process cells (zone 4) via leakage from the room through HEPA filters installed near the floor. Zones 3 and 4 are normally maintained at negative pressures relative to the atmosphere to prevent the movement of airborne material out of the building. Exhaust ventilation air from zone 3 passes through single-stage testable HEPA filters before reaching the 234-5Z Building E-3 HEPA filters (also single-stage). Zone 4 exhaust air is filtered by a single-stage testable HEPA filter in room 308 of the 234-5Z Building, and then is filtered through the two-stage, testable E-4 filters in 234-5Z. Both streams then exhaust to the 234-5Z Building plenum and the 291-Z-1 stack.

All electrical power to the building has been disconnected.

The following Hazard Evaluation table identifies stack CAMs as a preventive/mitigative feature for several postulated failure events. The CAMs perform a passive function, which is to detect airborne radioactive material and to activate alarms should the alarm set-point on the CAM be exceeded. They do not provide an active function which would actuate equipment or systems to prevent or mitigate an accident. In most cases the CAMs do not serve to reduce the consequences associated with a release of airborne radioactive material because most accidents involve a sudden release of material over a short period of time. Therefore, by the time the stack CAM detects the release there would be insufficient time to mitigate the event. In addition, the CAM's location in the ventilation discharge stack precludes any preventive/mitigative action since the release would have already occurred. Potentially chronic releases from process operations, or due to equipment failures (e.g., failed HEPA filters), tend to be small in nature.

If these releases are sufficient to actuate the CAM alarm, operator action is generally adequate to limit the release so there is no significant consequence. It should be noted that accidents evaluated in the Chapter 9.0 analyses did not rely on the CAMs to serve a preventive/mitigative function.

Table 9A.8

APPENDIX 9B

RELEASE FRACTIONS FOR PLUTONIUM POWDERS

This page intentionally left blank.

APPENDIX 9B

RELEASE FRACTIONS FOR PLUTONIUM POWDERS

The release fraction for Pu powders dispersed from the seismically unqualified glovebox depends on the forces acting on the powder. The Pu powder is contained in either sealed or open containers that are free to move around the glovebox, or are fixed in place by pedestals. The release fraction is a function of whether the glovebox topples or not, whether the powder leaves the container, and if so, the force on the powder outside of the container. It should be recognized that many gloveboxes are in the category of "unqualified". Most of the containers in these gloveboxes are open.

Gloveboxes are rigid rectangular enclosures of all welded 3/16" in. or thicker stainless steel construction, except for windows and gloveports. Gloveboxes have either small diamond shaped panels with the majority of the face area being steel, as depicted in Figure 9B-1, or large plastic panels as shown in Figure 9B-2. The panels are held in place by numerous bolted studs that are spaced every 2 in. Analysis of seismic loads on glovebox plastic panels in the *Glovebox and Filter Box Plastic Panel Seismic Evaluation*, WHC-SD-CP-SA-010 (Ocoma 1990a), determined the panels do not break or come out of the glovebox frames. Tests in which hydrogen explosions were intentionally set off in similar gloveboxes with large panels, as reported in "Fire and Explosion Test of Plutonium Gloveboxes" (Rhude 1962), resulted in gloves that were blown out but showed no damage to the panels. The *PFP Safety Systems and Components Seismic Evaluation*, DAR-RHO-0017, Rev. 1, p. 9A-124, (Ocoma 1990b), analyzed the accelerations of powder pans caused by seismic forces to see if the pans would be propelled out of the glovebox. The powder pans weigh 13 lb when loaded. They were accelerated to 20.6 ft/sec before impact. The plastic glovebox panels withstood impact within margin. Therefore, containers will not be propelled out of the glovebox.

The plutonium powder is contained in a variety of containers. There are poly-jars with screw top lids, slip-lid cans, (a "tin" can with a lid that stays on via friction), sealed food-pack cans, and open plastic "beakers." The strength of some of these containers has been tested. The sealed cans and slip-lid cans are constructed of 0.009 in.-thick steel sheets coated with a thin film of tin. Testing of the sealed cans in *The Effectiveness of Corrective Actions Taken to Prevent Events Involving Tin Cans and Plutonium*, RHO-HS-SA-SAP (Szempruch 1984), showed that they can withstand internal pressures up to 100 lbf/in^2. In another test entitled *One-Pound Slip-Lid Tin Drop Evaluation*, SD-CP-TRP-027 (Reichmuth 1988), slip-lid cans were loaded with between 400 and 600 g of damp sand or basalt cuttings, and were dropped from heights of 2 to 5 m onto a concrete floor. Neither the cans that had lids sealed with tape, nor those that were not taped, had any loss of material. The lids were slightly displaced on the untaped cans. None of the cans lost integrity.

In order for powder to be released to the room, the glovebox and open containers must topple, the closed containers must be opened, the glovebox must loose integrity before, or as it impacts the floor, and there must be a mechanism to push the suspended powder out.

The first accident analysis assumption is that all of the unqualified gloveboxes completely toppled. While this may be true for some, there are many gloveboxes for which the failure mode is much less severe, some lean to one side because of failure of the leveling bolts that are typically 2 or 3 in. long, and some "walk" away from their normal position. The failure mode depends on the size of the glovebox, the attachment to other gloveboxes (e.g., MT-4, MT-5 and MT-6 are attached to a conveyor glovebox), and attachment from above (ventilation piping, and electrical conduit).

Seismic analyses of the PFP gloveboxes (Ocoma 1990a, 1990b) determined that glovebox toppling caused by inadequate anchoring was the predominant failure. No cases of glovebox wall collapse or breakage was identified. Toppling of a glovebox can occur if the center of gravity is displaced horizontally beyond the width of its support. The glovebox would topple as a rigid structural unit (i.e., rectangular enclosure). The second assumption is that the glovebox looses its confinement function after it topples. This may be envisioned to occur as a result of a disconnection of the glovebox from ventilation ducts or the breakage of glovebox windows. No credit is given to the fact that glovebox exhaust filters, although not testable, are integral to the glovebox construction and disconnection from the ducting would most probably be downstream of these filters. Likewise the glovebox windows are either sheet plastic, laminated safety glass, or wire glass. All these materials are likely to substantially provide their confinement function even after the glovebox topples, however, it is not practical to perform analysis to provide a defensible quantitative fraction.

The third assumption is that all of the powder suspended is forced out of the glovebox. Gloveboxes that do not disconnect from the exhaust duct would remain under negative pressure if the ventilation system continued to function. Very few gloveboxes have energy sources within them that would force suspended powder out of them.

Determining the release fraction for a variety of closed-versus-open containers requires an understanding of the time and type of impact that can exist during a seismic event. The powder in open containers will initially be acted on by both horizontal and vertical seismic forces. If the container topples before significant glovebox movement, the release fraction is extremely small because the distance the powder travels is about the height of the can. After toppling, the powder remains on the working surface to the leading corner as the glovebox topples. The force on the particles is much less than that experienced during a free-fall because the powder is not free. The release fraction is much less that of a 1-m spill.

If the powder remains in the open container and the open container remains on the glovebox floor, without significant sliding as a result of an engineered restraint, the container's position, with regards to other surfaces and equipment, or combination of forces and friction, will either spill out on the way down or the container will fall to the leading face of the glovebox. If the powder spills out on the way down, the release fraction is again less than a 1 m spill because the working surface starts at 1 m above the floor. It is also realized that the powder may fall from a height of a little more than 1 m, depending on how the glovebox fails. It is assumed here that failure resulting in a topple starts with the buckling of the legs. For this analysis a 1-m spill value will be used. If the container falls to the floor

of the glovebox, the powder is forced out because of impact forces on the container and the resulting forces on the powder. A similar situation was studied in the experiments and reported in the *Simulated Seismic Event Release Fraction Data - Progress Report April 1986-1987*, RFP-4101, (Langer 1987). The powder in two of Langer's experiments was constrained in a similar fashion. The experimental setup is similar to the accident assumption of a container falling to the floor. The mass of the container is about the same as (or at most double) that used in Langer and the height is approximately 1/4 of Langer's study. It is assumed that the release fraction is a function of potential energy or a function of mass times height. Therefore, the release fraction is 1/2 that found by Langer, or 10^{-5} based on Test No. 2.

Another case for open containers occurs when the container slides to the back of the glovebox as it topples, and remains there until impact. The height is again 1/4 of that used by Langer and the mass is at most doubled. The factor of 1/4 will be ignored to account for any energy impacted to the container by the glovebox. The release fraction is therefore 4×10^{-5}.

The last case occurs where the powder free-falls to the leading face. It is assumed that on impact the equipment mounting bolts fail, a glovebox window breaks, or loose equipment (such as wrenches) become airborne and impact the powder on the floor. Again, the height is 1/4 of that used in Langer and the weights range from equal to that of Langer, to around 10 times more than his calculation. For this case, Langer's data for powder on the floor will be tripled (taken from the product of 10 times 1/4) to find the release fraction for the large equipment pieces. The result is a respirable release fraction that ranges from 10^{-2}% (1/4 of 3.3×10^{-2}% of Case 5) to 10^{-1}% (three times the 3.3×10^{-2}% of Case 5), or 10^{-4} to 10^{-3}.

It is important to note that in the last three cases Langer's data was used, as it appears in his report, because the conditions postulated are almost identical to those of the test. Closed containers falling with the glovebox will not open per the experiments by Reichmuth. There is no release in these cases.

If equipment falls onto a sealed can, a slip-lid can or a poly-jar with a screw on lid, it may be possible that they would break open. It is assumed that if a large piece of equipment falls on any of the sealed containers they will fail. Slip-lid cans holding 1 to 1.5 lb of sand did not fail after a drop from 14 ft; therefore, equipment falling from 6 ft, the approximate top of the average glovebox, would have to weigh more than 2 to 3 lb to cause damage to the slip-lid cans. This assumes that failure is directly related to potential energy and that the materials of construction are the same.

Studies discussed in Szempruch (1984) show sealed cans deformed significantly at pressures less than 50 lbf/in^2 and lose integrity at internal pressures slightly below 100 lbf/in^2. Cans deformed by impact from external forces would be expected to loose integrity at lower internal pressures. Data for pressurized releases from *Aerosols Generated by Releases of Pressurized Powders and Solutions in Static Air*, NUREG/CR-3093 (Sutter 1983), pg. B.1, for 350 g sources (the source load is at least that and larger; up to 2,500 g), and the Ballinger (1987) version of the document could be used to determine the maximum release fraction if the rupture pressure is known. Typical bulk PuO_2 or PuF_4 powder density is approximately 2 g/cm^2. The theoretical density

is approximately 11.5 g/cm^2. As a result, there is much air entrapped in the powder. Assuming a 0.625-L can containing 1,250 g of plutonium oxide, the actual volume of the Pu oxide is 108 cm^3, leaving 517 cm^3 of air. Comparisons to fuel-fabrication pellet-manufacturing practices makes it obvious that compression of the powder in a full can takes tons of force. Such forces will not occur if the glovebox topples. If the cans are partially full, the pressure to compress a can is much less, because there is air available to compress. For conservatism the release fraction from pressurized release based on 25 lbf/in^2 (gauge) will be used. The value for the release is 0.076% for 350 g sources and 0.127% for 100 g sources at 25 lbf/in^2 (gauge) as determined by *New Data for Aerosols Generated by Releases of Pressurized Powders and Solutions in Static Air*, NUREG/CR-4779 (Ballinger et al. 1987), Table 9A-6 . A value of 0.1% or 1 x 10^{-3} will be used in the analysis to account for uncertainties. Because the actual quantities are typically greater than 350 g, a realistic value could be 0.05% or less.

The following must be noted when considering use of this release fraction. First, the container will likely split open because of the impact. Depending on the pressure at the time of the split, the release could be much less. Second, a significant force must be applied to pressurize the can to 25 lbf/in^2. If the surface of the top of the can were 7 in^2 (3-in.-dia can), the force would have to be approximately 175 lb to cause the necessary change in volume, assuming that there is no mechanical strength in the can walls. Most of the seismically unqualified gloveboxes are in laboratories that contain almost no large pieces of equipment capable of generating 175 lb of force caused by a fall from approximately 6 ft (average height). While large pieces of equipment do exist in the other gloveboxes, only a very small fraction of the containers are envisioned to be directly and squarely impacted such that any significant compression is possible. The rest will release no plutonium (See earlier discussion on sealed containers falling with the glovebox). It is therefore believed that use of a release fraction of 0.1% for all sealed containers is overly conservative.

It is assumed that the slip-lid can and poly-jar fail at a pressure much less than 25 lbf/in^2. The plastic poly-jars crack fairly easily upon impact. Dented walls of a slip-lid can near the lid easily vent the can. The release fraction is much less than 0.1%.

The results of the above are summarized in Table 9B-1. It is noted from the summary, that the only case where the release fraction is larger than that used in the safety assessment occurs where large pieces of equipment impact powder on the floor, or impact the closed containers and fail them. There is no mechanism within the glovebox that could completely transport the suspended powder outwards and the small fraction of the total powder contained in gloveboxes, in sealed containers, will limit the release fraction of the material into the room to below that used in the safety assessment, except possibly for a few isolated very low probability cases.

The total release is judged to be appropriately calculated if the entire inventory in all of the unqualified gloveboxes is multiplied by 1.5 x 10^{-4}. By comparison to the envisioned range, the release is found to increase by 30% if 95% of the powder is assumed to be released with a release fraction of 1.5 x 10^{-4} and 5% released at the larger value of 10^{-3} based on free powder and sealed containers. The 5% is considered to be a very conservative estimate of

"direct hit" impacts onto free powder and sealed containers. The total release decreases by a factor of approximately 2 over that assumed in the safety assessment (which used a release fraction of 1.5×10^{-4}), if 95% is released using 4×10^{-5} (a more realistic case) and the remaining 5 % is released using 10^{-3}. Thus the range of the "real" release fraction would be considered as 7.5×10^{-5} to 2×10^{-4}. This range is calculated assuming the entire inventory is dispersible powder. Much of the inventory typically in the facility is damp-process residues, sludges, and liquid laboratory samples. Considering these form differences reinforces the appropriateness of the selected release fraction of 1.5×10^{-4}.

Table 9B-1. Summary of release fractions.

Condition	Release fraction
1-Value used in the safety assessment (WHC 1994).	1.5×10^{-4}
2-Powder falls out of container before significant glovebox motion.	Much less than a 1 m spill $<4 \times 10^{-5}$
3-Powder falls out of the open container as the glovebox falls. Open container remains in place.	4×10^{-5}
4-Powder remains in container, container slides off surface and strikes leading face.	10^{-5}
5-Powder remains in container, container slides to back of the glovebox and then strikes surface on impact.	4×10^{-5}
6-Equipment impacts powder on floor.	10^{-4} to 10^{-3}
7-Slip-lid and sealed cans falling with the glovebox.	0.0
8-Equipment impact directly onto closed, sealed containers.	0.0 to 1×10^{-3}
9-Impact directly onto closed poly-jars and slip-lid cans.	0.0 to $<1 \times 10^{-3}$

APPENDIX 9C

MODEL FOR DETERMINING RELEASES FROM FACILITIES

This page intentionally left blank.

APPENDIX 9C

MODEL FOR DETERMINING RELEASES FROM FACILITIES

Section 9.2.4.6.4, "Summary of Release Into Facility," presents the number of grams of respirable plutonium (i.e., with a particle size 10 μm or less) released into facilities as the result of a seismic event. The following sections present a model for estimating the number of grams released from the facilities to the environment.

9C.1 Accident Analysis-Calculations, Release Out of Facility, Particle Characteristics. Discussion in Section 9.2.2A.3.1 shows that only a small fraction of plutonium powders is considered respirable.

Based on the more conservative figure for particle density of 7 g/cm^3, spherical particles greater than 4 μm are not respirable. The dose models require particle size in AED. The AED is defined, in aerosol physics, as the diameter of a hypothetical particle of unit density (water) having the same settling velocity as the given particle.

The AED particle is assumed to be spherical, but the actual particles are not. The AEC (1968), p. 203 states that "the effect of shape upon fall velocities is, on the average, to reduce the velocity by about two-thirds from that of a smooth sphere." It is assumed that this means the velocity for an actual particle equals two-thirds times the velocity of a spherical particle.

Since, per AEC (1968), p 202

$$v_s = \frac{2r^2 g\,\rho}{9\mu}, \text{ for spherical particles}$$

$$v_s = \frac{2\ (2)}{3}\ \frac{r^2 g\,\rho}{9\mu} = \frac{4}{27}\ \frac{r^2 g\,\rho}{\mu}, \text{ for nonspherical particles}$$

$$v_s = \frac{2r^2 g}{9\mu}, \text{ for unit density spherical particles}$$

equating these to find AED

$$\frac{4r^2 g\,\rho}{27\ \mu} = \frac{2r_{AED}^2 g}{9\mu}$$

or,

$$= \frac{2r^2\,\rho}{3} = r_{AED}^2$$

so:

$$r^2 = \frac{r_{AED}^2\ (3/2)}{\rho} \text{ and } = \frac{r_{AED}\ (\sqrt{3/2})}{\sqrt{\rho}}$$

substituting:

$$r = r_{AED} \frac{\sqrt{3/2}}{\sqrt{7}} = r_{AED}\ 0.463$$

A 10-μm AED particle is therefore equivalent to a 4.6-μm particle of density 7 g/cm^3. The value of 5 μm will be used in this analysis so that 4.3% of the $PuFO_2$ powder is respirable.

9C.2 Accident Analysis-Calculations, Release out of Facility, Airflow Patterns. Air can enter the building through open doors or the building joint. There are at least three doors on each of all four sides of 234-5Z. The building joint is a 2-in.-wide gap between the 234-Z and 235-Z Buildings (hence the name 234-5Z). The following calculations assume that the doors opening to the outside at the first level of 234-5Z are left fully open after the seismic event. The ambient wind then blows through the building and transports aerosolized plutonium particles to the environment. The flow in the building is based on flow down corridors 5 and 6 (Figure 9-3) conservatively assuming that the numerous airlock doors remain blocked open after the seismic event. All of the airborne plutonium from the seismic accident analyses in 9.2.4 is available for transport out of the building. This is a significant conservatism since it ignores deposition over the tortuous pathways that the aerosols must travel to reach the corridors. Section 9.2.4.8.1, "Dose Calculations", will use the equations and information presented here in the calculation of dose but will use a more realistic assumption of door open-area.

For the building "breathing" case, it is assumed that a 5-mi/h wind blows on the east or west side, through the first floor, and out of the opposite side. The door dimensions are assumed to be 3 ft by 7 ft. The flow is

$$\frac{5\ \text{mi}}{\text{h}} \left(\frac{5{,}280\ \text{ft}}{\text{mi}}\right) \frac{\text{h}}{60\ \text{min}}\ (3)\ (3\ \text{ft by}\ 7\ \text{ft}) = 27{,}720\ \frac{\text{ft}^3}{\text{min}}$$

The cloud of suspended powders is mainly in the center of the building. The *Safety and Risk Assessment Technical Information to Support PFP Restart*, WHC-SD-SQA-TI-013, Rev. 2 (Marusich 1988, p Add-33) provides an equation for settling rate

$$\lambda = \frac{(\text{vel})\ A}{V}$$

where:

$\lambda = s^{-1}$

vel = Settling velocity, ft/min

A = Surface area along path, ft^2

V = Volume of path, ft^3.

Marusich (1988, p Add-34) shows how this is used

$$\frac{dM_b}{dt} = - M_{out} - M_{dep}$$

where:

M_b = Mass of powder dispersed in the building at any time

M_{out} = Mass flow rate out of the building

= Concentration of powder in the building at any time multiplied by the flow rate out of the building

$$= M_b \frac{q}{V}$$

q = Flow rate out of the building, ft^3/min

V = Volume of building

M_{dep} = Mass rate deposited

$= \lambda M_b$.

$$\frac{dM_b}{dt} = - \left[\frac{q}{V} + \lambda M_b\right]$$

The solution is

$$M_b = M_{bo} \exp\left[\left(- \frac{q}{V} - \lambda\right) t\right]$$

where:

M_{bo} = Quantity present at t = 0

t = Time, min.

To solve the equation:

q = 27,720 ft^3/min

A = [16(22 ft)] x (22+22+26+26+21+21)

where:

The first bracketed term in the equation for A is the length from column 7 to column 23 and the second bracketed term is the width from column A to column G.

$$A = 48{,}576 \text{ ft}^2$$

Since the ceiling is 9 ft high,

$$V = A(9) = 437{,}184 \text{ ft}^3$$

Substituting into the equation:

$$M_b = M_{bo} \exp\left(- \frac{27{,}720}{437{,}148} - \frac{\text{vel } (48{,}576)}{437{,}148} \, t\right)$$

$$= M_{bo} \exp\left[-(0.063 + 0.111 \text{ vel})t\right]$$

The quantity that gets out of the facility is

$$\frac{q}{V} M_b = \frac{q}{V} M_{bo} \exp\left[-(0.063 + 0.111 \text{ vel})t\right]$$

$$= 0.063 M_{bo} \exp\left[-(0.063 + 0.111 \text{ vel})t\right]$$

Now the suspended powders must be put into size bias so that "vel" can be obtained. Brown (1950), p 74 gives the deposition velocity in laminar flow as

$$v = \frac{(\rho_s - \rho_l) \, g \, D^2}{18\mu}$$

where, per Brown (1950), p 68:

$$v = \text{ft/s}$$

$$\rho_s = \text{Particle density} = \frac{4 \text{ g}}{\text{cm}^3} \frac{\text{lb}}{454 \text{ g}} \frac{30.5^3 \text{ cm}^3}{\text{ft}^3} = 25 \frac{\text{lb}}{\text{ft}^3}$$

For conservatism bulk density is being used rather than actual density of 11 g/cm^3.

ρ_l = Density of air = 0.068 lb/ft^3

$g = 32.2 \text{ ft/s}^2$

$$D = \text{Particle diameter} = d \text{ (microns)} \left(10^{-6} \frac{\text{m}}{\mu\text{m}}\right)\left(\frac{3.28 \text{ ft}}{\text{m}}\right)$$

$$\mu = \text{Viscosity} = 0.018 \text{ centipoise} \left(6.7 \times 10^{-4} \frac{\text{lb}}{\text{ft-s-centipoise}}\right)$$

For 1-μm particles

$$v = \frac{250(32.2)\ (d^2)(3.28\text{x}10^{-6})^2}{18(0.018)\ (6.7\text{X}10^{-4})} = 0.0004(d^2)\left(\frac{ft}{s}\right) = 0.024(d^2)\ \frac{ft}{min}$$

The respirable particles will be grouped as follows:

Particle size (μm)	Deposition velocity (ft/min)
1	0.024
2	0.096
3	0.215
5	0.598
10	2.39
20	9.57
50	59.8

Particle size (μm)	Fraction (of total weight)	Deposition velocity (ft/min)
0 - 2	0.005	0.024 (1 μm)
2 - 3	0.009	0.15 (2.5 μm)
3 - 5	0.029	0.38 (4 μm)

Note: The weight fractions are based on the data in Table 9-10.

The total released over time is given by

$$M_{TOT} = 0.063\ M_{bo} \int_o^t \exp\ [-(0.063 + 0.111\ vel)t]$$

This equation is of the form

$$M_{TOT}\ A \int_o^t \exp\ (-bt)\,dt$$

$$= \frac{A}{-b} \exp\ (-bt)\ \Big|_o^t$$

$$= \frac{A}{-b}\ [\exp\ (-b[t]) - 1]$$

Values for b range from 0.039 for 1-μm particles to 0.68 for 20-μm particles. Values of exp [-b(120)] range from 0.009 for 1-μm particles to 0 for 20 μm particles. For long times in the plume (i.e., hours) the value in the brackets is one and therefore:

$$M_{TOT} = \frac{A}{-b} = \frac{0.038\ M_{bo}}{0.038 + 0.111(vel)}$$

where M_{TOT} is the total release out of the facility assuming no evacuation.

To find the fraction of particles in each size group, assume that the respirable particles have sizes as on the previous page.

Particle size (μm)	Percentage	Percentage of total respirable for each size
0 - 2	0.5	12
2 - 3	0.9	21
3 - 5	2.9	67
	4.3 percent of total weight is respirable	

To solve for M_{TOT}, using the equation above and the fact from Section 9.2.4.7.2 that there are 1.87 g respirable

Particle size (μm)	Deposition velocity	Percent of respirable or nonrespirable	"M_{bo} Mass in each size "bin"*		M_{TOT}
0 - 2	0.024	12	0.22	0.22	
2 - 3	0.15	21	0.39	0.31	1.28 g
3 - 5	0.38	67	1.25	0.75	respirable

*Mass = "mass of respirable or nonrespirable" times percent.

9C.3 Accident Analysis-Calculations, Release Out of Facility, Sensitivity to Wind Speed. The flow rate through the building is proportional to the wind velocity. If the wind were 15 mi/h and not 5 mi/h, the flow rate through the building would be three times the 5-mi/h value, or 83,160 ft^3/min. If the wind were 2.2 mi/h, the flow rate through the doors would be 12,197 ft^3/min, or approximately 44% of the 5-mi/h value. Changing the flow through the building changes the 0.063 value derived from dividing flow rate by the volume. In the 15-mi/h wind scenario, 0.063 is changed to 0.190 and for the 2.2-mi/h wind 0.063 is 0.028. The fraction of each particle group is now determined using

$$\frac{M_{TOT}}{M_{bo}} = \frac{0.063}{0.063 + 0.111\ (vel)} \text{ or } \frac{0.190}{0.190 + 0.111\ (vel)}$$

$$\text{or } \frac{0.028}{0.028 + 0.111\ (vel)}$$

for 5 mi/h, 15 mi/h, or 2.2 mi/h, respectively.

Particle size (μm)	Deposition velocity	M_{TOT}/M_{bo}		
		2.2 mi/h	15 mi/h	5 mi/h
0 - 2	0.02	0.91	0.99	0.96
2 - 3	0.15	0.63	0.92	0.79
3 - 5	0.38	0.40	0.82	0.60

If the release into the building is 1.87 g and the quantity in each group is as given in the table above, then the release out is

Wind (mi/h)	Respirable mass (g)
5.0	1.28
15.0	1.61
2.2	0.95

PFP Production Vertical Denitration Calciner HAZOP

1.0 PRODUCTION VERTICAL DENITRATION CALCINER HAZOP

This appendix describes the methodology, organization, and results of the Plutonium Finishing Plant (PFP) Vertical Denitration Calciner (VDC) Hazards and Operability analysis (HAZOP).

1.1 METHODOLOGY

This section of the appendix presents the methodology used to identify and characterize hazards of the PFP VDC.

1.1.1 Hazard Identification Methodology

A Hazards and Operability Study (HAZOP) was chosen as the primary method of Hazard Identification/Hazard Evaluation for the PFP VDC. A HAZOP is a systematic approach used to identify and evaluate safety hazards in a process or operation and to identify operability problems which, although not hazardous, could compromise the ability to achieve design productivity. The HAZOP accomplishes this by evaluating the process or operation at specific points called "study nodes." These nodes can be process sections, operating steps, or support systems and are generally chosen in an order that follows the process or operation flow.

At each node potentially hazardous process deviations are identified using guide words. A general set of guide words is shown in Table 9D-1. By combining the guide words with specific process parameters, deviations from the intended process operation can be specified. For example, the guide word "low" combined with the process parameter "level" at the Feed Receipt Tank node results in the deviation "low level" for the Feed Receipt Tank. The use of guide words ensures that all relevant potential causes and consequences of deviations of process parameters are identified.

Although this technique captures a wide variety of conditions, initiators relating to Natural Phenomena and External Events were evaluated specifically and added to the end of the completed HAZOP table as nodes numbered 1000.x.x. Worker safety issues are addressed in this HAZOP as a general part of the information contained under the "Immediate Consequences" column as it relates to the "Possible Causes/Hazardous Event" column entry. However, most industrial safety concerns are not specifically identified in this HAZOP even though it is recognized that hazards such as cuts, abrasions, pinches, slips, trips, falls, and other similar things are associated with the calcining process. An energy source checklist, Table 9D-2, is included to provide a general indication of the presence of industrial hazards. Industrial hazards unique to the calcining process such as high temperatures, exposure to caustics and acids, and bottles of high pressure air are noted explicitly in the HAZOP. The completed HAZOP is contained in Table 9D-4.

1.1.2 HAZOP Data Description

The HAZOP, Table 9D-4, is made up of 13 columns. The following provides a description of each column.

Column 1 - "Bin ID" - An alpha-numeric identifier for designating the event category that the event of that row is assigned. This allows sorting the information into groups of events with similar characteristics.

Column 2 - "ID" - A unique alpha-numeric identifier that permits identification of the node from which the information contained in the HAZOP was derived. It is most useful when data is sorted in non-node order. This designation is comprised of a number in decimal/alphabetic form. The number preceding the decimal indicates the primary node being addressed. The primary nodes are described in Section 1.2 and follow a general "front-to-back" process flow path through the calciner glovebox.

Column 3 - "Node Description" - Specifies the area of the calciner being evaluated.

Column 4 - "Design Function" - Describes the function of the node and was used to assist the HAZOP team in evaluating the system.

Column 5 - "Parameter/Guide Word" - Specifies the HAZOP parameter and guide word being applied to the specific node. The combination of the process parameter and guide word is not normally done in a HAZOP table, but was done to reduce the amount of space taken up by this information.

Column 6 - "Possible Causes/Hazardous Event" - Contains a description of the event and lists the potential cause or causes of the hazardous event or failure.

Column 7 - "Material at Risk" - Describes the type and quantity of hazardous material that may be involved in the Hazardous event.

Column 8 - "Immediate Consequences" - Lists the potential consequences of the Hazardous Event.

Column 9 - "Engineered Safety Features" - Lists the plant's available hardware features that mitigate or prevent the event being evaluated.

Column 10 - "Administrative Safety Features" - Lists the plant's available administrative controls such as procedures, training, practices, etc., that could mitigate or prevent the event.

Column 11 - "Cons Cat" - Contains an estimate of the result of the event, assuming that no controls, engineered or administrative, are present. However, naturally occurring phenomena that limit the consequence of an event are assumed to take place (rules of the universe). The Consequence Ranking column is a "first cut," qualitative, consensus estimate of the safety severity of the consequences. An alphanumeric system is used to designate the severity.

Column 12 - "Freq Cat" - A "first cut," qualitative, consensus estimate of the frequency of the consequences assuming that no engineered or administrative

safety features are present. An alphanumeric system is used to designate the frequency.

Column 13 - "Remarks" - Contains information that the team judges requires documentation. This can include (but is not limited to) assumptions about facility operation or recommendations for changes in the planned design or operation.

1.1.3. HAZOP Scope

This HAZOP evaluates the HC-230C-2 glovebox and associated support systems present in room 230C and the solution transfer line from the Load-in/Load-out (LI/LO) glovebox, HC-227S. The LI/LO operation in glovebox HC-227S is not included since they are the same operations as previously performed and are essentially unchanged by the operations of the VDC except for an additional transfer line to glovebox HC-230C-2. Also not included are the processes that occur after the Pu oxide leaves glovebox HC-230C-2 since these processes are identical to the ones performed for the reactive material (thermal) stabilization operations. These are processes such as sampling, thermogravimetric analysis (loss-on-ignition) testing, packaging, movement between gloveboxes and buildings, and temporary as well as permanent storage.

Although this HAZOP was conducted in a manner that allowed consideration of the widest ranging possible causes of undesirable events that could result from operation of the VDC, two constraints were applied to maintain consistency with the existing PFP FSAR. The first is no consideration of random concurrent failures of E-3 or E-4 ventilation system high-efficiency particulate air (HEPA) filters. The existing FSAR analyses take credit for the presence of filters unless the event under consideration can be shown to adversely affect the filters. It is stated that the HEPA filters are Safety Class except for the seismic case. The second constraint is no consideration of random concurrent failures of the ventilation system fans and ductwork. Again, the existing FSAR analyses take credit for the operation of these fans unless the event being considered can be shown to adversely affect the fans and ductwork.

The HAZOP was performed by the following individuals:

Brett Hall - Fluor Daniel Northwest
Milton V. Shultz - Fluor Daniel Northwest

With assistance from the following personnel from the project and Plutonium Finishing Plant:

Greg Funston
Jerry Durnil

1.2 HAZOP ORGANIZATION

The general flow of the HAZOP is according to glovebox HC-230C-2 process flow of the Pu nitrate being converted into Pu oxide for long term storage.

There were 25 study nodes defined for the HC-230C-2 VDC glovebox. Figure 9D-1 shows the nodes on a schematic of the VDC glovebox. The nodes are:

HAZOP Node 1- VDC Feed Receipt Tank (includes transfer line and encasement from glovebox HC-227S)

HAZOP Node 2- VDC Feed Pump Tank

HAZOP Node 3- VDC Flush Tank

HAZOP Node 4- VDC Feed Pump P-230-A

HAZOP Node 5- VDC Injector Nozzle

HAZOP Node 6- VDC Vessel

HAZOP Node 7- VDC Offgas Line between calciner vessel and scrubber

HAZOP Node 8- VDC Offgas Scrubber

HAZOP Node 9- VDC Scrubber Phase Separator Tank

HAZOP Node 10- Glovebox HC-230C-2 spent scrub solution Receiver Tank

HAZOP Node 11- Glovebox HC-230C-2 spent scrub solution drain line from MOV 230-P to Tank D8

HAZOP Node 12- Glovebox HC-230C-2 Vacuum Trap

HAZOP Node 13- Glovebox HC-230C-2 Vent Catch Tank

HAZOP Node 14- Transfer line between glovebox HC-230C-2 pump P-230-E and HC-227S Receiver Tank

HAZOP Node 15- VDC Filter pulsing supply air piping (downstream of EV solenoid valves)

HAZOP Node 16- VDC Pulse/atomizing air supply upstream of pulse air 3 way valve (EV-230-A)

HAZOP Node 17- Sodium Hydroxide Feed Supply line downstream of pump P-230-B (pump and sodium hydroxide supply drum outside glovebox HC-230C-2)

HAZOP Node 18- VDC Offgas Scrubber Chiller

HAZOP Node 19- Glovebox HC-230C-2 Chemical Addition Tank (external to glovebox - feeds Flush Tank)

HAZOP Node 20- PFP plant compressed process air system

HAZOP Node 21- Calciner bottled compressed air supply (supplies VDC filter pulsing system and injector nozzle atomizing air)

HAZOP Node 22- Glovebox HC-230C-2 physical structure

HAZOP Node 23- E-4 exhaust duct at outlet of glovebox HC-230C-2

HAZOP Node 24- VDC product collection jars and slip lid convenience cans including handling within glovebox and transfer to conveyor system

HAZOP Node 25- VDC vacuum sensing line between calciner and vacuum regulator valve VRV-230-1

1.3 HAZARD EVALUATION METHODOLOGY

The qualitative potential consequence and likelihood estimates for the identified events were generated by the HAZOP team using a modified Delphi approach based on the team members' experience and judgment. The criteria for the consequence and likelihood categories are as follows.

The Consequence Ranking is defined as follows.

S0 No effect outside the facility confinement systems and no safety concerns for the facility worker, the onsite worker, or members of the general public.

S1 Potential industrial injury, radiological dose consequences or chemical exposure to the facility worker; limited environmental discharge of hazardous material outside the facility

S1* Potential serious injury or acute fatality from industrial hazard, or radiological or chemical exposures to the facility worker; limited environmental discharge of hazardous material outside the facility

S2 Potential significant radiological dose consequences or chemical exposure to the maximum onsite worker outside the facility; environmental discharge of hazardous material within the Hanford site boundary

It should be noted that no events with significant offsite consequences were identified and therefore, no S3 rankings were assigned.

Frequency of the consequences, assuming there are no engineered or administrative safety features, are defined as follows.

F0 Events not expected to occur and categorized as beyond extremely unlikely. The frequency range is <1E-06/yr.

F1 Events not expected to occur within the lifetime of a typical facility and categorized as extremely unlikely. The frequency range is $1E\text{-}06/yr \leq f < 1E\text{-}04/yr$.

F2 Events which could occur during the lifetime of the facility and categorized as unlikely. The frequency range is $1E\text{-}04/yr \leq f < 1E\text{-}02/yr$.

F3 Events which are expected to occur one or more times during the lifetime of the facility and categorized as anticipated. The frequency range is $1E\text{-}02yr \leq f < 1/yr$.

All events were classified by Category and Type. The categories are: Internally Initiated accidents (process accidents), accidents initiated by Natural Phenomenon, and accidents initiated by causes external to the facility (External Events).

Each internally initiated event identified in the HAZOP was assigned an accident bin identifier related to the event phenomena such as release from glovebox, fire in glovebox, explosion, toxic chemical release, criticality, etc. Events assigned to a given bin challenge analogous barriers. Analogous barriers reflect the same design philosophy for prevention and mitigation of the same event type. Events resulting from external events and natural phenomena were assigned their own specific bins. This was done because external events and natural phenomena related events result in multiple barriers being challenged in the PFP facility. This grouping was also related to the organization of the existing PFP FSAR Chapter 9 analyses. Event bins were also given an Event Type designation in keeping with the designations used in the PFP FSAR Chapter 9 analysis. The designations are Accident (AC), Abnormal Operation (AB), and Not Applicable (NA). NA is a type of accident that is not currently addressed in the PFP FSAR. The accidents represented by this designation relate to process upsets that can affect mission success, are as low as reasonably achievable (ALARA) concern only, or are related to industrial accidents normally addressed by institutional programs such as industrial health and safety.

The results of the binning process are summarized in Table 9D-3. There are a number of reasons that a summary table is used. The first reason is that the process flow orientation of the evaluation process does not create any kind of grouping of information suitable for the selection of accidents requiring additional analysis. For example, similar releases of radioactive material can occur from different parts of the calciner and its glovebox. This results in a significant number of similar hazards that are widely separated within the HAZOP table. Another reason is that information in HAZOP tables consists of abbreviated notes capturing a dynamic and creative process; they can be somewhat cryptic and often not easily compared and grouped by reviewers who were not part of the process. This condition, present in all qualitative Hazards Evaluation techniques, is referred to as "inscrutability" (Guidelines for Hazard Evaluation Procedures).

1.3.1 Binning Approach

The hazardous events were categorized into 15 Bin IDs. The Bin IDs are:

A1 - Process Upset - no worker impacts
A2 - Process upset - worker ALARA concern
B - Release inside glovebox
C - Release from transfer line
D - Deflagration in glovebox (ignition of flammable gas in calciner)
E - Criticality
F - Fire in glovebox (ignition of combustible materials present in glovebox)
G - Industrial hazards - not resulting in severe worker injury
H - Radiological release from glovebox (due to internal events) excludes categories Ds and Fs
I - Release to vacuum system

J - Toxic chemical release inside facility
K - Severe worker injury - impacts by high velocity objects
L - Storage canister rupture
NPH - Natural Phenomena initiator: Seismic Event, Ash Fall, and High Wind
XTRN - Initiator external to the facility (facility wide loss of power, range fire, and aircraft crash)

Events that resulted in process upsets but posed no significant radiological or toxic chemical threat to the facility worker were assigned the NA Event Type designation. Events representing only industrial hazards were also assigned this designation. Events with the potential for only minor consequence to the facility worker were assigned the AB designation. Events with the potential for onsite consequence or severe worker impact were assigned the AC designation. Event Type NA was assigned to bins A1, A2, and G. Event Type AB was assigned to bins B and I. Event Type AC was assigned to bins C, D, E, F, H, J, K, L, NPH, and XTRN.

1.4 DISCUSSION OF HAZARDOUS EVENT BINNING RESULTS

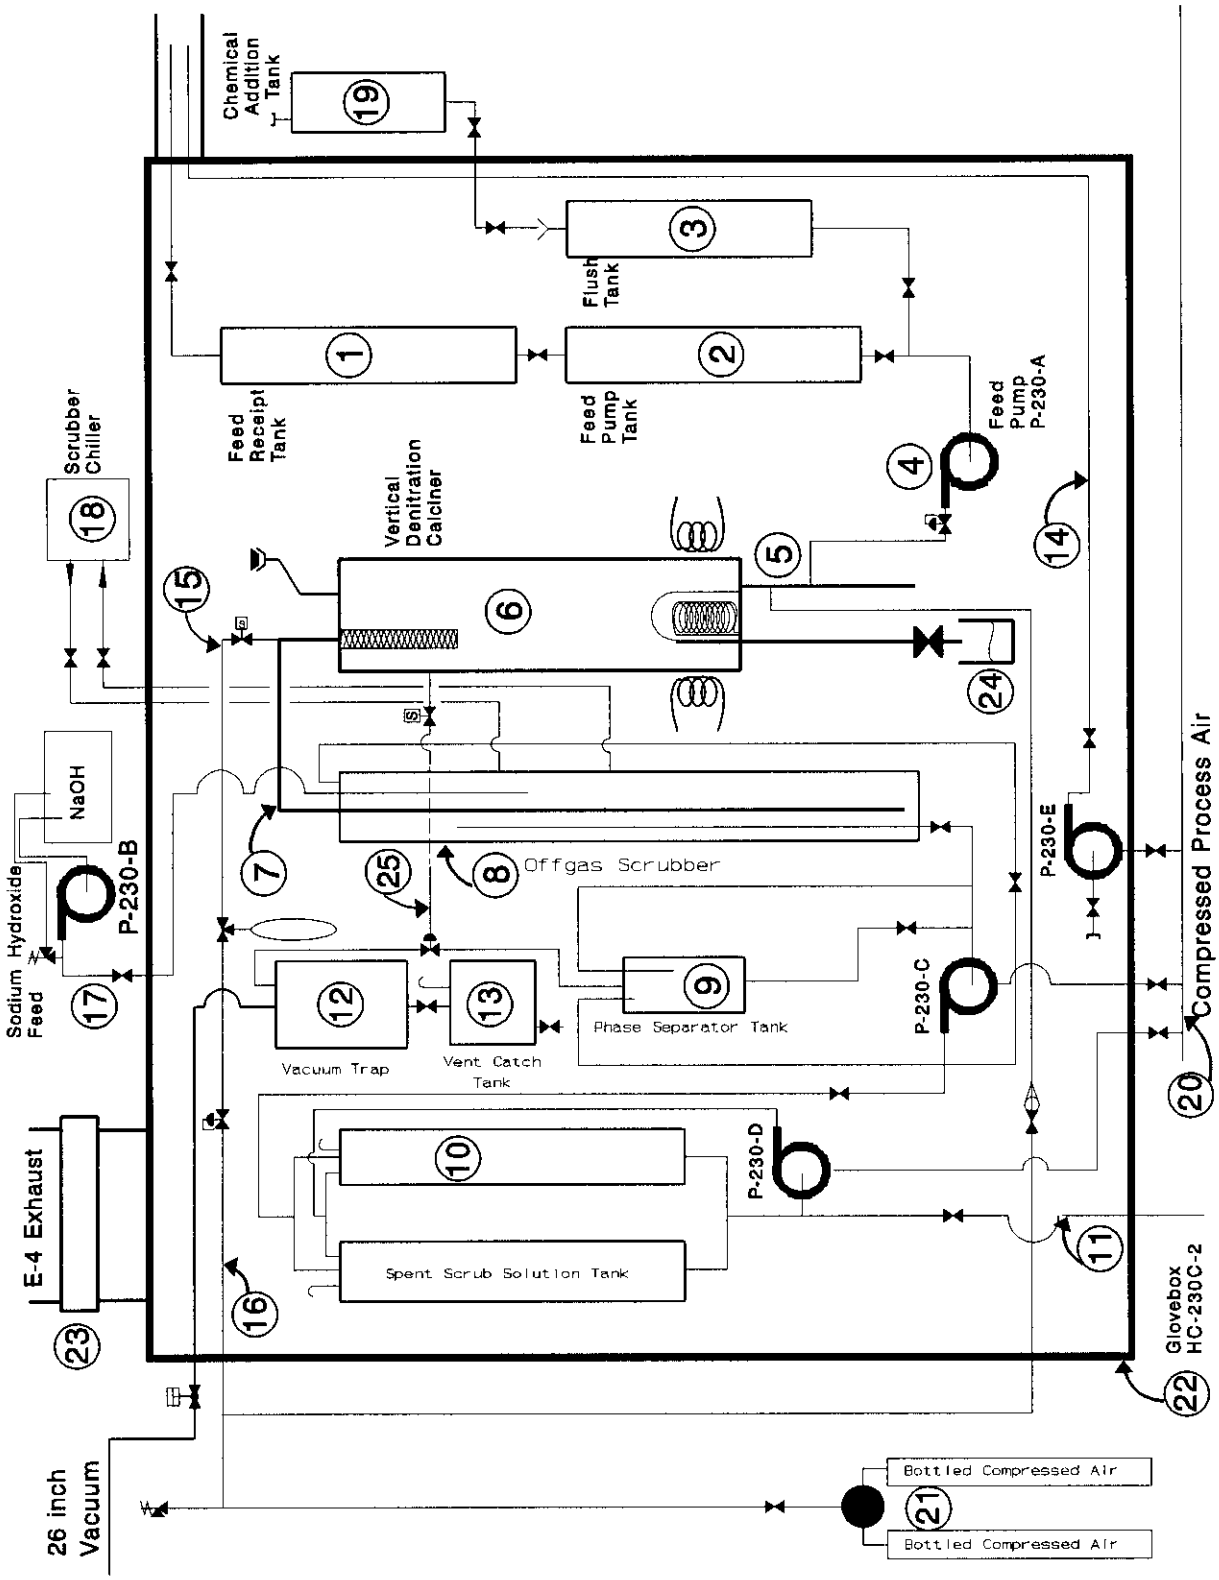
The total number of events in each bin are as follows:

Bin	No. of Events	Bin	No. of Events	Bin	No. of Events
A1	19	E	32	J	9
A2	47	F	5	K	2
B	79	G	2	L	12
C	3	H	18	NPH	3
D	2	I	27	XTRN	3

1.4.1 Special Considerations for NPH and XTRN Events

There are three natural phenomena grouped under the bin NPH. These are Seismic Event, Ash Fall, and High Wind. These events are single entry items in the table. However, each of these phenomena can cause multiple consequences. Using a single entry in the table for each of these events reduces the size of the table but does not cause a loss of information. In the case of the High Wind and Ash Fall events, the PFP FSAR provides sufficient information to show that the effect of adding glovebox HC-230C-2 and the calciner system will not materially affect the consequences from these events. High Wind and Ash Fall effects are described in Chapter 3.0 of the PFP FSAR. Ash Fall represents a roof loading concern, abrasive concern for moving equipment, and an electrical concern because of the conductivity of the ash. High Wind represents a threat to the 234-5Z Building but not to an individual glovebox inside the building. Chapter 9.0 considers the effect of a wind-driven plank striking the 234-5Z Building and concludes that no significant consequences result. The seismic event is considered in detail in Chapter 9.0 of the PFP FSAR. The addition of glovebox HC-230C-2 should be evaluated to determine the effect of continuous dispersion mechanisms inherent in the calcining process as well as the additional radioactive and chemical material inventory present in the process on the overall release from the seismic event.

There are three phenomena grouped under the bin XTRN. These are Facility Wide Loss of Power, Range Fire, and Aircraft Crash. These events are also single entry items in the table and can cause multiple consequences. However, as indicated above, using a single entry in the table for each of these events reduces the size of the table but does not cause a loss of information. Facility wide loss of power, and Range Fire result in essentially the same effect, loss of power to 234-5Z (and, therefor, the VDC). Range fire causing a building fire is not considered because a wide area devoid of vegetation exists and is maintained around the facility (vegetation control specified in Chapter 3.0 of the FSAR). The addition of glovebox HC-230C-2 does not materially alter the consequence of facility loss of power because all aspects of the calcining process ceases on loss of power. The effects of loss of power on the HC-230C-2 glovebox caused by internal initiators is addressed specifically in the HAZOP. Chapter 9.0 of the PFP FSAR currently addresses Aircraft Crash and determined that the frequency of such an accident is less than 1E-6 per year when flight restrictions that prohibit helicopter operation in proximity to PFP are implemented. Therefore, no further consideration of the Aircraft Crash is required.



1.5 ENVIRONMENTAL PROTECTION

The facility features, such as a ventilation system with multiple stages of HEPA filtration that maintains a negative pressure relative to the atmosphere outside of the 234-5Z facility, protects the facility worker as well as serving to prevent and mitigate environmental releases of hazardous material. Under stagnant ventilation conditions the facility structure itself provides confinement of radioactive materials, limiting release to the environment. These features are listed in the HAZOP table (Table 9D-4) in the engineered and administrative safety features columns. These features are valid controls for environmental protection because in protecting the worker or public the environment is also protected. No release scenarios were identified where a release occurred that did not impact the worker but did impact the environment. In addition, there are generic programs of environmental monitoring which help discover unacceptable discharges.

1.6 REFERENCES USED DURING HAZOP

See last page of the HAZOP Table 9D-4.

Table 9D-3. Summary of HAZOP results based on Event Bin Grouping
(5 sheets)

Bin ID[1]	Event Description	Event Type[2]	General Hazardous Event Considered	Cons Cat [3]
A1	Process upset - no worker impacts	NA	Failure to maintain Pu nitrate solution supply to calciner feed pump Misadjustment of calciner feed pump Scrubber chiller recirculation loop leaks Incorrect pressurized gas connected to calciner compressed air system Glovebox ventilation upsets - supply and exhaust Leaks in glovebox gloves or windows Failure of calciner compressed air or plant compressed air	S0
A2	Process upset - worker ALARA concern	NA	Inability to transfer Pu nitrate solution from HC-227S glovebox Failed valves or plugged Pu nitrate supply lines within glovebox HC-230C-2 Off gassing chemical reactions caused by accidental mixing of incompatible materials Use of low concentration nitric acid for calciner feed system flushes Plutonium polymerization/precipitation in glovebox tanks, without criticality Identified presence of separable organic phases in Pu nitrate calciner feed system Pu nitrate supply to calciner failures such as failed feed pump, loss of power, calciner nozzle plugging. Calciner failures such as calciner agitator motor failure, agitator shaft failure, loss of power, bearing failures, filter plugging, calciner powder drain plugging Scrubber failures such as failure to recirculate, solids accumulation, overflow of nitrate from calciner into scrubber, and other failures requiring downtime and operator exposure to correct	S1

Table 9D-3. Summary of HAZOP results based on Event Bin Grouping
(5 sheets)

Bin ID[1]	Event Description	Event Type[2]	General Hazardous Event Considered	Cons Cat [3]
B	Release inside glovebox	AB	Pu nitrate transfer line failures that remain inside encasement and drain to glovebox Mistransfers to gloveboxes other than HC-230C-2 Ruptures of feed receipt tank, feed pump tank Overflows of feed receipt tank, feed pump tank caused by overfill, double batching of flush solution, or backup from overflows into vent system Creation of vapors and aerosols from solution heating from addition of concentrated nitric acid or incompatible chemicals Accidental draining of Pu nitrate solution to glovebox floor Spray leaks of Pu nitrate solution due to piping and connection failures in calciner feed pump system Conditions and events that result in calciner overpressurization and release of nitric acid vapors, water vapor, NOx, and Pu oxide powder from pressure relief device such as excessive injection rate, plugged filters, vacuum failure, excess atomizing air flow or pressure, and similar causes Failure of calciner seals, welds, gaskets, collection bottle which result in release of Pu oxide to glovebox Ruptures of scrubber, phase separator, and spent solution tanks Spills of Pu oxide during removal of collection jar, filling of slip lid cans, or movement of cans on to conveyer	S1
C	Release from transfer line	AC	Failure of supply from HC-227S glovebox due to transfer line and encasement failure	S1*
D	Deflagration in glovebox	AC	Organics present in Pu nitrate injected into 1000C Pu oxide bed Explosion from injection of feed containing organics due to sampling or pretreatment errors Phase separation: presence of separable organics in feed stock due to failure in upstream sampling or pretreatment operations Butane explosion in calciner causes release of hot gases, steam, and very hot PU oxide to glovebox atmosphere	S1*

Table 9D-3. Summary of HAZOP results based on Event Bin Grouping (5 sheets)

Bin ID[1]	Event Description	Event Type[2]	General Hazardous Event Considered	Cons Cat [3]
E	Criticality	AC	Buildup of Pu oxide from spills and operating upsets Spills of Pu nitrate solution Buildup of Pu solids in tanks in glovebox HC-230C-2 due to precipitation reactions Overfilling calciner with Pu oxide or Pu nitrate solution Overflows of process solution into vacuum system Sampling and recirculation failures associated with the scrubber spent solution tanks Precipitation of Pu solids in HC-227S glovebox due to transfer of NaOH into tanks containing Pu nitrate Accumulation of too many containers of Pu oxide in the HC-230C-2 glovebox Floods in room 230 due to fire suppression system actuation	S1*
F	Fire in glovebox	AC	Incipient pump failure (high friction in piston area) Electric motor burnout due to deadhead conditions Electric motor spurious failure from wiring fault Low or no air flow results in hot injector pipe with flammable materials near pipe Control failure of heater power supply (full on) caused by controller failure, thermocouple failure,. software setpoint in error, human error Fire in room 230 due to ignition of combustibles in the room Loss of confinement due to overheating	S1*
G	Industrial hazards	NA	Inadequate time allowed for cooling prior to transferring Pu oxide to convenience can Failure to use high temperature gloves while removing product collection jar from calciner drop pipe	S1

Table 9D-3. Summary of HAZOP results based on Event Bin Grouping
(5 sheets)

Bin ID[1]	Event Description	Event Type[2]	General Hazardous Event Considered	Cons Cat [3]
H	Radiological release from glovebox	AC	Failures of compressed air supply regulators at high pressure air bottles coupled with system relief valve failure - results in possible line, accumulator, and calciner filter failures with resulting pressurized glovebox Releases from chemical supply tank due to open valves with venting from glovebox tank vent system Plant compressed air leaks or calciner compressed air leaks (catastrophic line failures and possibly air regulator failures) resulting in pressurized glovebox Flood in room 230 due to activation of room fire suppression system Glovebox ventilation system imbalances - both supply and exhaust failures causes pressurization of glovebox	S1*
I	Release to vacuum system	AB	Scrubber phase separator level control failures result in scrubber liquid being pulled into vacuum catch tank (scrubber solution may be contaminated with Pu oxide powder or solids) resulting in contamination of vacuum catch tank and vacuum system. Worker ALARA concern. Voiding of scrubber due to chiller failures allows nitric acid vapors and NOx to be drawn into vacuum system pH control failures permits nitric acid vapors and NOx to be released to vacuum system Failure of NaOh feed supply pump to supply NaOH (various mechanical or electrical failures) as continued operation of calciner neutralizes scrubber solution allows release of NOx to vacuum system and possible release out facility stack	S1
J	Toxic chemical release inside facility	AC	Breach of NaOH line outside glovebox results in potential spray leak and spill to room floor Failure of chiller refrigeration system allows release of refrigerant to room 230 atmosphere Chemical addition tank nitric acid leak to floor of room 230 Backflow from chemical flush tank to chemical addition tank permits release of Pu nitrate solution to room 230 (nitric acid and NOx concern for this category). Note: a funnel break has been added to preclude this mechanism.	S1*
K	Severe worker injury - Impacts by high velocity objects	AC	Failure of air bottles or supply valves due to mechanical impact or other manufacturing flaws Possible damage to confinement barriers because of mechanical impact with potential for radioactive material releases	S1*
L	Storage canister rupture	AC	Various process upsets and failures that result in inadequately stabilized Pu oxide result in material being canned and eventually experiencing can rupture in storage due to pressure buildup	S1*

Table 9D-3. Summary of HAZOP results based on Event Bin Grouping (5 sheets)

Bin ID[1]	Event Description	Event Type[2]	General Hazardous Event Considered	Cons Cat [3]
NPH	Natural phenomena	AC	Seismic event	S2
		AC	Ash fall	NA
		AC	High wind	S2
XTRN	External hazard	AC	Facility wide loss of power	S1
		AC	Range fire	S1
		AC	Aircraft crash	NA

1. Hazards binning ID key:

A1 - Process Upset - no worker impacts
A2 - Process upset - worker ALARA concern
B - Release inside glovebox
C - Release from transfer line
D - Deflagration in glovebox (ignition of flammable gas in calciner)
E - Criticality
F - Fire in glovebox (ignition of combustible materials present in glovebox)
G - Industrial hazards - not resulting in severe worker injury
H - Radiological release from glovebox (due to internal events) excludes categories D's and F's
I - Release to vacuum system
J - Toxic chemical release inside facility
K - Severe worker injury - impacts by high velocity objects
L - Storage canister rupture
NPH - Natural Phenomena initiator: Seismic event, Ash Fall, and High Wind
XTRN - Initiator external to the facility (facility wide loss of power, range fire, and aircraft crash)

2. Event Type key:

AC Event is to be treated as an ACCIDENT in the PFP FSAR
AB Event is to be treated as an ABNORMAL EVENT in the PFP FSAR
NA Event is not either an ACCIDENT or ABNORMAL EVENT

3. Consequence category is based on "no controls".
S0 - No significant consequence
S1 - Consequence to worker but does not result in acute fatality or serious injury
S1*- Event results in acute fatality or serious injury
S2 - Event results in onsite worker consequence

HazOp of Vertical Denitration Calciner Process

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
A1	1.00	Feed Receipt Tank	Lag storage to support continuous calciner operation Safely contain Pu nitrate solution	Level/low	Tank drained into feed pump tank without resupply (human error)	NA	Programmatic upset Delay in processing Pu nitrate solutions	None	Operator training and procedures	S0	F3	
B	1.01	Feed Receipt Tank	Lag storage to support continuous calciner operation Safely contain Pu nitrate solution	Level/low	Failure of supply from HC-227S glovebox due to transfer linE	10-40 L Pu nitrate at 450 g/L depending on whether RT or BT transfer is being made	Leak into encasement draining to either glovebox HC-230C-2 or 227-S resulting in : Splatter release to glovebox atmosphere Contamination of glovebox equipment and transfer line encasement	Transfer line encasement prevents release to zone 3 ventilation area Glovebox sump leak detectors and alarms Glovebox HC-230C-2 and HC-227S sump level alarms E-4 ventilation system maintains confinement E-4 ventilation system and HEPA filters mitigates release to atmosphere	Transfer procedures Operator visual surveillance of the feed receipt tank level (tank made out of glass) Operator alarm response procedures	S1	F3	S1/F3 for leak draining into glovebox
C	1.02.a	Feed Receipt Tank	Lag storage to support continuous calciner operation Safely contain Pu nitrate solution	Level/low	Failure of supply from HC-227S glovebox due to transfer line and encasement failure	10-40 L Pu nitrate solution at 450 g/L depending on whether RT or BT being used	Leak from encasement to duct level	E-3 ventilation system and HEPA filters mitigate release to atmosphere	Transfer procedures Operator visual surveillance of the feed receipt tank level (tank made out of glass) Operator alarm response procedures	S1*	F2	S1* /F2 for Pu nitrate release to duct level
E	1.02.b	Feed Receipt Tank	Lag storage to support continuous calciner operation Safely contain Pu nitrate solution	Level/low	Failure of supply from HC-227S glovebox due to transfer line or failure of vessel	NA	Potential criticality - from spill of solution to glovebox floor or by saturating calciner thermal insulation blanket	Glovebox sump leak detectors and alarms Glovebox criticality drains prevent accumulation of critical mass inside glovebox Glovebox HC-230C-2 and HC-227S sump level alarms	Transfer procedures Operator visual surveillance of the feed receipt tank level (tank made out of glass) Operator alarm response procedures	S1*	F1	S1*/F1 based on likelihood of criticality (criticality extremely unlikely given configuration of glovebox criticality drain - see CSER)

Table 9D-4

HazOp of Vertical Denitration Calciner Process

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
A2	1.03.a	Feed Receipt Tank	Lag storage to support continuous calciner operation Safely contain Pu nitrate solution	Level/low	Failure of supply from HC-227S glovebox due to human error (misvalving, etc.)	10 L Pu nitrate at 450 g/L	Programmatic upset - dump to glovebox floor	Sump leak detector and alarm in glovebox HC-7 (for misroutes to HC-7) Glovebox criticality drains (for line leaks inside HC-227S, HC-230C-2, or misroutes into HC-7) Inlet and outlet HEPA filters on gloveboxes E-4 ventilation system and HEPA filters (maintains glovebox confinement and filters releases to the environment) E-3 ventilation and HEPA filters (if leak outside gloveboxes)	Operator surveillance of the feed receipt tank level	S1	F3	S1/F3 ranking assigned for release inside glovebox HC-227S, HC-7, or HC-230C-2
B	1.03.b	Feed Receipt Tank	Lag storage to support continuous calciner operation Safely contain Pu nitrate solution	Level/low	Failure of supply from HC-227S glovebox due to human error (misvalving, etc.)	10-40 L Pu nitrate at 450 g/L depending on whether RT or BT transfer is being made	Release of Pu nitrate from unanticipated location (not in room 227 or room 230), possibly glovebox HC-7 Deadhead transfer pump 227-P-B (in HC-227S) if no outlet valves are open; potential line failure due to overpressure Spray or splatter release inside glovebox	Sump leak detector and alarm in glovebox HC-7 (for misroutes to HC-7) Glovebox criticality drains (for line leaks inside HC-227S, HC-230C-2, or misroutes into HC-7) Inlet and outlet HEPA filters on gloveboxes E-4 ventilation system and HEPA filters (maintains glovebox confinement and filters releases to the environment)	Operator surveillance of the feed receipt tank level	S1	F3	
C	1.03.c	Feed Receipt Tank	Lag storage to support continuous calciner operation Safely contain Pu nitrate solution	Level/low	Failure of supply from HC-227S glovebox due to human error (misvalving, etc.)	10-40 L Pu nitrate solution at 450 g/L depending on whether RT or BT being used	Liquid leak into zone 3 areas if from unencased line or from line with failed encasement	E-3 ventilation and HEPA filters (if leak outside gloveboxes) Potential leak or mistransfer volume limited by batch transfer volume Transfer line encasement mitigates potential spray leak from primary line	Operator surveillance of the feed receipt tank level	S1*	F2	S1*/F2 for potential leak into zone 3
B	1.04	Feed Receipt Tank	Lag storage to support continuous calciner operation Safely contain Pu nitrate solution	Level/low	Feed receipt tank rupture (spurious tank failures, failure at glass weld, seal failures, etc)	10 L Pu nitrate solution at 450 g/L	Splatter release of aerosols to glovebox atmosphere Contamination of glovebox equipment	Tank high level shutoff interlock Glovebox sump level alarm Glovebox criticality drain Glovebox structure, E-4 ventilation system and filters maintain confinement in event of spill	Operator surveillance of level in glass tank	S1	F3	S1 ranking for contamination of glovebox equipment and increased worker exposures criticality requires several tank failures and plugged criticality drain (criticality assumed to be extremely unlikely)

Table 9D-4

HazOp of Vertical Denitration Calciner Process

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
A2	1.05	Feed Receipt Tank	Lag storage to support continuous calciner operation Safely contain Pu nitrate solution	Level/low	Failure of transfer pump 227-P-B in HC-227S (due to loss of power or various equipment failures)	NA	Loss of Pu oxide production Programmatic upset	None	Operator surveillance of feed receipt tank level	S1	F3	S1 for operator exposure replacing pump
B	1.06	Feed Receipt Tank	Lag storage to support continuous calciner operation Safely contain Pu nitrate solution	Level/low	Transfer line plugging with spray leak of liquid in glovebox	10-40 L Pu nitrate at 450 g/L depending on whether RT or BT transfer is being made	Deadhead transfer pump 227-P-B Programmatic upset Potential transfer line failure due to overpressure	Encasement pipe contains leak and directs leak to glovebox HC-230C-2 or HC-227S should primary transfer line leak due to overpressure Glovebox sump alarms (should leak occur) Glovebox inlet and outlet filters B-4 ventilation system and filters	Operator surveillance of feed receipt tank level	S1	F3	The potential for overpressurizing transfer line should be further assessed. failure of line conservatively assumed here.
B	1.07	Feed Receipt Tank	Lag storage to support continuous calciner operation Safely contain Pu nitrate solution	Level/low	Drain to Feed Pump Tank left open while filling the Feed Receipt Tank	10-40 L Pu nitrate at 450 g/L depending on whether RT or BT transfer is being made	Overflow of solution from Feed Pump Tank into Flush Tank via vent line Potential overflow into Vent Catch Tank and spill of solution to glovebox floor if multiple transfers from HC-227S are made or if transfer from HC-227S originates from batch tank instead of receipt tank Splatter aerosol release to glovebox atmosphere (if VCT overflows) and contamination of glovebox equipment	High level interlock in feed pump tank shuts DOV in supply line between feed receipt tank and the feed receipt tank Indicating light for high level in tank Inlet and outlet HEPA filters on glovebox B-4 ventilation system and HEPA filters Glovebox criticality drains Glovebox sump level alarm	Operator surveillance of feed pump tank (and other tanks that are glass)	S1	F2	
A2	1.08.a	Feed Receipt Tank	Lag storage to support continuous calciner operation Safely contain Pu nitrate solution	Level/ high	Operator fails to shut down transfer before tank reaches high level	10-40 L Pu nitrate at 450 g/L depending on whether RT or BT transfer is being made	Overflow into flush tank via vent Overflow to glovebox floor if transfer volume greater than capacity of flush tank, feed pump tank, and vent catch tank Transfer volume limited normally to RT volume (approx 12L)	Capacity of flush tank, feed pump tank and vent catch tank minimize potential for spill High level interlock in Feed Receipt Tank shuts diaphragm operated valve (DOV) on supply line on high level Indicating light for high level	Operator surveillance of feed receipt tank level	S1	F3	S1/F3 for operator exposure during glovebox cleanup
B	1.08.b	Feed Receipt Tank	Lag storage to support continuous calciner operation Safely contain Pu nitrate solution	Level/high	Feed receipt tank not emptied prior to transfer from HC-227S	10-40 L Pu nitrate at 450 g/L depending on whether RT or BT transfer is being made	Overflow into flush tank via vent Overflow to glovebox floor if transfer volume greater than capacity of flush tank, feed pump tank, and vent catch tank Transfer volume limited normally to RT volume (approx 12L)	Capacity of flush tank, feed pump tank and vent catch tank minimize potential for spill High level interlock in Feed Receipt Tank shuts diaphragm operated valve (DOV) on supply line on high level Indicating light for high level	Operator surveillance of feed receipt tank level	S1	F2	S1/F2 for overflow of vent catch tank to glovebox floor

Table 9D-4

HazOp of Vertical Denitration Calciner Process

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
A2	1.09	Feed Receipt Tank	Lag storage to support continuous calciner operation Safely contain Pu nitrate solution	Level/other than	Phase separation: presence of separable organics in feed stock due to failure in upstream sampling or pretreatment operations	NA	Operations shut down, if organic noticed Programmatic upset	None	Operator surveillance of feed receipt tank level	S1	F2	S1 for increased operator exposures to take care of solids layer
D-XREF	1.10	Feed Receipt Tank	Lag storage to support continuous calciner operation Safely contain Pu nitrate solution	Level/other than	Phase separation: presence of separable organics in feed stock due to failure in upstream sampling or pretreatment operations	———	Possible deflagration/explosion due to injection of organics into calciner - see injector nozzle feed composition/other than (Node 5.34)					
A2	1.11.a	Feed Receipt Tank	Lag storage to support continuous calciner operation Safely contain Pu nitrate solution	Level/other than	Phase separation: plutonium polymerization/precipitation due to tank pH greater than 2 (nitric acid solution too dilute)	NA	Programmatic upset		Procedures governing mixing of materials in HC-227S Operator surveillance of feed receipt tank solids level Blending and sampling in the HC-227S glovebox	S1	F3	S1/F3 for programmatic upset requiring operator exposure to correct Incorrect pH could be caused by using nitric acid solution that's too dilute or flushing transfer line or tanks with water
E	1.11.b	Feed Receipt Tank	Lag storage to support continuous calciner operation Safely contain Pu nitrate solution	Level/other than	Phase separation: plutonium polymerization/precipitation due to tank pH greater than 2 (nitric acid solution too dilute)	NA	Potential criticality spec violation due to accumulation of solids in the tank Potential criticality if layer allowed to build up too deep	CAS (criticality alarm system)	Criticality prevention specifications Procedures governing mixing of materials in HC-227S Operator surveillance of feed receipt tank solids level Blending and sampling in the HC-227S glovebox	S1*	F1	S1*/F1 for criticality
A2	1.12	Feed Receipt Tank	Lag storage to support continuous calciner operation Safely contain Pu nitrate solution	Pressure/high	Off gassing chemical reaction that exceeds vent capacity (caused by accidental mixing of incompatible materials)	10 Pu nitrate at 450 g/L	Potential for rupture of tank and spill to glovebox floor NOx release to glovebox atmosphere	Glovebox outlet filters and B-4 ventilation system Glovebox sump level alarm	Solution makeup, sampling, and transfer setup procedures for the HC-227S glovebox Operator surveillance of feed receipt tank	S1	F3	
B	1.13	Feed Receipt Tank	Lag storage to support continuous calciner operation Safely contain Pu nitrate solution	Pressure/high	Feed receipt tank filled with blocked vent line (e.g., V-71 closed during filling)	20 L Pu nitrate solution at 450 g/L	Potential rupture of feed receipt tank, feed pump tank and flush tank Spill of Pu nitrate solution to glovebox floor Release of aerosols to glovebox atmosphere	Glovebox structure B-4 ventilation system and filters confine release to glovebox Glovebox sump level alarm Criticality drain	Operator training and procedures Operator monitoring of tank liquid level (tank is glass)	S1	F1	
NA	1.14	Feed Receipt Tank	Lag storage to support continuous calciner operation Safely contain Pu nitrate solution	Pressure/low	Not applicable	NA						

Table 9D-4

HazOp of Vertical Denitration Calciner Process

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
B	1.15	Feed Receipt Tank	Lag storage to support continuous calciner operation Safely contain Pu nitrate solution	Temperature/high	Heat of reaction due to addition of concentrated nitric acid to water from prior flush or water added to concentrated nitric acid during a flush	10 L Pu nitrate solution at 240 g/L	Potential boiling with steam generation and release of aerosols to vent system and glovebox atmosphere	Tanks made of pyrex glass which is resistant to temperature shock Glovebox and E-4 ventilation system maintain secondary confinement Vent prevents overpressurization	Procedures for the makeup and use of flush solutions Blending and sampling procedures in 227S	S1	F3	
B	1.16	Feed Receipt Tank	Lag storage to support continuous calciner operation Safely contain Pu nitrate solution	Temperature/high	Heat from organic-nitrate reaction (requires organic containing solution to be mixed with highly acidic HNO3 solution to be present with addition of concentrated nitric acid from next evolution)	NOx in 10 L Pu nitrate solution Pu in 10 L Pu nitrate solution	Production of NOx Possible increase in particulate releases from vent system Possible production of small quantities of flammable gasses	None	Operator surveillance of feed receipt tank to identify organic liquids Training and procedures	S1	F3	Not expected to result in large temperature increase or flammable gas concentration in glovebox Temperatures above 135°C are required for autocatalytic reaction
E	1.17	Feed Receipt Tank	Lag storage to support continuous calciner operation Safely contain Pu nitrate solution	Pu concentration/high	Sampling error Makeup error at source of Pu nitrate	NA	Potential criticality specification violation Programmatic upset	Criticality alarm system (CAS) Criticality drains for spills 6 inch tank geometrically unfavorable to criticality	Criticality prevention specifications Blending and sampling procedures in HC-227S	S1*	F1	Criticality highly unlikely given tank geometry
XREF	2.00	Feed Pump Tank	Lag storage for feed to calciner Safely contain solution Provides net positive suction head for feed pump	Level/low	Tank not resupplied from feed receipt tank when required (miscellaneous causes related to feed receipt tank)	———	See nodes for feed receipt tank for Level/low (Nodes 1.03-1.06)					
B-XREF	2.01	Feed Pump Tank	Lag storage for feed to calciner Safely contain solution Provides net positive suction head for feed pump	Level/low	Tank leak or rupture	———	See node for feed receipt tank for Level/low (Node 1.04)					
A2	2.02	Feed Pump Tank	Lag storage for feed to calciner Safely contain solution Provides net positive suction head for feed pump	Level/low	Blocked line or inability to open valve between feed receipt tank and feed pump tank	NA	Potential pump damage Programmatic upset ALARA concern	None	None	S1	F3	Do positive displacement pumps cavitate on loss of supply
A2	2.03	Feed Pump Tank	Lag storage for feed to calciner Safely contain solution Provides net positive suction head for feed pump	Level/low	Human error by not refilling tank when required	NA	Programmatic upset	None	None	S1	F3

HazOp of Vertical Denitration Calciner Process

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
E	6.02	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Powder bed Level/low	High air flow with failed ceramic filter	NA	Deposition of Pu oxide in scrubber (and possibly the phase separator) precipitation of Pu hydroxides have potential for criticality if solids build up too deep	Clear glass tank allows visual detection of contamination Scrubber geometry favorable for preventing criticality	Visual observation of scrubber solution color by operator	S1*	F1	S1* for potential criticality (criticality extremely unlikely given configuration of calciner - see CSER)
B	6.03.b	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Powder bed Level/low	Pressurization event causing release through relief cap	Pu oxide contained in calciner and nitric acid vapor from 4 L/hr injection rate	Release of Pu oxide in glovebox	Calciner vacuum pressure monitor E-4 ventilation systems and filters The glovebox (provides confinement)	Operator surveillance of feed receipt tank to identify organic material	S1	F3	S1 based on operator exposure potential
B	6.03.a	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Powder bed Level/low	Pressurization event causing release through relief cap (excessive Pu nitrate injection, loss of vacuum, etc.)	Pu oxide contained in calciner and nitric acid vapor from 4 L/hr injection rate	Release of Pu oxide in glovebox	Calciner vacuum pressure monitor E-4 ventilation systems and filters The glovebox (provides confinement)	Operator surveillance of feed receipt tank to identify organic material	S1*	F3	S1* based on operator exposure potential (assumes glovebox loss of confinement)
B	6.04.b	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Level/high (powder)	Product overflow tube set too high (potential for plugging tube)	Pu oxide contained in calciner and nitric acid vapor from 4 L/hr injection rate	Ceramic filter plugging and potential calciner pressurization	Calciner pressure relief device prevents catastrophic overpressure Filter delta pressure monitoring (DPT 230-2) Calciner delta pressure to atmosphere (DPT 230-1)	Operating procedures Pu mass balances performed during processing Operator training	S1	F3	S1/F3 based on release to glovebox

Table 9D-4

HazOp of Vertical Denitration Calciner Process

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
B	6.04.a	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Level/high (powder)	Product overflow tube set too high (potential for plugging tube)	NA	Potential criticality from packing calciner full	Criticality alarm system Calciner geometry unfavorable to criticality Calciner pressure relief device prevents catastrophic overpressure Filter delta pressure monitoring (DPT 230-2) Calciner delta pressure to atmosphere (DPT 230-1)	Operating procedures Pu mass balances performed during processing Operator training	S1*	F1	Top of notch in dome considered an acceptable level (criticality extremely unlikely given configuration of calciner - see CSER)
B	6.05.b	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Level/high (powder)	Plugging of product overflow tube due to scale, cake formation, etc. (could be caused by high injection rate, lack of sufficient atomizing air)	Pu oxide contained in calciner and nitric acid vapor from 4 L/hr injection rate	Ceramic filter plugging and potential calciner pressurization with release of Pu oxides to glovebox	Filter delta pressure monitoring (DPT 230-2) Calciner delta pressure to atmosphere (DPT 230-1)	Operating procedures Pu mass balances performed during processing Operator training	S1	F3	S1/F3 for release to glovebox
E	6.05.a	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Level/high (powder)	Plugging of product overflow tube due to scale, cake formation, etc. (could be caused by high injection rate, lack of sufficient atomizing air)	NA	Potential criticality from packing calciner full	Criticality alarm system Calciner geometry unfavorable to criticality Filter delta pressure monitoring (DPT 230-2) Calciner delta pressure to atmosphere (DPT 230-1)	Operating procedures Pu mass balances performed during processing Operator training	S1*	F1	S1* for potential criticality (criticality extremely unlikely given configuration of calciner - see CSER)
B	6.06.b	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Level/high (powder)	Loss of agitation allows buildup away from overflow	Pu oxide contained in calciner and nitric acid vapor from 4 L/hr injection rate	Ceramic filter plugging and potential calciner pressurization	Filter delta pressure monitoring (DPT 230-2) Calciner delta pressure to atmosphere (DPT 230-1)	Operating procedures Mass balances Operator training	S1	F3	S1/F3 for pressurized release to glovebox

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
E	6.06.a	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Level/high (powder)	Loss of agitation allows buildup away from overflow	NA	Potential criticality from overloading calciner	Criticality alarm system Calciner geometry unfavorable to criticality Filter delta pressure monitoring (DPT 230-2) Calciner delta pressure to atmosphere (DPT 230-1)	Operating procedures Mass balances Operator training	S1*	F1	S1* for potential criticality (criticality extremely unlikely given configuration of calciner - see CSER)
B	6.07.b	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Level/high (powder)	Initial overcharge of calciner bed (double batching)	Two times Pu oxide contained in calciner and nitric acid vapor from 4 L/hr injection rate	Ceramic filter plugging and potential calciner pressurization	Filter delta pressure monitoring (DPT 230-2) Calciner delta pressure to atmosphere (DPT 230-1)	Operating procedures Mass balances Operator training	S1	F3	S1/F3 for pressurized release into glovebox
E	6.07.a	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Level/high (powder)	Initial overcharge of calciner bed (double batching)	NA	Potential criticality	Criticality alarm system Calciner geometry unfavorable to criticality Filter delta pressure monitoring (DPT 230-2) Calciner delta pressure to atmosphere (DPT 230-1)	Operating procedures Mass balances Operator training	S1*	F1	S1* for criticality (criticality extremely unlikely given configuration of calciner - see CSER)
B	6.08	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Pressure/high (positive or less negative)	Plugged ceramic filters	Pu oxide contained in calciner and nitric acid vapor from 4 L/hr injection rate	Release of Pu oxide into glovebox due to pressure relief cap being displaced	Filter delta pressure monitoring (DPT 230-2) Calciner delta pressure to atmosphere (DPT 230-1) B-4 ventilation system and HEPA filters provide confinement Glove box provides confinement	Operator training and procedures	S1	F3	S1 based on ALARA concerns for cleanup operations

Table 9D-4

HazOp of Vertical Denitration Calciner Process

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
B	6.09	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Pressure/high (positive or less negative)	Pump stoke too large (large quantity of vapor generated)	Pu oxide contained in calciner and nitric acid vapor from 4 L/hr injection rate	Release of Pu oxide into glovebox due to pressure relief cap being displaced	Filter delta pressure monitoring (DPT 230-2) Calciner delta pressure to atmosphere (DPT 230-1) E-4 ventilation system and HEPA filters provide confinement Glove box provides confinement	Operator training and procedures	S1	F3	S1 based on ALARA concerns for cleanup operations
D	6.10	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Pressure/high (positive or less negative)	Explosion from injection of feed containing organics due to sampling or pretreatment errors	Pu oxide powder in calciner	Release of Pu oxide into glovebox due to pressure relief cap being displaced	E-4 ventilation system and HEPA filters Glove box provides confinement	Operator training and procedures Operator monitoring for separable layers in feed pump tank and feed receipt tank Sampling and pretreatment to remove organics in HC-227S and HC-7 respectively	S1*	F3	S1* based on potential to degrade glovebox confinement
B	6.11	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Pressure/high (positive or less negative)	Filter pulse system failure allowing excess flow to filters	Pu oxide contained in calciner and nitric acid vapor from 4 L/hr injection rate	Release of Pu oxide into glovebox due to pressure relief cap being displaced	Filter delta pressure monitoring (DPT 230-2) Calciner delta pressure to atmosphere (DPT 230-1) E-4 ventilation system and HEPA filters Glove box provides confinement	Operator training and procedures	S1	F3	S1 based on ALARA concerns for cleanup operations
B	6.12	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Pressure/high (positive or less negative)	Loss of or reduced vacuum due to: Loss of vacuum pump Vacuum line valved closed (AOBV-230-L shut) Vacuum regulator valve (VRV-230-1) fails closed or regulates low due to sensing line EV-230-G remaining shut following filter pulse or due to plugged sensing line	Pu oxide contained in calciner and nitric acid vapor from 4 L/hr injection rate	Release of Pu oxide into glovebox due to pressure relief cap being displaced	Filter delta pressure monitoring (DPT 230-2) Calciner delta pressure to atmosphere (DPT 230-1) E-4 ventilation system and HEPA filters Glove box provides confinement	Operator training and procedures	S1	F3	S1 based on ALARA concerns for cleanup operations

Table 9D-4

HazOp of Vertical Denitration Calciner Process

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
B	6.13	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Pressure/high (positive or less negative)	Valve V-32 at scrubber closed prevents flow from calciner	Pu oxide contained in calciner and nitric acid vapor from 4 L/hr injection rate	Release of Pu oxide into glovebox due to pressure relief cap being displaced	Filter delta pressure monitoring (DPT 230-2) Calciner delta pressure to atmosphere (DPT 230-1) E-4 ventilation system and HEPA filters Glove box provides confinement	Operator training and procedures	S1	F3	S1 based on ALARA concerns for cleanup operations
B	6.14	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Pressure/high (positive or less negative)	Vacuum regulator VRV 230-1 fails closed	Pu oxide contained in calciner and nitric acid vapor from 4 L/hr injection rate	Release of Pu oxide into glovebox due to pressure relief cap being displaced	Filter delta pressure monitoring (DPT 230-2) Calciner delta pressure to atmosphere (DPT 230-1) E-4 ventilation system Glove box provides confinement	Operator training and procedures	S1	F3	S1 based on ALARA concerns for cleanup operations
NA	6.15	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Pressure/low (excessive vacuum)	Failure of vacuum regulator VRV 230-1 (fails open)	NA	No significant consequence identified			NA	NA	
B	6.16	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Pressure/low (excessive vacuum)	Pressure relief cap left on during calciner cool down (human error)	Pu oxide contained in calciner and nitric acid vapor from 4 L/hr injection rate	Suck scrubber solution back into calciner vessel Pressurized release through relief cap due to flashing of scrubber solution Plug up the calciner with long term loss of production	E-4 ventilation system and glovebox maintain confinement Vent system filters minimize release through stack Inleakage through DPTs minimizes potential for suckbacks	Operator training and procedures	S1	F2	

Table 9D-4

HazOp of Vertical Denitration Calciner Process

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
F	6.17	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Temperature/high	Control failure of heater power supply (full on) caused by controller failure, thermocouple failure, software setpoint in error, human error	Total inventory of Pu in glovebox	Structural failure of calciner (partially melts) with spill of hot Pu oxide to floor of glovebox Pressurization of glovebox due to heat released and flashed liquid, damage to glovebox and loss of confinement Pu oxide and NOx released to room	Glovebox temperature interlock (TSH 230-A) to heater elements Calciner temperature interlock (TSH 230-B) to heater elements Calciner temperature controller (TSH 230-A) E-3 ventilation system E-4 ventilation system Multiple temperature elements located throughout calciner heater system read out on recorders	Procedures for setting and monitoring calciner temperature	S1*	F2	S1* due to loss of glovebox confinement (burn hole through bottom of glovebox or overpressurize glovebox) Heater elements may short out and fail before melting of calciner occurs
F	6.18	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Temperature/high	Control failure of heater power supply (full on) caused by controller failure, thermocouple failure,. software setpoint in error, human error	Total inventory of Pu in glovebox	Glovebox overheat and fire with potential for release of Pu particulates and aerosols to room 230	Glovebox temperature interlock (TSH 230-A) to heater elements Calciner temperature interlock (TSH 230-B) to heater elements Calciner temperature controller (TSH 230-A) Multiple temperature elements located throughout calciner heater system read out on recorders E-3 ventilation system E-4 ventilation system Glovebox dry fire suppression system	Procedures for setting and monitoring calciner temperature	S1*	F3	
B	6.19	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Temperature/high	Control failure of heater power supply (full on) caused by controller failure, thermocouple failure,. software setpoint in error, human error	Pu oxide contained in calciner and nitric acid vapor from 4 L/hr injection rate	Vaporization (boiling) of scrubber solution due to hotter gases from overheated calciner resulting in NOx, water vapor, and nitric acid vapor to vacuum system Pressurization of calciner vessel (assuming calciner doesn't fail) with release of Pu oxide, NOx, acid vapor to glovebox	Glovebox temperature interlock (TSH 230-A) Calciner temperature interlock (TSH 230-B) Calciner temperature controller (TSH 230-A) Multiple temperature elements located throughout calciner heater system read out on recorders	Procedures for setting and monitoring calciner temperature	S1	F3	Postulated elevated NOX release to stack

Table 9D-4

HazOp of Vertical Denitration Calciner Process

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
B	6.20	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Temperature/high	Control failure of heater power supply (full on) caused by controller failure, thermocouple failure,. software setpoint in error, human error	Less than 5 kg Pu oxide powder	Possibility of failing collection jar with release of Pu oxide to glovebox	Glovebox temperature interlock (TSH 230-A) Calciner temperature interlock (TSH 230-B) Calciner temperature controller (TSH 230-A) Multiple temperature elements located throughout calciner heater system read out on recorders E-3 ventilation system E-4 ventilation system	Procedures for setting and monitoring calciner temperature	S1	F3	S1 based on ALARA concerns for cleanup
L	6.21	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Temperature/low	Incorrect setting of heater controller (human error) Failure of heater controller Failure of heater elements Start processing cycle before calciner up to temperature (human error)	4.5 kg/can Pu oxide powder	Inadequate stabilization of Pu oxide (if temperature above boiling point but not close to 1000°C) Potential canister rupture in storage vault if inadequate stabilization not detected via TGA testing	Interlock between calciner temperature elements and feed pump P-230-A shuts off supply if calciner temperature too low E-3 ventilation system for mitigating releases inside storage vaults or other areas of PFP	TGA testing of Pu oxide powder before canning	S1*	F3	S1* for potential convenience can rupture in storage vault
E	6.22	Vertical Denitrator Calciner (VDC) Vessel	Convert Pu nitrate into dry stable Pu oxide Confine offgasses and particulates generated in the denitrating process Contain Pu oxide powder bed Prevent heat of process from threatening integrity of glovebox, starting a fire, or injuring workers	Temperature/low	Incorrect setting of heater controller (human error) Failure of heater controller Failure of heater elements Start processing cycle before calciner up to temperature (human error)	NA	Bed buildup in calciner vessel	Interlock between calciner temperature elements and feed pump P-230-A shuts off supply if calciner temperature too low Calciner vessel geometry and volume minimize likelihood of criticality	Pu mass balances performed during processing to indicate mass accumulation in calciner vessel	S1*	F1	(criticality extremely unlikely given configuration of calciner - see CSER)
A2	6.23	Vertical Denitrator Calciner (VDC) Vessel		Temperature/low	Incorrect setting of heater controller (human error) Failure of heater controller Failure of heater elements Start processing cycle before calciner up to temperature (human error)	NA	Cake or cement formation in calciner vessel, nozzle plugging, and seizing of calciner agitator Programmatic upset	Interlock between calciner temperature elements and feed pump P-230-A shuts off supply if calciner temperature too low Indicating light on agitator motor	Operator surveillance of feed pump level and product collection jar level	S1	F3	S1 for operator exposure to cleanout calciner or replace equipment

Table 9D-4

HazOp of Vertical Denitration Calciner Process

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[2]	Remarks
A2	10.04	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Level/low	Transfer pipe failure	40 L spent scrub solution	Spill of solution to glovebox floor Programmatic impact Solution has to be pumped back to HC-227S	Glovebox sump level alarm	Operator surveillance of tank level Operator training and procedures	S1	F3	
A2	10.05	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Level/low	Evaporation of solution in tanks leaving solids layer (of $NaNO_3$, NaOH, etc.)	NA	Programmatic impact - necessity of cleaning tanks	None	Operator observation of tanks	S1	F3	S1 based on ALARA concerns for cleanup activities
E	10.06	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Level/low	Tank 1 drain open while filling or recirculating tank 1 (same scenario for tank 2)	NA	Material drained to tank D-8 that has not been sampled for pH or Pu content - potential for buildup of Pu solids with potential for criticality	3 way valve interlocks prevent draining the same tank that is being filled or recirculated Keyswitch in MOV-230-P cannot open without key from supervisor. Prevents transfer to Tank D-8	Operator training and procedures	S1*	F1	S1*/F1 for potential criticality in tank D-8
E	10.07	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Level/solids layer	Filter failure at calciner	NA	Buildup of Pu oxide sludge in tanks with possibility of criticality	DPS-230-A pressure switch and alarm on high pressure DPT-230-1 and DPT-230-2 delta pressure transducers across calciner filters and recorder 230-1 Criticality alarm system	Recirculation and sampling for Pu content Operator observation of solution color Operator observation of tanks (glass for visibility of solids layer) Operator training and procedures for response to process parameter indications	S1*	F1	S1* based on criticality event
E	10.08	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Level/solids layer	Filter failure at calciner	NA	Possible transfer of Pu material to tank D-8 with potential criticality specification violation	DPS-230-A pressure switch and alarm on high pressure DPT-230-1 and DPT-230-2 delta pressure transducers across calciner filters and recorder 230-1 Keyswitch in MOV-230-P cannot open without key from supervisor. Prevents transfer to Tank D-8	Recirculation and sampling for Pu content Operator observation of solution color Operator observation of tanks (glass for visibility of solids layer) Operator training and procedures for response to process parameter indications	S1*	F1	S1* for potential criticality in tank D-8
A2	10.09	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Level/solids layer	Filter failure at calciner	Less than 1.5 kg Pu oxide powder	Programmatic impact in having to remove and reprocess material	DPS-230-A pressure switch and alarm on high pressure DPT-230-1 and DPT-230-2 delta pressure transducers across calciner filters and recorder 230-1 Keyswitch in MOV-230-P cannot open without key from supervisor. Prevents transfer to Tank D-8	Recirculation and sampling for Pu content Operator observation of solution color Operator observation of tanks (glass for visibility of solids layer) Operator training and procedures for response to process parameter indications	S1	F3	S1 for worker exposures during recovery

Table 9D-4

HazOp of Vertical Denitration Calciner Process

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
B	10.10	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Level/solids layer	Nitrate oversupply in calciner resulting in overflow of calciner into scrubber	NA	Buildup of Pu oxide sludge in tanks with possibility of criticality	Criticality alarm system Calciner geometry unfavorable to criticality Filter delta pressure monitoring (DPT 230-2) Calciner delta pressure to atmosphere (DPT 230-1)	Recirculation and sampling for Pu content Operator observation of solution color Operator observation of tanks (glass for visibility of solids layer) Operator training and procedures for response to process parameter indications	S1*	F1	S1* based on criticality event
B	10.11	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Level/solids layer	Nitrate oversupply in calciner resulting in overflow of calciner into scrubber	NA	Possible transfer of Pu material to tank D-8 with potential for criticality specification violation in tank D-8	DPS-230-A pressure switch and alarm on high pressure DPT-230-1 and DPT-230-2 delta pressure transducers across calciner filters and recorder 230-1	Recirculation and sampling for Pu content Operator observation of solution color Operator observation of tanks (glass for visibility of solids layer) Operator training and procedures for response to process parameter indications	S1*	F1	S1*/F1 for potential criticality
A2	10.12	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Level/solids layer	Nitrate oversupply in calciner resulting in overflow of calciner into scrubber	10 L Pu nitrate solution at 450 g/L	Programmatic impact in having to remove and reprocess material	DPS-230-A pressure switch and alarm on high pressure DPT-230-1 and DPT-230-2 delta pressure transducers across calciner filters and recorder 230-1	Recirculation and sampling for Pu content Operator observation of solution color Operator observation of tanks (glass for visibility of solids layer) Operator training and procedures for response to process parameter indications	S1	F3	
B	10.13	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Pressure/high	Both vents on a "tank" blocked (a "tank" is comprised of two tanks connected by a common header on both inlet, drain, and recirculation)	40 L spent scrub solution	Possible failure of "tank" with spill to glovebox floor (assuming deadhead pressure of transfer pump P-230-C sufficient)	None	None	S1	F1	F1 based on two passive vents plugging from unknown processes
NA	10.14	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Pressure/high	Chemical reaction in "tank" from incompatible material mixing (a "tank" is comprised of two tanks connected by a common header on both inlet, drain, and recirculation)	NA	No significant chemical reactions identified			NA	NA	
A1	10.15	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Pressure/low (vacuum in "tank")	Both vents blocked and drain opened	NA	Inability to drain tanks - programmatic impact	Tank vents have no valves	None	S0	F1	

Table 9D-4

HazOp of Vertical Denitration Calciner Process

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
NA	10.16	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Pressure/low (vacuum in "tank")	Both vents blocked and significant cooling of solution occurs	NA	No significant impact	None	None	S0	F1	
A1	10.17	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Pressure/low	Both vents blocked and significant cooling of solution occurs	NA	No significant impact	Tank vents have no valves		S0	F1	
NA	10.18	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Temperature/high	Chemical reaction in "tank" from incompatible material mixing (a "tank" is comprised of two tanks connected by a common header on both inlet, drain, and recirc)	NA	No significant chemical reactions could be identified			NA	NA	
I	10.19	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	pH/low (<13)	pH controller failure at scrubber	NOx and nitric acid vapors produced in calciner at injection rate of 4 L/hr	Inadequate scrubbing of calciner offgas allowing NOx and acid release to vacuum system		Recirculation and sampling for Pu content	S1	F3	
A1	10.20	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	pH/low (<13)	pH controller failure at scrubber	NA	No significant impact to spent scrub solution receiver tanks; however pH of tank D-8 could be significantly affected	Keyswitch for MOV-230-P valve to prevent inadvertent sending to D-8	None	S0	F3	Potential effect on tank D-8 unknown
NA	10.21	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	pH/high		NA	Design intent, no significant consequence			NA	NA	
E	10.22	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Composition/high Pu	Filter failure at calciner	NA	Buildup of Pu oxide sludge in tanks with possibility of criticality	DPS-230-A pressure switch and alarm on high pressure DPT-230-1 and DPT-230-2 delta pressure transducers across calciner filters and recorder 230-1 Criticality alarm system	Recirculation and sampling for Pu content Operator observation of solution color Operator observation of tanks (glass for visibility of solids layer) Operator training and procedures for response to process parameter indications	S1*	F1	S1* based on criticality event
E	10.23	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Composition/high Pu	Filter failure at calciner	NA	Possible transfer of Pu material to tank D-8 with potential for criticality due to buildup of Pu solids	DPS-230-A pressure switch and alarm on high pressure DPT-230-1 and DPT-230-2 delta pressure transducers across calciner filters and recorder 230-1 Keyswitch for MOV-230-P valve to prevent inadvertent sending to D-8	Recirculation and sampling for Pu content Operator observation of solution color Operator observation of tanks (glass for visibility of solids layer) Operator training and procedures for response to process parameter indications	S1*	F3

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
A2	10.24	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Composition/high Pu	Filter failure at calciner	Less than 1.5 kg Pu oxide powder	Programmatic impact in having to remove and reprocess material	DPS-230-A pressure switch and alarm on high pressure DPT-230-1 and DPT-230-2 delta pressure transducers across calciner filters and recorder 230-1	Recirculation and sampling for Pu content Operator observation of solution color Operator observation of tanks (glass for visibility of solids layer) Operator training and procedures for response to process parameter indications	S1	F5	
E	10.25	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Composition/high Pu	Nitrate oversupply in calciner resulting in overflow of calciner into scrubber	NA	Buildup of Pu oxide sludge in tanks with possibility of criticality	DPS-230-A pressure switch and alarm on high pressure DPT-230-1 and DPT-230-2 delta pressure transducers across calciner filters and recorder 230-1 Criticality alarm system	Recirculation and sampling for Pu content Operator observation of solution color Operator observation of tanks (glass for visibility of solids layer) Operator training and procedures for response to process parameter indications	S1*	F1	S1* based on criticality event
E	10.26	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Composition/high Pu	Nitrate oversupply in calciner resulting in overflow of calciner into scrubber	NA	Possible transfer of Pu material to tank D-8 with resulting criticality concern due to Pu solids buildup	DPS-230-A pressure switch and alarm on high pressure DPT-230-1 and DPT-230-2 delta pressure transducers across calciner filters and recorder 230-1 Keyswitch for MOV-230-P prevents inadvertent sending to D-8. Need key from supervisor to operate	Recirculation and sampling for Pu content Operator observation of solution color Operator observation of tanks (glass for visibility of solids layer) Operator training and procedures for response to process parameter indications	S1*	F3	S1* based on criticality event
A2	10.27	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Composition/high Pu	Nitrate oversupply in calciner resulting in overflow of calciner into scrubber	10 L Pu nitrate solution at 450 g/L	Programmatic impact in having to remove and reprocess material	DPS-230-A pressure switch and alarm on high pressure DPT-230-1 and DPT-230-2 delta pressure transducers across calciner filters and recorder 230-1	Recirculation and sampling for Pu content Operator observation of solution color Operator observation of tanks (glass for visibility of solids layer) Operator training and procedures for response to process parameter indications	S1	F3	
A1	10.28	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Mixing/no/low	V-91 or V-92 closed, or MOV 230-M & N set to drain	NA	Programmatic impact	None	Operator training and procedures for setting up recirculation	S0	F3	

Table 9D-4

HazOp of Vertical Denitration Calciner Process

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
E	10.29	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Mixing/no/low	Recirculation pump failure Failure of process air to recirculation pump (P-230-D)	NA	Inaccurate Pu sample results, ultimately could result in excessive quantities of Pu to tank D-8 with potential for criticality from buildup of Pu solids	None	Operator training and procedures for setting up recirculation	S1*	F1	S1*/F1 for potential criticality in tank D-8
E	10.30	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Mixing/no/low	Failure to operate pump (human error)	NA	Inaccurate Pu sample results, ultimately could result in excessive quantities of Pu to tank D-8 with potential for criticality from buildup of Pu solids	Keyswitch for MOV-230-P prevents sending to D-8. Need key from supervisor to operate	Operator training and procedures for setting up recirculation	S1*	F1	S1*/F1 for potential criticality in tank D-8
B-XREF	10.31	Spent scrub solution receiver tank (tank in bank 1 representative of all four tanks)	Provide lag storage of spent scrub solution for blending and sampling prior to transferring solution to Tank D8 for disposal	Mixing/no/low	Recirculation piping failure	_____	See Level/low node for scrubber receipt tanks (Node 10.01)					
E	11.00	Spent Scrub Solution Drain Line from MOV 230-P to Tank D8	Transfer spent scrub solution to tank D8 to permit eventual transfer to tank farms	Composition/high Pu concentration	Calciner filter failure permits movement of Pu into scrubber and failure to detect visually or by sampling	NA	Potential for buildup of Pu in tank D8 and possible criticality concern	Keyswitch for MOV-230-P prevents sending to D-8. Need key from supervisor to operate	Procedure for sampling spent scrubber solution before being sent to tank D8 Operator observation of scrubber solution color in scrubber	S1*	F1	S1* based on criticality concern
I-XREF	12.00	Vacuum Trap	Prevent liquids from entering the 26" process vacuum system	Level/high	See phase separator node for Level/ high (Nodes 8.04-8.06)	_____						
I	12.01	Vacuum Trap	Prevent liquids from entering the 26" process vacuum system	Level/high	Level element failure (assumes entrained liquid will eventually accumulate to significant level)	Small quantity of scrubber solution	Liquid permitted to enter vacuum system with possible damage to the vacuum pumps resulting in programmatic impact Contamination of vacuum system with radioactive caustic solution	Two level indications on vacuum trap interlocked to isolate the calciner system from the plant vacuum system Seal pots in the plant vacuum system	Operator observation of level in vacuum trap (glass tank)	S1	F3	
B-XREF	12.02	Vacuum Trap	Prevent liquids from entering the 26" process vacuum system	Pressure/high (lack of vacuum)	Failure of plant vacuum system valve AOBV-230-L closed	_____	Pressurization of scrubber and calciner - see calciner Pressure/ high (Node 6.12) & Temperature low (Node 6.25)					
B-XREF	12.03	Vacuum Trap	Prevent liquids from entering the 26" process vacuum system	Pressure/high (lack of vacuum)	Vacuum trap drain valve V-72 left open	_____	Pressurization of scrubber and calciner - see calciner Pressure/ high (Node 6.12)					
NA	12.04	Vacuum Trap	Prevent liquids from entering the 26" process vacuum system	Pressure/high (lack of vacuum)	Excessive inleakage from various points in the calciner system due to piping and vessel failures	NA	Addressed at various nodes specific to the rest of the system			NA	NA	
XREF	13.00	Vent Catch Tank	Provide a liquid catch volume for the Feed Receipt Tank vent, Feed Pump Tank vent, Flush Tank vent that can be recovered by use of valve V-74 Provide a drain volume for the Vacuum Trap with recovery by use of valve V-74	Level/high	Overflow of feed receipt tank, flush tank or feed pump tank	_____	See feed receipt tank, feed pump tank and flush tank nodes Level/ high (Nodes 1, 2, 3)					

Table 9D-4

HazOp of Vertical Denitration Calciner Process

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
B	13.01	Vent Catch Tank	Provide a liquid catch volume for the Feed Receipt Tank vent, Feed Pump Tank vent, Flush Tank vent that can be recovered by use of valve V-74 Provide a drain volume for the Vacuum Trap with recovery by use of valve V-74	Level/high	Vacuum trap drained to vent catch	2.5 L Pu nitrate solution at 450 g/L	Potential overflow vent catch tank (depending on vacuum trap quantity) Aerosol release to glovebox atmosphere of scrubber solution due to splatter	Level monitoring in vacuum trap limits quantity drained to vent catch tank	Visual observation of tank levels	S1	F3	
B	13.02	Vent Catch Tank	Provide a liquid catch volume for the Feed Receipt Tank vent, Feed Pump Tank vent, Flush Tank vent that can be recovered by use of valve V-74 Provide a drain volume for the Vacuum Trap with recovery by use of valve V-74	Pressure/high	Blocked overflow vent and gas generation or heat generation due to chemical reaction in feed receipt tank, feed pump tank, flush tank, or vent catch tank	20 L Pu nitrate solution at 450 g/L	Potential rupture of vent catch tank, flush tank, or feed receipt tank Spill of Pu nitrate solution to glovebox floor NOx release to glovebox atmosphere	Glovebox sump and level alarm Criticality drain Glovebox structure and E-4 ventilation system maintains confinement	Visual observation of gas bubbles in affected tank	S1	F1	
B	13.03	Vent Catch Tank	Provide a liquid catch volume for the Feed Receipt Tank vent, Feed Pump Tank vent, Flush Tank vent that can be recovered by use of valve V-74 Provide a drain volume for the Vacuum Trap with recovery by use of valve V-74	Pressure/high	Blocked overflow vent and waste transferred into feed receipt tank from HC-227S	20 L Pu nitrate solution at 450 g/L	Potential rupture of vent catch tank, flush tank, or feed receipt tank (if pump pressure potential high enough) Spill of Pu nitrate solution to glovebox floor	Glovebox sump and level alarm Criticality drain Glovebox structure and E-4 ventilation system maintains confinement	Visual observation of gas bubbles in affected tank	S1	F1	
B	13.04	Vent Catch Tank	Provide a liquid catch volume for the Feed Receipt Tank vent, Feed Pump Tank vent, Flush Tank vent that can be recovered by use of valve V-74 Provide a drain volume for the Vacuum Trap with recovery by use of valve V-74	Pressure/low (vacuum)	V-72 valve open (valve between vent catch tank and vacuum tank) and vent catch tank overflow vent plugged	Pu oxide contained in calciner and nitric acid vapor from 4 L/hr injection rate	Reduced vacuum draw on scrubber and calciner; potential release from calciner due to overpressure Slight vacuum draw on feed receipt tank, feed pump tank, flush tank; no significant consequence	Tanks judged to survive full system vacuum Pressure indicator 230-3 on vacuum trap indicates inleakage or vacuum system failure If severe enough other pressure transducers in system would indicate inleakage	Operator training and procedures	S1	F3	S1/F3 for potential release through calciner pressure relief cap
A2	14.00	Transfer line between pump P-230-E and HC-227S receipt tank	Transfer solutions out of feed pump tank, feed receipt tank, flush tank, or vent tank back to HC-227S (tanks may need to be emptied to unplug or repair calciner or to rework solutions)	Flow/low	Pump fails when required Valve V-81 downstream of pump closed when required	NA	Programmatic upset (repairs can't be made or out of spec solution can't be reprocessed)	None	Operator surveillance of source and receipt tanks	S1	F3	How do you recover should Pu content in scrub receiver tanks exceed 2 g/L? Solution is incompatible with acidic waste in glovebox HC-227S and probably shouldn't be sent there via pump P-230-E

Table 9D-4

HazOp of Vertical Denitration Calciner Process

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
K	21.00.c	Calciner bottled compressed air supply	Safely contain pressurized air Supply filter pulse air and atomizing air to VDC	Containment/breach	Failure of air bottles or supply valves due to mechanical impact or other manufacturing flaws	Radioactive material contained in RMC line area	Potential damage to facility walls and processing equipment leading to spread of radioactive material from Zone 4 and 3a areas to less contaminated areas and facility worker exposures	Bottle design limits potential for spurious failures Bottle racks minimize potential for bottle to topple or be impacted by other objects Zone 3 ventilation system and building limit ultimate release of radioactive material to the atmosphere should confinement boundaries be compromised	Operator training and procedures regarding the handling, storage and setup of compressed gases	S1*	F2	
B	21.01	Calciner bottled compressed air supply	Safely contain pressurized air Supply filter pulse air and atomizing air to VDC	Composition/other than standard air	Bottles containing pure oxygen installed in place of bottles containing air - human error	Pu oxide contained in calciner and nitric acid vapor from 4 L/hr injection rate	Potential catastrophic damage to calciner due to accelerated oxidation of vessel and nozzle with release of Pu oxide to the glovebox if vessel seals or body fail Potential for excessive heating in glovebox from heat produced by accelerated oxidation process	Thermocouples measuring temperature in calciner Bottle threads are different for different bottles to prevent hookup of wrong bottle	Bottles are color coded and marked Training of plant personnel	S1	F3	
A1	21.02	Calciner bottled compressed air supply	Safely contain pressurized air Supply filter pulse air and atomizing air to VDC	Composition/other than standard air	Bottles containing non oxidizing gasses installed in place of bottles containing air - human error	NA	No apparent consequence - the chemistry of the calcination process does not require additional oxygen to produce Pu oxide from Pu nitrate	Bottle threads are different for different bottles to prevent hookup of wrong bottle	Bottles are color coded and marked Training of plant personnel	S0	F3	
XREF	21.03	Calciner bottled compressed air supply	Other failures addressed previously in this table	Containment/breach		———						
A1	22.00	Glovebox HC-230C-2	Provide confinement of gasses and particulates for calciner process Contain spilled fluids in critically safe manner Provide structure to support equipment within glovebox Provide shielding to minimize operator exposure	Pressure/low (excessive vacuum)	E-4 exhaust system imbalance (dampers in E-4 system set incorrectly or dampers fail open) Failure of dry air supply to RMC line gloveboxes (air supplied via conveyer glovebox HC-2)	NA	No significant consequence-- glovebox not expected to fail at credible vacuums	Glovebox to room DP gauge Self regulating valve on dry air supply to RMC line	Procedure requires operator to verify glovebox to room DP prior to initiating glovebox operations	S0	F3	
NA	22.01	Glovebox HC-230C-2	Provide confinement of gasses and particulates for calciner process Contain spilled fluids in critically safe manner Provide structure to support equipment within glovebox Provide shielding to minimize operator exposure	Pressure/low (excessive vacuum)	Damper control failures in E-5 reduce pressure in both E-4 and E-3 areas	NA	NO significant consequences as relative pressure difference maintained			NA	NA	

Table 9D-4

HazOp of Vertical Denitration Calciner Process

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
H	22.02	Glovebox HC-230C-2	Provide confinement of gasses and particulates for calciner process Contain spilled fluids Provide structure to support equipment within glovebox Provide shielding to minimize operator exposure	Pressure/high (less vacuum--DP between room and glovebox > -0.5 in W.G)	Ventilation imbalance between Zone 3 and Zone 4 (dampers in E-4 and/or E-3 ventilation set or modulated incorrectly)	Pu oxide in glovebox atmosphere	Potential for reverse flow through glovebox penetrations to room 230; contamination spread to room 230	Glovebox connected to multiple gloveboxes and their exhausts minimizing potential for glovebox to go more positive than Zone 3 Glovebox structure and penetration design minimizes potential contamination spread should room pressure drop below glovebox pressure Glovebox to room DP gauge CAMS in room 230 to detect contamination spread Emergency exhaust dmpr valves in RMC line open at vacuum in RMC line gloveboxes approach -0.5 in w.g.	Procedure requires operator to verify glovebox to room DP prior to initiating glovebox operations (procedures Z0-190-502 and Z0-190-506)	S1	F3	
NA	22.03	Glovebox HC-230C-2	Provide confinement of gasses and particulates for calciner process Contain spilled fluids Provide structure to support equipment within glovebox Provide shielding to minimize operator exposure	Pressure/high (less vacuum--DP between room and glovebox > -0.5 in W.G)	Damper control failures in E-3 increase pressure in both E-4 and E-3 areas	NA	No contamination spread--relative pressure in glovebox still more negative than room pressure			S0	F3	
H	22.04	Glovebox HC-230C-2	Provide confinement of gasses and particulates for calciner process Contain spilled fluids Provide structure to support equipment within glovebox Provide shielding to minimize operator exposure	Pressure/high (less vacuum--DP between room and glovebox > -0.5 in W.G)	Plant air or compressed air leak inside glovebox (catastrophic line failure and possibly air regulator failures)	Pu oxide in glovebox atmosphere	Contamination spread to room 230C through glovebox seals and penetrations blow out gloves	Glovebox HC-230C-2 connected to conveyor system and other gloveboxes providing large volume for compressed gases to expand into Pressure gauges on plant air and compressed air lines Glovebox to room DP gauge	Operator/audio detection of catastrophic leak	S1*	F2	S1* based on potential operator exposure to airborne Pu
XREF	22.05	Glovebox HC-230C-2	Provide confinement of gasses and particulates for calciner process Contain spilled fluids Provide structure to support equipment within glovebox Provide shielding to minimize operator exposure	Pressure/high (less vacuum--DP between room and glovebox > -0.5 in W.G)	Pressurized releases from calciner due to various causes	———	See calciner Pressure/high (Nodes 6.08-6.14)					

Table 9D-4

HazOp of Vertical Denitration Calciner Process

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
XREF	22.06	Glovebox HC-230C-2	Provide confinement of gasses and particulates for calciner process Contain spilled fluids Provide structure to support equipment within glovebox Provide shielding to minimize operator exposure	Pressure/high (less vacuum--DP between room and glovebox > -0.5 in W.G)	Releases from other glovebox tanks due to chemical reactions	———	See nodes for glovebox tanks previously in table					Total volume of HC-230C-2 glovebox, conveyer glovebox and other connected gloveboxes minimize potential for pressurization as does E-4 ventilation system capacity
H	22.07	Glovebox HC-230C-2	Provide confinement of gasses and particulates for calciner process Contain spilled fluids Provide structure to support equipment within glovebox Provide shielding to minimize operator exposure	Pressure/high	Imbalance between exhaust from and dry air supply to RMC line gloveboxes caused by: - Loss of exhaust flow (resulting from exhaust fan failures, damper closures, etc.) combined with continued dry air supply to conveyer glovebox or - Excessive dry air supply to the RMC line due to dry air supply regulator failure	Pu oxide in glovebox atmosphere	Pressurization of HC-230C-2 glovebox (and other gloveboxes in the RMC line) with spread of contamination to Zone 3 areas (e.g., room 230C)	Dry air supply and E-4 exhaust system instrumentation HC-230C-2 glovebox pressure gauge and indicator Exhaust system damp valves open as RMC line glovebox vacuum approaches -0.5 inches w.g. Self regulating valve on dry air supply to RMC line	Operator training and procedures regarding glovebox and ventilation system instrument readings and alarms	S1*	P3	HC-230C-2 is connected to other RMC line gloveboxes via conveyor gloveboxes HC-3 and HC-2
F	22.08.a	Glovebox HC-230C-2	Provide confinement of gasses and particulates for calciner process Contain spilled fluids Provide structure to support equipment within glovebox Provide shielding to minimize operator exposure	Temperature/high	Fire in room 230 due to ignition of combustibles in the room	Total inventory of Pu in glovebox	Potential loss of confinement by glovebox breach by failure of seals, windows, gloves, etc.	Room fire suppression system Glovebox dry fire suppression system Glovebox constructed primarily of metal and has fire resistance windows	Housekeeping procedures limit combustible loading	S1*	P2	S1*/P2 ranking for fire that engulfs glovebox
XREF	22.08.b	Glovebox HC-230C-2	Provide confinement of gasses and particulates for calciner process Contain spilled fluids Provide structure to support equipment within glovebox Provide shielding to minimize operator exposure	Temperature/high	Fire in glovebox (due to loss of control of calciner heaters, or combustibles in contact with hot equipment described previously in table)	———	See calciner temp/high (Node 6.18) See feed pump temperature/high (Node 4.06)					

Table 9D-4

HazOp of Vertical Denitration Calciner Process

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
D-XREF	22.09	Glovebox HC-230C-2	Provide confinement of gasses and particulates for calciner process Contain spilled fluids Provide structure to support equipment within glovebox Provide shielding to minimize operator exposure	Temperature/high	Butene explosion in calciner causes release of hot gases, steam, and very hot PU oxide to glovebox atmosphere	———	See calciner temperature/high (Node 6.10)					
XREF	22.10	Glovebox HC-230C-2	Provide confinement of gasses and particulates for calciner process Contain spilled fluids Provide structure to support equipment within glovebox Provide shielding to minimize operator exposure	Temperature/high	Overheated calciner due to temperature control failures on calciner heaters	———	See calciner temperature/high (Nodes 6.17-6.20)					
XREF	22.11	Glovebox HC-230C-2	Provide confinement of gasses and particulates for calciner process Contain spilled fluids Provide structure to support equipment within glovebox Provide shielding to minimize operator exposure	Temperature/high	Thermal degradation of materials and components inside glovebox such as flexible hose, electrical wiring insulation, elastomer gloves, elastomeric seals, etc.	———	Electrical shock hazard to operator during manual operations inside glovebox Possible failure of pump seals allowing sprays and leaks of material being pumped	Glovebox temperature elements and recorders E-4 ventilation system instrumentation Procurement specifications requiring materials placed in glovebox be able to survive the environment Glovebox gloves act as insulator Electrical equipment has protective switch gear to trip on faults	Operator training and procedures	S1*	F3	S1* based on possibility of electrocution
H	22.12	Glovebox HC-230C-2	Provide confinement of gasses and particulates for calciner process Contain spilled fluids Provide structure to support equipment within glovebox Provide shielding to minimize operator exposure	Temperature/high	Loss of glovebox ventilation (loss of E-4 exhaust fans or exhaust path valved closed) Loss of dry air supply to RMC line reduces airflow through glovebox	Pu oxide in glovebox atmosphere	Heat given off by calciner and piping surfaces increases temperature in the glovebox Glovebox confinement boundary potentially compromised due to thermal expansion of structural components and effect on heat on glovebox seals	Glovebox temperature elements and recorders Room Cams to detect spread of contamination from glovebox Glovebox pressure gauges, indicators and annunciators E-4 ventilation system instrumentation Glovebox HC-230C-2 connected via conveyor glovebox HC-2 to several other RMC line gloveboxes, providing additional volume for thermal expansion of air	Operator training and procedures regarding glovebox and ventilation system instrument readings and alarms	S1	F3	Significant pressurization of glovebox not expected due to expansion volume provided by other connected gloveboxes

Table 9D-4

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
B	22.21	Glovebox HC-230C-2	Provide confinement of gasses and particulates for calciner process Contain spilled fluids Provide structure to support equipment within glovebox Provide shielding to minim	Confinement integrity/water intrusion	Flood in room 230 due to activation of room fire suppression system	NA	Potential initiator for criticality	Glovebox support structure elevates glovebox several feet above floor Glovebox top is sealed No open paths in top of glovebox for water intrusion (exhaust duct is seismically qualified) Vessels in glovebox are designed to be geometrically unfavorable to criticalities even if fully moderated Glovebox criticality drain	Mass of fissile material controlled by crit specifications and procedures Specifications require use of movable vessels with shapes and volumes that are criticality unfavorable	S1*	F1	If large ingress of fire water occurs criticality drain may not keep up with flowrate Are there drains in this room? Potential ingress of water in other parts of the RMC line should be investigated.
NA	22.22	Glovebox HC-230C-2	Provide confinement of gasses and particulates for calciner process Contain spilled fluids Provide structure to support equipment within glovebox Provide shielding to minim	Confinement integrity/explosion external to glovebox	Explosion in room 230 due to ignition of bottled heating gasses (portable torch system)	NA	Addressed in PFP FSAR Section 9.2.1F					
H	22.23	Glovebox HC-230C-2	Provide confinement of gasses and particulates for calciner process Contain spilled fluids Provide structure to support equipment within glovebox Provide shielding to minim	Confinement integrity/water intrusion	Flood in room 230 due to activation of room fire suppression system	Pu oxide powder in calciner	Potential for spread of Pu oxide to room 230	Glovebox support structure elevates glovebox several feet above floor Glovebox top is sealed Room CAMs alert workers to airborne hazard	Operator training	S1	F3	
H	23.00	E-4 exhaust duct at outlet of Glovebox HC-230C-2	Prevents movement of contamination from glovebox to room 230 by maintaining a negative pressure in glovebox Provides removal of heat produced by calciner through movement of air through glovebox	Air flow/low/no	Loss of E-4 exhaust fans loss of power	Pu oxide in glovebox atmosphere	Stagnation of glovebox with possible contamination release to room 230 (assumes that some contamination exists in the glovebox at all times) Overheating glovebox due to no air movement in box resulting in migration of contamination to room	CAMs in room Ventilation system failure alarm Glovebox temperature detection elements and recorders Glovebox pressure indication	Operator training and alarm response procedures Procedure requires checking dP before working in glovebox	S1	F3	S1 based on simple migration of contamination
H	23.01	E-4 exhaust duct at outlet of Glovebox HC-230C-2	Prevents movement of contamination from glovebox to room 230 by maintaining a negative pressure in glovebox Provides removal of heat produced by calciner through movement of air through glovebox	Air flow/low/no	Plugged glovebox E-4 exhaust filter	Pu oxide in glovebox atmosphere	Overheating glovebox due to no air movement in box resulting in greater migration of contamination to room	Other gloveboxes in communication with conveyer system sustain negative pressure on the system Glovebox high temperature alarm and calciner heater shutdown interlock	Operator training and alarm response procedures Procedure requires checking dP before working in glovebox	S1	F3	Overheating glovebox due to no air movement in box (glovebox remains negative with respect to room due to communication with conveyer glovebox)

Table 9D-4

HazOp of Vertical Denitration Calciner Process

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
H	23.02	B-4 exhaust duct at outlet of Glovebox HC-230C-2	Prevents movement of contamination from glovebox to room 230 by maintaining a negative pressure in glovebox Provides removal of heat produced by calciner through movement of air through glovebox	Air flow/low/no	B-3 or E-4 flow dampers closed or set incorrectly	Pu oxide in glovebox atmosphere	Overheating glovebox due to no air movement in box resulting in greater migration of contamination to room	Glovebox pressure gauge and indicator Ventilation system instrumentation (E-3 and E-4 systems) Glovebox high temperature alarm and calciner heater shutdown interlock	Operator training and alarm response procedures Procedure requires checking dP before working in glovebox	S1	F3	
H	23.03	E-4 exhaust duct at outlet of Glovebox HC-230C-2	Prevents movement of contamination from glovebox to room 230 by maintaining a negative pressure in glovebox Provides removal of heat produced by calciner through movement of air through glovebox	Air flow/low/no	Dry air supply PRV in glovebox HC-2 fails to regulate inlet flow to RMC line to setpoint value (fails closed)	Pu oxide in glovebox atmosphere	Overheating glovebox due to no air movement in box resulting in greater migration of contamination to room	Other gloveboxes in communication with conveyer system main. negative pressure on the system Glovebox high temperature alarm and calciner heater shutdown interlock	Operator training and alarm response procedures Procedure requires checking dP before working in glovebox	S1	F3	
A1	23.04	E-4 exhaust duct at outlet of Glovebox HC-230C-2	Prevents movement of contamination from glovebox to room 230 by maintaining a negative pressure in glovebox Provides removal of heat produced by calciner through movement of air through glovebox	Air flow/high	E-4 ventilation system exhaust dampers open fully	NA	No significant effect		Operator training and procedures Procedure requires checking dP before working in glovebox	S0	F3	
A1	23.05	E-4 exhaust duct at outlet of Glovebox HC-230C-2	Prevents movement of contamination from glovebox to room 230 by maintaining a negative pressure in glovebox Provides removal of heat produced by calciner through movement of air through glovebox	Air flow/high	Failure of glovebox gloves or windows	NA	No significant effect		Operator training and procedures	S0	F3	
A1	23.06	E-4 exhaust duct at outlet of Glovebox HC-230C-2	Prevents movement of contamination from glovebox to room 230 by maintaining a negative pressure in glovebox Provides removal of heat produced by calciner through movement of air through glovebox	Air flow/high	Gross failure of compressed instrument air piping or gross failure of plant compressed air system	NA	No significant effect	Piping design of compressed air supply PRVs on plant and compressed air supplies limit potential flowrates	Operator training and procedures	S0	F3	Pressurization of glovebox not expected unless bottled air supply PRVs fail. Even then line so small probably can't cause pressurization
H	23.07	E-4 exhaust duct at outlet of Glovebox HC-230C-2	Prevents movement of contamination from glovebox to room 230 by maintaining a negative pressure in glovebox Provides removal of heat produced by calciner through movement of air through glovebox	Air flow/high	Dry air supply PRV to RMC-RMA conveyor fails to regulate inlet flow to RMC line to setpoint value (fails open)	Pu oxide in glovebox atmosphere	Potential pressurization of RMC line gloveboxes with release of contamination to Zone 3 areas	Room CAM Glovebox pressure indication E-3 ventilation system and HEPA filters		S1	F3	

Table 9D-4

HazOp of Vertical Denitration Calciner Process

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
B	23.08	E-4 exhaust duct at outlet of Glovebox HC-230C-2	Prevents movement of contamination from glovebox to room 230 by maintaining a negative pressure in glovebox Provides removal of heat produced by calciner through movement of air through glovebox	Filtration/lack of	Glovebox exhaust filter failure	Normal concentration of Pu in glovebox atmosphere	Elevated contamination release to E-4 system (normal operation) Elevated Pu oxide, Pu nitrate aerosol release to E-4 system if failed filter in place at time of process upsets identified elsewhere in this table	E-4 stage 1 HEPA filters (in duct level) Final E-4 ventilation system filters to limit release to environment Stack exhaust CAM	Periodic aerosol testing of E-4 exhaust filters	S0	F3	S0 based on no significant release through stack due to safety class E-4 filters
B	23.00	Product collection jars and slip lid convenience cans (handling within glovebox and transfer to conveyor system)	Contain Pu oxide Product collection jar maintains confinement for calciner while connected to product collection down pipe	Containment/lack of	Spill during transfer of collection jar contents to slip lid can	Less than 5 kg Pu oxide powder	Release of Pu oxide particulate to glovebox atmosphere	glovebox exhaust filter E-4 exhaust system filters (2 stages) Glovebox structure, seals, and E-4 exhaust to maintain confinement	Operator training and procedures	S1	F3	
B	24.01	Product collection jars and slip lid convenience cans (handling within glovebox and transfer to conveyor system)	Contain Pu oxide Product collection jar maintains confinement for calciner while connected to product collection down pipe	Containment/lack of	Drop or topple slip lid can during movement to conveyer Slip lid can toppled by air line leak; entrained Pu oxide in glovebox atmosphere	2.5 kg Pu oxide powder	Release of Pu oxide particulate to glovebox atmosphere	Glovebox exhaust filter E-4 exhaust system filters (2 stages) Glovebox structure, seals, and E-4 exhaust to maintain confinement	Operator training and procedures	S1	F3	
B-XREF	24.02	Product collection jars and slip lid convenience cans (handling within glovebox and transfer to conveyor system)	Contain Pu oxide Product collection jar maintains confinement for calciner while connected to product collection down pipe	Confinement/lack of	Broken product collection jar while connected to calciner	———	Spill of Pu oxide to glovebox atmosphere Inrush of air into calciner	See calciner confinement/low (Node 6.30)				
B-XREF	24.03	Product collection jars and slip lid convenience cans (handling within glovebox and transfer to conveyor system)	Contain Pu oxide Product collection jar maintains confinement for calciner while connected to product collection down pipe	Confinement/lack of	Improperly attached product collection jar while processing occurring in calciner	———	Spill of Pu oxide to glovebox atmosphere Inrush of air into calciner	See calciner confinement/low (Node 6.31)				
NA	24.04	Product collection jars and slip lid convenience cans (handling within glovebox and transfer to conveyor system)	Contain Pu oxide Product collection jar maintains confinement for calciner while connected to product collection down pipe	Temperature/high	Normal condition of the product collection jar while collecting Pu oxide from calciner process	NA	NA			NA	NA	
G	24.05	Product collection jars and slip lid convenience cans (handling within glovebox and transfer to conveyor system)	Contain Pu oxide Product collection jar maintains confinement for calciner while connected to product collection down pipe	Temperature/high	Inadequate time allowed for cooling prior to transferring Pu oxide to convenience can	NA	Operator burns	None	Operator training and procedures	S1	F3	
XREF	24.06	Product collection jars and slip lid convenience cans (handling within glovebox and transfer to conveyor system)	Contain Pu oxide Product collection jar maintains confinement for calciner while connected to product collection down pipe	Temperature/high	Inadequate time allowed for cooling prior to transferring Pu oxide to convenience can	———	Small fire in glovebox if combustibles in glovebox (gloves, rags, egg cartons) contact hot can	See calciner Temperature/high (Node 6.18) See feed pump Temperature/high (Node 4.06)				

Table 9D-4

HazOp of Vertical Denitration Calciner Process

Bin ID[1]	Node ID	Node Description	Design Function	Parameter/Guide Word	Possible Causes/ Hazardous Event	Material at Risk	Immediate Consequences	Engineered Safety Features	Administrative Safety Features	Cons Cat[2]	Freq Cat[3]	Remarks
G	24.07	Product collection jars and slip lid convenience cans (handling within glovebox and transfer to conveyor system)	Contain Pu oxide Product collection jar maintains confinement for calciner while connected to product collection down pipe	Temperature/high	Failure to use high temperature gloves while removing product collection jar from calciner drop pipe	NA	Melt gloves and burn operator	None	Operator training and procedures	S1	F3	
B	25.00	Vacuum sensing line between calciner and vacuum regulator valve VRV-230-1	Transmit accurate calciner vacuum signal to vacuum regulator valve	Vacuum/not representative	Solenoid valve EV-230-C remains closed following pressure pulse through ceramic filter (due to valve failure or controller failure)	Pu oxide contained in calciner and nitric acid vapor from 4 L/hr injection rate	Pressure rise in calciner not corrected by vacuum regulating valve VRV-230-1; potential overpressurization of calciner with release of NOx, Pu oxide, acid vapor and steam to glovebox atmosphere through pressure relief cap	Glovebox structure and E-4 ventilation system and filters maintain confinement and mitigate radiological releases through the building exhaust stack	None	S1	F3	
L	25.01	Vacuum sensing line between calciner and vacuum regulator valve VRV-230-1	Transmit accurate calciner vacuum signal to vacuum regulator valve	Vacuum/not representative	Solenoid valve EV-230-C remains closed following pressure pulse through ceramic filter (due to valve failure or controller failure)	4.5 kg/can Pu oxide powder	Higher pressures in calciner may force steam back into Pu oxide bed causing wet Pu oxide powder to be produced Potential for canister ruptures in storage vault	TGA testing prior to oxide canning Storage vault ventilation system and filters mitigate potential release to the environment	None	S1*	F3	
L	25.02	Vacuum sensing line between calciner and vacuum regulator valve VRV-230-1	Transmit accurate calciner vacuum signal to vacuum regulator valve	Vacuum/not representative	Solenoid valve EV-230-C fails to close during pulse cleaning of ceramic filters due to valve failure, timer failure or controller failure	4.5 kg/can Pu oxide powder	High pressure pulses travel down sensing line causing vacuum regulator to cycle resulting in vacuum fluctuations in calciner Vacuum fluctuations may cause increased particle loading on filters with subsequent plugging and momentary or continuous pressurization of the calciner vessel with release of Pu oxide and NOx to the glovebox atmosphere through the calciner relief cap, and inconsistent Pu oxide product that doesn't meet stabilization criteria	Glovebox structure and E-4 ventilation system and HEPA filters maintain confinement and mitigate radiological releases through the building exhaust stack Differential pressure indication across ceramic filters and between the calciner vessel and the glovebox atmosphere (DPT 230-1, DPT 230-2, and DP recorder DPR 230-1)	Visual detection of steam in product collection jar or surging in phase separator tank	S1	F3

APPENDIX 9E

CALCULATION OF RUPTURED COMPRESSED AIR CYLINDER ACCELERATION, VELOCITY, AND TRAVEL DISTANCE AS A FUNCTION OF TIME

This page intentionally left blank.

9E.1 PURPOSE

One of the accidents considered in this FSAR is a handling accident involving a compressed air cylinder being brought into the 234-5Z Building to support operation of the Vertical Denitration Calciner. The postulated handling accident results in the supply valve being sheared off the cylinder. In such an accident, compressed air expelled from the cylinder through the sheared off supply valve would cause the cylinder to accelerate as a missile, potentially injuring facility workers and causing damage to the facility. Clearly, a ruptured cylinder presents a significant hazard to facility workers. The purpose of this appendix is to develop the equations for estimating the cylinder's potential momentum as a function of distance from the point of the handling accident, to allow an assessment of potential damage to the facility to be made.

Specifically provided in this appendix are the calculations for determining the compressed air cylinder's acceleration, velocity, and travel distance as a function of time after the supply valve is sheared off. The cylinder's velocity within a reasonable distance from the point of a potential handling accident inside the PFP is used in Section 9.2.9.3 to determine if vault walls protecting radiological material within the PFP can be penetrated.

9E.2 METHODOLOGY

Equations for Estimating Cylinder Acceleration As a Function of Time

At any given time, the thrust produced by the compressed air expelled through the sheared off supply valve is equal to the product of the mass ejection rate and the velocity of the expelled gases relative to the cylinder missile:

$$\text{Thrust} = - v_a \, (dM_a/dt)$$

where,

v_a = velocity of the expelled air relative to the velocity of the cylinder
M_a = mass of air in the cylinder
dM_a/dt = mass ejection rate of air from the cylinder

The sign in the above equation is negative because the gas is ejected in the opposite direction to the thrust force on the cylinder.

The acceleration, a, of the cylinder at any given time is equal to the thrust force divided by the mass of the cylinder and its contained air at that instant:

$$a = - v_a \, (dM_a/dt)/(M_c + M_a) \qquad \text{(Eqn. 1)}$$

where, M_c = mass of the cylinder, without air.

M_a and dM_a/dt change with time as the cylinder depressurizes and the air is expelled from the cylinder. The following equation (equation 3-22, from Crane 1985) can be used to estimate dM_a/dt:

$$dM_a/dt = 0.525\, Y d_1^2\, C \sqrt{\frac{\Delta P}{V_s}} \qquad \text{(Eqn. 2)}$$

where,

dM_a/dt = mass flowrate of air from the cylinder, in lb/s
d_1 = diameter of the orifice, in inches
Y = net expansion factor for compressible flow through the orifice, constant while flow through orifice is sonic
C = flow coefficient for the orifice, constant for a given sized orifice
ΔP = pressure drop across the orifice, in psi
V_s = specific volume of gas expelled, in ft^3/lb

The expansion factor Y is a function of the specific heat ratio, k, of the air, the ratio of the orifice or throat diameter to inlet diameter, ß, and the ratio of downstream to upstream absolute pressures. k is a constant for a given gas. ß is constant for a given orifice or throat. In this case, air flow through the sheared off supply valve will be choked, limited to sonic velocity, while the majority of the cylinder depressurization. Hence, the pressure drop across the orifice is constant over most of the accident and Y can be treated as a constant as well. The value of Y used in the analysis is provided in Section 9E.4 (Input Data). The flow coefficient C is also a constant for a given orifice or throat, dependent only on ß, provided flow is turbulent through the orifice.

The pressure drop for choked flow of compressible gas through an orifice or nozzle is given by (see pg. A-21 of Crane):

$$\Delta P = P_1(1 - r_c) \qquad \text{(Eqn. 3)}$$

where P_1 equals the pressure of the air in the cylinder and r_c equals the critical pressure ratio. The critical pressure ratio is the largest ratio of downstream pressure to upstream pressure capable of producing sonic velocity. Flow in this case is sonic until $P_1(n) \times r_c = 14.7$ psi. It will be shown that r_c in this case is 0.527, so flow is sonic until cylinder pressure drops below 28 psia (14.7 psia/0.527).

V_s can be related to P_1 using the ideal gas law, as follows:

$$V_s = R\, T/(144\, M_w\, P_1) \qquad \text{(Eqn. 4)}$$

where R is the universal gas constant, 1545 ft-lb_f/lbmole-R, M_w equals the molecular weight of air, 28.8 lb_m/lbmole, T equals the absolute temperature of the gas in degrees Rankine (given in Section 9E.4), and the constant 144 converts the pressure term, P_1, from psi to lb/ft^2.

Substituting Equations 3 and 4 into Equation 2 gives:

$$dM_a/dt = - 0.525\ Y\ d_1^2\ C\ (P_1^2\ M_w\ 144\ (1 - r_c)/(R\ T))^{1/2} \qquad \text{(Eqn. 5)}$$

P_1 can in turn be converted to a mass basis also using the ideal gas law:

$$P_1 = (M_a\ R\ T/(M_w\ V_1\ 144)) \qquad \text{(Eqn. 6)}$$

where V_1 equals the interior volume of the cylinder, in ft^3.

Substituting equation 6 into equation 5 gives:

$$dM_a/dt = - 0.525\ Y\ d_1^2\ C \sqrt{\frac{M_a^2\ R\ T\ (1-r_c)}{M_w\ V_1^2\ 144}}$$

Simplifying the above equation gives:

$$dM_a/dt = - K\ M_a \qquad \text{(Eqn. 7)}$$

where,

$$K = 0.525\ Y\ d_1^2\ C\ [R\ T\ (1 - r_c)/(M_w\ V_1^2\ 144)]^{1/2}$$

Separating variables and integrating Eqn. 7 gives:

$$M_a(t) = M_{a,o}\ e^{-Kt} \qquad \text{(Eqn. 8)}$$

where $M_a(t)$ denotes the mass of air in the bottle as a function of time, $M_{a,o}$ equals the initial mass of air in the cylinder (at t = 0, when the cylinder is completely full), and t is the time in seconds after the supply valve has been sheared off the cylinder.

Substituting Eqn. 8) into Eqn. 1) gives:

$$a(t) = - [M_{a,o}\ v_a/(M_c + M_{a,o}\ e^{-Kt})]d(e^{-Kt})/dt$$

However, $d(e^{-Kt})/dt = -K\ e^{-Kt}$; therefore:

$$a(t) = M_{a,o}\ v_a\ K\ e^{-Kt}/(M_c + M_{a,o}\ e^{-Kt}) \qquad \text{(Eqn. 9)}$$

As discussed previously, the relative velocity of the gas ejected from the cylinder is sonic until most of the gas has been expelled. The sonic velocity of an ideal gas is a function only of its temperature. While flow is choked, the sonic velocity of the air, v_a, is given by the following equation (Crane, Eqn. 3-8):

$$v_a = (k\ g_c\ R\ T/M_w)^{1/2} \qquad \text{(Eqn. 10)}$$

where,

k = ratio of specific heat at constant pressure to specific heat at constant volume (c_p/c_v), which for air = 1.4
g_c = gravitational constant, 32.2 ft-lb_m/s^2-lb_f
R = universal gas constant = 1545 ft-lb_f/lbmole-R
T = absolute temperature, in degrees Rankine
M_w = molecular weight of air, 28.8 lb_m/lbmole

Equations for Estimating Cylinder Velocity As a Function of Time

The acceleration of the cylinder represents its change in velocity with respect to time:

$$d(v_{cyl})/dt = a(t) = M_{a,o}\ v_a\ K\ e^{-Kt}/(M_c + M_{a,o}\ e^{-Kt})$$

The velocity attained by the cylinder, v_{cyl}, over a given time frame can therefore be determined by integrating the acceleration equation, Eqn. 9), with respect to time, as follows:

$$v_{cyl}(t) = v_a \int \frac{K M_{a,o}\ e^{-Kt}}{M_c + M_{a,o}\ e^{-Kt}}\ dt$$

Let $U = M_{a,o}\, e^{-Kt}$; then $dU = -K\, M_{a,o}\, e^{-Kt}\, dt$, and:

$$v_{cyl} = -v_a \int \frac{1}{M_c + U} dU$$

Integrating the above equation between the limits of U_f and U_i gives:

$$v_{cyl}(t) = -\, v_a\, \ln[(M_c + U_f)/(M_c + U_i)]$$

Substituting back in the original relationship for U, between the limits of $t_f = t$ and $t_i = 0$, gives:

$$v_{cyl}(t) = -\, v_a\, \ln[(M_c + M_{a,o}e^{-Kt})/(Mc + M_{a,o})] \qquad \text{(Eqn. 11)}$$

Methodology for Estimating Cylinder Travel Distance As a Function of Time

The distance travelled by the cylinder over a give time frame can be estimated by integrating Eqn. 11. An analytical solution is not possible, so the integral is solved numerically. A numerical approximation is facilitated by breaking the accident down into small time steps. The change in distance travelled between two time steps is approximated by taking an average of the velocities for the two time steps, and multiplying by the difference of the two time steps, as follows:

$$\Delta D_{n,n-1} = 1/2(v_{cyl,n-1} + v_{cyl,n})(t_n - t_{n-1})$$

where,

$\Delta D_{n,n-1}$ is the incremental change in distance between time steps n-1 and n. The subscripts n and n-1 indicate the current and previous time steps, respectively. The cumulative travel distance over a given elapsed time is the sum of incremental distance changes estimated for successive time steps up to the total desired elapsed time, i.e:

$$D_n = \sum_{i=0}^{n} \frac{(v_{cyl,i-1} + v_{cyl,i})}{2} (t_i - t_{i-1})$$

9E.3 ASSUMPTIONS

The following assumptions are used in this analysis:

1. The compressed air cylinder is assumed to be a standard size specialty gas cylinder meeting DOT Specification 3AA2265.

2. Flow characteristics and frictional losses through the sheared off supply valve are assumed to be analogous to compressible fluid flow through a square edged orifice.

3. The diameter of the hole left by the sheared off valve is assumed to be 1 in.

4. The compressed air in the bottle acts as a ideal gas.

5. The temperature of the gas in the bottle remains constant at 535 °R (75 °F) during the accident. Ideal gases do not decrease in temperature during an isenthalpic pressure change.

9E.4 INPUT DATA

To solve for cylinder acceleration and velocity as a function of time using Equations 9 and 11, values are first needed for the constants ß, k, r_c, Y, d_1, C, R, T, M_w, V_1, $M_{a,o}$, and M_c, g_c, and v_a:

- The constants ß, and k are used along with r_c to determine the net expansion factor Y. ß is the ratio of the orifice diameter to the diameter of the cylinder upstream from the orifice. For a specialty gas cylinder meeting DOT Specification 3AA2265 (Assumption 1), the inner diameter of the cylinder is approximately 9 in. The orifice diameter is 1 inch (Assumption 3). Therefore ß is 1/9, or 0.11. The specific heat ratio, k, for air is 1.4. The critical pressure ratio, r_c, is used to determine the ratio of the absolute pressure downstream from the orifice to the absolute pressure upstream of the orifice ($\Delta P/P_1$). $\Delta P/P_1 = 1 - r_c$. Values for r_c and Y can be determined from charts on Pg. A-21 of Crane (1985). For a gas with a k = 1.4 and an orifice with a ß = 0.11, r_c was determined from the appropriate chart to be 0.527. This gives a $\Delta P/P_1 = 0.473$, which is constant as the cylinder depressurizes (until flow goes subsonic at P_1 = 28 psia). From another chart on pg. A-21 of Crane, Y was determined to be approximately 0.86 for a square edged orifice with a ß less than 0.2. This value gives conservative (high) volumetric flow estimates because the sheared off supply nozzle is expected to have flow resistance intermediate between a square edged orifice and a nozzle. Net expansion factors for nozzles are lower than for square edged orifices.

- For d_1, the diameter of the hole left by sheared of supply valve, a value of 1 inch is used (see Assumption 3).

- The flow coefficient, C, for a square edged orifice depends on ß and the Reynolds number. Flow through the orifice will be turbulent. For a square edged orifice with a ß less than 0.2, the appropriate chart on Pg. A-20 gives a C = 0.6.

- R is the universal gas constant and is equal to 1545 ft-lb_f/lbmole-R.

- The temperature of gas in cylinder at the time of the accident, T, is set at 535 R (Assumption 5).

- The molecular weight of air, M_w, is 28.8 lb/lbmole.

- The internal volume of the compressed air cylinder, V_1, is 1.55 ft^3 (average internal volume for high pressure specialty gas cylinder meeting DOT Specification 3AA2265, see Assumption 1).

- The capacity of the compressed air cylinder is 250 standard cubic feet (scf) (from Stubbs (1997)). Standard conditions are 14.7 psia and 60 °F, or 520 °R. Using the ideal gas law:

$$M_{a,o} = P\ V\ M_w/(RT)$$

$$= (14.7\ lb_f/in^2)(250\ ft^3)(28.8\ lb/lbmole)(144\ in^2/ft^2) /[(1545\ ft\text{-}lb_f/lbmole\text{-}R)(520\ R)]$$

$$= 19\ lb.$$

- The weight of cylinder without air (average tare weight for specialty gas cylinder meeting DOT Specification 3AA2265), M_c, equals 119 lb.

- The gravitational constant, g_c, = 32.17 lb_m-ft/lb_f-s^2.

- Using Eqn. 10), at the assumed gas temperature of 535 °R, the sonic velocity of the air expelled from the cylinder is

$$v_a = [(1.4)(32.17\ ft\text{-}lb_m/lb_f\text{-}s^2)(1545\ ft\text{-}lb_f/lbmol\text{-}R)(535\ R) /(28.8\ lb_m/lbmol)]^{1/2}$$

$$= 1137\ ft/s.$$

9E.5 RESULTS

To examine the cylinder's acceleration and velocity as a function of time, Eqn's 9 and 11 were solved in time increments of 0.4 s using a spreadsheet. Equation 6 was also solved at each time step to track cylinder air pressure. Cumulative travel distance at the end of each time step was estimated using the numerical approximation method discussed at the end of Section 9E.2. The results of the analysis are summarized in Table 9E-1. The calculations are only reported up to 2.8 s as the cylinder air pressure has dropped below 28 psia and air flow from the cylinder is subsonic at that point. The majority of the air has been expelled at that point and the cylinder velocity is approaching its asymptotic value of 167 ft/s, so further calculations are not necessary. The spreadsheet results show that the cylinder will travel approximately 366 ft in 2.8 s if not constrained. The spreadsheet results also show that the cylinder needs room to develop momentum. The cylinder requires approximately 16 ft of free space to accelerate to a velocity 50% of its maximum asymptotic value. The cylinder

has to travel approximately 56 ft without impacting anything to reach a speed of 123 ft/s, 74% of its maximum value.

The results of the analysis are depicted graphically in Figure 9E-1.

APPENDIX 9F

Preliminary Hazards Analysis for Thermal Stabilization of Plutonium Oxide

This page intentionally left blank.

PRELIMINARY HAZARDS ANALYSIS FOR THERMAL STABILIZATION OF PLUTONIUM OXIDE

9F.1 STABILIZATION OF PLUTONIUM OXIDE PHA

The hazards associated with thermally stabilizing Pu Oxide in the Glovebox HC-21C muffle furnaces were identified and evaluated using a Preliminary Hazards Analysis (PHA) approach. A detailed discussion of the PHA technique can be found in *Guidelines for Hazard Evaluation Procedures* (AIChE 1992).

9F.2 PHA METHODOLOGY

The PHA process is a systematic approach in which a system or process is broken down into basic elements and the hazards associated with operations in the system or process are identified, potential causes of those hazards are determined, potential consequences of the hazards are evaluated, and possible corrective and/or preventative measures are examined. The PHA was developed using a table to guide and record the results of a "brainstorming" process. Brainstorming was performed by individuals with detailed knowledge of the system or process being examined, and was supported by a multi-disciplinary team.

9F.2.1 PHA Data Description

The purpose and contents of each column in the PHA table, Table 9F-1, are described in detail in the following paragraphs.

Column 1, Item #: This column provides an alpha-numeric identifier for each hazard postulated in the table. The identifier is primarily used for cross referencing within the table and as an identifier for accident sequences discussed in Chapter 9 of the PFP FSAR.

Column 2, Process Step/Equipment: The step or steps and the important equipment involved in performing each set of operations is identified in this column. Listing each piece of equipment involved ensures that all relevant hardware failures are considered in the analysis and that the operational faults associated with use of each piece of equipment are considered.

Column 3, Failure/hazardous condition: The hardware failures or operational faults of concern are identified in this column. The hazards are identified first by postulating failures of the safety function(s) listed in the previous column. Simply postulating functional failure of hardware, however, is insufficient for identifying the wide range of things that can go wrong. Additional hazards are identified by asking "what-if" type questions, such as, "what if the operation is not performed," "what if the operation is performed out of order," "what if the operation is performed too fast". Guideword deviations such as are used in HAZOP analysis (AIChE 1992) were also utilized to identify hazardous conditions. Guidewords are process parameters such as pressure, temperature, flow, concentration etc. Relevant deviations include "low/no," "high," "other than."

Column 4, Causes: This column identifies the causes for the failures/hazardous conditions postulated in Column 4. Identifying causes is important to identifying potential preventative controls for significant hazards. In many cases, multiple hardware of operational fault's are required to produce a hazardous event. This column identifies the sequence of hardware and operational faults required to produce the postulated hazardous event.

Column 5, Consequences: This column describes the potential consequences that could result from the postulated hazards identified in Column 4. The focus of this column is to identify effects to the glovebox confinement system and to facility workers. None of the hazards associated with opening cans containing Pu metal and with processing the metal were found to be energetic enough to compromise building confinement or to pose a threat to onsite workers outside the plant or to the offsite public.

Column 6, Existing Engineered Features: This column identifies the engineered features (hardware items) intended or available to prevent or mitigate the consequences identified in Column 6. The engineered features in this column are candidates for designation as Safety Significant items for hazards that pose a significant threat to the health of facility workers.

Column 7, Existing Administrative Controls: This column identifies the administrative requirements that reduce the likelihood of the hazardous event identified in Column 4, or that help minimize the potential consequences of the hazardous event. The controls listed in this column are candidates for operational safety requirement (OSR) designation for hazardous events with the potential to significantly harm facility workers.

Column 8, Consequence Rank: This column is used to capture a code designator for the level of consequence associated with a hazardous event. The consequence ranking is a "first cut," qualitative estimate of the safety severity of the consequences. An alphanumeric system has been used at the PFP to designate the severity of hazardous events. The system has the following "S" rankings characterizing safety consequences:

S0 No effect outside the glovebox confinement systems; negligible safety concerns for the facility worker.

S1 Potential industrial injury, low radiological or chemical exposure dose consequences to the facility worker. Such a hazard would be an operator injury where glovebox gloves are penetrated by the can punch causing worker injury and possible skin/wound contamination.

S1* Potential severe harm or potential death from industrial injury, radiological dose or chemical exposure to the facility worker. Hazards of this severity level warrant Safety Significant controls. Hazards at this severity level for the process examined in this analysis are typically those that result in significant pressurization or damage to the glovebox structure causing release of radiological material from the glovebox. All events with enough energy to cause a significant release of radiological material from the glovebox are assigned an S1* consequence rank. This is conservative as such events will not necessarily cause severe harm to facility workers.

S2 Potential significant radiological dose consequences or chemical exposure to onsite workers located outside the facility. No hazards postulated for processing Pu oxide were found to be energetic enough to compromise building confinement and lead to an S2 consequence.

S3 Potential significant radiological dose consequences or chemical exposure to the offsite population. No events were postulated with potential S3 consequences.

The engineered safety features and controls specific to the processing of plutonium oxide are not credited in assigning the above consequence rankings. This is to allow determination of whether the controls warrant Safety Significant designation.

The mitigative effects of features previously designated as Safety Significant or Safety Class in the PFP FSAR (WHC 1995) are credited in assigning the consequence rankings. For example, the glovebox structure E-4 ventilation system, and E-4 HEPA filters are credited with mitigating the effects of releases inside gloveboxes. This means that a spill of Pu oxide powder inside a glovebox (e.g., due to dumping the furnace boat after removal from the furnace) results in an S0 consequence ranking because the glovebox structure and E-4 ventilation system can be expected to prevent a significant exposure to facility workers. The effects of energetic events (such as flammable gas deflagration in a muffle furnace) on the glovebox structure, however, are assessed to determine if the hazardous event can compromise the Safety Significant confinement function provided by the glovebox structure and ventilation system. Similarly, the Safety Class Building 234-5Z structure and E-3 ventilation system are credited with protecting onsite workers and the offsite public outside the PFP from accidents that breach glovebox confinement.

Column 9, Frequency Ranking: The frequency ranking is a first cut, qualitative estimate of the likelihood of the hazardous event. The following ranking system is used.

F3 Events that are expected to occur one or more times during the lifetime of the facility, categorized as "anticipated" events. The frequency range associated with this category is 1E-02/yr to 0.1/yr.

F2 Events that could occur during the lifetime of the facility, but with low probability. Such events are categorized as "unlikely" and fall in the range of 1E-04/yr to 1E-02/yr.

F1 Events not expected to occur during the lifetime of the facility, categorized as "extremely unlikely." The frequency range associated with this category is 1E-06/yr to 1E-04/yr.

F0 Events categorized as "beyond extremely unlikely," with a frequency less than 1E-06/yr. Events in this category (such as meteor strike) are so unlikely they generally do not require special controls.

The frequency estimate, like the consequence ranking, is assigned taking no credit for active engineered features. The frequency ranges shown above

are based on the risk acceptance criteria for the onsite receptor from the PFP FSAR (WHC 1995).

Column 10, Comments: This column contains miscellaneous observations or clarifying comments for a given hazard. There are many hazards identified in the PHA that are adequately covered in the PFP FSAR (WHC 1995) or in other authorization basis documents (e.g., CSERs). The comments column is used to flag those hazards that are adequately addressed in other documentation.

9F.2.2 SCOPE OF THE PRELIMINARY HAZARDS ANALYSIS

The PHA covers the operations performed within the RMC line glove boxes, from seal-in of containers of Pu Oxide into Glovebox HC-21A to bag-out of the thermally stabilized plutonium oxide from Glovebox HC-18M. Within the RMC Line glove boxes, the Pu Oxide is handled, thermally stabilized, and placed in sealed containers. Transfer of containers between the vaults and RMC line and storage of containers in vaults (before and after thermal stabilization) is not covered in this PHA, as the hazards associated with these operations are adequately covered in the PFP FSAR (WHC 1995). The specific activities evaluated within this PHA are identified in Section 9F.3.

9F.3 PHA ORGANIZATION

The PHA table used in this analysis is provided in Table 9.F1. The PHA table is structured to ensure a systematic and thorough review of potential hazards. The thermal stabilization of plutonium oxide within the RMC line is broken down into logical sets of operations performed at specific locations. The breakdown of operational steps covered in the analysis were identified from verbal descriptions provided by the cognizant engineers, and other available information. The operational steps evaluated and documented in the PHA table (Table 9F.2) are identified with an alpha-numeric designator in rows that traverse the width of the table. The groups of operations performed in each Glovebox and evaluated in the PHA are listed below:

Glovebox HC-21A:

- Seal-in Pu oxide storage container into Glovebox HC-21A.
- Open outer cans and make empty cans into "non-containers".
- Weigh storage container (inner can and overpacks) and furnace boat (before and after filling) for accountability and operational requirements.
- Open innermost Pu oxide storage containers, sieve, and place material in furnace boat..
- Identify and remove contaminants from oxide in furnace boat.

Conveyer Glovebox HC-2:

- Transfer covered furnace boat from Glovebox HC-21A to Glovebox HC-21C.

- Transfer covered furnace boat from Glovebox HC-21C to Glovebox HC-18BS.

Glovebox HC-21C:

- Uncover furnace boat and thermally stabilize material in the muffle furnace in Glovebox HC-21C.

Glovebox HC-18BS:

- Transfer furnace boat from Glovebox HC-2 to Glovebox HC-18M (includes temporary storage of boat and canned stabilized material awaiting LOI awaiting LOI sample results in Glovebox HC-18BS).

Glovebox HC-18M:

- Sieve, grind (as necessary), sample, and can material in Glovebox HC-18M.

- Bag-out canned material from Glovebox HC-18M for transfer to storage vault.

As a part of the thermal stabilization process evaluation, the E-4 ventilation system that exhausts the glove boxes, the power supply to the RMC Line equipment, and the 26-inch-Hg vacuum system that exhausts the muffle furnaces in Glovebox HC-21C were included in the evaluation.

9F.4 HAZARDS EVALUATION RESULTS

9F.4.1 BINNING RESULTS

The PHA is a discovery tool. Many failures or hazardous conditions that are identified in the PHA lead to similar consequences and controls. It is useful to group similar hazardous events for further discussion and analysis. The failures/hazardous conditions identified in the 3rd column of the PHA table and the consequences identified in the 5th column of the PHA table can be used to define hazardous events. Events with similar phenomenology and consequences that challenge similar mitigative barriers or that require similar preventative controls can be logically grouped together.

Event bins were also given an Event Type designation in keeping with the designations used in the PFP FSAR Chapter 9 Analysis. Events bins that contained hazardous conditions that resulted in process upsets but posed no significant radiological or toxic chemical threat to the facility worker were assigned an Event Type designator of NA. Accident designator NA is not currently addressed in the PFP FSAR. Events bins having hazardous conditions representing only industrial hazards were also assigned this designation. Events bins with the potential for only minor consequence to the facility worker were assigned the designator AB. Events bins with the potential for onsite consequences or severe worker impact were assigned the designator AC. The Event Type designations are shown in parenthesis following the event bin description. If an Event bin contained hazardous conditions that met the criteria of more than one Event Type, the appropriate designator for each Event Type was assigned.

The hazardous conditions were grouped together into 18 Event bins. The bins are:

Contaminated Wound (**NA**)
Criticality (**AC**)
Dispersal of Pu Oxide Powder - Inside Glove Box (**AB**)
Dispersal of Pu Oxide Powder - Outside Glove Box (**AB**)
Dropped Container Outside Glove Box (**NA**)
External Events - Aircraft Crash, Facility Wide Power Loss, Range Fire (**AC**)
Flammable Gas Deflagration in Glove Box (**AC**)
Flammable Gas Deflagration in Waste Drum (**AB**)
Loss of Glove Box Confinement - Mechanical Breach (**AB**)
Loss of Glove Box Confinement - Ventilation Failure (**AC**)
Natural Phenomena - Seismic, Ashfall, High Wind (**AC**)
Occupational Hazards (**NA**)
Operational Upset (**NA**)
Pyrophoric Reaction in Furnace (**AB**)
Pyrophoric Reaction in Glove Box (AB - **AC**)
Radiation Protection (**NA**)
Rupture of Container in Storage Vault (AB - **AC**)
Uncontrolled Fire in Glove Box (**AC**)

Tables 9F.3 - 9F.20 present the hazardous conditions by bin category with hazardous conditions ordered by consequence and frequency.

9F.4.2 Natural Phenomena and External Events

There are three natural phenomena that are grouped under the Event bin Natural Phenomena. These are Seismic Event, Ash Fall, and High Wind. Each of these phenomena can cause multiple consequences. In the case of the High Wind and Ash Fall events, the PFP FSAR provides sufficient information to show that the effect of adding thermal stabilization of Plutonium Oxide in glovebox HC-21-C will not materially affect the consequences from these events. High Wind and Ash Fall effects are described in Chapter 3.0 of the PFP FSAR. Ash Fall represents a roof loading concern, abrasive concern for moving equipment, and an electrical concern because of the conductivity of the ash. High Wind represents a threat to the 234-5Z Building but not to an individual glovebox inside the building. Chapter 9.0 considers the effect of a wind-driven plank striking the 234-5Z Building and concludes that no significant consequences result. The seismic event is considered in detail in Chapter 9.0 of the PFP FSAR. The addition of thermal stabilization of plutonium oxide in glovebox HC-21-C does not represent a significant change in the quantity of dispersible material as compared to other processes that have been authorized in the past in this glovebox.

There are three phenomena grouped under the Event bin External Events. These are Facility Wide Loss of Power, Range Fire, and Aircraft Crash. Facility wide loss of power, and Range Fire result in essentially the same effect, loss of power to the 234-5Z (and therefore the thermal stabilization process in HC-21-C). Range fire causing a building fire is not considered credible because a wide area devoid of vegetation exists and is maintained around the facility (vegetation control specified in Chapter 3.0 of the FSAR). The addition of plutonium oxide thermal stabilization does result in a potential hazardous condition due to facility wide power loss. If plastic contaminants are present in a batch of plutonium oxide being thermally

stabilized and a facility wide power loss occurs, there is a potential for flammable gas to be generated that will not be swept out of the furnace by the ventilation system. If a sufficient quantity of flammable gas builds up and a return of power occurs there could be and ignition of the flammable gas that could result in significant pressurization of the glove box. The effects of loss of power on the thermal stabilization of plutonium oxide due to internal initiators is also addressed in the PHA. Chapter 9.0 of the PFP FSAR currently addresses Aircraft Crash and determined that the frequency of such an accident is less than 1E-6 per year when flight restrictions that prohibit helicopter operation in proximity to PFP are implemented. Therefore, no further consideration of the Aircraft Crash is required.

9F.4.3 CONSEQUENCE GROUPING

Tables 9F.21 through 9F.23 break down the hazardous events identified in the PHA into consequence groups. Table 9F.21 summarizes the S0 event groups developed from the PHA. Table 9F.22 summarizes the S1 hazardous event groups, and Table 9F.23 summarizes the S1* hazardous event groups. The hazardous event groups are described in the 2nd column of each table. The third column in each table describes the hazardous conditions/failures. The fourth column in each table describes the causes of the hazardous conditions, i.e., the specific sequences of hardware failures or procedural errors that produce the hazardous event. The line item numbers in these tables correspond to those used in the PHA table, demonstrating that every line item from the table is covered in at least one of the hazardous conditions in the three tables. Some hazardous conditions in the PHA table warranted placement in two different groups due to the potential to produce hazardous conditions with different phenomenology or with different levels of severity (depending on how many concurrent failures were assumed). These items have lower case alphabetical characters added to the PHA table item number to maintain the relationship with the PHA table data. The sixth and seventh columns in each of the tables present the controls (engineered features and administrative controls) identified in the PHA table that can be used to prevent or mitigate each of the identified hazardous event sequences. The last column shows the frequency assigned to the hazardous condition.

9F.4.3.1 S0 Events

The S0 hazardous events are those that pose no significant threat to the facility worker. Events in this category are shown in Table 9F.21 and can be summarized as follows:

- Dispersal of Pu Oxide Powder - Inside Glovebox
  - Release of plutonium oxide from pressurized can when it is opened.
  - Spill of unstabilized plutonium oxide resulting in increase of contamination level in glovebox and process stoppage to perform cleanup.
  - Spill or entrainment of stabilized plutonium oxide in glovebox air causing an increase in the contamination level of the glovebox.

- Dropped container outside glovebox
  - Pu storage container handling accident outside glovebox resulting in no release of radiological material.
- Natural Phenomena - High Wind (already addressed in PFP FSAR)
- Operational Upsets
  - Equipment failures or human errors resulting in programmatic delays but no safety consequence other than increased direct dose exposures to operators incurred in recovering from the event.
  - Release of radioactive particulate into the 26-inch-Hg vacuum system.
  - Pu fluoride powder processed causing corrosion damage to glove box HC-21C stabilization furnaces.

The specific event sequences, engineered features and administrative controls that minimize the likelihood or consequences of the S1 events are shown in Table 9F.22.

9F.4.3.2 S1 Events

S1 hazardous events are those that can physically injure workers or that can result in chemical or radiological exposures that would not be considered severe (e.g., not immediately threatening to the workers health). Events in this category are shown in Table 9F.22 and can be summarized as follows:

- Contaminated Wound
  - Injuries resulting in Pu oxide being introduced below the skin surface of a worker. Hazardous conditions include punctures, cuts, and abrasions.
- Dispersal of Pu Oxide Powder Outside Glove Box
  - Escape of contamination during waste bagout operations.
  - Releases from sample bottles or product cans after bagout from glove box HC-18M.
- Flammable Gas Deflagration In Waste Drum
  - Hydrogen generation from radiolysis in waste bags combined with spark source results in flammable gas deflagration in waste drum in satellite accumulation area.
- Loss of Glove Box Confinement Due To Mechanical Breach
  - Damage to confinement boundary due to overheating panels or glove box structures (not associated with general glovebox

fire). Associated with radiant heat from stabilization furnace operation. This event results in the potential for release of minor amounts of contamination. Credit is taken for the mitigating effects of the E-4 ventilation system which prevents significant amounts of radiological materials from escaping the glovebox.

- Events that result in holes in gloves, glove box structure, significant release of contamination during glove replacement, seal in, or bagout operations. These events do not result in significant inhalation uptake of radiological materials outside of the glovebox.

- Loss of Glove Box Confinement Due To Ventilation Failure

  - Stagnant conditions due to ventilation flow imbalances with no other failures of present.

- Natural Phenomena - Ash Fall (already considered in PFP FSAR)

- Natural Phenomena - Seismic Event

  - Seismic events that cause dispersal of plutonium oxide powder inside glove box. Magnitude insufficient to damage glove box confinement integrity.

- Occupational Hazards (general category represented by electrical shock concerns)

- Pyrophoric Reaction In Furnace

  - Hazardous conditions involving pyrophoric contaminants in the plutonium oxide that may result in hydrogen release and burn in glove box. Failure of the glove box confinement boundary not expected due to small quantities of pyrophoric material postulated to be present.

- Pyrophoric Reaction In Glove Box

  - Pyrophoric reaction and hydrogen burn when can is opened. This event is not expected to result in significant pressurization of the glove box.

- Radiation Protection (captures concerns of worker exposure due to can handling activities)

- Rupture of Container In Storage Vault

  - Canister ruptures that result from unreacted metal being sealed in storage canister that eventually oxidizes and increases material volume in canister sufficiently to result in can failure. This is assumed to be a low energy event that will not involve energetic expulsion of Pu oxide from can.

- Uncontrolled Fire In Glove Box

  - Combustibles present in glove box are ignited as a result of pyrophoric reactions in glove box. Size of fire is assumed to be limited for the S1 case.

The specific event sequences and the engineered features and administrative controls that minimize the likelihood or consequences of the S1 events are shown in Table 9F.22.

9F.4.3.3 S1* Events

The S1* hazardous events are those with the potential to cause severe physical injury, or radiological or chemical exposures above acceptance limits to facility workers. The S1* hazardous events identified from the PHA table are shown in Table 9F.23 and can be summarized as follows:

- Criticality

  - Criticality in glovebox caused by exceeding Pu mass, spacing, or moderator limits in the glove boxes. This is a S1* hazard due to the potential for lethal worker exposures to ionizing radiation.

- Flammable Gas Deflagration In Glove Box

  - Flammable gas deflagrations in glovebox causing glovebox failure resulting from hydrogenous material contaminates in Pu oxide powder producing flammable gas during thermal stabilization.

  - Flammable gas deflagrations in glovebox causing glovebox failure resulting from hydrogen burn when containers are opened and built-up hydrogen is released and ignited.

- Loss of Glove Box Confinement Due To Mechanical Breach

  - Loss of glovebox confinement resulting from panel failure combined with inadvertent fire suppression system actuation.

- Loss of Glove Box Confinement Due To Ventilation Failure

  - Significant pressurization of glove box due to ventilation flow loss or imbalance. This event assumes that significant quantities of material escape from the glove box and result in large uptake by the operations personnel that are present.

  - Failure of the ventilation system allows temperature increases in the glove box that result in significant failure of the glove box structure.

- Natural Phenomena - Seismic Event

  - Failure of glovebox confinement due to seismic event. This is an S1* hazard due to the potential for large quantities of dispersable material to be introduced into the building atmosphere where workers can acquire large inhalation doses.

- Pyrophoric Reaction In Glove Box

  - As material is poured into the furnace boat a pyrophoric reaction occurs that results in significant pressurization of the glove box.

- Rupture of Container In Storage Vault

  - Rupture of container in storage vault due to over pressurization caused by inadequate stabilization of material. This is an S1* hazard due to the potential for large inhalation doses to workers entering the storage vaults after a canister rupture.

- Uncontrolled Fire In Glove Box

  - Uncontrolled fire in glovebox resulting in failure of the glovebox confinement boundary and release of radiological material from the glovebox.

- External Event - Aircraft Crash (Already addressed in PFP FSAR)

- External Event - Facility Wide Loss of Power (Currently addressed in the PFP FSAR with the following exception)

  - If plastic contaminants are present in a batch of plutonium oxide being thermally stabilized and a facility wide power loss occurs, there is a potential for flammable gas to be generated that will not be swept out of the furnace by the ventilation system. If a sufficient quantity of flammable gas builds up and a return of power occurs there could be and ignition of the flammable gas that could result in significant pressurization of the glove box.

- External Event - Range Fire (Currently addressed in PFP FSAR with the following exception)

  - Range fire could be an initiator of a facility wide loss of power. If plastic contaminants are present in a batch of plutonium oxide being thermally stabilized and a facility wide power loss occurs, there is a potential for flammable gas to be generated that will not be swept out of the furnace by the ventilation system. If a sufficient quantity of flammable gas builds up and a return of power occurs there could be and ignition of the flammable gas that could result in significant pressurization of the glove box.

The above S1* event categories warrant analysis as accidents due to their potential health threat to facility workers. Each of the S1* event categories is evaluated as an accident in Chapter 9 of the PFP FSAR.

9F.5 ENVIRONMENTAL PROTECTION

The facility features, such as a ventilation system with multiple stages of HEPA filtration that maintains a negative pressure relative to the atmosphere outside of the 234-5Z facility, protects the facility worker as well as serving to prevent and mitigate environmental releases of hazardous material. Under stagnant ventilation conditions the facility structure itself provides confinement of radioactive materials, limiting release to the environment. These features are listed in the PHA table (Table 9F.2) in the engineered and administrative safety features columns. These features are valid controls for environmental protection because in protecting the worker or public the environment is also protected. No release scenarios were identified where a release occurred that did not impact the worker but did impact the environment. In addition, there are institutional programs of environmental monitoring which help discover unacceptable discharges.

A. General Glove box Hazards									
A.1.01	Electrical Equipment in glove box .	Fire in glove box caused by electrical short	Failure to properly inspect power cords or failure to identify frayed cords results in condition that leads to an electrical short that ignites combustibles in the glovebox Failure to control combustibles in glove box allows significant fire that damages glove box confinement.	Burn through of gloves seal out bags resulting in breach of containment Ignition of Polymethyl Methacrylate or Polycarbonate glove box panels and spread of fire to other gloveboxes Release of soot, hot embers, and water vapor to the E-3 and E-4 ventilation systems. Pluggage or failure of glovebox and E-4 filterbox HEPA filters. Potential pluggage of E-3 room prefilters or E-3 filterbox HEPA filters, with spread of contamination to clean portions of the plant. Worker uptake of airborne Pu	Glovebox dry fire suppression system Glovebox (E-4) ventilation system maintains negative glovebox pressure and confines release until several gloves or bag ports are burned out or window panels are breached, giving operators time to manually extinguish fire. Long length of E-3/E-4 ductwork between RMC line and filter room filters and dilution airflow from other E-3/E-4 areas of the plant are expected to cool offgasses from the fire enough to prevent heat damage to, or plugging of the E-3/E-4 filter-room HEPA filters. E-3/E-4 filter-room HEPA filters mitigate release to the environment CAMS alert workers to presence of airborne contamination.	MgO sand available in gloveboxes for extinguishing small fires Bayonet fire extinguisher is near glovebox for manually extinguishing fire. Housekeeping practices minimize combustible loading in glovebox. Senior supervisory watch OSHA inspections can identify frayed cords. Electrical safety program of cord inspection reduces the likelihood of the presence of frayed cords. Institutional occupational safety program of requirements and inspections reduces the likelihood of the presence of frayed cords. Hanford fire department located within a few miles of PFP	S1*	F3	Polymethyl Methacrylate panels are easier to ignite and spread flames more readily than Polycarbonate panels. Polymethyl Methacrylate panels have been replaced by Polycarbonate panels in Gloveboxes HC-21A and HC-21C (verify this). Several kg of burning plastic can generate enough radiant heat to ignite Polycarbonate panels. See RMC line fire accident analysis in Section 9.2.2 of the PFP FSAR.
A.1.02	Electrical Equipment in glovebox	Electrical shock to operator	Cord frayed in the glovebox Frayed cord contacts glovebox frame while operators body or leg is in contact with the glovebox frame.	Operator injury	None	Senior supervisory watch OSHA inspections can identify frayed cords. Electrical safety program of cord inspection reduces the likelihood of the presence of frayed cords. Institutional occupational safety program of requirements and inspections reduces the likelihood of the presence of frayed cords.	S1	F3	Commonly accepted industrial hazard. The likelihood of electrical shock injury is reduced by the presence of rubber mats that are placed on floor grating to protect shoe covers Hypalon glovebox gloves may provide some protection

A. General Glove box Hazards									
B.1.03	Seal container into Glovebox HC-21A through bag in port or sphincter seal	Glovebox loss of confinement during seal in.	Sphincter seal failure Ice cream carton or can in sphincter seal inadvertently pushed into glovebox without can or carton behind it results in open sphincter seal. Seal in bag torn or pulled off port during seal in (also applies to change out of port bags) (see item A.1.04). Pressurized glovebox during seal in (see item A.3.01)	Minor release of contamination from the glovebox into the room. Potential worker uptake of Pu.	Glovebox ventilation system maintains negative pressure and confinement velocity across failed sphincter seal or port bag which minimizes the potential contamination spread. Backup glovebox (E-4) ventilation system maintains confinement on loss of primary ventilation. Room CAMs alert operators to presence of airborne contamination. PRV on supply restricts flow rate on low glovebox DP. Emergency exhaust valves open on low glovebox negative. Sphincter seal design prevents release unless no can or carton in seal.	Operator training and procedures	S1	F3	S1 ranking assumes minor release of contamination from glovebox. Hazards associated with seal in of containers into gloveboxes is covered in the PFP FSAR. This accident is not unique to seal in of containers containing PuO_2. Room CAMs are designated safety significant in the PFP FSAR.
B.2.01	Open outer cans and make empty cans into "Non containers"	Flammable gas (i.e. H_2) release and burn when overpack can opened.	Radiolysis of plastic bag around slip lid can and organic can seal during storage in vault. Ignition due to mechanical spark from can opener, static release from ejected powders, or electrical spark.	Potential deflagration involving H_2 released from can causing pressurization of glovebox, potential failure of port bags or gloves and release of Pu into the room air. Inhalation uptake of Pu by workers.	Glovebox and E-4 ventilation system confine release unless deflagration large enough to fail port bags or gloves. E-3 ventilation system filters mitigate release to the environment. Room CAMs alert workers to presence of airborne radiological material	Operators verify glovebox DP and filter DP before opening cans. Pressurized cans containing a dangerous amount of hydrogen are easily identified due to bulging.	S1*	F2	Recommend bulged containers not be opened in air. "Ruler test" can be used to eliminate highly pressurized cans. Catastrophic failure of glovebox structure not expected due to limited quantity of H_2 possible in the can. Many pressurized cans have been opened at PFP without a resultant deflagration. Ignition of hydrogen released from the can by the can opener or static discharge is unlikely.

Table 9F.2
PHA - Thermal Stabilization of PuO_2

Item #	Process Step/ Equipment	Failure/ Hazardous Condition	Causes	Consequences	Existing Engineered Features	Existing Administrative Controls	Cons Rank	Freq Rank	Comments
A. General Glove box Hazards									
B.2.02	Open outer cans and make empty cans into "Non containers"	Operator injury and damage to glovebox glove compromising glovebox confinement integrity.	Operator punches through glove with can opener or cuts glove on sharp edges of the can or can lid	Operator injury with contamination of wound Small hole in glovebox confinement boundary Small contamination release from glovebox as hands withdrawn from glovebox gloves	Glovebox (E-4) ventilation system maintains negative pressure and confinement velocity across small holes preventing release of Pu to room.	Leather gloves are used over glovebox gloves when opening cans Operators are surveyed for contamination every 15 minutes while working in glovebox gloves. Self survey on exit from radiological area to detect skin contamination HPT deconning of skin or injury Surgical excision of contaminated tissue. Leather gloves used when crushing or folding cans	S1	F3	
B.2.03	Open outer cans and make empty cans into "Non containers"	Outer cans not properly made into non-container	Can not crushed and folded, can with bottom removed set upright instead of on its side, can not turned upside down.	CPS infraction Margin of criticality safety reduced	None	Operator training and procedures Glovebox CPS posting (tells operator maximum open container volume to unit mass ratio)	S0	F3	
B.2.04	Open outer cans and make empty cans into "Non containers"	Operator injury and damage to glovebox glove compromising glovebox confinement integrity.	Operator suffers injury and ruptures glove while crushing empty can with hammer	Operator injury with contamination of wound Small hole in glovebox confinement boundary leading to contamination release from glovebox.	Glovebox ventilation system maintains confinement velocity across hole in glove	Operator training and procedures Operators are surveyed for contamination every 15 minutes while working in glovebox gloves. Self survey on exit from radiological area to detect skin contamination HPT deconning of skin or injury Leather gloves used when crushing or folding cans	S1	F3	

Table 9F.2
PHA - Thermal Stabilization of PuO_2

Item #	Process Step/ Equipment	Failure/ Hazardous Condition	Causes	Consequences	Existing Engineered Features	Existing Administrative Controls	Cons Rank	Freq Rank	Comments
A. General Glove box Hazards									
B.3.01	Weigh storage container (inner and overpacks) and furnace boat (before and after filling) for Pu accountability and operational requirements	No safety hazard identified for this step.	--	--	--	--	--	--	Pu content of item is set by Accountability prior to placing container in vault. Scale can't necessarily detect overbatch of Pu or potential criticality hazard since it only measures gross weight.
B.4.01	Open innermost can (can containing PuO_2)	Operator injury and damage to glovebox glove compromising glovebox confinement integrity.	Worker penetrates glove while opening sealed can with can opener, taped slip lid can with scissors, while handling can or lid.	Operator injury with contamination of wound Small hole in glovebox confinement boundary Small contamination release from glovebox	Glovebox (E-4) ventilation system maintains negative pressure and confinement velocity across small holes preventing release of Pu to room.	Leather gloves use when opening cans Operators are surveyed for contamination every 15 minutes while working in glovebox gloves. Self survey on exit from radiological area to detect skin contamination HPT deconning of skin or injury Leather gloves used when crushing or folding cans	S1	F3	
B.4.02	Open innermost can (can containing PuO_2)	Hydrogen gas release and burn when can opened	Radiolytic degradation of plastic contaminant, brush bristles, tool handle, bottle caps, etc. in oxide during storage generates hydrogen in can. Hydrogen ignited during release from can due to static or electrical discharge High water content in oxide (above 1%) due to prior inadequate stabilization results in can pressurization due to hydrogen buildup from reaction of the water with PuO_2 and radiolysis of the water.	Potential deflagration involving H_2 released from can causing pressurization of glovebox, potential failure of port bags or gloves and release of Pu into the room air. Inhalation uptake of Pu by workers.	Glovebox and E-4 ventilation system confine release unless deflagration large enough to fail port bags or gloves. E-3 ventilation system filters mitigate release to the environment. Room CAMs alert workers to presence of airborne radiological material	Operators verify glovebox DP and filter DP before opening cans. Pressurized cans containing a dangerous amount of hydrogen are easily identified due to bulging.	S1*	F2	Recommend bulged containers not be opened in air. "Ruler test" can be used to eliminate highly pressurized cans. Catastrophic failure of glovebox structure not expected due to limited quantity of H2 possible in the can. Many pressurized cans have been opened at PFP, all without a resultant deflagration. Ignition of hydrogen released from the can by the can opener or static discharge is unlikely.

Table 9F.2
PHA - Thermal Stabilization of PuO_2

Item #	Process Step/ Equipment	Failure/ Hazardous Condition	Causes	Consequences	Existing Engineered Features	Existing Administrative Controls	Cons Rank	Freq Rank	Comments
A. General Glove box Hazards									
B.4.03	Open innermost can (can containing PuO_2)	PuO_2 particulate release from pressurized can when it is opened	Can temperature higher than when canned causes pressurized can Alpha decay causing pressure buildup (Helium usually diffuses out of can) High water content in oxide (above 1%) due to prior inadequate stabilization results in can pressurization due to hydrogen buildup from reaction of the water with PuO_2 and radiolysis of the water.	Pu particulate release inside glovebox Increased dose rate to workers near glovebox from spilled PuO_2.	E-4 ventilation system and glovebox confines release E-4 ventilation system HEPA filters mitigate release to the environment through the facility exhaust stack.	Housekeeping; spilled material is swept up and placed in cans and sealed out of glovebox. Institutional radiation protection program: Radiological control technicians set glovebox dose rates to limit operator direct dose exposure. Operators verify glovebox DP and filter DP during pre-job walkdown which ensures ventilation is operating correctly.	S0	F3	
B.4.04	Open innermost can (can containing PuO_2)	Flammable gases (alkanes, H_2, etc) from organic in container released and ignited when can opened (can pressurized)	Container containing organic (e.g., sludge, floor sweeps) inadvertently sealed into glovebox and opened. Wrong container selected due to inaccurate labeling or human error. Flammable gases generated due to radiolytic decay of organic material (e.g., sludge) in the container. Ignition due to mechanical or electrical spark, or static discharge.	Pressurization of glovebox Potential damage to glovebox confinement boundary Pu release into room and worker inhalation uptake.	Glovebox and E-4 ventilation system confine release unless deflagration large enough to fail port bags or gloves. E-3 ventilation system filters mitigate release to the environment. Room CAMs alert workers to presence of airborne radiological material.	Operators verify glovebox DP and filter DP before opening cans. Pressurized cans containing a dangerous amount of flammable are easily identified due to bulging. Blend plan identifies appropriate cans to stabilize in PuO_2 campaign. Labeling of containers Operator training and procedures Shift technical advisor sign off for material acceptability required by procedure. Sludges which may contain organic are stored in vented polyjars which are easily distinguishable from cans containing PuO_2.	S1*	F2	Recommend bulged containers not be opened in air. "Ruler test" can be used to eliminate highly pressurized cans. Catastrophic failure of glovebox structure not expected due to limited quantity of flammable gas possible in the can. Many pressurized cans have been opened at PFP, all without a resultant deflagration. Ignition of flammable gas released from the can by the canopener or static discharge is unlikely.

Table 9F.2
PHA - Thermal Stabilization of PuO_2

Item #	Process Step/ Equipment	Failure/ Hazardous Condition	Causes	Consequences	Existing Engineered Features	Existing Administrative Controls	Cons Rank	Freq Rank	Comments
A. General Glove box Hazards									
B.4.05	Open innermost can (can containing PuO_2)	Pyrophoric reaction and hydrogen burn when can opened	PuH_2 hydride contaminant in can Pu metal may be in can due to incomplete prior stabilization. PuH_2 forms from metal if plastic or organic contaminants are also present in can. Or if hydrogen from degradation of the plastic bag outside the can diffuses into the can. Can under vacuum due to catalyzed formation of oxides and nitrides in the container. When can is opened air is sucked in which reacts with the hydrided material. Hyride reactions releases heat and hydrogen gas which is ignited on exiting the can.	If sufficient hydride contamination present, slight pressurization of the glovebox could occur. Potential burn through of gloves and operator injury due to contact with hot embers. Embers burn through PVC ports Minor contamination spread from glovebox if gloves or port bags damaged. Potential ignition of combustibles in glovebox producing glovebox fire.	Glovebox (E-4) ventilation system maintains confinement if damage limited to holes in gloves E-3 ventilation system filters release to environment if glovebox confinement lost Rooms CAMs alert worker to airborne contamination Glovebox dry fire suppression system for putting out glovebox fire Glovebox high temperature alarm	MgO sand for putting out small fire Bayonet fire extinguishers available near glovebox for putting out small fire Operator training and procedures Only material passing previous LOI test will be processed through the furnaces during this campaign. Blend plan identifies which containers are acceptable for processing. Container labeling and material processing records identify contents of containers. Shift technical advisor sign off for material acceptability required by procedure. Combustible loading in glovebox is controlled by procedure.	S1 S1*	F3 F2	S1/F3 for sparking reaction and small hydrogen flash with maximum consequence being burn through of glove or port bag S1*/F2 for ignition of significant combustibles in the glovebox causing glovebox fire. Evaluate use of Pu net wt% to detect presence of Pu hydride in can before opening. Cans with relatively large quantities of hydride will be "panelled," making them easy to identify and not open in this campaign.

Table 9F.2
PHA - Thermal Stabilization of PuO_2

Item #	Process Step/ Equipment	Failure/ Hazardous Condition	Causes	Consequences	Existing Engineered Features	Existing Administrative Controls	Cons Rank	Freq Rank	Comments
A. General Glove box Hazards									
B.5.01	Transfer contents to furnace boat	Pyrophoric reaction as material poured through air	Pu metal, PuH_2, Uranium hydride; Pu_2O_3 contaminant in can Pu or U metal may be in can due to incomplete prior stabilization. PuH_2, UH_3 forms from metal if plastic or organic contaminants are also present in. Or if hydrogen from degradation of the plastic bag outside the can diffuses into the can.	Sparks potentially initiating a glovebox fire. Hot embers entrained in air may burn hole in glovebox HEPA filters. Dispersal of Pu in glovebox Potential burn through of gloves and operator injury due to contact with hot embers. Burn through of PVC port bags. Minor contamination spread from glovebox if gloves or port bags damaged Potential ignition of combustibles in glovebox producing glovebox fire If sufficient hydride contamination present, slight pressurization of the glovebox could occur	Glovebox (E-4) ventilation system maintains confinement if damage limited to holes in gloves E-3 ventilation system filters release to environment if glovebox confinement lost Rooms CAMs alert worker to airborne contamination Glovebox dry fire suppression system for putting out glovebox fire Glovebox high temperature alarm	MgO sand for putting out small fire Bayonet fire extinguishers available near glovebox for putting out small fire Operator training and procedures Only material passing previous LOI test will be processed through the furnaces during this campaign. Blend plan identifies which containers are acceptable for processing. Container labeling and material processing records identify contents of containers. Cans with relatively large quantities of hydride will be "paneled" and easily identified. Combustible loading in glovebox is controlled by procedure	S1 S1*	F3 F2	Evaluate use of Pu net wt% to detect presence of Pu or U metal in can before opening. S1/F3 for sparking reactions with maximum consequence being burn through of glove or port bag. S1*/F2 for ignition of significant combustibles in the glovebox.
B.5.02	Transfer contents to furnace boat	Can/boat contents spilled to glovebox floor	Human error	Violation of criticality prevention specification limit regarding depth of powder allowed on glovebox floor Increased operator exposures during cleanup of spill	E-4 ventilation system and glovebox confinement release	Housekeeping Operator training and procedures	S0	F3	Operational upset only Significant dose to operator in cleaning up spill not expected.

Table 9F.2
PHA - Thermal Stabilization of PuO_2

Item #	Process Step/ Equipment	Failure/ Hazardous Condition	Causes	Consequences	Existing Engineered Features	Existing Administrative Controls	Cons Rank	Freq Rank	Comments
A. General Glove box Hazards									
B.5.03	Transfer contents to furnace boat	Material other than Pu oxide poured into furnace boat (e.g., metal button, sludge or glovebox floor sweeps) resulting in process upset.	Wrong can opened due to mislabeling or human error.	Process upset. Material would have to be canned up and bagged out of the glovebox for later processing. Potential adverse reaction in furnace in Glovebox HC-21C if wrong material not noticed by operator.	--	Labeling and paperwork associated with each container identify contents making it unlikely for wrong material to be processed. Operator training and procedures.	S0	F2	X-ray or Pu mass ratio information could be used to provide added assurance against processing materials other than Pu oxide. Sludges are stored in polyjars in Glovebox HA-23S, not in the vaults with the Pu oxide. Highly unlikely that container of sludge would get mixed up with container of oxide. Glovebox floor sweeps are stored in gloveboxes, not in the vaults with the Pu oxide, making selection of can with floor sweeps very unlikely. H/X ratio on sludges will indicate high organic loading. Hazards associated with inadvertently processing Pu fluoride are covered in this PHA since it may be difficult to visually tell the difference between fluoride and oxide through the yellowed glovebox windows (see items B.1.02 and D.3.10).

Table 9F.2
PHA - Thermal Stabilization of PuO_2

Item #	Process Step/ Equipment	Failure/ Hazardous Condition	Causes	Consequences	Existing Engineered Features	Existing Administrative Controls	Cons Rank	Freq Rank	Comments
A. General Glove box Hazards									
B.6.01	Identify and remove contaminants from oxide in furnace boat	Contaminants not identified or removed from oxide result in reaction hazards in Glovebox HC-21C furnaces. Contaminants can include unburned metal pieces from prior stabilization run, metal hydrides, and plastics including: tool handles, brush bristles, PVC or polyethylene bag fragments, polycarbonate pieces, etc.	Human error; step not performed correctly Contaminants not readily identifiable due to color, size, etc. Poor visibility through glovebox windows.	Pyrophoric reaction in furnace in Glovebox HC-21A. See item D.3.08. Fires or deflagrations of flammables the furnaces in Glovebox HC-21C. See item D.3.07.	See items D.3.07 and D.3.08 for engineered features to mitigate reactions in the HC-21C furnaces.	Previous LOI testing results provide confidence that significant quantities of plastic contaminant are not in product to be stabilized in this campaign. Procedures with sign off by Shift Technical Advisor.	S1* S1*	F2 F2	S1*/F2 for pyrophoric reactions in furnace. S1*/F2 for flammable gas deflagration in furnace resulting from excessive plastic contaminant in oxide feed to furnace.

Table 9F.2

Item #	Process Step/ Equipment	Failure/ Hazardous Condition	Causes	Consequences	Existing Engineered Features	Existing Administrative Controls	Cons Rank	Freq Rank	Comments
A. General Glove box Hazards									
B.7.01	Bag out waste (crushed cans, tape, plastic); replace port bag.	Breach in glovebox confinement boundary during waste bagout or glove change.	Sharp object punctures bag Bag not properly horsetailed or taped Bag inadvertently pulled off port Original or replacement bag glove tears Bungee chord used to hold replacement bag slips or fails while removing inner (original) bag Replacement glove inadvertently pull off lip of port Bag/glove pinched when tightening port ring Replacement bag/glove has undetected hole in it	Spread of contamination to room, external contamination of workers, and potential inhalation uptake by workers	Glovebox (E-4) ventilation system maintains glovebox negative pressure and confinement velocity across small holes; minimizes potential spread of contamination from glovebox Glovebox port designed to minimize likelihood of loss of confinement during bag changes (notches, ridges to facilitate, 2 bags or gloves)	Workers on mask during bag out of waste, bag/glove changes Room put on ARA status during bagouts, bag changes, glove changes. Operator certification.	S1	F3	
B.7.02	Bag out waste (crushed cans, tape, plastic); replace port bag.	Spread of contamination from waste bag	Waste bag squeezed causing release of radiological material through taped vent Isolated transport container (ITC) dropped during handling causing bag to vent or rupture	Contamination of workers and potential uptake of radiological material	E-3 ventilation system filters release to environment. Room CAMs alert workers to airborne contamination.	Operator training and procedures Waste bags are put in Isolated transport container (ITC) immediately after applying second bag. ITCs have lids to minimize spread of release from pail. Radiological control program. Survey of workers with alpha poppy probes to detect skin contamination. Worker decontamination by RCT if necessary.	S1	F3	

Table 9F.2
PHA - Thermal Stabilization of PuO_2

Item #	Process Step/ Equipment	Failure/ Hazardous Condition	Causes	Consequences	Existing Engineered Features	Existing Administrative Controls	Cons Rank	Freq Rank	Comments
A. General Glove box Hazards									
B.7.03	Bag out waste (crushed cans, tape, plastic); replace port bag.	Hydrogen deflagration inside waste drum in satellite accumulation area.	Hydrogen generation from radiolysis in waste bags in waste drum. Ignition caused by spark generated while moving drum.	Pressurization of drum, drum damage and release of radiological material from waste drum in satellite accumulation area (Room 166) Potential worker injury	Waste drum is vented through a filter to prevent hydrogen accumulation Room CAMs alert workers of airborne contamination in room 166 Room 166 ventilated by the E-3 system which confines and filters any release from waste drum.	Drum seal is verified. Periodic surveillance of rooms to detect bulging drums.	S1	F2	S1 ranking instead of S1* due to small quantity of Pu in drum. This hazard is not unique to the thermal stabilization process as it applies to drums containing bagged out waste from all gloveboxes. Hazards associated with drum storage are covered in the PFP FSAR. The Pu content of the bagged waste is so low that significant pressurization of a drum is not expected during its storage life at PFP even if vent plugs.

Table 9F.2
PHA - Thermal Stabilization of PuO_2

Item #	Process Step/ Equipment	Failure/ Hazardous Condition	Causes	Consequences	Existing Engineered Features	Existing Administrative Controls	Cons Rank	Freq Rank	Comments
A. General Glove box Hazards									
D. Activities in Glovebox HC-21C									
D.1.01	Take boat out of boat house, adjust furnace hearth, and place boat in furnace	Spill/dispersal of Pu oxide powder in glovebox	Furnace boat spilled while loading into furnace	Added dose to workers in recovering from spill. Increased direct dose to workers working near glovebox due to increase in contamination level of glovebox.	Glovebox confinement boundary and E-4 ventilation system confine release. E-4 HEPA filters mitigate release to the environment through the 291-Z exhaust stack.	Housekeeping practices: spilled material is swept up, placed in cans, and sealed out of glovebox to minimize direct dose to workers. Institutional radiation protection program: radiological control technicians set glovebox dose rates to limit worker direct dose exposure. Operators verify glovebox DP and filter DP during pre-job walkdown which ensures the E-4 ventilation system is operating properly before initiating operations. Boat is transferred in a "boat cover" which limits the potential for Pu oxide dispersal should the boat tip over on the conveyor.	S0	F3	
D.2.01	Prepare for furnace operation, includes: - close furnace door - adjust offgas (vacuum) flowrate - check ceramic offgas filter DP - pull gloves out of glovebox and secure with bungee cords - remove combustibles from glovebox	Operator injury/glove damage	Glove pinched in door when closed or glove punctured by sharp object.	Operator injury with contamination of wound Small hole in glovebox confinement boundary leading to contamination release from glovebox.	Glovebox ventilation system maintains confinement velocity across hole in glove	Operator training and procedures Operators are surveyed for contamination every 15 minutes while working in glovebox gloves. Self survey on exit from radiological area to detect skin contamination HPT deconning of skin or injury Leather gloves used when crushing or folding cans	S1	F3	

Table 9F.2
PHA - Thermal Stabilization of PuO_2

Item #	Process Step/ Equipment	Failure/ Hazardous Condition	Causes	Consequences	Existing Engineered Features	Existing Administrative Controls	Cons Rank	Freq Rank	Comments
A. General Glove box Hazards									
D.2.02	Prepare for furnace operation, includes: - close furnace door - adjust offgas (vacuum) flowrate - check ceramic offgas filter DP - pull gloves out of glovebox and secure with bungee cords - remove combustibles from glovebox	Breach in glovebox confinement boundary during bagout of combustibles or while withdrawing gloves from glovebox.	Sharp object punctures port bag while bagging out combustibles or while changing bag. Bag not properly horsetailed or taped after removing combustibles from glovebox. Bag inadvertently pulled off port during bagout of combustibles. Glove tears while being pulled out of the glovebox to prevent contact with hot furnace.	Spread of contamination to room, external contamination of workers, and potential inhalation uptake by workers	Glovebox (E-4) ventilation system maintains glovebox negative pressure and confinement velocity across small holes; minimizes potential spread of contamination from glovebox Glovebox port designed to minimize likelihood of loss of confinement during bag changes (notches, ridges to facilitate, 2 bags or gloves)	Workers on mask during bag out of waste, bag/glove changes Room put on ARA status during bagouts, bag changes, glove changes. Operator certification.	S1	F3	
D.2.03	Prepare for furnace operation, includes: - close furnace door - adjust offgas (vacuum) flowrate - check ceramic offgas filter DP - pull gloves out of glovebox and secure with bungee cords - remove combustibles from glovebox	Gloves melted by contact with furnace compromising glovebox confinement.	Gloves not withdrawn from glovebox before starting furnace; gloves contact hot surface of furnace and melts. Gloves not secured properly with bungee cords after being pulled out of the glovebox; negative pressure causes gloves to be pulled into glovebox contacting hot spot on furnace.	Burned out glove allows contamination to spread from glovebox; potential uptake by workers. Operator burned while trying to pull glove back from furnace.	Glovebox (E-4) ventilation system maintains negative pressure in glovebox and prevents contamination spread unless several gloves are lost. Emergency exhaust valves on RMC line opens up on low glovebox vacuum. Fire brick insulates outer surfaces of furnace from the intense heat produced in the furnace. Only limited areas around the door of the furnace are hot enough to melt or burn gloves. Room CAMs alert workers to presence of airborne contamination. E-3 ventilation system filters any release from Zone 3 area to the environment.	Operator training and procedures. Gloves are pulled out of glovebox and secured with bungee cords before operating furnaces.	S1	F3	Hypalon gloves are expected to melt not burn on contact with hot surface of furnace.

Table 9F.2
PHA - Thermal Stabilization of PuO_2

Item #	Process Step/ Equipment	Failure/ Hazardous Condition	Causes	Consequences	Existing Engineered Features	Existing Administrative Controls	Cons Rank	Freq Rank	Comments
A. General Glove box Hazards									
D.2.04	Prepare for furnace operation, includes: - close furnace door - adjust offgas (vacuum) flowrate - check ceramic offgas filter DP - pull gloves out of glovebox and secure with bungee cords - remove combustibles from glovebox	Fire in glovebox compromises glovebox confinement.	Combustibles not controlled in glovebox come in contact with hot surface of furnace while it is operating. Combustible loading allows fire to spread. Port bag comes un-horsetailed gets sucked in and contacts hot surface of furnace.	Potential burn through of gloves or port bags, softening or ignition of glovebox windows leading to spread of Pu from compromised glovebox confinement boundary.	Glovebox (E-4) ventilation system maintains negative pressure in glovebox and prevents contamination spread unless several gloves or port bags are lost. Emergency exhaust valves on RMC line opens up on low glovebox vacuum. Fire brick insulates outer surfaces of furnace from the intense heat produced in the furnace. Only limited areas around the door of the furnace are hot enough to ignite combustibles. Room CAMs alert workers to presence of airborne contamination. E-3 ventilation system filters any release from Zone 3 area to the environment.	Operator training and procedures. Combustible loading in glovebox is minimized by procedure.	S1*	F2	
D.3.01	Set furnace controller, ramp up furnace temperature and stabilize oxide for 2 hours at > 950 C. (Temperature controller upsets)	Temperature ramped up too fast (temperature controller fails high)	Controller failure. Programmer error. Relay contact fails closed.	Burn out of furnace coils leading to shutdown of process. No hazard found for heating oxide too fast.	Furnace temperature controller and furnace thermocouples: Controller shuts off furnace if program temperature and furnace temperature differ by more than 200 C. Controller limits maximum current to 17 amps which prevents coil burnout. Temperature alarm switch (TAS) shuts off power to furnace if temperature exceeds 1050 C. Temperature deviation alarm provides indication of furnace temperature treater than 20 degrees from controller setpoint at any given time.	Operator training and procedures. Calibration of controller.	S0	F3	

Table 9F.2
PHA - Thermal Stabilization of PuO_2

Item #	Process Step/ Equipment	Failure/ Hazardous Condition	Causes	Consequences	Existing Engineered Features	Existing Administrative Controls	Cons Rank	Freq Rank	Comments
A. General Glove box Hazards									
D.3.02	Set furnace controller, ramp up furnace temperature and stabilize oxide for 2 hours at > 950 C. (Temperature controller upsets)	Inadequate stabilization of material leads to rupture of container in storage vault.	Failure of furnace heating element. Loss of power during stabilization. Temperature controller failure (temperature not held high enough for required 2 h). Power shut off early by operator.	Rupture of container sometime after it is place in storage vault if furnace upset not detected and LOI test fails to determine high moisture content. PuO_2 reacts with water to form a binary oxide and hydrogen gas which overpressurizes the container. Potential worker inhalation hazard upon entering vault.	Vault ventilation system and HEPA filters mitigate release to the environment. Pedestals in vault are instrumented to detect bulging cans. CAMs in vault alert workers to airborne contamination. Thermocouples monitor furnace temperature. Temperature is recorded as a function of time using a chart recorder. The chart recorder readings reveal furnace upsets that could result in moisture not being adequately driven off the oxide product. Temperature deviation alarm provides indication of furnace temperature treater than 20 degrees from controller setpoint at any given time.	Operator training and procedures. Radiological control program: Routine sampling of vault air. Blend plan identifies material processed in this campaign to be previously stabilized oxide material, minimizing likelihood of material containing excess moisture from being recanned even if undetected furnace upset occurs. Furnace chart recorder readings are used to verity proper furnace operation and soak time. LOI testing is performed on representative sample of material after stabilization in the furnace. Material found to lose more than 0.5 wt% in LOI testing will be run back through the furnace.	S1*	F2	
D.3.03	(Furnace vacuum system upsets)	Reduced air flow or no air flow during stabilization of material in furnace.	Plugged ceramic filter. Vacuum system valved out or otherwise blocked. Failure of vacuum pump or loss of power to vacuum pump. Other loads placed on 26 in vacuum system reduce airflow through furnace. Airflow not set properly before operating furnace.	Hot air from furnace vents into glovebox while heating oxide. Furnace not cooled down in intended time period after stabilization oxide. Potential damage to glovebox gloves and operator burn when boat removed from furnace.	DP across ceramic filter allows identification of plugged filter. Flow meter on vacuum line. Glovebox (E-4) ventilation system adequately removes hot air vented from furnace preventing overheating of glovebox. Temperature recorder tells operator when furnace is cooled down. DP and orifice place in vacuum system indicate flowrate.	Flow through vacuum system is verified to be in proper range before each furnace use. By procedure, operators are not allowed to remove furnace boat until furnace is below 200 C.	S1	F3	

Table 9F.2

A. General Glove box Hazards									
D.3.06	(E-4 ventilation upsets)	Overheating of glovebox	Loss of E-4 ventilation flow during operation of furnace due to equipment failures, damper closures, etc.	Overheating of glovebox leading to possible failure of port bags and gloves and inadvertent operation of the glovebox dry fire suppression system. Potential softening and sagging of glovebox windows. Release of contamination through failed gloves or bag ports (or failed windows). Potential Pu uptake by workers. Evacuation of Zone 3 process areas leading to unattended glovebox which could result in inability to control fire if combustibles ignited.	Insulating blankets protect glovebox panels from heat damage from nearby hot vacuum lines. Backup E-4 exhaust fans run by emergency generators or steam kicks on on loss of normal exhaust flow protecting glovebox from overheating. Alarms if dP is lost Halon system designed to put out fire by displacing a fraction of the air in the glovebox. It is designed not to discharge enough material to pressurize the glovebox. .	Alarms in power control room activate on loss of E-4 exhaust flow. Process areas are evacuated on loss of E-4 ventilation protecting workers from Pu potentially released from the glovebox. Work to restore ventilation flow on dampers or other equipment can occur as they are outside process areas. Operators are trained to hit "kill switch" shutting down furnaces before evacuating. Emergency plan	S1*	F3	
D.3.07	(contaminants in Pu oxide)	Plastic contaminants in Pu oxide feed result in fire/deflagration in furnace.	Plastic contaminants not noticed in feed or not removed by operator (plastic contaminants can include PVC, polyethylene, polycarbonate, polystyrene, Polymethyl Methacrylate).	Fire or deflagration involving flammable gases (alkanes, alkenes, hydrogen, carbon monoxide) generated inside the furnace. Fire extending out from gaps around furnace door can ignite combustibles, burn through gloves or port bags. Deflagration can damage furnace, throw furnace door open and produce a jet of flames that can burn through gloves, or port bags.	Furnace door does not latch and thereby provides vent path to prevent catastrophic explosion of the furnace. Furnace vacuum system sweeps air through the furnace to dilute flammable gas concentration or to completely oxidize (burn) plastic contaminant in a controlled manner.	Plastic contaminants are looked for and removed when the oxide is poured and sieved into the furnace boat in Glovebox HC-21A. Previous LOI testing results provide confidence that significant quantities of plastic contaminant are not in product to be stabilized in this campaign. Shift technical advisor sign off for material acceptability required by procedure.	S1*	F2	Recommend that material be poured through a sieve in Glovebox HC-21A to help identify plastic or other contaminants. Combination of airflow rate and ramp up rate should be used to ensure complete and controlled oxidation of plastic in furnace, taking into account the maximum quantity of plastic likely to slip past detection in Glovebox HC-21A.

Item #	Process Step/ Equipment	Failure/ Hazardous Condition	Causes	Consequences	Existing Engineered Features	Existing Administrative Controls	Cons Rank	Freq Rank	Comments
A. General Glove box Hazards									
D.3.08	(contaminants in Pu oxide)	Metal contaminant in feed results in pyrophoric reactions in the furnace.	Metal turnings or pieces not noticed or removed from feed in Glovebox HC-21A.	Reaction of pyrophoric metal or hydrided metal contaminant in furnace, leading to hydrogen release and burn in the furnace. Potential furnace damage. Failure of glovebox not expected due to small quantity of hydrided metal expected in feed.	Glovebox ventilation system confines material dispersed from furnace.	Visual identification of "non oxides" in Glovebox HC-21A when material poured into furnace boat. Blend plan identifies previously stabilized oxide to restabilize in this campaign. Labeling of cans. Operator training and procedures.	S1	F3	
D.3.09	(Materials other than primarily oxide processed through furnace)	Glovebox sweeps containing organic (plastics or sludge) processed through furnace results in flammable gas deflagration in furnace.	Wrong can selected from storage area opened in Glovebox HC-21A due to mislabeling or human error. Plus Failure to notice plastic contaminant or sludge in furnace boat during visual inspection in Glovebox HC-21C.	Deflagration in furnace, failure of furnace, and potential burn through of gloves, bag ports, or glovebox panels. Release of Pu from glovebox and potential uptake by operators.	E-3 ventilation system filters release to environment should Pu be released into room from glovebox.	Labelling and paperwork associated with each can identify contents: glovebox sweeps are indicated in labelling and paperwork minimizing likelihood or processing wrong material. Glovebox sweeps are not stored in same vault with Pu oxides to be processed in this campaign. Sweeps from wet gloveboxes are stored in polyjars which are difficult to mistake for a PuO_2 container.	S1*	F2	Sweeps could contain much more plastic contaminant than the oxide planned to be processed in this campaign.
D.3.10	(Materials other than primarily oxide processed through furnace)	Pu fluoride powder processed through furnace.	Wrong can selected for processing due to mislabeling or human error.	Fluorine gas release due to reaction with water vapor in air run through furnace. Damage to furnace vacuum exhaust system. Increased direct dose to operators. Pu fluoride produces higher direct dose than oxide (due to alpha-n reactions). See item B.1.02.	None	Labeling and paperwork associated with each container identify contents making it unlikely for wrong material to be processed.	S0	F2	PuF_4 powders may be difficult to distinguish from PuO_2 through yellow glovebox windows.
