13a. Description of Change

13b. Design Baseline Document? [X] Yes [ ] No

The Plutonium Finishing Plant (PFP) Final Safety Analysis Report (FSAR), HNF-SD-CP-SAR-021 Rev.1, is changed as a part of the annual update to reflect all approved changes with negative Unreviewed Safety Question (USQ). Changes that constitute positive USQ have also been incorporated for DOE approval. All chapters were revised according to the Criteria Document (HNF-5738) for year 2000. Refer to the chapter prefaces for a summary of specific information regarding the changes in each chapter. All changes are highlighted by redlines and strikeouts. This updated FSAR once approved by DOE will be Revision 2, and it will supersede Revision 1. The Revision 2 incorporates in its entirety the Addendum 0-K analysis. After the approval of Revision 2, 0-K will no longer be the Authorization Basis.

0-L 6/28/00

~~Also see USQ Evaluation #ECN-660525 attached.~~

See EDT 630164 for the USQs. 2/23/01

14a. Justification (mark one)

Criteria Change	[X]	Design Improvement	[ ]	Environmental	[ ]	Facility Deactivation	[ ]
As-Found	[X]	Facilitate Const	[ ]	Const. Error/Omission	[ ]	Design Error/Omission	[ ]

14b. Justification Details

The annual FSAR update required by the DOE Orders. Refer to each chapter for additional information for specific changes. Some changes were editorial in nature to reflect current configuration and correct description of system.

15. Distribution (include name, MSIN, and no. of copies)

See attached sheet for distribution.

	Continued Rev.2: See attached listing of ECNs showing status of ECNs incorporated in Rev.2.		

ENGINEERING CHANGE NOTICE STATUS OF INCORPORATION

(6 sheets)

ECN No.	Change Description	Release Date	Incorp. in SAR Rev. No.
191508	Incorporate Project B-610-transfer control of Bldg. 2736-ZB HVAC from Allen-Bradley Programmable controller to PFP distributed control system (MICON™)	1/10/96	1
605799	Complete revision and reissue of entire FSAR	8/99	1
611939	Incorp. Installation of ANN-714 for safety class and safety significant alarms (part of MICON™ system)	2/5/97	1
616606	Changed sanitary sewer source description	3/16/00	2
616618	Change effluent sources to Sanitary Drain 2607-Z	6/19/98	1
629275	Change ventilation zones and controller setpoints to improve ventilation operations	6/14/96	1
631022	Implement changes to the air sample systems HEPA filtration	5/17/96	1
632069	Add Thermal Stabilization addendum and related chapter page changes to FSAR	6/16/99	0-K
634398'	241-Z Tank concentration changed	5/99	2
638707	Add Laboratory Prototype Calciner Addendum and related chapter page changes to FSAR	6/24/99	0-L
638722	ECN not issued	-	-
638850L	ESPC - plant change not done - no FSAR change	4/99	N/A
638853	ESPC - plant change not done - no FSAR change	3/99	N/A
638854	ESPC - plant change not done - no FSAR change	3/99	N/A
638855	ESPC - plant change not done - no FSAR change	3/99	N/A
640208'	Seismic shutdown switch connection to Laboratory Prototype Calciner	6/99	2
642356	Add description of calibration, functional testing and check source for neutron detectors	7/24/97	1
642358'	HA-21I glovebox criticality prevention features	2/00	2

643016L	ESPC -plant change not done - no FSAR change	3/99	N/A
643207	Delete PRF CCL_4 alarm	7/6/98	1
645216	Production Calciner seismic solenoid valves - no FSAR change - Production Calciner operation not authorized.	12/12/97	N/A
646356	Sprinkler head designation -No FSAR change	5/99	N/A
646359	Production Calciner seismic solenoid valve - No FSAR change - Production Calciner operation not authorized.	2/10/98	N/A
646623	Beta CAM removal from PPSL	4/21/98	1
646781	Deletes use of hygrometer and relocates hygrometer	3/24/99	2
646804	Include a description of the access delay door override feature of the CAS	4/21/98	1
647385[1]	Change fire protection safety designation	7/99	2
647395	Delete specific locations of fire extinguishers	12/8/98	2
648960[1]	Relocate hygrometer	3/99	2
648973[1]	Adds drains in duct level	7/99	2
649626[1]	Updates glovebox dispersible plutonium limits in the OSR document for PFP	9/1/98	1
649765	Clarify CAS battery charger description	8/18/98	1
649770	Revise CAM & CAS text and location drawings	9/24/98	1

ENGINEERING CHANGE NOTICE STATUS OF INCORPORATION

(6 sheets)

ECN No.	Change Description	Release Date	Incorp. in SAR Rev. No.
649771	Affects evacuation alarms	10/98	2
649932	Affects glovebox shielding description for gloveboxes HC-18M & HC-18BS	7/99	2
649940	Air compressor for Laboratory Calciner	7/99	2
649956	Added or changed material relating to thermal stabilization operations in Glovebox HC-21C and related gloveboxes. Complete revision of Chapter 12.0, revised glovebox inventory limits, and added appendix of PFP Hazard Evaluation	10/30/98	1
649957	Updates glovebox dispersible plutonium limits in the OSR document for PFP	9/17/98	1
649958	Revise table of Safety Systems and related equipment	10/30/98	1
650067	ECN not issued.	-	-
650068	ECN not issued	-	-
650830	Adds drains in duct level	7/99	2
650869	Disconnects unused evacuation alarms	2/99	2
651332	Vault fire sprinklers deactivation	3/99	2
651333	Vault fire sprinklers deactivation	3/12/99	2
651334	Vault fire sprinklers deactivation	3/12/99	2
651369	Electrical transformer removal	2/99	2
651387	Disconnect various electrical supplies - no impact on FSAR	3/99	N/A
651396	Affects safety designation of filters	3/99	2
651397	SEL changes - no impact on FSAR	3/99	N/A
651398	Supplemental ECN for miscellaneous changes to update FSAR	9/99	2
651399	Supplemental ECN to update filter loading in the seismic event accident analysis	9/99	2

ENGINEERING CHANGE NOTICE STATUS OF INCORPORATION

(6 sheets)

ECN No.	Change Description	Release Date	Incorp. in SAR Rev. No.
651491	Seismic shutdown switch connection to Laboratory Prototype Calciner	5/99	2
651784	PRF roof repairs - no FSAR change required	1/99	N/A
651787	PRF roof repairs - no FSAR change required	1/99	N/A
651788	PRF roof repairs - no FSAR change required	1/99	N/A
651812	PRF roof repairs - no FSAR change required	1/99	N/A
651820	PRF roof repairs - no FSAR change required	2/99	N/A
652208	PR container drum sleeve added for 3 L polybottle	12/99	2
652804	Electrical transformer modifications	3/99	2
652825	Laboratory Calciner seismic shutdown -no change required	6/99	N/A
652967	Seismic shutdown switch connection to Laboratory Prototype Calciner	6/99	2
653352	Building 234-5Z and 242-Z description	4/6/99	2
653367	Changes building designations	7/99	2
653584	Remove Tank A-114 from Building 236-Z; work not done - no change to FSAR.	3/99	N/A
653595	Adds thermal stabilization in Glovebox HA-21I	1/25/00	2
653598	Changes operational control for Glovebox HA-21I	2/23/00	2
653739	Related to Cementation - not incorporated in FSAR	8/99	N/A
654336	Related to Cementation - not incorporated in FSAR	9/99	N/A
654348	Seismic shutdown switch connection to Laboratory Prototype Calciner	8/99	2
654414	Air compressor for Calciner	7/99	2
654420	PPSL sink removal	12/20/99	2
654879	Description of CO2 supply to Glovebox HC-21C	10/20/99	2
655239	Glovebox lead glass addition to Gloveboxes HC-18M & HC-18BS	11/99	2

PLUTONIUM FINISHING PLANT
FINAL SAFETY ANALYSIS REPORT

CHAPTER 1.0

INTRODUCTION AND GENERAL PLANT DESCRIPTION

FEBRUARY 2001

This page intentionally left blank.

PREFACE

Revision 2 of Chapter 1.0 of the Plutonium Finishing Plant (PFP) Final Safety Analysis Report (FSAR) includes modifications for the following:

- Changes in the management and organizational structure of the PHMC and the PFP
- Changes in the physical scope of the 234-5Z Building
- Changes in the list of active processes at the PFP
- Incorporation of the Magnesium Hydroxide Precipitation Process
- Incorporation of the Bagless Transfer System

Other minor changes include editorial changes and additional clarifications.

It is noted that various sections of Chapter 1.0 present information concerning plutonium-bearing solution stabilization operations using the Production Vertical Denitration Calciner located in the RMC Line and the Laboratory Prototype Calciner located in the Plutonium Process Support Laboratories. Operation of either the production calciner or the laboratory calciner for solution stabilization is not authorized at this time and the related portions of Chapter 1.0 will be updated, if necessary, prior to initiation of operations.

The new packaged boilers operated by Johnson Controls, Inc. which provide steam to the PFP were previously incorporated in the FSAR. This included switching the emergency exhaust fans from those which are steam-driven to those which are connected to the standby power system. However, the conversion from using steam-driven fans to standby power driven fans has not been fully implemented. The emergency exhaust fans are currently run by the new steam supply system installed under the Hanford energy conservation program. Electrically-driven emergency exhaust fans are planned to be connected to the diesel-generator standby power supply at some future date. The emergency exhaust fan functions are unchanged from that described in the FSAR regardless of the type and source of power.

The significant areas of change in Revision 2 are indicated by vertical bars in the margin of each page.

1.0 INTRODUCTION AND GENERAL PLANT DESCRIPTION

1.1 INTRODUCTION

The Plutonium Finishing Plant (PFP) is located on the U.S. Department of Energy (DOE) Hanford Site in south central Washington State. The DOE Richland Operations (DOE-RL) Project Hanford Management Contract (PHMC) is with Fluor Hanford Inc. (FH). Westinghouse Safety Management Systems (WSMS) provides management support to the PFP facility.

Since 1991, the mission of the PFP has changed from plutonium material processing to preparation for decontamination and decommissioning (D&D). The PFP is in transition between its previous mission and the proposed D&D mission. The objective of the transition is to place the facility into a stable state for long-term storage of plutonium materials before final disposition of the facility. Accordingly, this update of the Final Safety Analysis Report (FSAR) reflects the current status of buildings, equipment, and operations during this transition.

The primary product of the PFP was plutonium metal in the form of 2.2-kg, cylindrical ingots called "buttons". Plutonium nitrate was one of several chemical compounds containing plutonium that were produced as an intermediate processing product. Plutonium recovery was performed at the Plutonium Reclamation Facility (PRF) and plutonium conversion (from a nitrate form to a metal form) was performed at the Remote Mechanical C (RMC) Line as the primary processes. Plutonium oxide was also produced at the Remote Mechanical A (RMA) Line. Plutonium processed at the PFP contained both weapons-grade and fuels-grade plutonium materials. The capability existed to process both weapons-grade and fuels-grade material through the PRF and only weapons-grade material through the RMC Line although fuels-grade material was processed through the line before 1984. Amounts of these materials exist in storage throughout the facility in various residual forms left from previous years of operations.

Plutonium recovery, plutonium conversion, and oxide production are no longer performed at the PFP. Parts of the plutonium conversion process area are now used for reactive plutonium-bearing material stabilization and for plutonium-bearing solution stabilization operations. These operations convert the plutonium material into a more stable oxide form. Additional information concerning plutonium products can be found in Chapter 4.0.

Limited discussions of past plutonium conversion and recovery processes are retained in order to convey understanding of the current conditions. More detailed discussions of previous processes are presented in Chapter 6.0, Sections 6.4.3 and 6.6.

Plutonium material at the PFP is categorized according to the level of protection needed to prevent diversion. Individual Material Balance Area (MBA) inventories of category 1 material at any given time are classified information. The plutonium material inventory in any given location at the PFP is based on Criticality Prevention Specification (CPS) requirements and/or the limits established as a result of the accident analyses presented in Chapter 9.0. Control of these limits is assured by inclusion in the plant Operational Safety Requirements (OSR) (see Chapter 11.0) that are contained in

WHC-SD-CP-OSR-010, *Plutonium Finishing Plant Operational Safety Requirements* (WHC 1994). The theoretical maximum inventory at the PFP can be determined by summing the individual limits using the following assumptions.

- All process lines contain the maximum possible inventory based on the OSRs.
- All storage locations contain the maximum possible inventory based on the OSRs.
- All hoods, gloveboxes, and other nonprocess line operating areas contain the maximum inventory based on the OSRs.

It is not readily possible to separate the plant inventory into specific chemical or physical forms at any given point in time. Since processes have been curtailed, the principal solid chemical forms are plutonium oxide (PuO_2) and plutonium metal. The bulk of the plutonium solution is plutonium nitrate [$Pu(NO_3)_4$]. Other compounds, such as PuF_4 or plutonium oxalate, comprise a minor percentage of the limit and were normally found in the RMC Line. Additionally, there are a number of storage containers holding materials that are not well characterized chemically. See Chapter 4.0, Section 4.2.1, and Chapter 8.0, Section 8.2, for discussions of the various plutonium-bearing chemical compounds that may be identified in the PFP inventory.

The responsibility for operation of the facility is assigned to WSMS. Organizational responsibilities for the PFP are described in *Plutonium Finishing Plant Administration*, FSP-PFP-5-8. See Chapter 10.0 for discussion of the PFP organizational structure.

1.1.1 Safety Analysis Report Overview

This PFP FSAR replaces all previous PFP safety analysis reports. Efforts for developing an integrated FSAR for the PFP began in December 1988 using guidance from the January 1976 version of U.S. Nuclear Regulatory Commission Regulatory (NRC) Guide 3.39, *Standard Format and Content of License Applications for Plutonium Processing and Fuel Fabrication Plants*, (NRC 1976), and HNF-PRO-704, *Hazard and Accident Analysis Process.*

As originally prepared and approved by the DOE, the scope of Revision 0 of the FSAR included operation of the principal facility plutonium material processes and attendant activities. Accordingly, the FSAR presented detailed descriptions of production operations, equipment, and processes. The FSAR has been updated to more accurately reflect the current operational status of the PFP since fiscal year (FY) 1995 in accordance with operating contractor management agreement to maintain the FSAR by performing annual updates and by implementing the Unreviewed Safety Question (USQ) process. This update of the PFP FSAR also serves to incorporate commitments made to DOE as documented in the *Plutonium Finishing Plant Safety Evaluation Report* issued by the DOE (DOE 1995a) and addenda. As a result of changes in the plant mission, many of the operations described and analyzed in the original FSAR are now inactive or shut down. Active processes are those that are both operational (i.e., equipment is in place and functional) and authorized by this FSAR to operate. Inactive or shutdown operations, equipment, or facilities may either be

operable (or operational) and not authorized for operations (not in use) or may not be operational and would require modifications before use. Additional supporting documentation, including safety analyses, must be approved before a new or modified process may be operated. From a safety analysis perspective, the PFP USQ Determination process ensures that changes to operable processes are properly incorporated into the PFP authorization basis. The current status of major portions of the PFP is as follows.

1.1.1.1 **Active Processes**. The following comprise the current, active processes at the PFP:

- Plutonium material storage and support activities in the 2736-Z, 2736-ZA, and 2736-ZB Buildings, 2736-ZD vault, and the gloveboxes and vaults in the 234-5Z Building
- Reactive plutonium-bearing material stabilization in the 234-5Z Building using Glovebox HC-21C and HA-21I.
- Waste packaging and reactive residue storage
- Transfer operations in gloveboxes HC-227S/T in the 234-5Z Building
- Low-level waste and waste water treatment in the 241-Z Complex and 243-Z Building, respectively
- The PFP Analytical Laboratory (PFP AL), Standards Laboratory, and PPSL in the 234-5Z Building
- Facility support systems [e.g., heating, ventilation, air conditioning (HVAC), radiation monitoring, steam, electricity, etc.].
- Bagless Transfer system operations in Glovebox HA-53BTS in the RMA Line in the 234-5Z Building
- Magnesium Hydroxide Precipitation Process operations in Gloveboxes HC-230C-3 and HC-230C-4 in the RMC Line in the 234-5Z Building

1.1.1.2 **Inactive Processes**. The following comprise the now inactive processes that are not currently authorized under the current mission objectives:

- Plutonium-bearing solution stabilization using the Production Vertical Denitration Calciner in Building 234-5Z
- Plutonium-bearing solution stabilization using the Laboratory Prototype Calciner in the Plutonium Process Support Laboratory (PPSL) in Building 234-5Z
- Plutonium recovery in the 236-Z Building
- Plutonium conversion in the 234-5Z Building
- Waste treatment in the 242-Z Building

- Laboratory waste concentrator.

1.1.2 Facility Overview

The PFP buildings and structures are shown in Figure 1-1. The majority of the buildings and structures that comprise the PFP are listed in Table 1-1. The principal PFP structure, the 234-5Z Building, was completed in 1949 to purify plutonium nitrate solutions, reduce the nitrate to plutonium metal, and fabricate plutonium metal into buttons. The 234-5Z Building houses plutonium processing operations, process support services, laboratories (PFP AL, Standards, and PPSL), and facility services. The 241-Z Liquid Waste Treatment Facility and the 291-Z Building, which houses ventilation exhaust fans and mechanical service equipment, were built at the same time as the 234-5Z Building. An incinerator, housed in the 232-Z Building, was completed in 1961 and was used to recover plutonium from combustible scrap. Plutonium reclamation and waste treatment equipment are housed in the 236-Z and 242-Z Buildings, respectively, which were completed in 1964. See Chapter 5.0, Sections 5.1 and 5.2, for details of PFP facilities construction history and current functions of specific buildings.

The original design of the PFP process facilities provided for all of the planned operations and laboratories to be located in the 234-5Z Building, except for waste collection and disposal. With increases in production, storage, and scrap recovery requirements, these major additions were made: the PRF (236-Z Building), the Waste Treatment Facility (242-Z Building), Waste Incinerator Facility (232-Z Building), and the Support/Storage Complex (2736-Z, 2736-ZA, 2736-ZB, and 2721-Z Buildings). Subsequently, the Low-Level Waste Treatment Facility (LLWTF) (also referred to as the 243-Z Building) and an upgraded men's changeroom (234-5ZA Building) became operational. See Chapter 5.0, Section 5.2, for details of specific facility buildings.

Various facilities are used for storage of compressed gases, chemicals, and other process materials. See Chapter 5.0, Sections 5.2, 5.4.4, and 5.4.13 for more details of specific facilities used for chemical and process materials storage.

1.1.2.1 General Services. The Hanford Site utilities servicing the PFP provide for electricity and water. A description of each is provided in Chapter 5.0, Section 5.4. A summary description is provided below.

- Normal power supply--Electrical power is supplied to the Hanford Site from the Bonneville Power Administration substation at Midway through a 230-kV loop to all outer areas. The H. J. Ashe switchyard provides a redundant supply of 230-kV electrical power. This source is switched automatically into the 230-kV loop to all outer areas on loss of power from the Midway substation. See Chapter 5.0, Section 5.4.2, for details of the electrical systems supporting the PFP facilities.

- Standby power--Standby power is available from three 325-kW diesel generators, housed in the 2721-Z Building. See Chapter 5.0, Section 5.4.2, for details of the backup power system used at the PFP.

- Uninterruptible power supplies--An uninterruptible power supply (UPS), in the form of batteries, is provided for operation of the seismic shutdown system, critical computer systems, critical equipment, some alarm systems, backup power systems, and communications system (i.e., the PAX system) when there is loss of normal and emergency power. See Chapter 5.0, Section 5.4.2, for details of the UPS system.

- Water supply and distribution system--All of the water supply needs for the PFP are provided by three sanitary water system lines. Water is routed from the 283-W filter plant and clear wells to the PFP sanitary water service loop via a 10 in. diameter line that feeds into the loop at the southeast corner, an 8 in. diameter line on the north side, and a 12 in. dia line that feeds into the loop at the northeast corner. See Chapter 5.0, Section 5.4.7, for details of the water system.

Steam is furnished to the PFP from dedicated oil-fired boilers located in Building 234-5Z-BA which is just to the north of the PFP facility, outside its security fence, and near the 231-Z Building. The steam supply from the dedicated boilers is used for space heating, heating of ventilation system supply air, steam-turbine-driven emergency exhaust fans, and jet transfers of liquid wastes.

1.1.3 Operations Overview

During the transition phase between operations (plutonium production-related activities) and D&D, the following activities are conducted in the PFP:

- Plutonium material receiving, storage, and shipping (includes transfer operations in gloveboxes HC-227S/T)

- Reactive plutonium-bearing material stabilization

- Plutonium-bearing solution stabilization using the Laboratory Prototype Calciner in Glovebox 188-1 (not authorized for operation)

- Plutonium-bearing solution stabilization using the Production Vertical Denitration Calciner in Glovebox HC-230C-2 (not yet authorized)

- Laboratory and engineering support

- Waste handling

- Active and inactive facilities surveillance.

Additional details of plutonium material receiving, storing, and shipping activities are provided in Chapter 6.0, Sections 6.2 and 6.3. Reactive plutonium-bearing material stabilization and plutonium-bearing solution stabilization are described more fully in Chapter 6.0, Section 6.4. The equipment associated with past operations of plutonium recovery and plutonium

conversion are identified in Chapter 5.0. Laboratory and engineering support is provided by the PPSL, Standards Laboratory, and the PFP AL. These laboratories are described in more detail in Chapter 5.0, Section 5.4.14, and Chapter 6.0, Section 6.5. Waste handling is discussed in Chapter 7.0. Active and inactive facility surveillance is discussed in Chapters 5.0, 6.0, and 8.0. Brief summaries of these activities are provided in Chapter 1.0, Section 1.3.

The operations listed above comprise the major activities considered in this FSAR. For clarity, some operations and the associated equipment are discussed briefly even though they are out of service and not expected to be used again. These former operations include the following:

- RMC Line plutonium conversion operations: 234-5Z Building
- PRF plutonium recovery operations: 236-Z Building
- Electrolytic metal dissolution: 236-Z Building/glovebox MT-3
- Incinerator ash calcination: 234-5Z Building/glovebox HA-40F
- Polycube calcination: 236-Z Building/glovebox MT-4
- RMA Line button and oxide production gloveboxes: 234-5Z Building/ rooms 235-A1, 235-A2, and 235-A3
- 232-Z Incinerator Building
- Waste treatment and americium extraction: 242-Z Building.

Plutonium conversion (i.e., from a nitrate form to a metal form) and plutonium recovery operations are no longer conducted in the 234-5Z and 236-Z Buildings. Reactive plutonium-bearing material stabilization operations and plutonium-bearing solution stabilization operations are performed in the 234-5Z Building (see Chapter 5.0, Section 5.2.1.2, for details of the equipment used in the stabilization processes and Chapter 6.0, Section 6.4, for details of the processes). If plutonium conversion or recovery operations are resumed at the PFP, new analyses will be performed, if necessary, and the FSAR will be updated appropriately.

To properly evaluate the impact to the environs from catastrophic natural events, the residual plutonium material remaining from former campaigns are included in the source terms used in the accident analyses. The impact of these source terms has been addressed in the analyses in Chapter 9.0 and other chapters where appropriate.

Since the PFP startup in 1949, operations necessary to decontaminate and decommission (D&D) obsolete process lines and cleanout facilities have been conducted as required. At the PFP these activities are referred to variously as facility cleanout, or terminal cleanout operations and D&D. Information on conduct of operations for D&D activities is found in Chapter 10.0. The status of specific facilities at the PFP is discussed in Chapter 5.0.

1.2 GENERAL PLANT DESCRIPTION

1.2.1 Site Characteristics

The PFP is located in a semi-arid desert in south-central Washington State (Figure 1-2). The facility is in the west-central portion of the Hanford Site, in the 200 West Area (Figure 1-3). Major activities of various areas of the Hanford Site are as follows.

- 100 Areas--These areas contain retired plutonium production reactors and spent fuel storage facilities.
- 200 East and 200 West Areas--The 200 Areas are dedicated to waste management activities, laboratory support, waste characterization, and nuclear material processing.
- 300 Area--The major activity in this area is nuclear research and development. Unirradiated nuclear fuel is also stored in this area.
- 400 Area--This area contains the shutdown Fast Flux Test Facility (FFTF), the Fuel Cycle Plant (i.e., Fuels and Materials Examination Facility, which was never activated) and related support facilities for the liquid metal reactor program (inactive).
- 600 Area--The 600 Area includes all of the Hanford Site not occupied by the other listed areas. Some of the land uses include the Fitzner/Eberhardt Arid Lands Ecology Reserve; a small 100-acre tract privately leased for the burial of commercial low-level nuclear waste; the Energy Northwest lease for the operation of the Columbia Generating Station nuclear power plant; a U.S. Fish and Wildlife Refuge; a recreational game site leased to the Washington State Department of Game; and the Laser Interferometer Gravitational Observatory.
- 700 Area--The 700 Area primarily serves as an administrative center for government employees involved in overseeing contractor-operated facilities and programs at the Hanford Site.
- 1100 Area--This area serves as a center for central warehousing and transportation/distribution.
- 3000 Area--This area is not generally used by the Hanford Site contractors.

The location of the PFP relative to other plants located in the 200 West Area is shown in Figure 1-4. The PFP Emergency Response Zone in the 200 West Area is shown in Chapter 5.0, Figure 5-4. The PFP is well above the present groundwater and flood plains of nearby rivers, as discussed in Chapter 3.0.

Chapter 3.0 provides the site characteristics of the PFP. Typical meteorological conditions include a small amount of precipitation, light snowfall, moderate temperatures, and winds primarily from the northwest. Tornado occurrence is so low that it need not be analyzed per *Standard*

Architectural Civil Design Criteria, Design Loads for Facilities, SDC-4.1 (DOE-RL 1993), which is based on UCRL 15910, *Design and Evaluation Guidelines for DOE Facilities Subjected to Natural Phenomena Hazards* (Kennedy et al. 1990). Hydrological events; severe cold; acute thaws; and heavy rain, snow, or ice storms do not occur with intensities requiring special design. Design criteria (e.g., criteria for natural phenomena hazards) for the PFP Complex are discussed in Chapter 4.0.

The nearest known geological fault lies within 5 mi of the PFP site (see Chapter 3.0, Section 3.6. The nearest volcanic activity is 100 mi away (see Chapter 3.0, Section 3.6.6).

1.2.2 Facility Description

1.2.2.1 Plutonium Finishing Plant Buildings. The buildings and support facilities/structures comprising the PFP are shown in Figure 1-1 and listed in Table 1-1. The major PFP buildings are briefly described below with more detailed descriptions given in Chapter 5.0, Section 5.2. More detailed descriptions of the facilities listed in Table 1-1 are provided in Chapter 5.0. The PFP design criteria and compliance with codes and standards is presented in Chapter 4.0, while waste-handling facilities are discussed in Chapter 7.0. Discussion of the facilities' support systems can be found in Chapter 5.0, Section 5.4. Discussion of the processes performed in the buildings is provided in Chapter 6.0.

1.2.2.1.1 The 234-5Z Building. The 234-5Z Building is approximately 180 ft wide by 500 ft long and extends from 9.5 ft below grade to 46.8 ft above grade. Floor levels are designated as the basement, first floor, duct level, second floor, and roof level. Noncombustible materials of construction are used. The frame is of structural steel with an outer sheathing of aluminum panels over rock wool insulation and 16-gauge sheet steel. The first floor is a concrete slab, the duct level is sheet metal roof decking, and the second floor is a concrete slab. The roof is insulated metal decking. Interior walls are reinforced-concrete steel structure, metal studs, metal lath, and plaster. The vault and process area doors are constructed of steel with combination safe-type locks. An aerial view of the PFP with a cutaway view of the 234-5Z Building is shown in Figure 1-5.

The 234-5Z Building basement primarily consists of pipe tunnels containing drain piping and sumps. The first floor houses the two former plutonium processing lines (RMA and RMC Lines) and associated control rooms; reactive plutonium-bearing material stabilization gloveboxes; plutonium-bearing solution stabilization gloveboxes; plutonium storage vaults; the plutonium nitrate feed load-in/load-out (LI/LO); blending and storage facilities; the PPSL, Standards Laboratory, and PFP AL; the instrument maintenance shops; the building maintenance shops; locker rooms with change facilities and restrooms; and office spaces. The duct level contains most of the service piping, ventilation ducts, and some filterboxes.

The lunchroom, a plastics shop, conference room, materials storage room, chemical feed preparation and aqueous makeup rooms, locker rooms with change facilities and restrooms, and office spaces are on the second floor. The second floor also contains exhaust-air ductwork including filterboxes, filter

rooms, and the fan room. The fan room houses the ventilation supply fans, the steam inlet and distribution system, air dryers, the distilled water still, air chilling units, and the vent and balance control room.

1.2.2.1.2 The 236-Z Building. The 236-Z Building, commonly known as the PRF, is south of the southeastern corner of the 234-5Z Building and is connected to it by the 242-Z Building. A cutaway view of the building is shown in Figure 1-6. The 236-Z Building is essentially a four-story structure, surmounted by a two-story penthouse. Its dimensions are approximately 79 ft wide by 71 ft long. Its principal internal feature is a single process equipment cell that is 32 ft wide by 52 ft long.

The 236-Z Building is of reinforced-concrete construction, with the exception of the roof and the fourth-floor ceiling. The roof is of open-web steel joist framing, steel decking, rigid insulation, and graveled built-up roofing. A portion of the southern building wall is also the south wall of the process cell and includes an opening in the reinforced concrete wall, filled by a door and surrounding block wall. The concrete block wall has been steel-plated and reinforced to withstand seismic effects.

Maintenance shop facilities are located on the service (east) side of the building on the ground floor. The second floor of the service side is used for a maintenance glovebox and ventilation exhaust filters. Building service equipment and electrical switch gear are on the third floor of the service area. The fourth floor was used for chemical preparation, miscellaneous treatment, operating control room, slag and crucible dissolver equipment, and a column room in which vertical sections of two liquid extraction columns penetrating the room from above and below are housed in a glovebox. The first through the fourth floors are serviced by a service elevator on the east side of the building.

1.2.2.1.3 The 232-Z Building. The 232-Z Building (shown in Figure 1-7) housed the contaminated waste recovery process and is commonly called the "Incinerator Building." The contaminated waste recovery process underwent partial D&D in 1984 and again in 1995 and 1996. The 232-Z Building is located approximately 200 ft south of the main portion of the 234-5Z Building and is approximately 100 ft west of the 291-Z-1 stack.

The 232-Z Building is of concrete block construction and is approximately 37 ft wide by 57 ft long. It is divided into areas for processing, storage, a changeroom, chemical preparation, ventilation, and electrical equipment.

1.2.2.1.4 The 241-Z Complex. The 241-Z Complex (shown in Figure 1-8) is the liquid waste treatment facility. It is the Resource Conservation and Recovery Act (RCRA)-permitted treatment, storage, and disposal facility for PFP radioactive mixed waste. It is a buried, reinforced-concrete structure with a sheet metal enclosure over the top. The enclosure houses a hoist for removing cell covers and the ventilation piping and filters. The buried structure consists of five separate ventilated cells, each containing a 20,000-L tank (one tank, TK-D6, has been isolated and left in place). The tanks (TK-D4, TK-D5, TK-D7, and TK-D8) are used to accumulate and treat the radioactive liquid wastes (RLW) generated in the PFP before transfer to the tank farms. The 241-Z Building is approximately 20 ft wide, 92 ft long,

and 22 ft deep, and is located approximately 330 ft south of the 234-5Z Building.

At the southwest corner of the 241-Z vault deck is a weather enclosure containing the equipment for the 241-Z vessel vent filters and vault ventilation system. The 24-ft-high stack, 296-Z-3, and its associated fans, and controls are located on a 14-ft by 18-ft concrete pad.

The 241-Z Complex also consists of the 241-ZA Sampling Building, 241-ZB Caustic Tank, and the 241-Z-RB Retention Basin (the caustic tank and retention basin are to be removed soon).

1.2.2.1.5 The 242-Z Building. The 242-Z Building houses portions of the waste treatment facility and the americium facility, which are inoperable. A cutaway view of the 242-Z Building is shown in Figure 1-9. The 242-Z structure lies between the southeastern corner of the 234-5Z Building, and the 236-Z Building. A corridor along the east side connects the 234-5Z, 242-Z, and 236-Z Buildings. An entrance enclosure along the west side is for outside entry into both 242-Z and the analytical laboratory area in the 234-5Z Building. Both the east side corridor and the west side entrance are considered to be part of the 234-5Z Building, not the 242-Z Building.

The building is approximately 40 ft wide, 26 ft long, and 23 ft high. The south portion, approximately 40 ft wide by 10 ft long, is the tank room (tank cell). This room extends the full inside building height. The north portion, designated the control room, has a mezzanine over its west half for chemical addition tanks.

The south wall of the 242-Z Building is of reinforced concrete. The remainder of the building has a structural steel frame covered with metal lath and plaster internally, and insulating material wall panels externally. The slightly peaked roof is constructed of metal decking, covered by insulation and built-up asphalt and gravel.

The tank room in the 242-Z Building houses large, empty process vessels, with pipe connecting to the process gloveboxes in the control room. The 242-Z Building shares its ventilation system with the main ventilation system in the 234-5Z Building. All nonessential utilities and services have been isolated.

1.2.2.1.6 The 291-Z Building. The 291-Z Building (also known as the Exhaust Fan House, Exhaust Air Stack Building, and Compressor and Fan House) is a reinforced-concrete structure approximately 53 ft south of the central part of the 234-5Z Building. A cutaway view is shown in Figure 1-10. Of irregular shape, its approximate dimensions are 74 ft wide by 143 ft long. Its overall height is approximately 23 ft, with only 4 ft above grade. This building houses the exhaust fans, the mechanical service equipment, and an electrical substation.

Auxiliary to the 291-Z Building is the 200-ft-high 291-Z-1 stack. Constructed of reinforced concrete, its center is 63 ft from the near end of 291-Z and 230 ft from the south wall of the 234-5Z Building.

1.2.2.1.7 The 2736-Z Complex.

The 2736-Z Building. The 2736-Z Building, shown in Figure 1-11, is the primary PFP plutonium storage facility. The 2736-Z Building is approximately 65 ft long by 56 ft wide. The building consists of four vaults for the storage of plutonium materials, divided by a corridor running the width of the building. Each storage room is approximately 28 ft by 28 ft in size. The building is constructed of reinforced concrete walls, 14 in. thick, supported by cast-in-place concrete columns. The roof is a cast-in-place concrete slab, 6.5 in. thick.

The 2736-ZA Building. The 2736-ZA Building, approximately 5 ft west of the 2736-Z Building, contains exhaust fans and HEPA filters, stack CAMs and sampler, and instrumentation related to operation of the 2736-Z Building.

The 2736-ZB Building. The 2736-ZB Building, located immediately to the south of the 2736-Z Building, is approximately 132 ft by 90 ft with reinforced concrete walls (except for administrative areas) and roof. A cutaway view is shown in Figure 1-12.

The 2736-ZB Building shipping and receiving areas are each provided approximately 1,000 ft^2 of floor space to accommodate a maximum of 100 shipping containers the size of 55-gal drums. Adequate spacing is provided between containers to meet criticality prevention and personnel exposure specifications, as well as allowing corridor access to staging areas. The two areas are physically separated by a wall.

Separate airlocks are provided for personnel and material access. In addition, administrative controls maintain security and safeguards control during the shipping and receiving operations.

The 2736-ZC Loading Dock. The 2736-ZC consists of an enclosed loading dock and corridor for the 2736-ZB Building.

The 2736-ZD Vault. The 2736-ZD storage vault is an outside, cylindrical concrete vault used to store three Experimental Breeder Reactor (EBR)-II casks.

The 2721-Z Building. The 2721-Z Building houses the backup electrical power generators for the PFP Complex.

1.2.2.1.8 The 243-Z Building.

The 243-Z Building, known as the Low-Level Waste Treatment Facility, provides for treatment of the PFP effluents to remove low-level radioactive and chemical contamination. The building consists of five rooms with a vestibule providing direct access to the change room and then from there, into the process area. The associated 243-ZA Building contains the sump for the 243-Z tanks. The 243-ZB is a concrete slab for the closed-loop cooling water system.

The process area contains tanks, pumps, filters, and the associated piping and instrumentation necessary for operation and monitoring the equipment and incoming waste streams. After the building influent has been processed, it is monitored to ensure that it meets the environmental

requirements for release. If the effluent does not meet requirements, it can be recycled and retreated.

1.2.2.2 Principal Design Criteria. The principal safety-related design criteria for the PFP facilities met applicable criteria at the time of construction. A detailed discussion of design criteria is provided in Chapter 4.0. The design criteria for the major PFP buildings are discussed in Chapter 5.0, Section 5.2.

1.2.2.3 Utility and Service Systems. The only utilities distributed throughout the Hanford Site are electricity, water, and telecommunications. Other utilities (e.g., steam and sewer) are confined to specific operating areas. The DOE has a contract with the Bonneville Power Administration that gives the Hanford Site electricity supply priority over other users.

Four 13.8-kV electrical overhead distribution lines provide electrical power to the 200 West Area (two of which supply the PFP) from the 251-W substation. Major components in the supply of electric power to the PFP are high voltage transmission lines, transformers, large switchgear units, diesel generators, and battery stations. Backup electricity generators are provided to supply electrical power for the PFP following the interruption of normal power. A detailed description of the electrical system for the PFP is presented in Chapter 5.0, Section 5.4.2.

The water supply system for the PFP is obtained from the 283-W filter plant and clear wells via three feed lines that lead into the sanitary water loop. The PFP process buildings are supplied with main branches that are connected directly to the PFP sanitary water loop. The majority of these mains are for fire protection and the rest are for sanitary and process water. The largest normal use of sanitary water is to feed the ventilation supply units for air washing and evaporative cooling for air conditioning the supply air. A detailed description of the water supply system for the PFP is presented in Chapter 5.0, Section 5.4.7.

1.2.2.3.1 Supply Air and Gas Systems. The PFP has three categories of compressed-air supply systems available: process, instrument, and dry. The process air system is provided as a general purpose air supply throughout the PFP for air cylinders, aspirators, air tools, etc., by two water-cooled, two-stage, reciprocating compressors. Process air is distributed from a receiver tank in the 291-Z Building to a general distribution air header in the 234-5Z Building. Separate lines provide general purpose air to other buildings. The instrument air system is also provided via the same air compressors. The dry air system in the 234-5Z Building is currently used to supply compressed air only while a separate system is functional in the 2736-ZB Building. A detailed description of the compressed air system for the PFP is presented in Chapter 5.0, Section 5.4.3.

Breathing air is provided by the Portable Cascade Bottle System for use in radiation or toxic areas where respiratory protection is required. Breathing air at the PFP is discussed in Chapter 8.0, Section 8.5.1.

Process air for plutonium-bearing solution stabilization operations using the production vertical denitration calciner process is supplied by compressed air cylinders in the 234-5Z Building. The air is used to atomize the calciner

feed solutions and to backwash filters in the calciner. Compressed air for solution stabilization operations is discussed in Chapter 5.0, Section 5.2.1.2.2 and Chapter 6.0, Section 6.4.1.1.1A.

Air supply for operation of the laboratory prototype calciner in PPSL Room 188 is provided by a dedicated high-quality air compressor located at the west end of the Building 234-5Z duct level.

Nonradioactive gases are supplied from bottle storage buildings (sheds) located adjacent to the major PFP Buildings. Gases include P-10, oxygen, compressed argon, etc. Detailed descriptions of the PFP gas systems are presented in Chapter 5.0, Section 5.4.4.

1.2.2.3.2 Vacuum Systems. There are three basic types of vacuum systems used in the PFP processes; the 26-in. mercury system, 17-in. mercury systems, and the 5-in. mercury system. The 26-in. mercury system is used for vacuum transfers of process liquids, to provide the vacuum requirements needed for the plutonium-bearing solution stabilization process and for other high vacuum requirements, the 17-in. mercury system provides the motive force for the continuous air monitors and fixed air samplers, and the 5-in. mercury system is used to draw offgasses during the thermal stabilization process. Detailed discussions of these systems are presented in Chapter 5.0, Section 5.4.5. A detailed discussion of plutonium holdup associated with the vacuum systems is located in Chapter 8.0, Section 8.2.1.

1.2.2.3.3 Facility Confinement Features. Several design features are included in the PFP to assure confinement of the radioactive materials in their designated areas (see Chapters 4.0 and 8.0 for details of the facility confinement features in use at the PFP).

Features of the process areas in the 234-5Z Building (e.g., arrangement of piping) ensure the confinement of radioactive materials and reduce personnel exposure. The arrangement of the areas provide the following features:

- Many, but not all, gloveboxes are connected by an enclosed conveyor so that removal of product from gloveboxes is not required during processing.
- Process steps are combined to reduce transfers.
- Maintenance and Operations personnel access is provided through doors from a separate corridor along the back of the rooms housing the gloveboxes.
- Access to all sides of the gloveboxes is provided wherever practicable.

In all cases practicable, piping for radioactive materials is within an encasement that can be monitored for leaks. Ongoing system upgrades are replacing the concrete encasements for liquid effluent lines with encased piping (i.e., a pipe within a pipe). Vacuum is used wherever practical to transfer radioactive solutions to avoid transfer of solutions under pressure.

Standard confinement zone designations specify the inner contaminated zones as zone 1 and the outer clean zones as zones 3, 4, etc. However, except for the 2736-ZB Building, the PFP zone designations are reversed such that zones 3 and 4 are the contaminated inner zones and zone 1 is the clean outer zone.

Design criteria for new facilities specify that zone 3 and zone 4 areas be surrounded by zone 1. This buffer zone provides additional assurance of containment. Some of the PFP buildings have exterior walls that provide containment for zone 3 and zone 4 areas [e.g., the south side of Building 234-5Z (zone 3) and the south and west sides of the 232-Z Building (zone 3); the south wall of 236-Z (zone 4 the canyon cell)]. The separation of zone 3 or 4 from the environment by only an exterior wall is no longer an acceptable practice.

Glovebox Ventilation. The ventilation of process areas provides ambient air pressures that are lower than any adjoining space so that incidental leakage will flow toward the negative pressures (i.e., into areas of successively higher contamination potential). The lowest pressures of all are within the processing gloveboxes.

Nontestable high-efficiency particulate air (HEPA) filters are provided on the ventilation exhaust outlet from all gloveboxes so that, to the degree practicable, the radioactive particulates can be kept out of the ventilation duct work and prolong the life of filters further down the exhaust line. However, much of the duct work has become contaminated over time. All gloveboxes supplied air from the room around the glovebox are equipped with HEPA filters on the inlet to the glovebox to reduce the amount of particulate matter that would be carried out of the glovebox to the room in case of a pressure reversal. A detailed discussion of the glovebox ventilation system is presented in Chapter 5.0, Section 5.4.1.

1.2.2.3.4 Heating, Ventilation, and Air Conditioning Systems. The PFP buildings are provided ventilation by six separate systems:

- 2736-Z and 2736-ZA Buildings
- 241-Z and 241-ZA Buildings
- 243-Z Building
- 232-Z Building
- 234-5Z, 236-Z, 242-Z, and 291-Z Buildings
- 2736-ZB Building.

All buildings served by the PFP ventilation systems are zoned (i.e., zones 1, 3, or 4) to ensure confinement of radioactive materials. Note that zones 2 and 3 have been combined and designated zone 3. Zone 1 areas in the 234-5Z, 232-Z, 236-Z, 241-Z, and 242-Z Buildings are those where plutonium contamination is not normally present (e.g., office areas, lunchrooms, certain maintenance shops, hallways). Zones 3, 3A, and 3B (collectively referred to as zone 3) consist of areas where radioactive materials (e.g., plutonium) are stored or handled in contained form, where there is potential for contamination to occur (e.g., rooms with hoods and gloveboxes). Zone 4 consists of the inside of hoods, gloveboxes, and process cells where there is direct contact with radioactive materials and gross contamination may be present.

Within the 2736-Z Complex (2736-Z, 2736-ZA, and 2736-ZB Buildings), ventilation zones conform to standard designations (they are reversed in the other PFP buildings). Zone 1 designates the area having the highest potential for contamination (e.g., the repackaging hood) and zone 4 designates areas where contamination is not normally present.

Radioactive materials in process areas are confined as close to the point of origin as practicable through the use of HEPA filters installed on the exhaust ducts of hoods and on both the supply and exhaust ducts of gloveboxes. Exhaust ventilation air from zone 3 areas is filtered via one stage of testable HEPA filtration before discharge to atmosphere via a stack. Exhaust ventilation air from zone 4 areas is filtered via two stages of testable HEPA filtration before discharge to atmosphere via a stack. These designations are reversed in the 2736-Z Complex where zone 1 is the area of higher contamination potential.

Ventilation is on a "once-through" basis except for small-volume recycle of room air to supply laboratory refrigeration air-conditioning systems and for the 2736-ZB Building.

Differential pressures are maintained between areas so that air flows from areas of lower contamination potential to areas of higher contamination potential. Detailed descriptions of the PFP ventilation systems are presented in Chapter 5.0, Section 5.4.1. Chapter 7.0 provides a description of ventilation exhaust monitoring.

1.2.2.3.5 Steam Systems. Steam at up to 100 lbf/in^2 gauge is furnished to the PFP Complex from three dedicated Johnson Controls oil-fired packaged boilers located in Building 234-5Z-BA which is to the north of the PFP facility (outside the security fence) near the 231-Z Building. See Chapter 5.0, Section 5.4.6, for a detailed discussion of the steam supply and distribution system.

1.2.2.3.6 Lighting. Fluorescent lighting is used throughout the PFP. Shower rooms, tunnels, and underground fan and compressor rooms use incandescent fixtures. In the ceiling over processing areas, open fluorescent fixtures are mounted over airtight glass panels.

No PFP process building has natural lighting. Emergency lighting is provided by incandescent lamps provided at strategic locations in the building. Emergency lighting is discussed in Chapter 5.0, Section 5.4.10.

1.2.2.3.7 Communication and Alarm Systems. The PFP Complex communication and alarm systems are comprised of the following:

- Plant or "outside" telephones
- Internal telephone and public address system
- Intercom system
- Wailing siren (take cover)
- Steady siren (evacuation)
- Criticality alarm system
- Continuous air monitor system
- Audible fire alarm system.

The PFP communication and alarm systems provide audible and/or visual information concerning abnormal conditions. The communication systems provide standard and emergency communication exchanges. Standard alarm signals are used at the PFP to provide notification of specific abnormal conditions. Chapter 5.0, Section 5.4.10, provides additional detail on the PFP Complex communication and alarm systems.

1.2.2.3.8 Cold Chemical Systems. Cold (nonradioactive) chemical systems consist of storage, transfer, and makeup of chemical solutions used in plutonium processing and the PPSL, Standards Laboratory, and PFP AL. Since the shutdown of plutonium recovery and conversion operations, large quantities of process chemicals have been removed from the PFP. Small quantities of chemicals stored and used in the laboratories present no significant hazard other than those normally associated with industrial laboratories. Detailed descriptions of the cold chemical systems for the PFP are presented in Chapter 5.0, Section 5.4.13. Administrative controls and engineered barriers help prevent the release of chemicals to the environment (see Chapter 7.0, Section 7.2.2).

1.2.2.3.9 Fire Protection Systems. The PFP fire protection systems consist of many individual communication and operating systems (e.g., fire alarms and sprinkler systems). The PFP design includes compartmentalization and placement of fire barriers to protect against exposure hazard and provide for fire isolation to limit damage and allow personnel egress. Fire protection is discussed in more detail in Chapter 5.0, Section 5.4.11.

1.2.2.4 Program Support.

1.2.2.4.1 Criticality Safety. The criteria used to establish acceptable criticality safety control and the engineered and administrative controls used for prevention of criticality accidents are provided in Chapter 4.0, Section 4.4.4. PHMC contractor requirements and responsibilities for criticality safety are contained in procedures HNF-PRO-334 and HNF-PRO-537 through 550 which implement the DOE requirements.

1.2.2.4.2 Radiological Safety. Shielding is provided to reduce radiation intensities in occupied spaces during all phases of the PFP operation. The activities in the PFP are designed and controlled to limit personnel radiation exposure. A detailed discussion of radiological safety appears in Chapter 8.0.

The *Hanford Site Radiological Controls Manual*, HSRCM-1 (DOE-RL 1995) sets forth the requirements to be followed by all employees who perform work with radioactive materials and radiation-generating devices. All radiation workers are required to understand and abide by the requirements stated in radiation work permits issued in accordance with this manual. The spread and release of contamination is mitigated by several different methods. Radiation survey instruments are provided at strategic locations throughout the facility and continuous air monitors (CAMs) monitor ambient workplace air to provide workers with alarms warning of airborne radioactivity. Also, exhaust air stack and liquid effluent monitoring and alarm systems are provided to monitor a release to the environment. A detailed discussion of radiological safety appears in Chapter 8.0.

1.2.2.4.3 Industrial Health and Safety. Hanford Site Contractor requirements and responsibilities for industrial hygiene and industrial safety are contained in the Occupational Safety and Health topical series of procedures which implement the DOE requirements. The procedures apply to all contractor activities that affect industrial hygiene and safety. A discussion of industrial safety appears in Chapter 4.0, Section 4.4.

1.2.2.4.4 Hazardous Substances. The requirements for working with or near hazardous substances are embodied in the overall PFP health and safety programs that include such items as hazardous material training, hazard communication programs, plant operating procedures, and operator training programs. These programs ensure that employees are fully informed of the potential hazards in their work area and of the necessary protective measures that must be taken (See Chapters 4.0, Section 4.3 and Chapter 10 Section 10.4.5).

1.2.2.4.5 Emergency Preparedness. It is Hanford Site policy to maintain emergency preparedness plans that provide for the protection of people, the environment, and property in the event of emergencies.

These plans provide a coordinated emergency response organization with the capability of handling nuclear, industrial, security, radiological, and nonradiological hazardous materials events. The plans contain mutual aid agreements, identify lines of communication and responsibility, and specify other relationships with local, state, and federal emergency response organizations. These emergency plans also include response to natural phenomena or national emergencies that effect Hanford Site personnel or facilities.

The Emergency Preparedness Plan is implemented by HNF-IP-0263-PFP, *Building Emergency Plan for Plutonium Finishing Plant Complex* (HNF 1998), through subtler plans and procedures as described in Chapter 10.0, Section 10.5, and meets the requirements of local, state, and federal emergency planning agencies.

1.3 GENERAL PROCESS DESCRIPTION

1.3.1 Process Description

During the transition phase between operations (plutonium production-related activities) and D&D, the following activities are conducted within the PFP Complex:

- Plutonium material receiving, storage, and shipping
- Reactive plutonium-bearing material stabilization
- Plutonium-bearing solution stabilization using the Laboratory Prototype Calciner in Room 188 in Building 234-5Z (not authorized for operation)

- Plutonium-bearing solution stabilization using the Production Vertical Denitration Calciner in Room 230C in Building 234-5Z (not authorized for operation)
- Plutonium-bearing solution stabilization using the Magnesium Hydroxide Precipitation Process in Room 230C in Building 234-5Z
- Plutonium material packaging using the Bagless Transfer System in the RMA Line in Building 234-5Z
- Laboratory and engineering support
- Waste handling
- Active and inactive facilities surveillance.

Detailed descriptions of process operations are presented in Chapter 6.0 and summarized below.

1.3.1.1 Special Nuclear Material Receiving, Storage, and Shipping.

1.3.1.1.1 Receiving. Shipments of plutonium material are received at the 2736-ZC loading dock. Shipment to the PFP from offsite requires a preapproved shipping plan that assure that plutonium material containers and contents comply with PFP storage specifications. Shipment is made by the safe secure transport (SST) truck and is unloaded at the 2736-ZC loading dock. The plutonium material shipping documents are checked and the shipping containers are moved into the 2736-ZB Building for inspection, weighing, and nondestructive analysis (NDA) measurement of fissile material contents. If the material requires repackaging, this also is done in the 2736-ZB Building. If the materials are determined to be unstable (e.g., gas evolution, liquid, etc.), a recovery plan that provides for interim safe storage and stabilization is developed and implemented. Stable materials are moved to the 2736-Z Building vaults for storage until final disposition. Chapter 6.0, Section 6.2, provides greater detail of plutonium material shipping and receiving. Chapter 7.0 provides a description of waste handling operations. See Chapter 5.0, Section 5.2.8.4, for more details on the 2376-ZC off-loading dock.

Transfer Operations in Glovebox HC-227S and Hood HC-227T. Previous operations of this glovebox and hood supported the RMC Line conversion of plutonium nitrate to plutonium metal which started with a batch (lot) of nitrate solution selected from various sources to give the correct mix of plutonium isotopes. The batch was loaded into the glovebox HC-227S bank tanks via the hood HC-227T load-in head. The solutions were blended by circulating through the HC-227S bank tanks. This served as a staging glovebox for feed to the RMC Line. The RMC Line is no longer used for conversion of plutonium nitrate to plutonium metal. Currently, the glovebox and hood are used in the LI/LO operations, plutonium-bearing nitrate solutions blending and sampling processes and transfer of nitrate solutions to the RMC Line for stabilization processing using the Production Vertical Denitration Calciner process in glovebox HC-230C-2 (see Chapter 6.0, Sections 6.2 and 6.4.1, for details of these processes). Plutonium nitrate solutions are also transferred to Room 188 in the PPSL for stabilization processing using the Laboratory Prototype

Calciner in Glovebox 188-1 (see the Laboratory Prototype Calciner FSAR addendum for details of this process).

1.3.1.1.2 Storage. Plutonium-bearing materials at the PFP can generally be divided into three categories: (1) stable/shippable material, (2) reactive material (generates gas), and (3) potentially reactive material. The stable/shippable materials (e.g., plutonium metal and PuO_2) are stored in the various PFP vaults. The majority of the cans containing plutonium material are stored on pedestals inside cubicles in the 2736-Z vaults, with additional cans of plutonium material temporarily stored in the 2736-ZB Building which are in transition to and from the NDA laboratory or vault storage in the 2736-Z storage vaults. The concrete walls of the cubicles isolate the pedestals from neutron interaction with the other cubicles. Thermal loading for the cans of materials in storage is limited to 15 W each at the time of storage. The heat output is determined by calculations based on isotopic analytical data and weight of the material. The amount of plutonium in a can is reduced if it is determined to generate more than 15 W. Plutonium nitrate solutions are stored in product receiver (PR) and 10-L polyethylene bottles that are specifically vented to prevent pressurization. The product receiver and bottles are shipping containers that are also used for long-term vault storage. See Chapter 5.0, Sections 5.2.8.3.2 for details on the 2736-ZB Building. See Chapter 6.0, Section 6.3, for details on storage processes. See Chapter 8.0, Section 8.2, for details on the characteristics of the types of plutonium-bearing materials at the PFP and the storage methods of such materials.

1.3.1.1.3 Shipping. Only stable, solid plutonium-bearing materials are shipped offsite. The materials are contained in packages of food pack cans in compliance with shipping containers certificate of compliance. The packages to be shipped are placed in shipping containers and moved to the 2736-ZC dock, where they are placed in cargo restraint transporters which are, in turn, secured in the SST Truck for shipment. See Chapter 6.0, Section 6.2, for details on shipping processes.

1.3.1.2 Reactive Plutonium-bearing Material Stabilization. Miscellaneous plutonium-bearing materials were produced during previous PFP operations. This inventory of plutonium is in the form of pure and mixed oxides, fluorides, oxalates, silicates, and organic-based sludges and residues. Reactive plutonium-bearing materials must be stabilized before long-term storage to prevent the formation of excessive hydrogen or nitrated organic compounds.

1.3.1.2.1 Thermal Stabilization. The thermal stabilization process uses gloveboxes HC-21C and HA-21I, with gloveboxes HC-21A, HC-18BS, HA-23S, HC-18M, HC-13MD, HC-1, HC-2, HC-3, HC-4, HA-22B and HA-28 providing support. The reactive plutonium-bearing materials are converted to a stable form by heating the material to high temperatures in a furnace. See Chapter 6.0, Section 6.4.1, for more details on the thermal stabilization process. See Chapter 5.0, Section 5.2.1.2, for descriptions of the components used in the thermal stabilization process.

1.3.1.2A Plutonium-bearing Solution Stabilization. The PFP currently contains significant quantities of plutonium-bearing solutions which are in a

form considered unsuitable for long-term storage. These solutions primarily consist of:

- Product plutonium nitrate solutions
- Concentrated filtrate solutions
- Flush solutions.

As part of the PFP cleanout operations, these solutions are stabilized by conversion to plutonium oxide which is suitable for long term storage. A vertical denitration calciner (VDC) process is used to stabilize the solutions by heating the material to a temperature of 1000 °C. Either of the two calciners may be used for stabilization of solutions: the Production VDC and/or the Laboratory Prototype Calciner. Only the product plutonium nitrate solutions are suitable for direct stabilization using the VDC process. The other two solutions require pretreatment prior to processing in the VDC. Only processing of the plutonium nitrate solutions in the VDC are covered in this revision of the PFP FSAR. The pretreatment and processing of the other two solutions will be added in a future revision of the FSAR.

1.3.1.2A.1 Production Vertical Denitration Calciner. Processing using the Production VDC begins by loading in the plutonium nitrate solutions using the LI/LO glovebox and hood, HC-227S/HC-227T. The solutions are sampled and blended, as needed, and pumped to the VDC glovebox, HC-230C-2, where it is processed through the VDC. The finished product is transferred to glovebox HC-18M where a sample is removed. The sample is transferred to the PFP analytical laboratory where the loss-on-ignition (LOI) is determined. In the future, it is planned to do LOI testing in Glovebox HC-18M using thermogravimetric analysis equipment which is to be installed. If the LOI results are acceptable, the finished product is appropriately packaged and transferred to the storage vaults. If the LOI results are unacceptable, the material is further stabilized using the reactive material stabilization furnaces as discussed in Section 1.3.1.2.

See Chapter 6.0, Section 6.4.1, for details of the solution stabilization operations using the Production VDC and Chapter 5.0, Section 5.2.1.2, for descriptions of the components used in the solution stabilization operations.

1.3.1.2A.2 Laboratory Prototype Calciner. Processing of plutonium-bearing solutions using the Laboratory Prototype Calciner is described in the addendum to the FSAR titled, *Laboratory Prototype Calciner*. The addendum describes the process and equipment, provides the hazards and accident analyses, and defines the operational controls required.

1.3.1.3 Laboratory and Engineering Support. The laboratories are chartered to operate nonradioactive and radioactive chemically-oriented process and equipment demonstration laboratories to support numerous programs across the Hanford Site and, on occasion, other DOE sites. The PPSL facilities include necessary connections to essential building services including ventilation, drains, vacuum, electricity, water, distilled water, and compressed air. The PPSL supports process facility flowsheet evaluation, troubleshooting, new technology implementation, and process demonstration. The above activities are performed on both bench- and pilot-plant scales. The PPSL also analyzes nonroutine samples for process support and develops new methods that are transferred to other organizations when the methodology is well established

and the need becomes routine. The PPSL also processes limited quantities of plutonium material to demonstrate processes whenever the PPSL has exclusive expertise. See Chapter 6.0, Section 6.5, for details on laboratory support. See Chapter 5.0, Section 5.4.11, for laboratory descriptions.

1.3.1.4 Waste Handling. Waste streams from the PFP are categorized as gaseous, liquid, or solid wastes. Waste streams are either nonradiological or radiological, with liquid and solid wastes also being either nonhazardous or hazardous.

The PFP effluents are managed in accordance with Hanford Site procedures as described in Chapter 7.0. The procedures define the requirements and guidelines used by Hanford contractors to: (1) protect the environment from radioactive materials and other dangerous substances, (2) protect people from radionuclides and other dangerous substances in the environment, and (3) provide a centralized technical interpretation of DOE orders and other pertinent state, federal, and local laws, rules, or regulations promulgated for environmental protection.

Hanford contractors have undertaken an aggressive program to upgrade facilities, laboratories, and administrative systems and to enhance personnel training, etc., to comply with the June 1987 DOE directive to manage radioactive hazardous constituents in accordance with the *Resource Conservation and Recovery Act of 1976* and the subsequent *Hazardous and Solid Waste Amendments of 1984*. Detailed assessments of the PFP environmental compliance to applicable regulations have been conducted during this period. With the aid of these assessments, the PFP management has developed and is implementing upgrade plans to achieve compliance with the applicable regulations. A more detailed description of waste management regulations and processes at the PFP is provided in Chapter 7.0.

1.3.1.5 Active and Inactive Facilities Surveillance. Active and inactive facilities remain on ventilation control and effluent monitoring as long as dispersible radioactive materials remain. Continuous air monitors are also maintained active or portable units are brought in if infrequent entry into an area where dispersible plutonium is present is required. Fire protection and alarms are also generally maintained active. Criticality incident detection is normally not maintained for inactive facilities once fissile material quantities, forms, or configurations ensure criticality prevention. Also, for inactive facilities, equipment is isolated from electrical power and motor control centers may be removed.

Surveillance of the inactive facilities is conducted on a once-per-shift to infrequent basis. For example, surveillance of 242-Z is made only when corrective action maintenance or repairs are necessary in the 242-Z facilities. Surveillance is conducted in the 232-Z Building on a shiftly (at least once every 12 h) frequency for detection of abnormalities. The remaining inactive facilities, which are within the 234-5Z Building, are checked on a daily to once-per-shift basis.

Surveillances are conducted primarily to ascertain that conditions within the facility have not changed. The condition of gloveboxes and equipment are noted. Particular emphasis is placed on noting if water is present. Ventilation is checked to determine if it is operating. Radiation surveys are

made on a prescribed frequency depending on the facility, the potential for loss of control, and the potential consequences of a loss of control.

1.3.2 Process Support Activities

1.3.2.1 Plutonium Finishing Plant Analytical Laboratory. The PFP AL, located in the east end of the 234-5Z Building, is used to perform chemical analysis and physical test analysis on plutonium samples. The samples come from transition operations (within the PFP), the PPSL, and a few special test samples from other locations. A more detailed description of the PFP AL is presented in Chapter 5.0, Section 5.4.14.

The samples received and analyzed represent process control, material accountability, and product analysis. Both chemical analyses and physical tests are performed. The samples may be liquids, solids (metal and oxide), or filter media.

Chemical analyses are performed to determine major and minor element content, isotopic ratios, radiochemical characteristics, and pH. Physical tests to determine LOI, particle size, and density are also performed.

All laboratory activities are done by procedure. The activities performed by trained personnel and their performance is controlled and monitored by a quality control program that includes analysis of standards, compliance overchecks, and audits.

1.3.2.2 Standards Laboratory. The standards preparation unit support provided in rooms 221-C, 221-D, and 221-E is devoted to the formulation, verification, packaging, and distribution of actinide-containing destructive and nondestructive standards needed in the laboratories. A detailed description of the Standards Laboratory is presented in Chapter 5.0, Section 5.4.14.

1.3.2.3 Plutonium Process Support Laboratory. The PPSL is located in the southwest corner of the 234-5Z Building in rooms 179B through 191, and room 202. The laboratory is chartered to operate chemical demonstration facilities involving both nonradioactive and radioactive materials. The PPSL also analyzes nonroutine samples for process support, develops new methods that are transferred to other organizations after the methodology is well established and the need becomes routine, and processes limited quantities of SNM to demonstrate processes whenever the PPSL has exclusive expertise.

1.3.2.4 Safeguards and Security. The Hanford Site Safeguards and Security program is designed to protect SNM, government facilities and equipment, and classified information. DOE Order 470.1, *Safeguards and Security Program* (DOE 1995b), requires that line management be directly responsible for assuring a secure operation.

Security is maintained to provide the protection to materials through the use of fences, guards, secured facilities, and other physical protection. The details of these systems are classified.

1.3.2.5 Special Nuclear Material Management. Plutonium, in a number of physical and chemical forms, can be received, stored, processed, and staged for shipment at the PFP. There are a number of classified plans, reports, and forecasts that support the long-term plans.

1.3.2.6 Cleanout Operations and Decontamination and Decommissioning.

1.3.2.6.1 Cleanout Operations. The cleanout operations of processing areas is intended to (1) allow recovery and stabilization of residual scrap plutonium and (2) leave the areas in a stable standby condition requiring minimal surveillance pending final disposition.

Recovery of plutonium scrap will occur at selected sites based on the amount of plutonium available for recovery, ease of access, and technology requirements for recovery. These sites consist of gloveboxes, plutonium processing equipment installed in gloveboxes and process cells, and service systems for the processing areas (ventilation, vacuum, and transfer lines).

Facility stabilization will occur throughout the plutonium processing areas identified for cleanout operations. All service piping should be disconnected with the exception of those required for ventilation and fire protection. Electrical services, with the exception of lighting, should be disconnected to remove potential ignition sources. Most combustible material should be removed from the facility and all glovebox openings, with the exception of inlet and outlet HEPA filters, should be covered with metal plates. The cleanout operations include the stabilization and storage of potentially unstable scrap recovered during cleanout operations.

1.3.2.6.2 Decontamination and Decommissioning. Facilities selected for D&D are those previously placed in a stable condition through terminal cleanout operations (TCO) of areas identified for cleanout, which include gloveboxes, plutonium processing equipment installed in gloveboxes and process cells, and service systems (ventilation, vacuum, and transfer lines) for these areas. The objective of D&D is to remove these facilities and appropriately characterize and dispose of them as waste. See Chapter 4.0, Section 4.5 for a discussion of D&D activities.

1.3.2.7 Waste Processing. Liquid TRU-containing wastes are disposed of via 241-Z and transferred to tank farms. Low-level (non-TRU) waste water is treated by the 243-Z Building (LLWTF) and sent to the Treated Effluent Disposal Facility (TEDF) for disposal. Solid wastes are disposed of by transfer to the Central Waste Complex low level waste burial grounds or an offsite TSD facility. See Chapter 7.0 for a discussion of waste processing activities.

1.3.2.8 Maintenance Support. Maintenance support consists mainly of in-plant forces backed up by area shop personnel when required. In-plant personnel perform routine maintenance on a day-to-day basis. Shop crews support the routine maintenance, perform major repairs, and provide a wide variety of shop prefabricated items. In-plant process work on contaminated equipment is carried out in either open-faced hoods, gloveboxes, or other means as required to maintain personnel contamination and exposure as low as reasonably achievable (ALARA) in the PFP. See Chapter 8.0 for discussion of the implementation of ALARA policies at the PFP.

1.3.2.9 Safety Analysis Report for Packaging. A Safety Analysis Report for Packaging (SARP) provides a comprehensive technical evaluation and review of the design, testing, operational procedures, maintenance procedures, and quality assurance program to demonstrate compliance with the NRC regulatory safety standards, U.S. Department of Transportation (DOT) standards, or equivalent standards established by the DOE for approving packaging and issuing certifications of compliance. All SARPs are implemented through PFP procedures.

1.4 IDENTIFICATION OF AGENTS AND CONTRACTORS

The FH Nuclear Material Stabilization (NMS), as the PFP facility operating contractor, interfaces with many Hanford Site organizations. Fluor Hanford Inc. (FH) is the Hanford Site integrating contractor. Finally, there are three other organizations that contract directly with DOE-RL for specific services at the Hanford Site. The integrating contractor, and other DOE-RL contractors are described in more detail in Chapter 10.0, Section 10.1.16.

1.5 MEMORANDUMS OF UNDERSTANDING

Memorandums of Understanding (MOUs) are documents used at the PFP to formally establish communication between the management and employees of two organizations regarding the assignment of responsibilities. They are prepared and implemented by cognizant personnel who are directly involved with each individual system or facility. Each MOU describes interface points between two organizations and assigns responsibilities for the operation, maintenance, and configuration management of a system or service.

1.5.1 Plutonium Finishing Plant Memorandums of Understanding

The following are MOUs that the PFP has with various supporting organizations, as identified in FSP-PFP-0821-PUO, *Plutonium Operations Administration*.

1.5.1.1 Steam and Water Interface Agreement. This document provides an agreement between 200 W Area Water Utilities. A similar agreement is in place with Johnson Controls to ensure steam delivery to the PFP.

1.5.1.2 Electrical Utilities. This document augments an agreement between the 200 West Area, PFP, and Electrical Utilities, and to further describe the interface points and responsibilities of the operation, maintenance, and configuration management of electrical systems and services.

(3 sheets)

Building number	Contents/purpose
200-Z	Maps, outside and underground facilities
207-Z	Retention basin
216-Z-1[c]	Crib (isolated: pipe has been capped or removed)
216-Z-1A[c]	Tile field, sanitary tile field (isolated: pipe has been capped or removed)
215-Z-1AA[c]	Tile field (isolated: pipe has been capped or removed)
216-Z-1AB[c]	Tile field (isolated: pipe has been capped or removed)
216-Z-1AC[c]	Tile field (isolated: pipe has been capped or removed)
216-Z-7[c]	Crib (isolated: pipe has been capped or removed)
216-Z-8[c]	French drain (isolated: pipe has been capped or removed)
216-Z-9[b,c]	Crib (isolated: pipe has been capped or removed)
216-Z-9A[b,c]	Contaminated soil removal facility
216-Z-9B[b,c]	Industrial building; prefab building
216-Z-9C[b,c]	Industrial building; prefab building
216-Z-10[c]	Reverse wells (isolated: pipe has been capped or removed)
216-Z-11[c]	Ditch (isolated: pipe has been capped or removed)
216-Z-12[c]	Crib (isolated: pipe has been capped or removed)
216-Z-13	French drain
216-Z-14	French drain
216-Z-15	French drain
216-Z-16[c]	Crib (isolated: pipe has been capped or removed)
216-Z-18[c]	Crib (isolated: pipe has been capped or removed)
216-Z-19	Ditch (abandoned)
216-Z-20[c]	Crib (isolated: pipe has been grout-capped), Z8 manhole grouted
216-Z-21[c]	Pond (isolated: pipe has been grout-capped)
231-Z[b]	Materials Engineering Laboratory/Building (200ADP facility - contains Plutonium Finishing Plant Plutonium material)
232-Z[a]	Waste Incinerator Facility (not used)
234-5Z[a]	Plutonium Finishing Plant; plutonium conversion facility
234-5ZA	Change room and MICON™ control station
234-ZB	Miscellaneous storage for construction forces (FFS-owned actylene, propane, oxygen, argon nitrogen storage)
234-ZC[a]	Loading dock for waste drums and special nuclear material containers (West End)
236-Z[a]	Plutonium Reclamation Facility (not used). Temporary storage of in-process material in access gloveboxes.
241-Z[a]	Liquid waste storage and treatment tanks in underground concrete cells
241-Z-RB	Waste water retention basin (not used)
241-ZA	Sample building: sample/loadout building
241-ZB	Curbed concrete pad housing the D-9 caustic tank
241-ZG	241-Z change room
241-Z-361	Underground liquid waste settling tank (no longer used)
242-Z[a]	Waste Treatment facility (not used)
242-ZA	Monitoring building (also known as TC-66)
243-Z[a]	Low-Level Waste Treatment Facility
243-ZA	Tank
243-ZB	Cooling towers and concrete pads for closed-loop cooling water system
252-Z-1	Electrical transformer (North of 234-5Z)
252-Z-2	Electrical transformer (in 291-Z Building)
2607-W-8	Septic tank
2607-WA	Septic tank
2607-WB	Septic tank

Table 1-1. Plutonium Finishing Plant Buildings and Structures. (3 sheets)

Building number	Contents/purpose
2607-Z	Septic tank
2607-Z-1	Septic tank
267-Z	Valve house for water supply to a 234-5Z sprinkler system (Riser #9 valve house)
270-Z	PFP support facility (office building) (houses emergency control center)
291-Z[a]	Ventilation exhaust fan house
291-Z-1[a]	Ventilation exhaust stack for 232-Z, 234-5Z, and 242-Z Buildings
296-Z-3[a]	Ventilation exhaust stack for 241 cells and tanks
296-Z-5[a]	Ventilation exhaust stack for 2736-ZB Building
296-Z-6[a]	Ventilation exhaust stack for 2736-Z Building
296-Z-14[a]	Ventilation exhaust stack for 232-Z Building
296-Z-15[a]	Ventilation exhaust stack for 243-Z Building
2503-Z	Electrical distribution system for PFP (switch yard)
2701-ZA	Central station alarm facility (criticality alarm portion)
2701-ZD	PFP badge house
2702-Z	Microwave tower
2704-Z	PFP support building (office building)
2705-Z	Operations control facility
2706-Z	Septic tank
2712-Z	291-Z-1 stack sampler and monitor shack
2715-Z	Paint shop (paint, oil, solvent, and drum storage)
2721-Z[a]	Backup electric power generators (diesel driven)
2722-Z	Concrete pad for truck load-out station
2727-Z	Storage of miscellaneous operations and laboratory equipment
2729-Z	Storage of miscellaneous maintenance materials
2731-Z	Storage of empty flushed plutonium drums
2731-ZA	Laundry storage
2734-Z	Gas bottle storage
2734-ZA	Empty cylinder storage
2734-ZB	Breathing air cylinder storage
2734-ZC	P-10 gas supply, P-10 and oxygen cylinder storage
2734-ZD	Empty non-flammable cylinder storage
2734-ZF	Standby gas bottle storage (not used)
2734-ZG	Nitrogen gas supply
2734-ZH	Argon bottle supply (not used)
2734-ZJ	Liquid nitrogen storage tank
2734-ZK	Gas bottle storage, acetylene, argon, propane
2734-ZL	HF gas bottles and supply piping (not used)
2735-Z	Chemical storage of HNO_3, and ANN (not used)
2736-Z[a]	Plutonium material storage
2736-ZA[a]	2736-Z exhaust fans
2736-ZB[a]	Shipping and receiving SNM
2736-ZC[a]	Loading dock
2736-ZD[a]	Experimental Breeder Reactor II cask storage
2900-Z	Underground lines
2901-Z	Water tower
2902-Z	Elevated sanitary water tank and valvepit (not used)
2904-Z	Monitoring building
2904-ZA[b]	Sheet metal structure that housed 216-Z-20 crib stream effluent sampling, flow measurement, pH and alpha monitoring equipment (not used)

PLUTONIUM FINISHING PLANT
FINAL SAFETY ANALYSIS REPORT

CHAPTER 2.0

SUMMARY SAFETY ASSESSMENT

FEBRUARY 2001

This page intentionally left blank.

PREFACE

Revision 2 of Chapter 2.0 of the Plutonium Finishing Plant (PFP) Final Safety Analysis Report (FSAR) includes modifications for the following:

- Addition of the summary for a new abnormal event; Loss of Filtration
- Revision to the existing summary for the Reactive Plutonium-Bearing Material Stabilization to include HC-21C and HA-21I
- Revised dose consequence summary tables
- Incorporation of the Magnesium Hydroxide Precipitation Process
- Incorporation of the Bagless Transfer System

Other minor changes include editorial changes and clarifications.

It is noted that various sections of Chapter 2.0 present information concerning plutonium-bearing solution stabilization operations using the Production Vertical Denitration Calciner located in the RMC Line and the Laboratory Prototype Calciner located in the Plutonium Process Support Laboratories. Operation of either the production calciner or the laboratory calciner for solution stabilization is not authorized at this time and the related portions of Chapter 2.0 will be updated, if necessary, prior to initiation of operations.

The new packaged boilers operated by Johnson Controls, Inc. which provide steam to the PFP were previously incorporated in the FSAR. This included switching the emergency exhaust fans from those which are steam-driven to those which are connected to the standby power system. However, the conversion from using steam-driven fans to standby power driven fans has not been fully implemented. The emergency exhaust fans are currently run by the new steam supply system installed under the Hanford energy conservation program. Electrically-driven emergency exhaust fans are planned to be connected to the diesel-generator standby power supply at some future date. The emergency exhaust fan functions are unchanged from that described in the FSAR regardless of the type and source of power.

The significant areas of change in Revision 2 are indicated by vertical bars in the margin of each page.

2.0 SUMMARY SAFETY ASSESSMENT

This chapter summarizes safety assessments presented in Chapters 3, 7, and 9 of this Final Safety Analysis Report (FSAR). Section 2.1 summarizes the detailed analyses of the Hanford Site and its potential impacts to the Plutonium Finishing Plant (PFP) as presented in Chapter 3.0, "Site Characteristics." Included, for example, are analyses of severe natural phenomenon and the effects of nearby industrial facilities.

Section 2.2 summarizes the radiological impact of normal operations. This impact is defined in terms of the quantities and characteristics of gaseous, liquid, and solid wastes generated by normal PFP operations as detailed in Chapter in 7.0, "Waste Management."

Section 2.3 summarizes analyses of abnormal operations, defined as events that occur from malfunctions of systems, operating conditions, or operator error. Examples include plutonium-bearing liquid and powder spills and ventilation system upsets. Detailed analyses of abnormal operations are presented in Section 9.1 of Chapter 9.0, "Accident Analysis."

Section 2.4 summarizes analyses of potential accidents presented in Chapter 9.0, Section 9.2. The analyses quantify the consequences and frequencies of potential accidents and compare the resultant values to risk acceptance guidelines. Conclusions are drawn in Section 2.5.

Many years of analysis have gone into assessing the ability of the PFP to serve the U.S. Department of Energy (DOE) environmental management mission. The FSAR documents that operations can be conducted safely and that the plant can continue its current mission with an acceptable level of risk. The following four items are provided in summary.

1. The PFP has been operating for 50 years with no significant radiological or toxicological impact to onsite (off plant) or offsite populations. The calculated offsite radiological exposure from normal operations is less than 0.005% of that received from natural background.

2. The PFP is located on the 560-mi^2 Hanford Site under the control of the DOE. The impact of severe site-specific natural phenomenon on the PFP has been analyzed and the associated risk found to be acceptable.

3. The PFP chemical processes are low energy and conducted in a sequential batch or campaign manner. The processes are fault tolerant, and a safe shutdown configuration can be accomplished in minutes.

4. The PFP process configuration is flexible and can be managed satisfactorily to safely perform current and future operations.

2.1 SITE ANALYSIS

The PFP is located within the 560-mi^2 Hanford Site. The closest public access to the PFP is State Route 240, 2.5 mi to the west, and the Columbia River approximately 7 mi to the north. Chapter 1, Section 1.2.1, "Site Characteristics," provides a summary description of the Hanford Site. A detailed description is provided in Chapter 3.

2.1.1 Natural Phenomena

Chapter 3.0 identifies and characterizes site-specific natural phenomena that could potentially impact the PFP. These phenomena include: flooding, strong wind (including wind-generated missiles), lightning, snow fall, earthquakes, and volcanic ash fall. The analysis identified only two forces, a sustained strong wind (and associated wind-generated missiles) and an earthquake, with the potential for initiating a release of radioactive or toxic materials.

2.1.1.1 Strong Wind. Hanford Site local meteorology has been recorded and studied for over 50 years. The U.S. Weather Bureau cooperative station records for precipitation date from 1912. Phenomena such as hurricanes and large tornadoes are inconsistent with the region. For analysis purposes, a sustained strong wind of 90 mi/h was used in accordance with Hanford Plant Standard SDC 4.1 (WHC 1991). The annual probability of this wind occurring is between 1.0×10^{-5} and 1.0×10^{-6}, which is within the credibility envelope used.

The wind-generated missile event is derived from UCRL 15910 (Kennedy et al. 1990) design and evaluation guidelines. The event consists of a strong wind driving a missile into the plant. Analysis and tests used a 12-ft 2 x 4 piece of lumber as the missile, being driven by the wind horizontally into the side of the facility. All facility side panels withstand the impact of the strike, with the exception of the 241-Z and 232-Z Buildings. Analysis of the combined probability of the sustained strong wind and a missile being driven into a critical portion of the plant was less than 1.0×10^{-6}, thus incredible. Outdoor hazardous material storage facilities are vulnerable to wind-generated missile strikes.

2.1.1.2 Earthquake. The primary earthquake-generating structures considered to be capable are the Rattlesnake-Wallula Alignment and the Gable Mountain/Gable Butte structure (see Section 3.6.1.2.1). The maximum acceleration at the Hanford Site from historical or instrumental earthquake data is estimated to have been 0.15 g. A peak acceleration of 0.20 g at ground surface has been assigned for the design basis earthquake (DBE) and is consistent with the Hanford Plant Standard SDC 4.1 (WHC 1991). The current seismic analysis for the PFP uses a 0.20-g seismic event as the DBE. Structural analyses conclude all significant process buildings, except the 232-Z Building resist DBE motion without collapse. Analyses of the 232-Z Building have shown it to survive seismic events up to 0.09 g in magnitude.

2.1.2 Safety Assessment

The PFP Complex is located in the 200 West Area of the Hanford Site. This remoteness, in conjunction with the ability to control access to the Hanford Site, enhances the margin of safety to the public of an existing, safe plant. Access control consists of three well-defined physical and administrative envelopes surrounding the PFP. These envelopes are as follows.

1. The DOE posts and controls access to the Hanford Site, including regular road patrols of State Route 240. This is equivalent to a 10 CFR 100 (NRC 1982) exclusion area.

2. The 200 West Area is a fenced area 2.5 mi from State Route 240. After entering the Hanford Site from one of the three controlled site entrances (Wye, Yakima, and Rattlesnake Barricades), there are three normally uncontrolled access gates to the 200 West Area.

3. The PFP is in the center of a secured restricted area inside 200 West Area. Access to the PFP is based upon the provisions of the *Atomic Energy Act of 1954*. The plant manager through the Hanford Patrol controls personnel and vehicular access. Authorized entry or exit is allowed only after satisfactory security inspection made by Hanford Patrol.

The location of the PFP, in relation to the prevailing winds and the rest of the Hanford Site, reduces the impact from any potential release to offsite personnel. The prevailing winds would direct the release plume away from areas of concentrated population.

2.1.3 Effects of Nearby Industrial, Transportation, and Military Facilities

There are no nearby industrial, transportation, or military facilities, other than those on the Hanford Site controlled by DOE, that can impact or be impacted by the PFP (see Section 3.2). The buildings within the PFP Emergency Response Envelope are located within the 200 West Area fence line.

The closest, routinely occupied onsite facility is the 272-WA Building, 0.6 km to the north northwest. Occupants of this building are defined as onsite receptors for Chapter 9.0 analysis purposes.

2.1.3.1 Industrial Facilities. The primary business in southeastern Washington is grazing and dry land or irrigated agriculture. No industrial facilities, nuclear facilities, gas pipeline, fuel or chemical storage sites, quarries or other such operations exist that would impact PFP. Bonneville Power Administration high-voltage transmission lines traverse the Hanford Site several miles from PFP.

2.1.3.2 Military Facilities. The U.S. Army Yakima Firing Range boundary is about 18 mi northwest of PFP. Live firing conducted has no impact on the Hanford Site. A military flight path (VR1350) is located 9 mi west of the PFP. This airway was analyzed and found to have no impact. There are no

other military operations that could conceivably be involved with the Hanford Site.

2.1.3.3 Transportation Facilities. Located 2.5 mi from PFP, State Route 240 is the closest transportation route to PFP. State Route 240 crosses the Hanford Site. This road along with other Hanford Site roads, are used for the commercial transport of fuel and common hazardous chemicals. There is no impact to PFP from these roadways and the PFP operations have no impact on these transport operations.

2.1.3.3.1 Aircraft Events. Hanford Site airspace is classified as uncontrolled airspace. Aircraft operators are requested by the Federal Aviation Administration to avoid flight below 2,400 ft mean sea level (msl) over the Hanford Site. There are three airports within 35 mi. A general aviation airport in Richland is closest, being 25 mi from the PFP. Three Federal Low Altitude Airways and one Military Training Route cross the Hanford Site.

Aircraft accident analysis based on NUREG-75/087 (NRC 1975) assessed the impact on the PFP. The annual probability of an accident resulting in consequences greater than 10 CFR 100 (NRC 1982) were less than 1.0×10^{-6}, and therefore considered incredible.

In addition to commercial and military air traffic, DOE-sponsored helicopter overflights of the Hanford Site have been performed for the purpose of gathering radiological survey data. These flights differ from those described above as the helicopters intentionally fly at low altitudes and in relatively close proximity to nuclear facilities. A helicopter crash into the PFP is judged to be an incredible event as long as the helicopters do not operate in the near proximity of the PFP (i.e., a 2,300 foot square centered on the 291-Z-1 stack).

2.1.3.4 Tall Structures. There are two tall structures associated with the plant, 291-Z-1 stack and the 50,000-gal elevated water tank. The 291-Z-1 stack is 200 ft tall and the release point for most gaseous effluents from PFP. Analysis confirmed that the stack will not fail in a DBE or strong wind. The elevated water tank will fail in the DBE. However, it is braced to control the mode of failure so that the building confinement boundary will not be breached. Tank failure will not impact the 270-Z Building.

2.2 RADIOLOGICAL IMPACT OF NORMAL OPERATIONS

Radioactive effluents generated during normal operations could potentially result in a significant radiological impact. Three radioactive effluent streams are generated; liquid, gaseous, and solid. Each effluent stream is individually managed based on radioactivity, toxicity, chemical and physical form. During normal operations, only the gaseous effluents result in a calculable offsite exposure.

2.2.1 Radioactive Gaseous Effluents

There are six gaseous effluent stacks for the PFP complex, five of which are routinely sampled and monitored. The effluents pass through one or two stages of high-efficiency particulate air (HEPA) filtration depending upon the area serviced. The principal isotopes present are $^{238,239,240,242}Pu$ and ^{241}Am. The activity released has historically been less than the regulatory-driven as low as reasonably achievable (ALARA) based emission control objectives. The associated offsite doses are a small fraction of that received from natural background radiation.

2.2.1.1 Quantity and Concentrations of Gaseous Effluent Streams. Five sampled and monitored gaseous effluent streams are associated with the PFP, 291-Z-1, 296-Z-3, 296-Z-5, 296-Z-6, and 296-Z-14 and one periodically sampled and unmonitored, 296-Z-15. Gaseous effluents from stack 291-Z-1, 200 ft tall, represent the majority of total exhaust from the PFP. The remaining five are minor stacks that release at an elevation of approximately 40 ft or less.

Gaseous effluent release data for 1990 through 1995 are provided in Table 2-1. The principle isotopes potentially released are $^{238,239,240,241}Pu$ and ^{241}Am. The release data in Chapter 7 demonstrates that the regulatory-driven ALARA based emission control objectives have been met.

2.2.1.2 Onsite and Offsite Receptors. Personnel located within the PFP Emergency Response Envelope, the PFP and associated buildings are defined as PFP facility workers and are not considered to be onsite personnel for consequence analysis purposes. The nearest onsite receptors occupy the 272-WA Building, 0.6 km north-northwest of the PFP.

To calculate consequences to the maximally exposed offsite individual, the offsite receptor is defined as the occupant at the nearest affected place just beyond the Hanford Site boundary. This individual is a hypothetical farmer living on the Hanford Site boundary at the point with the highest impact from the PFP plume. This farmer is 13.5 mi west-northwest from the PFP. An individual driving on State Route 240 or the recreational fisherman on the Columbia River is not considered as an offsite receptor as they are both judged to be within boundaries under the control of the DOE and could be evacuated in less than two hours.

2.2.1.3 Radiological Impact to Offsite Receptors. The GENII computer program (Napier et al. 1988) was used to calculate the doses to the maximally exposed offsite receptors and to the offsite population for gaseous effluent resulting from normal operations (Table 2-2). Two source locations were modeled: the 200 ft 291-Z-1 stack and a ground level release (for a release from any one of the three short stacks). The dose calculations for normal operations were based on the release data for the years 1989 through June of 1995. Using this data, the dose to the maximally exposed offsite individual is several orders of magnitude less than either the EPA limit (40 CFR 61, Subpart H) of 10 mrem/yr effective dose equivalent (EDE) (air pathway) or the DOE limit (DOE Order 5400.5) of 100 mrem/yr EDE continuous exposure over 5 years, 500 mrem/yr EDE occasional exposure.

2.2.2 Radioactive Liquid Wastes

There are three radioactive liquid waste (RLW) streams (one of which is currently being generated) discharged from the 236-Z and 234-5Z Buildings. The RLW is transferred to and stored temporarily in tanks at the 241-Z facility. There, it is treated to render it suitable for transport through underground pipelines to the Hanford Site tank farms for storage in double-shell tanks. The RLW streams are:

1. High-salt waste (HSW) from the Plutonium Reclamation Facility (PRF) in the 236-Z Building (the PRF is not authorized for production operation)

2. HSW from the Remote Mechanical C (RMC) Line in the 234-5Z Building (currently inactive)

3. Low-salt waste from laboratories and miscellaneous sources in the PFP.

These RLW streams are contained and isolated from the environment. During normal operations there is no impact to onsite or offsite receptors from these wastes.

Waste water with a radioactive interface includes cooling water, process steam condensate, and floor drains. The waste water, from drain lines D-1, D-2, and D-3 is sent to the Low-Level Waste Treatment Facility (LLWTF) (see Chapter 7). This stream was sent to the 216-Z-20 crib before the construction and operation of the Treated Effluent Disposal Facility (TEDF). The treatment at the LLWTF results in a decontamination factor of approximately 100 to 1. After treatment in the LLWTF, the stream meets the Derived Concentration Guides (DCGs) of DOE Order 5400.5, Chapter 3. The treated water from the LLWTF is routed to the TEDF for final disposal.

Steam condensate and floor drain discharges from the 291-Z Building are routed to French drains (see Chapter 7). Radiological inventories are not available for these streams, low-level radioactive contamination is not expected, but has been assumed.

2.2.2.1 Quantity and Concentrations of Liquid Effluent Streams. Currently there are two streams released to the environment (i.e., French drains 216-Z-13 and 216-Z-14). Prior to the construction and operation of the TEDF, waste water streams were also discharged to the 216-Z-20 crib.

2.2.2.1.1 French Drains. Three potentially contaminated French drains (216-Z-13, 216-Z-14, and 216-Z-15) are located at the PFP, only French drains 216-Z-13 and 216-Z-14 are in operation. The 291-Z Building evaporator cooler drainage, which was routed to French drain 216-Z-15, is now transferred to the LLWTF. The sources to the drains are not contaminated, but there is the potential for past radiological contamination. Radiological inventories are not available for these streams, low-level radioactive contamination is not expected, but has been assumed.

2.2.2.2 Radiological Impact on Offsite and Onsite Receptors. In the case of liquid effluents, the source term is retained on the soil column and not immediately available to any receptor. It is estimated that the source term is isolated from the groundwater by over 100 ft of soil column. Because the source term is immobilized, a complete analysis of this pathway was not performed. There is no scenario in which this source term would impact the current onsite or offsite population.

2.2.3 Radioactive Solid Wastes

Four categories of solid radioactive waste are generated by the PFP:

1. The LLW (or room waste)
2. The Waste Isolation Pilot Plant (WIPP) certifiable transuranic (TRU) waste (or hood waste)
3. Non-WIPP certifiable TRU waste
4. Polychlorinated biphenyl (PCB)/absorbed organic waste.

Room waste is potentially contaminated solid radioactive waste generated at the PFP, such as rags, paper, gloves, etc. The WIPP certifiable TRU waste is in excess of 100 nCi/g of plutonium and meets the acceptance requirements for transfer to WIPP. The non-WIPP certifiable waste contains aerosol cans. The TRU scrap with recoverable amounts of plutonium are stabilized and placed in storage.

2.2.3.1 Quantity and Types of Solid Waste Produced. Solid wastes are segregated based on ultimate disposal method. They are handled as WIPP waste, non-WIPP TRU solid waste transferred to 20-year retrievable storage and low-level solid wastes. The PCB/absorbed organic wastes are collected, sampled, and analyzed in accordance with U.S. Environmental Protection Agency (EPA) procedures. The PCB/absorbed organic wastes are stored according to applicable storage regulations for later transfer for processing.

The solid wastes are packaged based on the ultimate disposal option and are consistent with U.S. Department of Transportation regulations and Hanford contractor procedures. The outside containers of waste packages must be free of smearable contamination (20 dpm/100 cm^2 for alpha). The nominal solid waste volumes historically generated on an annual basis are shown in Table 2-3.

2.2.3.2 Radiological Impact on Offsite and Onsite Receptors. Within the scope of this FSAR there is no credible scenario in which solid waste generated would impact the onsite or offsite population. None of the waste has been transported offsite. Transportation of this material is addressed in appropriate packaging and shipping safety documentation.

2.3 RADIOLOGICAL IMPACT FROM ABNORMAL OPERATIONS

For the purposes of this FSAR, abnormal operations are defined as events that could occur from malfunctions of systems, operating conditions, or operator error. In general, the magnitude of the events discussed would not have a significant effect beyond the exclusion zone.

Chapter 9.0, Section 9.1, identifies and analyzes potential abnormal operations. The events presented are generic in nature and were developed, in part, from a composite of actual events recorded in the 50 years of PFP operating experience. The abnormal operations analyzed and their respective Chapter 9.0 section numbers are as follows:

- Radioisotope-Bearing Liquid Spills (Section 9.1.1)
- Radioisotope-Bearing Pressurized Liquid Container (Section 9.1.2)
- Radioisotope-Bearing Powder Spills (Section 9.1.3)
- Radioisotope-Bearing Pressurized Powder Container (Section 9.1.4)
- Stack Release Resulting from Filter Changes (Section 9.1.5)
- Ventilation System Upsets (Section 9.1.7)
  - Excessive Pressurization, 234-5Z Building (Section 9.1.7A)
  - Excessive Pressurization, 236-Z Building (Section 9.1.7B)
  - Excessive Pressurization, 2736-ZB Building (Section 9.1.7C)
  - Excessive Pressurization, 2736-Z Building (Section 9.1.7D)
  - Excessive Pressurization, 241-Z Building (Section 9.1.7E)
  - Excessive Depressurization — All PFP Operating Buildings (Section 9.1.7F)
- Loss of Ventilation (Section 9.1.8)
- Glovebox Glove Breach (Section 9.1.9).
- Pressurized Production Vertical Denitration Calciner (Section 9.1.10.1).
- Reactive Material Thermal Stabilization Process (Section 9.1.11).
- Laboratory Prototype Calciner (Section 9.1.12).
- Loss of Filtration (Section 9.1.13).
- Magnesium Hydroxide Precipitation Process (9.1.14).

- Bagless Transfer System (9.1.15).

The abnormal operations listed above are summarized in the following sections and in Table 2-4. In assessing the acceptance of certain abnormal operations, reference is made to risk acceptance guidelines. These guidelines, established for both radioactive and toxic materials, are presented in Chapter 9.0, Tables 9-49 and 9-50, respectively.

2.3.1 Radioisotope-Bearing Liquid Spills

Associated with the handling of almost any liquid at the PFP is the risk of a spill. The greatest likelihood of a spill, however, occurs during the handling of small plutonium-bearing laboratory samples. The composition of the spilled liquid could vary from slightly contaminated waste water to liquids containing significant amounts of radionuclides. All radionuclide-bearing liquids handled in the PFP are confined within protective systems that prevent or minimize a release to the environment resulting from the failure of a single system.

Although the spill of a laboratory sample is most probable, the worst case abnormal event conservatively assumes that the contents of a 10-L polyethylene or steel bottle containing concentrated plutonium nitrate solution are spilled from a height of 3 m onto the floor outside of a glovebox. As a result of the spill, it is estimated that 0.002% (by weight) of the plutonium nitrate solution with a 1,640 g/liter density, or 0.33 g (0.16 g Pu), becomes airborne as droplets. A single stage of HEPA filtration reduces the amount of Pu released to the environment to a level well below the risk acceptance guidelines for an event with a frequency of 1/yr.

2.3.2 Radioisotope-Bearing Pressurized Liquid Container

Containers of plutonium-bearing liquids, each having a small potential to become pressurized, are stored in the PFP in a variety of locations, quantities, and concentrations. Pressurization of containers can occur passively (e.g., chemical decomposition of the contained liquids and nuclear degradation of the primary container) or actively (e.g., external application of heat and physical crushing as a result of mishandling). It is assumed that the containers are handled using normal methods, including the performance of all venting and lid-removal procedures in open-faced hoods.

Pressurization of a container storing a liquid solution does not become an abnormal event until it results in failure of the primary container or causes a spill when an attempt is made to transfer the liquid. When an operator opens an overpack and determines that the primary container has failed due to overpressurization, the failure would, in most cases, be mitigated by the secondary container (overpack). If the pressure in a container has not been relieved due to plugging of the vent valve or improper venting before opening the container, the result could be personnel injury and contamination spread due to a rapid discharge of gases and liquids when the lid is removed.

The postulated event conservatively assumes that 5 L of a plutonium nitrate solution contained in a 10-L polyethylene bottle is ejected from the container and then spilled 3 m onto the floor outside of a glovebox. As a result of the spill, it is estimated that 0.002% (by weight) of the plutonium nitrate solution with a 1,640 g/liter density, or 0.16 g (0.08 g of Pu), may become airborne as droplets. A single stage of HEPA filtration reduces the amount of Pu released to the environment to a level well below the risk acceptance guidelines for an event having a frequency of 1/yr.

2.3.3 Radioisotope-Bearing Powder Spills

Associated with the handling of plutonium-bearing powders in the PFP is the risk of a spill occurring. Before removal from a glovebox the powder is placed in a metal slip-lid can, the lid is taped shut, and the can is placed in a plastic bag that is heat-sealed. After removal from the glovebox, the package is mechanically sealed into two successively larger cans. Tests have shown that slip-lid cans with untaped lids can withstand drops of 3 m without sustaining a loss of contents. Therefore, a series of errors must happen for a powder spill to occur.

The analysis conservatively assumes that 1 kg of PuO_2 powder (the maximum capacity of a slip-lid can) is spilled from a height of 3 m onto the floor outside of a glovebox. As a result of the free fall spill, it is estimated that 0.12% (by weight) of the PuO_2 powder, or 1.2 g, becomes airborne. Prior to release to the environment from the PFP stack, the 1.2 g of PuO_2 must pass through a single stage of HEPA filtration. Given a HEPA filter efficiency of 99.95%, only 6×10^{-4} g of Pu would reach the stack. The resultant dose is more than an order of magnitude lower than the risk acceptance guidelines for an event having a frequency of 1/yr.

2.3.4 Radioisotope-Bearing Pressurized Powder Container

The handling of a pressurized container of plutonium-bearing powder, both within and outside of process enclosures, has the potential to cause an abnormal event through the release of material. Plutonium powders are stored in a series of successively larger cans, providing head space to accommodate any expansion of the stored material. Pu-bearing material known to be capable of gas generation that could cause pressurization in a sealed container is stored in a vented configuration. The use of nested cans provides multiple confinement barriers, and the cans are stored in facilities with at least one stage of HEPA filtration.

The concentration of airborne radioactive material expected during abnormal occurrences is based on historical data from 1986 through 1988. The data shows that the concentrations of airborne radioactive material exceeding the operational plant limit of 2×10^{-12} μCi/mL (^{239}Pu) averaged 9.2×10^{-12} μCi/mL. Only two incidents resulted in concentrations as great as 10^{-10} μci/mL, with the highest concentration being 2.52×10^{-10} μCi/mL. A release at the highest concentration into a room would increase the stack concentration between 1.7×10^{-16} μCi/mL and 5.6×10^{-16} μCi/mL, concentrations

well below both the minimum detection level of 5 x 10^{-15} μCi/mL and the normal stack emission level of 4 x 10^{-14} μCi/mL.

2.3.5 Stack Release Resulting from Filter Changes

Ventilation exhaust from contaminated hoods, gloveboxes, process vessels, and potentially contaminated rooms around the gloveboxes is passed through a final, second stage of HEPA filtration in order to remove particulates prior to release. During the changeout of a secondary HEPA filter (the last barrier between contamination and the stack), it is possible for an error to occur (i.e., a filter is dropped) and result in a release to the environment via the 291-Z-1 stack.

The analysis assumes that a HEPA filter is dropped approximately 8 ft onto a concrete floor during a routine filter change in Room 309 or 310 of the 234-5Z Building resulting in the release of contaminated dust into the filter room. Nondestructive assays performed on HEPA filters removed from a filter room in the PFP after 14 years of service determined that the greatest loading on any a single filter tested was 3.7 x 10^{-3} g Pu. Assuming the dropped filter has the maximum Pu loading and assuming a safety factor of 2, the inventory at risk is 7.4 x 10^{-3} g. Given current plant operations are conducted on a smaller scale than when the assayed filters were in service, this value is appropriately conservative.

The analysis conservatively assumes that 1% of the inventory of a dropped HEPA filter would be released as respirable particles. Therefore, 7.4 x 10^{-5} g of respirable Pu powder would be released to the stack. The resultant dose is below the risk acceptance guidelines for an event having a frequency of 1/yr.

2.3.6 Ventilation System Upsets

2.3.6.1 Excessive Pressurization--All PFP Operating Buildings. All of the PFP operating buildings have been analyzed and there are no unacceptable consequences caused by excessive pressurization. The effects of pressurization on individual buildings are described below.

2.3.6.1.1 Excessive Pressurization, 234-5Z Building. Eight electric motor-driven supply fans furnish outside air to a supply plenum in the 234-5Z Building. The supply plenum also services the 236-Z Building. Nine electric motor-driven exhaust fans are located both in the 291-Z and 234-5Z Buildings. The ventilation is controlled by supply dampers A through F. Supply damper A feeds the office areas which are maintained at positive pressures with respect to all other areas. A failure of this damper would drive the zone additionally positive , which would have no effect on contamination control. Excessive building pressurization could occur from failure of supply dampers B, C, and D. These dampers feed air to rooms and corridors within the radiation zones of the 234-5Z Building. Pressure differentials of up to 1 in. w.g. between adjacent rooms could occur, but gloveboxes remain negative to room atmospheres. A small amount of the radioactive contamination free of confinement structures present in the building could be released by excessive

building pressurization. The amount of material released would be insignificant. The failure of damper E was not evaluated in detail as there are no unsealed sources of radioactive materials in the rooms that are supplied by this damper. In addition, the rooms would not be pressurized as the damper fails closed. Supply damper F services the 236-Z Building and is discussed in the next section.

2.3.6.1.2 Excessive Pressurization, 236-Z Building. The 236-Z Building is serviced by the same supply plenum and exhaust system that supports the 234-5Z Building. Failure to the open position of supply damper F could result in pressurization to 0.5 in. w.g. over normal. Were this to occur, the process cell and gloveboxes would remain negative to the surrounding rooms. If pressurization of the process cell occurs, the potential exists for a release to the environment via the airlock located at the south end of the cell. However, the airlock is equipped with a single stage of HEPA filtration resulting in an insignificant release.

2.3.6.1.3 Excessive Pressurization, 2736-ZB Building. A ventilation control failure could lead to a pressurization of 2 in. w.g. Such a pressurization is not expected to cause a breach of the building or release of material from the single glovebox located in the building.

2.3.6.1.4 Excessive Pressurization, 2736-Z Building. The 2736-Z Building could conceivably be pressurized close to the full 2 in. w.g. available in the supply plenum. The consequences of this action would be limited as there is no loose radioactive material stored in the facility.

2.3.6.1.5 Excessive Pressurization, 241-Z Building. There are no supply fans for the 241-Z Building. Therefore, there are no credible means of significantly pressurizing the structure.

2.3.6.2 Excessive Depressurization--All PFP Operating Buildings. All of the PFP operating buildings have been analyzed and there are no unacceptable consequences caused by excessive depressurization. The effects of depressurization on individual buildings are described below.

2.3.6.2.1 234-5Z Building. Depressurization could occur by valve adjustment errors or icing over of the humidifier pads on the supply unit air washers. In the case of a valve adjustment error, either the B or C supply plenum discharge damper could fail. Only certain parts of the building would be affected because the two dampers are tied to the same controller that has a single sensor in a room fed by both dampers. A failure of a supply damper would over pressurize the room housing the sensor, and the working damper would close down. The room served solely by the working damper will experience a drop in pressure. In general, intervening doors with adjoining rooms will open, and air from these rooms will flow into the rooms in an attempt to reestablish pressure. In the second case where there is a failure to sustain the supply air system, vacuum breakers on the supply plenum would open and limit the effect of the occurrence.

Depressurization by failure of supply damper B or C could result in airflow reversals. If doors are not securely latched, there would be a rush of air to the newly created low pressure rooms from the other rooms. If loose

radioactive materials were present from a separate event, the contamination could be spread by the depressurization. A depressurization of the building from a failure to sustain the supply air system would not result in a severe pressure differential. There may be a brief pressure reversal between zone 1 (frontside) and zone 3 (backside).

2.3.6.2.2 236-Z Building. This building is serviced by the same supply plenum and exhaust system that supports the 234-5Z Building. Accidental closure of supply damper F could result in depressurization to -6 in. w.g. This would be approximately equal to the 5.8 in. w.g. live load design of the roof. The sudden drop in pressure might cause personnel discomfort but would not compromise the structure nor affect the containment of radioactive material.

2.3.6.2.3 2736-ZB Building. No credible scenarios could result in significant depressurization of the building.

2.3.6.2.4 2736-Z Building. The radioactive materials in this building are either sealed in containers or are in containers with filtered vents. A pressure differential of a few inches of water would not cause leakage of the containers. A depressurization to -3 in. w.g. has occurred in the past in which no damage occurred.

2.3.6.2.5 241-Z Building. The simplicity and low flow rate of the system precludes any means to significantly depressurize the building.

2.3.7 Loss of Ventilation

A loss of ventilation would occur if both the supply fans and exhaust fans were to simultaneously lose power. This event would occur only during a simultaneous loss of two 13.8-kV electrical feeds and backup power from the diesel-generators located in Building 2721-Z. The supply fans and exhaust fans would coast to a stop. The supply fan dampers would open. Zone dampers B through E would open and dampers A and F would close. Zones 1 and 3B would be isolated from the rest of the system. The dampers to the exhaust fans would close except the dampers to the emergency exhaust fans, EM-1 and EM-2, that fail open.

Given a loss of ventilation, air in the facility would become essentially stagnant, except for natural circulation. The flow of air would be up the stack for most environmental conditions. Very slight reverse movement could be caused by specialized conditions of convection or differential pressures resulting from weather changes.

The generation of hydrogen gas from tanks containing plutonium solutions is a hazard under loss of ventilation conditions. Provided that solutions are present, calculations indicate it would take nearly four weeks to accumulate sufficient hydrogen to result in a structure-threatening deflagration.

Loss of ventilation would also result in increased temperatures and pressures for containers of plutonium stored in the vault. The storage cans would not burst under these conditions. There are no unacceptable

consequences resulting from loss of ventilation under the assumptions used in this analysis.

2.3.8 Glovebox Glove Breach

The handling and maintenance of glovebox gloves and the associated hand tools has the potential to breach a glove (i.e., breach of primary containment) resulting in the release of plutonium-bearing materials into an occupied area. Sources such as a hot surface, a sharp object, or deteriorated glove material can lead to glove failure. For a release to occur resulting from a glove breach, the event that breached the glove must also release contaminants, the negative glovebox differential pressure must be absent or reversed, or the event must create a reverse pressure pulse. While these events are considered to have the potential to expose individuals to radioactive material, the release would be small and the mitigating efforts of Radiological Control personnel would result in minimal health effects to workers. The consequences of a glovebox glove breach are bounded by the consequences of the spill of liquids and powders previously analyzed.

2.3.9 Pressurized Production Vertical Denitration Calciner

The production vertical denitration calciner (VDC) oxidizes plutonium nitrate solutions into plutonium oxide powder. Chapter 9.0, Section 9.1.10.1 analyzes pressurization of the VDC. A summary of the Chapter 9.0 analysis has not been prepared as VDC operation is not authorized at this time.

2.3.10 Reactive Material Thermal Stabilization Process

Chapter 9.0, Section 9.1.11 identified five event categories of abnormal operations associated with the reactive material thermal stabilization process. However, none of the abnormal operations in the categories were uniquely related to the stabilization process. Therefore, no additional analysis was performed for any of the events identified.

2.3.11 Laboratory Prototype Calciner

The Laboratory Prototype Calciner addendum to this FSAR identified six event categories of abnormal operations associated with the calciner operations. However, none of the abnormal operations in the categories were uniquely related to the operation of the calciner. Therefore, no additional analysis was performed for any of the events identified. It is noted that operation of the laboratory calciner is not currently authorized.

2.3.12 Loss of Filtration

Two buildings were evaluated to determine the potential consequences associated with a loss of filtration. The buildings evaluated are the 232-Z Building and the 241-Z Building. Both evaluations assume that filtration is

lost due to catastrophic breach in the HEPA filters or that a significant leak in the seals occur and the ventilation fans continue operating. Both exhaust systems are aerosol penetrant tested annually and releases from the individual exhaust stacks are continuously monitored. Section 9.1.13.1 describes the accident scenario and consequence calculations associated with an unfiltered release from Building 232-Z and Section 9.1.13.2 describes the accident scenario and calculated consequences associated with an unfiltered release from Building 241-Z.

2.3.13 Magnesium Hydroxide Precipitation Process

Abnormal operations associated with the Magnesium Hydroxide Precipitation Process are identified and evaluated in the related addendum (Carson 2000) to this FSAR.

2.3.14 Bagless Transfer System

Abnormal operations associated with the Bagless Transfer System are identified and evaluated in the related calculation notes (FH 2000).

2.4 ACCIDENTS

For the purposes of this FSAR, accidents are defined as situations where primary and/or secondary confinement may be credibly breached to the extent of releasing radioactive materials beyond the exclusion area or a quantity that could seriously endanger personnel within the exclusion and restricted areas. Included is consideration of industrial accidents that would not result in a release of radioactivity but could endanger onsite personnel.

The accident scenarios selected for analysis are hypothetical in nature and in many cases involve near incredible combinations of natural and operational conditions to achieve the worse case. The hypothetical events are deemed credible when their frequency exceeds 1.0×10^{-6}/yr. In some cases, analyses of incredible events were included because the public may deem them credible, as in the case of an aircraft accident. The accidents analyzed and their respective Chapter 9.0 section numbers are as follows:

- Explosions (Section 9.2.1)
  - Decomposition of Heavy Metal Nitrate-TBP Complexes (Section 9.2.1.2)
  - Flammable Gas Deflagration (Section 9.2.1F)
    - Slow Propane Releases (Section 9.2.1F.1.1)
    - Catastrophic Cylinder Failure (Section 9.2.1F.1.2)

- Fire (Section 9.2.2)
  - Remote Mechanical C Line and Remote Mechanical A Line Fire (Section 9.2.2A)
  - Hydraulic oil fire (Section 9.2.2B)
- Waste Drum Events (Section 9.2.2D)
  - Fire Release (Section 9.2.2D.2.1.1)
  - Mechanical Release (Section 9.2.2D.2.1.2)
  - Drum Explosion (9.2.2D.2.1.3)
- Criticality (Section 9.2.3)
- Seismic Event (Section 9.2.4)
- Strong Wind (Section 9.2.5)
- Aircraft Accident (Section 9.2.7)
- Toxic Chemical Release (Section 9.2.8).
- Accidents for the Plutonium-Bearing Solution Stabilization Process using the Production Vertical Denitration Calciner (VDC) (Section 9.2.9)
  - Flammable Gas Deflagration in the Production Vertical Denitration Calciner (Section 9.2.9.1)
  - Glovebox HC-230C-2 Fire (Section 9.2.9.2)
  - Compressed Air Cylinder Failure (Section 9.2.9.3)
  - Glovebox HC-230C-2 Seismic Release (Section 9.2.9.4)
  - Changes to the RMC Line Fire Analysis from Glovebox HC-230C-2 (Section 9.2.9.5)
- Accidents for Reactive Plutonium-Bearing Material Stabilization (Section 9.2.10)
  - Hydrogen Deflagration in Glovebox HC-21A from Opening Pressurized Containers (Section 9.2.10.1)
  - Deflagration in Glovebox HC-21C (Section 9.2.10.2)
  - Seismically Induced Deflagration in Glovebox HC-21C or HA-21I (Section 9.2.10.3)
  - Glovebox HC-21C or HA-21I Fire (Section 9.2.10.4)

- Seismically Induced Fire in Glovebox HC-21C or HA-21I (Section 9.2.10.5)
- Changes to the RMC Line Fire Analysis from Glovebox HC-21A and HC-21C (Section 9.2.10.6)

- Accidents for Plutonium-Bearing Solution Stabilization using the Laboratory Prototype Calciner (Section 9.2.11)
- Accidents for the Magnesium Hydroxide Precipitation Process (Section 9.2.12)
- Accidents for the Bagless Transfer System (Section 9.2.13)

The accidents listed above, with the exception of Plutonium-Bearing Solution Stabilization Process Accidents using either the Production VDC or the Laboratory Prototype Calciner, are summarized in the following sections and in Table 2-5. The solution stabilization accidents are not summarized as these processes are not currently authorized. The risk associated with each accident is defined by its associated probability and consequences as determined by the analysis. Probability estimates were derived from the accident scenarios by assigning equipment failure rates and human error probabilities to contributing factors. Radiological consequences are based on the source term and were calculated using the GXQ (Hey 1993) and GENII (Napier et al. 1988) computer codes. To determine risk acceptability, the probability and consequences for a given accident were compared to the risk acceptance guidelines (Chapter 9.0, Tables 9-49 and 9-50). These comparisons are shown in Figures 2-1 and 2-2 for onsite and offsite dose receptors, respectively. These comparisons are also made in Table 2-5. In all cases, the risk acceptance guidelines are met. In accordance with Hanford contractor procedure HNF-PRO-704, dose consequences to a receptor located at Highway 240 are provided in Table 2-5 for information only.

2.4.1 Explosions

The term explosion is used to identify any event which the general public would believe to be an explosion. This includes detonations, deflagrations, or overpressurizations due to gas generation. There are several systems within the PFP that have the potential to generate an explosion as a result of their operation. However, almost all of these systems are currently out of service. Two types of explosions, "red oil" and bottled flammable gas (i.e., propane) are summarized below. Additional flammable gas events (e.g., hydrogen) are summarized in Section 2.4.10.

2.4.1.1 Decomposition of Heavy Metal Nitrate-TBP Complexes. Red oil explosions result from the decomposition of heavy metal nitrate-tributyl phosphate (TBP) complexes. As discussed in Chapter 9.0, Section 9.2.1.2, heavy metal nitrate-TBP complexes decompose exothermically at elevated temperatures. If the rate of reaction is such that heat is generated faster than it can be removed, the reaction becomes autocatalytic. The rapid evolution of flammable gas (i.e., butene) may result in an explosion from (1) overpressurization of a process vessel or (2) ignition of the gas. Currently

authorized activities do not generate or process heavy metal nitrate-TBP complexes.

2.4.1.2 Flammable Gas Deflagration. The types and quantities of flammable gases used at the PFP were reviewed, and the greatest risk was determined to be presented by nominal 465 g (16.4 oz) U.S. Department of Transportation (DOT) 39 cylinders of liquid propane gas (LPG). Propane is used as needed at the PFP for a variety of maintenance activities. A preliminary hazards analysis identified the following hazards associated with the use of propane: fires, leaks, mechanical failures, and boiling liquid expanding vapor explosions. The hazards associated with the use of LPG in 465 g (16.4 oz) cylinders are divided into the general areas of slow leaks and catastrophic cylinder failures.

The former propane supply line in Bldg. 234-5Z is no longer in service and has been disconnected from a propane supply. The former supply header has been cut into segments, flushed, and capped. The line segments have been sampled and found not to contain explosive concentrations of propane (BWHC 1998). The segments of the former propane supply header will have vents installed in them to ensure propane concentrations in this header stay below the explosive limit (BWHC 1998a). Accordingly, deflagrations associated with the former propane header in Bldg 234-5Z have not been analyzed.

2.4.1.2.1 Slow Propane Releases. As discussed in Chapter 9.0, Section 9.2.1F.1.1, the slow discharge of propane from a 465 g (16.4 oz) DOT 39 LPG cylinder does not result in an explosion, but it could result in a deflagration.

Scenario. All DOT 39 cylinders are equipped with a safety relief valve that opens if the internal pressure exceeds 2,480-3,307 kPa (360-480 lb/in^2 [gauge]). This valve is significantly larger in size than valves used for normal gas consumption (i.e., 2.2 mm in diameter versus either 0.11 mm or 0.23 mm) such that an uncontrolled release would occur in a significantly shorter time (i.e., 20 seconds versus 20 hours and 6 hours, respectively). The worst-case discharge condition is therefore an uncontrolled discharge of propane from the 2.2-mm orifice.

Two release conditions are analyzed. In the first case, it is assumed that propane is released uncontrollably from the safety relief valve of a 465-g (16.4-oz) LPG cylinder into an unventilated 30-m^3 room (considerably smaller than any PFP process room). The propane is assumed to mix with the room air and deflagrate. In the second case, it is assumed that two cylinders simultaneous discharge via the safety relief valve into an unventilated 65-m^3 room. The propane is assumed to mix with room air and deflagrate.

Source Term. No radiological or toxicological source term was developed for this event as it was determined that the deflagration would not result in an uncontrolled release to the environment.

Probability. The frequency of safety relief valve failure was not estimated as it was determined that the risk would be acceptable at any event frequency.

Consequences. The worst-case deflagration results in peak pressures of 0.34 lb/in^2 and 0.35 lb/in^2 for the single-cylinder and two-cylinder events, respectively. These pressures are less than the 0.49 lb/in^2 required to fail the 234-5Z Building exterior wall panels. Accordingly, there is no release to the environment, and the associated risk is acceptable at any event frequency.

2.4.1.2.2 Catastrophic Cylinder Failure. As defined in Chapter 9.0, Section 9.2.1F.1.2, a catastrophic cylinder failure occurs when an LPG container ruptures and nearly all of the LPG instantaneously escapes.

Scenario. Possible mechanisms of a catastrophic cylinder failure include dropping, crushing, or an exposure to fire coincident with the failure of the safety relief valve.

- Dropping — The maximum potential drop height (based on the ceiling height of rooms in the 234-5Z Building) is 4.6 m (15 ft). A cylinder dropped from this height would deform but not rupture. If dropped onto a sharp object, the cylinder could be punctured, resulting in a slow release of propane (see Section 2.4.1.2.1); however, the puncture would not lead to a catastrophic cylinder failure.

- Crushing — Crushing-type accidents were investigated (e.g., mobile heavy equipment and falling heavy objects). No credible scenarios were identified.

- Exposure fire — The probability of a fire involving two DOT-39 cylinders and the coincident failure of the safety relief valves was investigated and found to be incredible.

Source Term. There is no radiological or toxicological source term for this event as no credible scenarios could be identified.

Probability. Dropping of cylinders does not lead to a catastrophic failure, therefore no probability was estimated. The potential for crushing-type accidents and a combined exposure fire/safety relief valve failure was analyzed through the development of event trees. The frequency of a crushing event leading to a catastrophic failure was determined to be 1.0×10^{-7}/yr. The frequency of a fire involving two cylinders occurring in combination with the failure of the safety relief valves was determined to be 4.14×10^{-7}/yr.

Consequences. There are no consequences for this event as no credible scenarios could be identified.

2.4.2 Fire

Fire is one of the accidents that has the potential for both breaching confinement and lofting radioactive materials. The scenarios summarized in this section are an RMC Line fire and a hydraulic oil fire on the top floor of the 234-5 Building. Additional fire analyses have been performed for waste drum storage (Section 2.4.3), a seismic event (2.4.5), vertical denitration calciner operations (Section 2.4.9), and thermal stabilization (2.4.10).

2.4.2.1 Remote Mechanical C Line and Remote Mechanical A Line Fire. The RMC Line and RMA Line were formerly used to produce plutonium metal from plutonium nitrate solutions. The majority of the RMC Line and RMA Line gloveboxes are now inactive. The RMC Line and RMA Line gloveboxes are constructed of polymethylmethracralate (PMMA) and polycarbonate panels on metal frames. These plastics represent a large fuel loading. The RMC/RMA Lines fire analysis is presented in Chapter 9.0, Section 9.2.2.A, and is summarized below.

Scenario. A fire is assumed to occur in a glovebox as a result of maintenance or retrofitting activities. It is assumed that the glovebox Halon fire suppression system does not extinguish the fire and that the Hanford Fire Department (HFD) fails to respond in normal time (i.e., approximately 15 minutes). The fire is assumed to be large enough to ignite the plastic glovebox panels. The fire could also start in Gloveboxes HC-21C or HA-21I as a result of operational of the high temperature furnaces.

The fire is assumed to propagate and involve all of the gloveboxes in Rooms 228A, B, and C and in Rooms 230-A, -B, -C, 232, 235A-1, A-2 and A-3, and 235-B and C. Although smoke loading could damage the in-line filterboxes servicing the glovebox (i.e., E-4) ventilation system, the final stage of E-4 HEPA filters would not be affected. The E-3 ventilation system servicing these rooms also provides one stage of HEPA filtration. The fire is assumed to be extinguished by the HFD after 40 minutes.

Source Term. To calculate the source term, it is assumed that all active gloveboxes are loaded with plutonium to their criticality prevention specification (CPS) limit. Applying the DOE-recommended airborne release fraction and respirable fraction to the inventory at risk for nonreactive compounds under thermal stress, the amount of respirable Pu made airborne is determined. Taking credit for one stage of HEPA filtration, the release from the 291-Z-1 stack is then determined.

Probability. The fire in the RMC/RMA Lines is assumed to be an anticipated event with an annual probability of 1×10^{-2}, without regard for the fire protection features. Taking credit for the failure of the fire protection system controls specified in Administrative Control 5.20 (HNF 2000) and the related fire protection features, is judged to lower the annual probability to 10^{-4} to 10^{-6}.

Consequences. For the accident as described above, the maximum onsite and offsite doses, expressed as rem EDE and rem to the bone surface, are summarized in Table 2-5. The risk acceptance guidelines applicable to this accident are also given in Table 2-5.

2.4.2.2 Hydraulic Oil Fire in Room 321. The PFP Fire Hazards Analysis (FHA) analyzed an unmitigated, worst case fire involving a hydraulic oil spill in Room 321 of the 234-5Z Building. The hydraulic oil is used in the elevator hydraulic lift. The FHA analysis is discussed in Chapter 9, Section 9.2.2B, and is summarized below.

Scenario. The FHA assumes that 150 gallons of hydraulic oil is spilled in Room 321, spreads over a large area, and ignites. Within 2 to 5 minutes

the temperature of such a fire would exceed the single point and average temperatures used to determine the fire resistive properties of steel. Exposed steel columns and beams supporting the 234-5Z Building roof assembly are assumed to fail resulting in collapse of the roof.

In accordance with FHA recommendations, a containment berm has been constructed around the hydraulic elevator components. This berm limits the spread of the fire thereby limiting the number of steel columns exposed.

Source Term. Taking credit for the containment berm, the fire is limited to Room 321. There are no radioactive materials in this area of the 234-5Z Building.

Probability. Taking credit for the containment berm, a hydraulic oil fire resulting in collapse of 234-5Z Building roof assembly is judged to be incredible.

Consequences. Taking credit for the containment berm, there are no radiological consequences associated with a hydraulic oil fire in Room 321. The 234-5Z Building structure is a Safety Class SSC. Because the containment berm directly serves to protect the building structure, it too is a Safety Class SSC.

2.4.3 Waste Drum Events

Drums containing radioactive wastes from the PFP are stored within the fenced security area outside the PFP. Three different accidents are postulated: a drum fire, a mechanical release resulting from a forklift accident, and a drum explosion.

2.4.3.1 Fire Release. As discussed in Chapter 9.0, Section 9.2.2D.2.1.1, a vehicle crash with ensuing fire is judged to be the bounding fire event involving drum storage.

Scenario. For a fire release, the postulated event is a vehicle traveling within the fenced security area of the PFP that crashes into stored waste drums. Upon impact, the fuel tank of the vehicle ruptures and quickly releases its fuel. The fuel is ignited and burns as it spreads as a pool fire encompassing the storage containers breached by the crash. The fire lasts only a matter of minutes before the fuel is consumed. However, as the vehicle fuel burns, the contaminated, combustible material from the breached containers begins to burn and releases the contamination.

Source Term. It is conservatively assumed that the entire 3 kg inventory of Pu allowed in the yard is at risk. A fire could release 1.28 g of respirable plutonium oxide.

Probability. A vehicle crash into the waste containers with or without a fire requires the combination of a number of unlikely events. It is judged to be incredible for such an accident to involve the maximum allowed inventory of all containers. Applying a graded approach, it is simpler to use the risk acceptance guidelines for an unlikely event (1×10^{-2}/yr) than it is to

quantify the actual frequency of such an event. The frequency of a vehicle accident within the fenced area is much less than 1×10^{-2}/yr.

Consequences. For the accident as described above, the maximum onsite and offsite doses, expressed as rem EDE and rem to the bone surface, are summarized in Table 2-5. The risk acceptance guidelines applicable to this accident are also given in Table 2-5.

2.4.3.2 Mechanical Release. As discussed in Chapter 9.0, Section 9.2.2D.2.1.2, the release of contaminants from a waste drum breached by mechanical forces (e.g., vehicle impact without fire, over-pressurization, falling, or forklift puncture) would be limited because the items in the containers are enclosed in multiple layers of plastic.

Scenario. For the mechanical release scenario it is assumed that a forklift punctures two drums containing the maximum amount of TRU.

Source Term. The maximum amount of Pu per drum is 15 g. Only 1.5×10^{-3} g of respirable plutonium nitrate would be dispersed in a mechanical release. The release amount is limited because of the relatively low amount of energy available for suspension of the Pu and because items in the drums are enclosed in multiple layers of plastic.

Probability. Although forklifts are operated by qualified operators, a forklift accident is an anticipated event (i.e., a frequency range of 1×10^{-2}/yr to 1/yr based on impacts to onsite receptor). The frequency of a forklift accident resulting in puncturing drums is bounded by 1×10^{-1}/yr.

Consequences. For the accident as described above, the maximum onsite and offsite doses, expressed as rem EDE and rem to the bone surface, are summarized in Table 2-5. The risk acceptance guidelines applicable to this accident are also given in Table 2-5.

2.4.3.3 Drum Explosion. Many organic materials can decompose when exposed to radiation. Alpha radiolysis of organics in TRU waste can cause gas generation and possible drum pressurization. Flammable gas also can be generated in waste containers containing hydrogenous materials. For a closed, unvented waste container, the buildup of an explosive mixture of hydrogen and oxygen within the void space of the containers can be postulated.

Scenario. As analyzed in Chapter 9.0, Section 9.2.2D.2.1.3, a drum explosion is postulated to occur from the ignition of a flammable concentration of hydrogen. The accumulation of a flammable concentration would require (1) the absence or failure of the drum vent and (2) the absence or failure of the catalytic recombiner. The explosion is assumed to breach the container, scatter some of the contents of the containers, release some of the contaminants to the atmosphere, and ignite combustible material in the drum.

Source Term. Based on the release mechanism and the maximum of 15 g of Pu per drum, an explosion could release 0.015 g of respirable plutonium nitrate and 0.006 g of respirable plutonium oxide.

Probability. A drum explosion is conservatively assumed to be an unlikely event (i.e, having a frequency of 1 x 10^{-2}/yr to 1 x 10^{-4}/yr). For determining risk acceptance, the upper bound of the range is used (i.e., a frequency of 1 x 10^{-2}/yr).

Consequences. For the accident as described above, the maximum onsite and offsite doses, expressed as rem EDE and rem to the bone surface, are summarized in Table 2-5. The risk acceptance guidelines applicable to this accident are also given in Table 2-5.

2.4.4 Criticality

Plutonium is present at the PFP in bare metal form, in powder form as PuF_4 and PuO_2, and in various liquid forms (primarily nitrates). The bare metal form of plutonium would reach criticality only in a compact, stacked, three-dimensional array. A criticality involving the powder form of plutonium would require a stacked array of powder pans to be moderated at a degree beyond that possible with normal powder densities. The majority of vessels storing or processing plutonium in a liquid form are constructed in a critically safe geometry. The exception is the 241-Z Building, which contains five 5,000-gal waste storage tanks. Gloveboxes cannot be of a critically safe geometry should they become flooded with water, but by enforcing strict administrative controls on mass, spacing, and form of materials, criticality can be prevented. The gloveboxes are also equipped with drains, where necessary, to prevent flooding.

Scenario. Chapter 9.0, Section 9.2.3 provides a detailed discussion of criticality safety as applied at the PFP to metal, powder, and liquid systems. Instead of developing detailed, PFP-specific criticality accident scenario, the design basis criticality from NRC Regulatory Guide 3.35 is used to assess consequences. This criticality produces an initial burst of 1 x 10^{18} fissions in 0.5 seconds followed successively, at 10 minute intervals, by 47 bursts of 1.9 x 10^{17} fissions for a total of 1 x 10^{19} fissions in 8 hours. The criticality is assumed to occur in a liquid system that is terminated by the evaporation of 100 L of solution.

Source Term. The amounts of radionuclides assumed to be produced by the criticality are presented in Chapter 9.0, Table 9-24. All of the noble gas fission products and 25% of the iodine radionuclides are released directly to a ventilated room with no holdup. The HEPA filter transmission factor for noble gas fission products and the iodine radionuclides is used as 1. The criticality is assumed to occur in a solution; therefore, an aerosol is assumed to be released due to evaporation directly into the room atmosphere. The aerosol is assumed to comprise 0.05% of the salt content of the solution that is evaporated or 1 mg PuO_2. No credit is given for holdup mechanisms in the room or duct work, but the filter system is assumed to be functional. The transmission factor for a single stage of HEPA filters is used as 5 x 10^{-4}.

Probability. In the approximately 50-year history of six major DOE sites, there have been six criticalities involving chemical processing. Thus, with overall raw statistics, the frequency of any one site suffering a criticality would be 6 in 240 years or 2.5 x 10^{-2}/yr.

Consequences. Two release models were used to evaluate a criticality accident. One model assumes the accident takes place in a building location ventilated via the 200-ft stack, and the other model assumes the accident takes place in a building location ventilated via a short stack. The two release models differ in the dose to onsite and offsite personnel due to differences in atmospheric dispersion and direct dose. For the accident as described above, the maximum onsite and offsite doses, expressed as rem EDE and rem to the bone surface, are summarized in Table 2-5. The risk acceptance guidelines applicable to this accident are also given in Table 2-5.

2.4.5 Seismic Event

The response of the PFP facilities to an assumed seismic event and the resultant releases of radioactive and toxic materials are analyzed in Chapter 9.0, Section 9.2.4. The following analytical approach was used:

- Determine the structural response of each facility and glovebox to seismic loads (see Section 9.2.4.1)
- On a facility-by facility basis and glovebox-by-glovebox basis, identify the potential accidents resulting from the response to seismic loads (see Section 9.2.4.2)
- Determine for each potential accident the release of radioactive and toxic materials into the facility (see Sections 9.2.4.3, 9.2.4.4, 9.2.4.5, and 9.2.4.6)
- Calculate the fraction of material transported out of facilities (see Section 9.2.4.7)
- Calculate the doses resulting from the total release out of the facilities (see Section 9.2.4.8)
- Add the contributions to the seismic analysis from the Magnesium Hydroxide Precipitation Process and Bagless Transfer System (See Sections 9.2.4.10 and 9.2.4.11).
- Add the contribution to the seismic analysis from seismically induced fires initiated in Gloveboxes HA-21I and HC-21C by operation of the high temperature furnaces (See Section 9.2.4.2.12.F).

The specific PFP facilities analyzed are as follows:

- 234-5Z
- 236-Z
- 241-Z
- 242-Z
- 232-Z
- 291-Z
- 2736-Z, ZA, and ZB
- Outside tanks around 234-5Z and 236-Z.

2.4.5.1 Scenario. Due to the differing structural responses of PFP buildings to various ground accelerations, two seismic events of differing magnitude were evaluated.

2.4.5.1.1 Greater than 0.09-g Ground Acceleration. The 232-Z and 241-Z Buildings are susceptible to structural damage at horizontal ground accelerations greater than 0.09-g. Significant structural damage to other PFP buildings does not occur below 0.2-g.

Given an earthquake with a horizontal ground acceleration greater than 0.09 g, the analysis assumes that the inactive incinerator glovebox in the 232-Z Building topples and that the roof of the building collapses. The resultant forces are assumed to suspend plutonium contained in the incinerator glovebox and other process equipment and enclosures. Plutonium released into the 232-Z Building is assumed to be released directly to the environment.

For the 241-Z Building, the structure is assumed to fail and fall on the cover blocks over the underground tanks. The cover blocks are assumed to fail and fall onto the tanks which, in turn, fail. A portion of the plutonium solution in the tanks is assumed to be released directly to the environment.

2.4.5.1.2 0.2-g Ground Acceleration. The DBE for Safety Class structures, systems, components, and equipment is defined in Hanford Plant Standard SDC 4.1 (WHC 1991) as having a ground acceleration of 0.2-g. Assuming an earthquake of this magnitude, the PFP buildings, with the exception of the 232-Z and 241-Z Buildings, will remain standing. Building internals (e.g., gloveboxes and piping) and services and utilities (e.g., water and electrical power) will be affected. Scenarios are developed for plutonium and toxic material dispersal by mechanical means, a seismically induced criticality, and seismically induced fires.

Plutonium Dispersal. Plutonium dispersal by mechanical means is postulated to occur as a result of seismically induced containment and confinement system failures. Non-seismically qualified gloveboxes, hoods, and filterboxes are assumed to topple, non-seismically qualified tanks and piping are assumed to fail, and filters are assumed to fall from non-seismically qualified filter frames. As a result of these postulated failures, plutonium is released into facilities and subsequently transported to the environment.

Toxic Material Dispersal. The risk associated with seismically induced toxic material dispersal is bounded by analyses of nitric acid (HNO_3) in Chapter 9.0, Section 9.2.8.

2.4.5.2 Source Term.

2.4.5.2.1 Greater than 0.09-g Ground Acceleration. The high value for the total inventory of the 232-Z Building is 661 g of plutonium. The majority of this material (i.e., 405 g) is located in the incinerator. The remaining 256 g is located in a cyclone separator, a scrubber glovebox, and miscellaneous glovebox ventilation ducting. The bounding release from the incinerator glovebox is 2.6×10^{-2} g. The release to the building for the cyclone separator is 1.5×10^{-3} g. The release from the scrubber glovebox and

ducting is 1.7×10^{-1} g. Combining these values, the total release from the 232-Z Building is 2.0×10^{-1} g.

The release to the environment of plutonium-bearing solution from failure of Building 241-Z was determined to be 0.10 g of plutonium.

2.4.5.2.2 0.2-g Ground Acceleration.

Plutonium Dispersal. The plutonium inventory-at-risk in PFP gloveboxes and hoods (excluding the 232-Z Building) is assumed equal to established Criticality Prevention Specifications mass limits with the exception of the Analytical, Standards, and Plutonium Process Support Laboratories, and gloveboxes HC-227S and HC-227T for which more restrictive administrative mass limits have been established. Table 2-6 shows the total plutonium released into PFP facilities due to seismically induced mechanical dispersal.

The plutonium releases from the 232-Z Building, the 241-Z Buildingand the 291-Z Building are assumed to be released directly to the environment based on the extent of structural damage. The plutonium release to the environment from the remaining buildings, i.e., that released from the 234-5Z and 236-Z Buildings, is calculated for two cases. In the first case, it is assumed that the 234-5Z and 236-Z Buildings ventilation systems shut down (no ventilation case). In the second case, it is assumed that the supply fans have shut down but that the exhaust fans continue to operate (ventilation case). It is also assumed, in the second case, that the HEPA filters have totally failed and provide no filtration. Note that the releases from the 234-5Z, 236-Z and 291-Z Buildings in the second case are via the 200-ft stack, 291-Z-1.

In addition to the seismically induced mechanical dispersal of plutonium from the facilities, releases were also postulated from seismically initiated fires in the thermal stabilization gloveboxes, HA-21I and HC-21C, and from seismic effects on the BTS and the Magnesium Hydroxide Precipitation Process gloveboxes.

2.4.5.3 Probability.

2.4.5.3.1 Greater than 0.09-g Ground Acceleration. The frequency of an earthquake with a 0.09-g ground acceleration is 2×10^{-3}/yr.

2.4.5.3.2 0.2-g Ground Acceleration. The frequency of an earthquake with a 0.2-g ground acceleration is 1×10^{-4}/yr.

2.4.5.4 Consequences.

2.4.5.4.1 Greater than 0.09-g Ground Acceleration. For the accident as described above, the maximum onsite and offsite doses, expressed as rem EDE and rem to the bone surface, are summarized in Table 2-5. The risk acceptance guidelines applicable to this accident are also given in Table 2-5.

2.4.5.4.2 0.2-g Ground Acceleration. For the "no ventilation" case, the maximum onsite and offsite doses, expressed as rem EDE and rem to the bone surface, are summarized in Table 2-5. The risk acceptance guidelines applicable to this accident are also given in Table 2-5.

For the "ventilation" case, the maximum onsite and offsite doses, expressed as rem EDE and rem to the bone surface, are summarized in Table 2-5. The risk acceptance guidelines applicable to this accident are also given in Table 2-5.

2.4.6 Strong Wind

The primary buildings and certain auxiliary structures of the PFP are analyzed in Chapter 9.0, Section 9.2.5, for potential damage due to the design basis wind, defined in the Hanford Plant Standard Architectural Civil Design Criteria SDC-4.1 (WHC 1991) as a wind speed of 90 mi/hr. In general, it was determined that either (1) the building/structure was capable of withstanding both the wind forces and the standard wind-generated missile or (2) the vulnerability of the building/structure to the wind forces (or wind-generated missile) did not lead to the release of hazardous materials. The exceptions were (1) the outside holding tanks, 2735-Z, for nitric acid (HNO_3) and aluminum nitrate nona-hydrate (ANN). Although the HNO_3 and ANN have been removed from the storage tanks, the analysis of HNO_3 in Chapter 9 has been retained.

2.4.6.1 HNO_3 Storage Tank Rupture.

Scenario. As analyzed in Chapter 9.0, Section 9.2.5.1, a steady 90-mi/h wind is assumed to generate a missile that breaches the transfer piping near the bottom of the HNO_3 storage tank in the 2735-Z area. The storage tank is assumed to contain 7,000 gal of 57% HNO_3 solution (maximum capacity) and the entire contents are assumed to spill into the surrounding retention basin. Ten percent (10%) of the solution is assumed to be immediately aerosolized as it exits the tank and the remaining 90% forms a pool with a surface area of 976 ft^2.

Source Term. The source term for the HNO_3 storage tank rupture has two components: the first results from the 10% of the tank contents which are aerosolized, and the second from the evaporation of the remaining 90% of the solution. Based on the peak mass flow rate of HNO_3 solution from the tank, the peak flow rate of HNO_3 vapor due to aerosolization is 0.3263 kg/s. Based on the wind speed, the spill area, and the volatility and temperature of the HNO_3, a conservative value for the steady state evaporation rate was empirically determined to be 0.046 kg/s. Thus, the peak mass release rate is 0.372 kg/s.

Probability. There are barriers around the HNO_3 storage tank, Building 234-5Z to the north and west, and various pipes, tanks, ladders, and walkways to the south, that serve to provide some protection against missile strikes. Considering the barriers and the annual frequency of a strong wind (10^{-5} to 10^{-6}/yr), a large HNO_3 spill is judged to be an incredible event.

Consequences. A simple straight-line Gaussian dispersion was found to be appropriate to determine the downwind concentration for this accident. The dispersion calculation, performed using conservative and very stable atmospheric conditions, determined the peak concentrations of HNO_3 experienced by the nearest onsite and offsite receptors which are summarized in Table 2-5.

The risk acceptance guidelines applicable to this accident are also given in Table 2-5.

2.4.7 Aircraft Accident

Aircraft accidents involving the PFP are evaluated in Chapter 9.0, Section 9.2.7. Airspace above the Hanford Site is used by many types of aircraft, but typically only on a limited basis. There are no public, military, or high-volume airports within 20 mi of the PFP, and no federal airways pass directly over the PFP. It has been determined that an aircraft impact is an incredible event.

DOE-sponsored helicopter overflights of the Hanford Site have been performed for the purpose of gathering radiological survey data. For these flights helicopters intentionally fly at low altitudes and in relatively close proximity to nuclear facilities. A helicopter crash into the PFP is considered to be an incredible event as long as the helicopters do not operate in the near proximity of the PFP (i.e., a 2,300 foot square centered on the 291-Z-1 stack).

Scenario. In order for an aircraft accident to result in a release of radiological or toxicological material, the aircraft must impact a PFP building and breach the wall or roof in a critical area. An accident with commercial or military aircraft involving the PFP has been determined to be an incredible event. Boundaries imposed by an Unreview Safety Question (USQ) Evaluation prohibit DOE-sponsored helicopters from operating in the near proximity of the PFP (defined above) where a crash into the PFP would be a credible event. A detailed scenario was not developed because it was determined that there are no credible scenarios for these events.

Source Term. No radiological or toxicological source term was calculated as it was determined that any aircraft impact is an incredible event.

Probability. The frequency of a commercial or military aircraft accident involving the PFP was determined for several of the most credible or consequential categories of overflights. Using the available data, the frequency of a commercial or military aircraft accident involving the PFP has been determined to have a total value of less than 1×10^{-7}/yr, indicating that it is an incredible event.

A helicopter crash into the PFP is an incredible event as long as the helicopters do not operate in the area prohibited by the USQ Evaluation (i.e., a 2,300 foot square centered on the 291-Z-1 stack).

Consequences. No radiological or toxicological consequences were calculated as it was determined that any aircraft accident involving the PFP is an incredible event.

2.4.8 Toxic Chemical Release

A 7,000 gal tank used to store HNO_3 at the 2735-Z storage facility. Although the HNO_3 has been removed and the tank is not in service, the analysis in Chapter 9 has been retained. The potential onsite exposure for chemicals used at the PFP is bounded by the analysis done for the HNO_3 storage tank.

Scenario. As analyzed in Chapter 9.0, Section 9.2.8, the postulated event conservatively assumes that the outside HNO_3 storage tank fails and releases the maximum 7,000 gallons of 57% HNO_3 to the retention basin. The area of the retention basin which is irregularly shaped is 976 ft^2 (90.7 m^2) (see Drawing H-2-77439). A HNO_3 plume is formed by pool evaporation and moves downwind from the spill site.

Source Term. Based on the wind speed, spill area, and the volatility and temperature of the nitric acid, a conservative value for the steady-state evaporation rate is empirically determined to be 4.9×10^{-3} kg/s.

Probability. The most likely cause for a large spill and for lack of mitigating actions would be a seismic event. The frequency of a 0.2-g seismic event is 1×10^{-4}/yr.

Consequences. For this release the nitric acid vapor is considered a passive tracer, and the normal Gaussian dispersion model is appropriate. The peak concentrations of nitric acid vapor are summarized in Table 2-5. The risk acceptance guidelines applicable to this accident are also given in Table 2-5.

2.4.9 Accidents for the Plutonium-Bearing Solution Stabilization Process Using the Production Vertical Denitration Calciner

The Production Vertical Denitration Calciner (VDC) oxidizes plutonium nitrate solutions into plutonium oxide powder. Chapter 9.0, Section 9.2.9.1 through 9.2.9.5 analyze potential VDC accidents. A summary of the Chapter 9.0 analyses has not been prepared as VDC operation is not authorized at this time.

2.4.10 Accidents for Reactive Plutonium-Bearing Material Stabilization

The following subsections summarize the subject accident analyses. Reactive plutonium-bearing material stabilization is performed in muffle furnaces located in gloveboxes HC-21C and HA-21I. Supporting activities (e.g., furnace charge preparation, sampling, interim storage) are performed in gloveboxes HC-21A, HC-18M, and HC-18BS.

2.4.10.1 Hydrogen Deflagration in Glovebox HC-21A from Opening Pressurized Containers. Plutonium oxide storage containers are opened in glovebox HC-21A. Flammable gasses, primarily hydrogen, may be present due to the thermal and radiolytic decomposition of plastic packaging materials and moisture.

Scenario. Plutonium oxide is stored in multiple overpack containers, the outer container of which is a 7-inch can. It is assumed that a 7-inch can pressurized to 30 psig is inadvertently sealed into glovebox HC-21A and is opened. At 30 psig, a 7-inch can would contain 0.10 moles of hydrogen. If this quantity was uniformly dispersed within the volume of the glovebox, the resultant hydrogen concentration would be 0.1%, significantly below the lower flammability limit of 4%.

As the hydrogen is released from the 7-inch can and mixes with the glovebox atmosphere, localized concentrations within the flammability range will exist for a short period of time. If all of the available hydrogen formed a stoichiometric cloud that was subsequently ignited, a hypothetical pressure increase of 0.4 psig can be calculated. The actual pressure increase would be significantly less because the efficiency of the burn would be less than 100% and because glovebox HC-21A is open to conveyor glovebox HC-2, i.e., glovebox HC-21A is not a sealed system. It is concluded that the pressure increase from burning hydrogen would not breach the glovebox.

Source Term. No source term was calculated as the glovebox is not breached by this event. The quantity of plutonium potentially suspended inside the glovebox is judged to be small relative to that suspended by normal operations (e.g., pouring oxide through a sieve).

Probability. The burning of flammable gas released from a 7-inch can pressurized to 30 psig is an unlikely event, defined as having an annual probability of 1×10^{-2} to 1×10^{-4}. This probability is based on the relatively small number of such cans at PFP and the fact that containers pressurized to 30 psig are visibly bulged.

Consequences. Onsite and offsite radiological consequences were not calculated for this accident based on the absence of a significant source term relative to normal operations.

2.4.10.2 Deflagration in Glovebox HC-21C or HA-21I. Thermal stabilization of plutonium oxide is accomplished by heating the material to 1,000 C in muffle furnaces. The potential exists for the presence of contaminants, primarily plastics, that can generate flammable gases when heated to high temperatures in the absence of oxygen.

Scenario. It is assumed that measures taken to prevent the introduction of contaminants are ineffective such that 10 g of plastic are assumed present in the plutonium oxide charged to the furnace. In addition, the furnace offgas system is assumed to fail such that the plastic pyrolizes forming flammable gases versus simply oxidizing and forming CO_2 gas and water.

The flammable gas formed by pyrolysis is assumed to be present in the furnace at a flammable concentration and to be ignited. The resultant pressure increase is sufficient to open the furnace door and is postulated to catastrophically fail the glovebox gloves directly opposite the furnace and disperse plutonium into the surrounding room.

Source Term. The deflagration is assumed to fill the volume of the room with respirable plutonium at a concentration of 10 mg/m^3. The room is

serviced by the E-3 ventilation system that provides one stage of testable HEPA filtration before release from the 291-Z-1 stack.

Probability. The annual probability of a flammable gas deflagration is 1×10^{-3} if the plastic contaminant is polyvinylchloride and 1×10^{-5} if it is polyethylene. The probability is lower for polyethylene because decomposition does not occur until the gas is at or above the autoignition temperature.

Consequences. For the accident as described above, the maximum onsite and offsite doses, expressed as rem EDE and rem to the bone surface, are summarized in Table 2-5. The risk acceptance guidelines applicable to this accident are also given in Table 2-5.

2.4.10.3 Seismically Induced Deflagration in Glovebox HC-21C or HA-21I. A seismically induced deflagration in glovebox HC-21C or HA-21I is not considered a credible event based on (1) the seismic event probability, (2) the presumed presence of plastics, (3) the time sequencing of the seismic event relative to furnace operations, and (4) required pre-existing failures or very specific seismic induced failures. Although a deflagration is not credible, flammable gases can be generated and subsequently burn.

Scenario. Similar to the analysis summarized in Section 2.4.10.2, it is assumed that 10 g of plastic are present in the plutonium oxide charged to the furnace and that the furnace offgas system fails. The seismic event is assumed to cause the furnace door to open. Flammable gas exiting the furnace is assumed to be ignited and burn in a flashfire.

Source Term. The flashfire is calculated to result in the suspension of a very small quantity of respirable plutonium. The seismic event is also assumed to cause a panel to fall from the glovebox providing a release path into Room 230-A.

Probability. The annual probability of a seismically induced flash fire is assumed to be the same as the annual probability of the seismic event, i.e., 1×10^{-4}.

Consequences. The consequences of the small quantity of respirable plutonium released are insignificant relative to other seismic releases.

2.4.10.4 Glovebox HC-21C or HA-21I Fire. The potential for a fire exists whenever combustible materials coexist with a source of ignition. Although the quantities of combustible materials in glovebox HC-21C or HA-21I are small, the furnaces represent a significant ignition source.

Scenario. It is assumed that combustible materials are present in glovebox HC-21C or HA-21I and are ignited due to contact with hot surfaces of the furnace. The fire is assumed to burn the polycarbonate windows. The fire is assumed to be of sufficient magnitude and intensity to breach the glovebox via burned-out gloves or failed windows.

Source Term. The maximum inventory at risk in either glovebox is 8,000 g of plutonium based on the Glovebox HA-21I criticality prevention specification. Applying the DOE-recommended airborne release fraction and

respirable fraction for non-reactive compounds undergoing thermal stress, the respirable plutonium made airborne by the fire is determined. The airborne plutonium is exhausted via either the E-4 or E-3 ventilation system through one stage of testable HEPA filtration out of the 291-Z-1 stack.

Probability. The annual probability that a fire will breach Glovebox HC-21C and not be rapidly extinguished is less than 1×10^{-6}. This value is based on the probability of accumulating and igniting a large quantity of combustible material, failure of the glovebox Halon fire suppression system and the room wet pipe sprinkler system, and a delayed response by the Hanford Fire Department. Seismically induced fires in these gloveboxes are discussed in Section 2.4.10.5.

Consequences. For the accident as described above, the maximum onsite and offsite doses, expressed as rem EDE and rem to the bone surface, are summarized in Table 2-5. The risk acceptance guidelines applicable to this accident are also given in Table 2-5.

2.4.10.5 Seismically Induced Fires in Gloveboxes HC-21C and HA-21I. A seismic event can result in a fire in gloveboxes HC-21C and HA-21I as both combustible materials (e.g., PMMA and polycarbonate windows) and an ignition source (e.g., furnaces) are present.

Scenario. It is assumed that the seismic event causes gloveboxes HC-21C and HA-21I to topple. As a result, it is assumed that either the furnaces move such that hot surfaces come into contact with the combustible windows or that the furnace doors open and radiant heat ignites the windows. The inventory at risk and quantity of respirable plutonium made airborne by the fire are defined in Chapter 9.0, Sections 9.2.4.2.12.F and 9.2.4.8. A seismic event may or may not result in failure of the exhaust fans in the ventilation system. If the ventilation exhaust system continues to operate, airborne material within the facility is released out of the 291-Z-1 stack. If the exhaust system fails, the release from the fire in the RMC/RMA Line areas is through leak paths around doors and out of the facility in the same manner as other material is released from the facility in the "no ventilation" case (See Chapter 9.0, Section 9.2.4.7).

For the accident as described above, the maximum onsite and offsite doses are included in the totals for the seismic event discussed in Section 2.4.5.

2.4.10.6 Changes to the RMC/RMA Lines Fire Analysis from Gloveboxes HC-21A, HC-21C and HA-21I. Section 2.4.2.1 summarized a worst case glovebox fire which included Gloveboxes HC-21A, HC-21C and HA-21I. Therefore, all changes due to these gloveboxes have been incorporated in the analysis discussed in Section 2.4.2.1.

2.4.11 Accidents for the Laboratory Prototype Calciner

Accidents which have been postulated to potentially result from operation of the Laboratory Prototype Calciner are as follows:

- Hydrogen deflagration in Room 188 from opening drum

- Hydrogen deflagration in Glovebox 188-1 from opening bagged polybottle
- Flammable gas deflagration in the Laboratory Prototype Calciner
- Glovebox 188-1 fire
- Glovebox 188-1 seismic event.

Each of these accidents is discussed in detail in the Laboratory Prototype Calciner addendum to this FSAR. The accident analysis provides a description of the accident scenario, mitigation, probability, consequences and conclusions for each event analyzed. A summary of the accident analysis for the laboratory calciner has not been prepared since the calciner is not currently authorized for operation.

2.4.12 Accidents for the Magnesium Hydroxide Precipitation Process

Accidents associated with operation of the Magnesium Hydroxide Precipiation Process are identified and analyzed in the related addendum (Carson 2000) to this FSAR.

2.4.13 Accidents for the Bagless Transfer System

Accidents associated with the operation of the Bagless Transfer System are identified and analyzed in the related calculation notes (FH 2000).

2.5 CONCLUSIONS

The PFP has been operating for 50 years with no significant radiological or toxicological impacts to onsite or offsite populations. The processes involve low energy reactions and the quantities of reagent involved are small. The remodeling and upgrades of process lines have increasingly compartmentalized the operations and added additional levels of safety. The separation of processes and the campaign operations reduce the probability of a combination of natural and human events resulting in an event with unacceptable radiological or toxicological impact.

The analysis of accident scenarios consistently shows that the risk associated with the current DOE authorized PFP mission and operations are within the risk acceptance guidelines.

Table 2-2. Offsite Doses for Ground and Stack Level Releases from PFP Based on Annual X/Qs (Chronic release).

Release Type	EDE		Max. Organ[a]
Maximum Individual	(rem)		(rem)
Ground Level	3.0 E-08		5.5 E-07
Stack Level	1.0 E-06		1.9 E-05
Population	(person-rem)	Health Effect (LCF)[b]	(person-rem)
Ground Level	8.0 E-04	4.0 E-07	1.5 E-02
Stack Level	4.4 E-02	2.2 E-05	8.2 E-01

[a]The maximum organ for all cases is the bone surface.
[b]Latent Cancer Fatality.

Table 2-3. Historical Solid Waste Generation Volume Summary.

Radioactive waste	ft^3/yr	Drums/yr
TRU waste to WIPP		
Contaminated plastic, cloth, rubber, and glass	3,400	460
Burial box mixed waste (lead panels and leaded glass windows)	75	--
TRU waste to 20-year retrievable storage		
8 in. x 8 in. HEPA filters	15	2
Leaded glovebox gloves	75	10
Burial box waste (waste too large for drums)	7,000	--
Low-level radioactive solid waste		
Nonhazardous, aerosol cans	15	2
Nonhazardous, Zone 3 waste	10,870	1,478
Nonhazardous, low-level burial box waste	100	--
Nonhazardous, 24" x 24" HEPA filters	600	--
Hazardous lead, alkaline dry cell batteries, and wet cell batteries	8	1
Hazardous fluorescent lamps (now recycled)	4	0.5
PCB-contaminated and -absorbed waste		
TRU Absorbed organics (if the PRF was in operation)	52	7
TRU PCB-contaminated solid waste	30	4
TRU PCB-contaminated burial box waste	50	--
TRU PCB Hydraulic fluids, etc.	50	7
Low-level waste		
Low-level absorbed organics	50	--
Low-level PCB hydraulic fluid	66	90

HEPA = High-efficiency particulate air (filter).
PCB = Polychlorinated biphenyl.
TRU = Transuranic.
WIPP = Waste Isolation Pilot Plant.

Table 2-4. Abnormal Operations. (2 sheets)

Number	Title	Synopsis
2.3.1	Radioisotope-Bearing Liquid Spills	A spill involving the entire contents of a 10-L bottle of plutonium solution is the bounding event. The event releases 0.16 g Pu into the building. Such a release, even without reduction by HEPA filtration, is well below the risk acceptance guidelines for an event with a frequency of 1/yr.
2.3.2	Radioisotope-Bearing Pressurized Liquid Container	A pressurized 10-L container is assumed to release half of its contents to a room. The resultant airborne release is 0.08 g Pu. Such a release, even without reduction by HEPA filtration, is well below the risk acceptance guidelines for an event with a frequency of 1/yr.
2.3.3	Radioisotope-Bearing Powder Spills	A powder spill is assumed that requires a series of errors to achieve. After one stage of HEPA filtration the release out of the stack (6.6 E-04 g) is more than an order of magnitude below the risk acceptance guidelines for an event with a frequency of 1/yr.
2.3.4	Radioisotope-Bearing Pressurized Powder Container	Plutonium stored in closed containers may be released if pressurization results in a container breach. Chemical reactions or radiolysis of hydrogenous material can lead to pressurization. The analysis shows storage room air concentrations to be on the order of 2.5×10^{-10} µCi/ml. Such a room concentration would be undetectable at the stack.
2.3.5	Stack Release Resulting from Filter Changes	During a final-stage HEPA filter change, Pu could be released if a filter is mishandled. If such an event occurred, the resulting dose (from the release of 7.4 E-05 g) would be well below the risk acceptance guidelines for an event with a frequency of 1/yr.
2.3.6	Ventilation System Upsets	Properly functioning ventilation systems provide a vital part of the equipment that makes it possible to handle plutonium safely. The following subsections detail the most important of the failure modes. In no case does upset directly result in a release of radioactive materials. Such events, in conjunction with loss of containment events, could, however, exacerbate the spread of contamination within a building. For most events within Buildings 234-5Z, 242-Z, and 236-Z, no automatic recovery systems would be available. However, operating procedures include instructions addressing the required operator response to abnormal operations.
2.3.6.1.1	Excessive Pressurization, 234-5Z Building	Excessive building pressurization can occur from failure of control dampers. Supply dampers B, C, D, and E each feed air to rooms and corridors within the radiation zones of the 234-5Z Building. A number of separate scenarios are presented under this heading. Pressure differentials of up to 1 in. w.g. between adjacent rooms will occur but gloveboxes remain negative to room atmospheres.
2.3.6.1.2	Excessive Pressurization, 236-Z Building	The 236-Z Building receives air from 234-5Z Building through Supply Damper F. Failure to the open position can cause pressurization of up to 0.5 in. w.g. over normal. As with the damper failures within the 234-5Z Building, the process cell and gloveboxes remain negative to the rooms.
2.3.6.1.3	Excessive Pressurization, 2736-ZB Building	A ventilation control failure could lead to a pressurization of ~2 in. w.g. Such a pressurization is not expected to cause a breach of the building or release of material from the single glovebox located in the building.
2.3.6.1.4	Excessive Pressurization, 2736-Z Building	A pressurization of the 2736-Z Building is not expected to cause any release of radioactive material into the building or to the outside as all materials stored in this facility are double or triple canned in metal cans or drums. The building could be pressurized to 2 in. w.g.
2.3.6.1.5	Excessive Pressurization, 241-Z Building	No building pressurization would happen as there are no supply fans.
2.3.6.2	Excessive Depressurization - All PFP Operating buildings	
2.3.6.2.1	234-5Z Building	Significant depressurization of the 234-5Z Building is prevented by a pair of gravity-operated supply relief dampers on the supply plenum and by control on the exhaust fans.

Table 2-4. Abnormal Operations. (2 sheets)

Number	Title	Synopsis
2.3.6.2.2	236-Z Building	Accidental closure of Supply Damper F could result in depressurization to -6 in. w.g. Such a depressurization is approximately equal to the 5.8 in. w.g. (30 lb/ft^2) live load of the roof. During such an event the pressure inside and outside gloveboxes would be the same but there would be no force to release radioactive materials to the rooms. There would be no release to the environment.
2.3.6.2.3	2736-ZB Building	No credible scenario was found.
2.3.6.2.4	2736-Z Building	An actual event once depressurized the building to ≈3 in. w.g. with no adverse effect.
2.3.6.2.5	241-Z Building	There is no way to significantly depressurize this building.
2.3.7	Loss of Ventilation	This section contains a number of events that result from loss of ventilation--none of which result in a significant spread of plutonium. The topics include air reversals due to convection and weather changes, radiolytic hydrogen accumulation, and spread of contamination in vaults due to container rupture from heat rise.
2.3.8	Glovebox Glove Breach	The most vulnerable part of the plutonium confinement system is the glove system. This section discusses various release mechanisms and concludes that the hazard to operating personnel is not great.
2.3.9	Pressurized Production Vertical Denitration Calciner	The VDC is assumed to pressurize due to a loss of vacuum. The pressurized calciner is estimated to release 127 mg of Pu to the HC-230C-2 glovebox atmosphere. Two testable stages of HEPA filtration within the E-4 ventilation system limit the release out the exhaust stack to an insignificant value. (A third testable stage of HEPA filters exists in the exhaust system but was not credited in the analysis).
2.3.10	Reactive Material Thermal Stabilization Process	No unique abnormal operations were identified that were associated with operation of the thermal stabilization process.
2.3.11	Laboratory Prototype Calciner	No unique abnormal operations were identified that were associated with operation of the Laboratory Prototype Calciner.
2.3.12	Loss of Filtration	Release due to a loss of filtration (catastrophic failure of the HEPA filters) result in releases roughly equivalent to filtered releases from the 291-Z stack.
2.3.13	Magnesium Hydroxide Precipitation Process	Abnormal operations associated with the Magnesium Hydroxide Precipitation Process are identified and evaluated in the related addendum (Carson 2000) to this FSAR.
2.3.14	Bagless Transfer System (BTS)	Abnormal operations associated with the BTS are identified and evaluated in the related calculation notes (FH 2000).

HEPA = High-efficiency particulate air (filter)

Table 2-5. Summary of Accident Analysis Consequences. (3 sheets)

Section	Scenario	Postulated event	Calculated annual probability	Postulated dose consequences (rem)	Risk acceptance guidelines (rem)	Highway 240 Dose (rem)
2.4.1.2	Flammable gas deflagration	Flammable gas deflagration resulting from: 1) slow leak of propane gas or 2) catastrophic failure of propane cylinder	Slow leak: 1.0 assumed Catastrophic Failure: Incredible (<1.0 E-06)	The slow leak event was found to have acceptable consequences even with an assumed probability of 1.0. For the event with a <1 E-06 probability, no consequence was calculated since the event is incredible.	The overpressure resulting from the deflagration is not large enough to breach any PFP wall panels.	N/A
2.4.2.1	RMC/RMA Lines Fire	Fire in trash igniting RMC/RMA Lines and adjacent rooms	10^{-4} to 10^{-6}	Onsite EDE = 0.012 Offsite EDE = 4.3 E-03 Onsite bone = 0.21 Offsite bone = 0.074	Onsite EDE: 25 Offsite EDE: 4 Onsite Bone: 250 Offsite Bone: 40	0.01
2.4.2.2	Hydraulic oil fire, Room 231 234-5Z	Roof collapse due to failed structural members	Incredible (<1.0 E-06)	None calculated as probability <1.0 E-06 and low source term	Not applicable	N/A
2.4.3	Waste Drum Events					
2.4.3.1	Fire Release	Vehicle crash with ensuing fire	<<1.0 E-02	Onsite EDE = 2.2 Offsite EDE = 0.04 Onsite Bone = 32.8 Offsite Bone = 0.64	(Probability = 1.0 E-02) Onsite EDE: 5 Offsite EDE: 0.5 Onsite Bone: 50 Offsite Bone: 5	0.06

2.4.6	Strong wind and missile strike	Wind driven missile breaches transfer line at the bottom of the outside HNO_3 storage tank causing a large pool and release of HNO_3 vapors	<1.0 E-02	HNO_3 Onsite = 18 ppm HNO_3 Offsite = 0.29 ppm	HNO_3 Onsite: 19 ppm HNO_3 Offsite: 3.9 ppm	0.92 ppm
2.4.7	Aircraft accident	Airplane crash into building	Incredible (<1.0 E-06)	Not calculated; probability <1.0 E-06	N/A	N/A
2.4.8	Toxic chemical release	7000 gal outside HNO_3 storage tank failure caused by seismic event; HNO_3 vapor release from spilled solution surface	1.0 E-04	Onsite: 1.8 ppm Offsite: 0.032 ppm	Onsite 24 ppm Offsite 7.7 ppm	0.13 ppm
2.4.9	Accidents for the Plutonium-Bearing Solution Stabilization Process Using the Production Vertical Denitration Calciner (not summarized as this process is not currently authorized)					
2.4.10	Accidents for Reactive Plutonium-Bearing Material Stabilization Operations in Gloveboxes HC-21C and HA-21I.					
2.4.10.1	Hydrogen Deflagration in Glovebox HC-21A from Opening Pressurized Containers	Deflagration	1.0 E-02 to 1.0 E-04	Negligible	NA	N/A
2.4.10.2	Deflagration in Glovebox HC-21C or HA-21I	Deflagration	1.0 E-04 to 1.0 E-06 for PE or PC 1.0 E-02 to 1.0 E-04 for PVC and PS	Onsite EDE 2.1 E-03 Offsite EDE 7.4 E-04 Onsite Bone 0.03 Offsite Bone 0.01	(Probability 1.0 E-02) Onsite EDE = 5.0 Offsite EDE = 0.5 Onsite Bone = 50 Offsite Bone = 5	1.7 E-3

Table 2-5. Summary of Accident Analysis Consequences. (3 sheets)

Section	Scenario	Postulated event	Calculated annual probability	Postulated dose consequences (rem)	Risk acceptance guidelines (rem)	Highway 240 Dose (rem)
2.4.10.3	Seismically Induced Deflagration in Glovebox HC-21C or HA-21I	Deflagration Flash Fire	Not credible 1.0 E-04 to 1.0 E-06	NA Negligible	NA	N/A
2.4.10.4	Glovebox HC-21C or HA-21I Fire	Fire	Not credible	Onsite EDE 2.2 E-04 Offsite EDE 7.7 E-05 Onsite Bone 3.5 E-03 Offsite Bone 1.2 E-03 Also included in Section 2.4.2.1	See 2.4.2.1	1.82 E-4
2.4.10.5	Seismically Induced Fire in Glovebox HC-21C and HA-21I	Fire	1.0 E-04	Included in total for Seismic Event, Section 2.4.5	See 2.4.5	
2.4.10.6	Changes to the RMC/RMA Lines Fire Analysis from Gloveboxes HC-21A, HC-21C, and HA-21I	All changes have been incorporated into the RMC/RMA Lines fire analysis in Section 9.2.2A and 2.4.2.1.				
2.4.11	Accidents for the Laboratory Prototype Calciner	Accidents for solution stabilization using the Laboratory Prototype Calciner are not summarized as this process is not currently authorized.				
2.4.12	Accidents for the Magnesium Hydroxide Precipitation Process	Refer to the Magnesium Hydroxide Precipitation Process addendum (Carson 2000) to this FSAR for information on analyzed accidents.				
2.4.13	Accidents for the Bagless Transfer System	Refer to the calculation notes for the Bagless Transfer System (FH 2000) for information on analyzed accidents.				

EDE = Effective dose equivalent.
LPG = Liquid propane gas.
PFP = Plutonium Finishing Plant.
RMC = Remote Mechanical C.

Note: 1. The consequences for the seismic event exclude the seismic analysis related to the laboratory Prototype Calciner shown in the Laboratory Prototype Calciner addendum to this FSAR since the calciner is not authorized for operation. Similarly, the seismic event consequences do not include the seismic releases associated with the Production Vertical Denitration Calciner since it is not authorized for operation.

Table 2-6. Releases into Plutonium Finishing Plant Facilities For Seismic Event: 1 x 10^{-4} Probability.

Facility	Room, Glovebox (or Hood)	Release into Facility (g Pu)	% ^{240}Pu	Reference Subsection

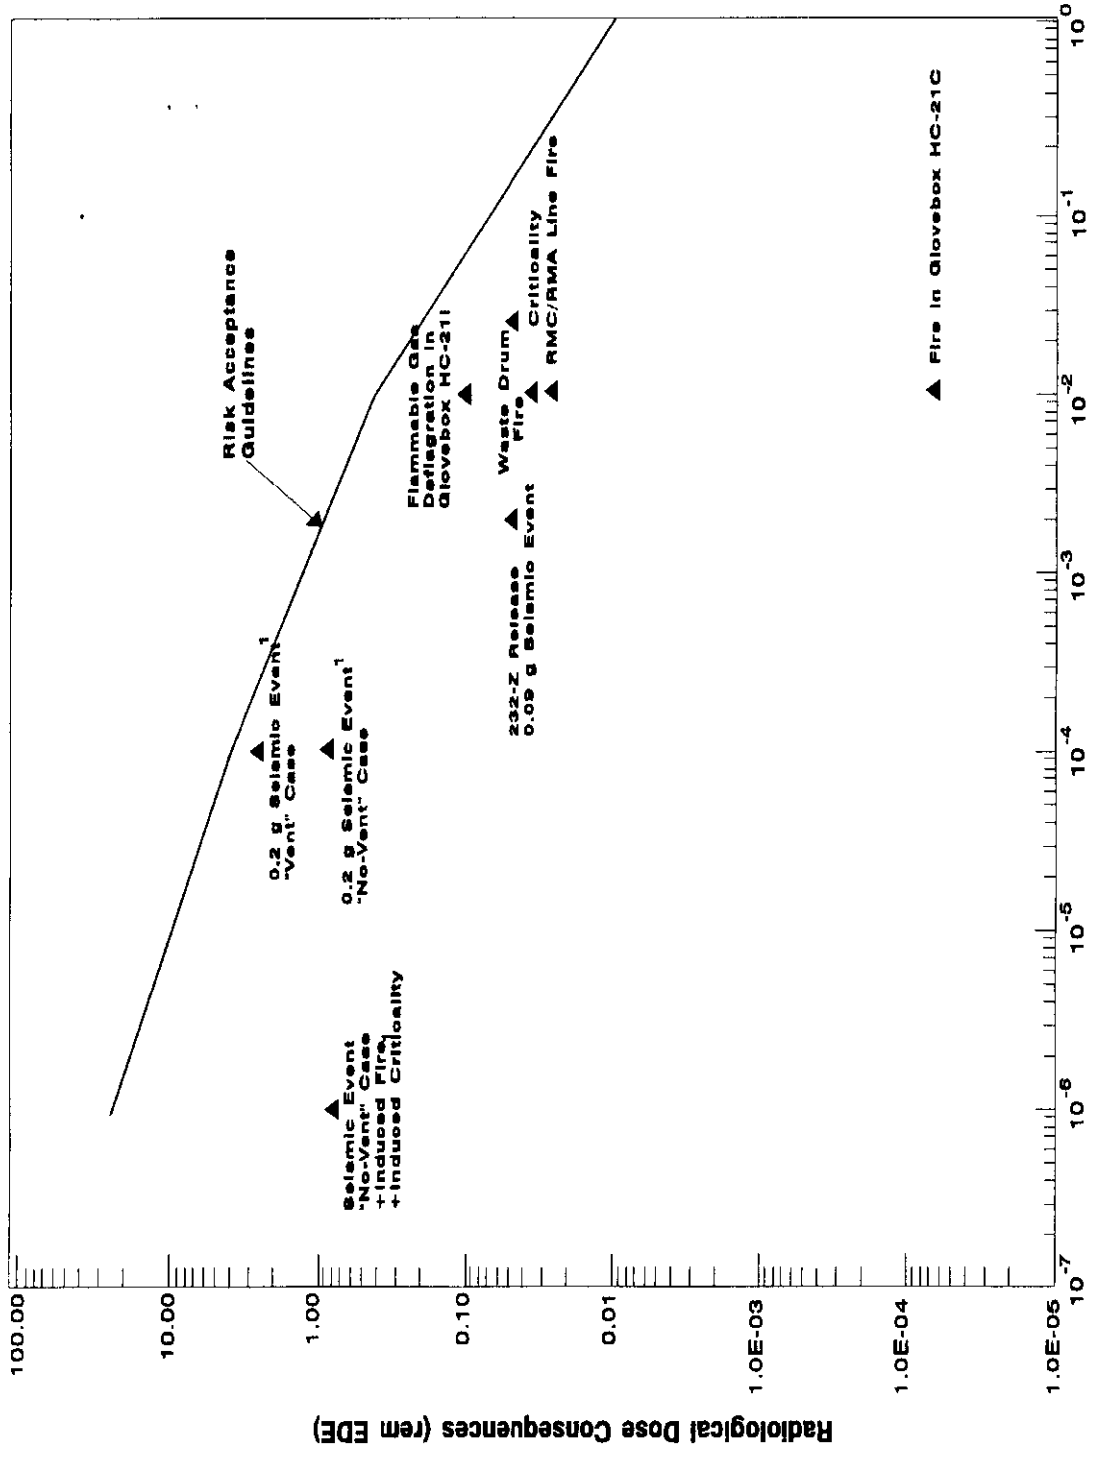
Notes: 1. The release values for the laboratories exclude the Laboratory Prototype Calciner in Room 188 of the PPSL since the calciner is not currently authorized for operation.

2. Denotes solution.

3. The releases from the Magnesium Hydroxide Precipitation Process and Bagless Transfer System gloveboxes are not shown in the table but are included in the releases from the facility due to a seismic event (See Section 2.4.5).



This page intentionally left blank.

Figure 2-1. Onsite Receptor Risk Acceptance Comparison.

Note 1: The consequences due to the various seismic event accident analyses include the seismic contributions from the Laboratory Prototype Calciner. Details of the Laboratory Prototype Calciner are found in the Laboratory Prototype Calciner addendum to this FSAR. Other accident analyses related tot he Laboratory Prototype Calciner are not on this figure but are discussed in the Laboratory Prototype Calciner addendum.

PLUTONIUM FINISHING PLANT
FINAL SAFETY ANALYSIS REPORT

CHAPTER 3.0

SITE CHARACTERISTICS

FEBRUARY 2001

This page intentionally left blank.

PREFACE

Revision 2 of Chapter 3.0 of the Plutonium Finishing Plant (PFP) Final Safety Analysis Report (FSAR) incorporates the following:

- Recent data on the elevation of the water table below the PFP

Other minor changes include editorial changes and addtional clarifications.

The significant areas of change in Revision 2 are indicated by vertical bars in the margin of each page.

This page intentionally left blank.

CONTENTS

3.0 SITE CHARACTERISTICS 3-1

3.1 GEOGRAPHY AND DEMOGRAPHY OF SITE 3-1
3.1.1 Plant Site Location 3-1
3.1.2 Plant Site Description 3-1
3.1.3 Population, Distribution, and Trends 3-2
3.1.4 Uses of Nearby Land and Waters 3-3

3.2 NEARBY INDUSTRIAL, TRANSPORTATION, AND MILITARY FACILITIES . . 3-5

3.3 METEOROLOGY 3-6
3.3.1 Climatology 3-6

3.0 SITE CHARACTERISTICS

3.1 GEOGRAPHY AND DEMOGRAPHY OF SITE

A description of the Plutonium Finishing Plant (PFP) site, its location, nearby population, and land usage is provided in the following subsections.

3.1.1 Plant Site Location

The PFP is located within the U.S. Department of Energy (DOE) Hanford Site. The Hanford Site is a 560-mi^2 area with limited access for reasons of national security in addition to health and safety considerations. Figure 3-1 shows the location of the Hanford Site in the State of Washington.

The 200 West Area is a 2,000-acre area near the center of the Hanford Site. Figures 3-2 and 3-3 are detailed maps of the Hanford Site and the 200 West Area, respectively.

The PFP is situated in Section 1, Township 12 North, Range 25 East, Willamette Meridian in Benton County. The coordinates of the PFP are 46°33'02.345" N. and 119°37'54.982" W. The North American Datum Lambert coordinates (NAD83) are N. 135670.830 and E. 566565.639.

3.1.2 Plant Site Description

The PFP is located in the 200 West Area within a protected area defined by a fence around the PFP complex, as shown in Figure 3-4. The elevation of the PFP is 676 ft above mean sea level (msl).

In general, the relief is gently sloping from the 200 West Area toward the Columbia River.

The vegetation mosaic of the Hanford Site, found in *Final Environmental Statement, Waste Management Operations, Hanford Site*, ERDA-1538 (ERDA 1975), consists of eight major kinds of shrub-steppe communities identified by the most conspicuous or most abundant plant species:

- Sagebrush/bluebunch wheatgrass
- Sagebrush/cheatgrass or sagebrush/Sandberg's bluegrass
- Sagebrush-bitterbrush/cheatgrass
- Greasewood/cheatgrass-saltgrass
- Winterfat/Sandberg's bluegrass
- Thyme buckwheat/Sandberg's bluegrass
- Cheatgrass-tumble mustard
- Willow.

The most broadly distributed vegetation type on the Hanford Site is the sagebrush/cheatgrass or sagebrush/Sandberg's bluegrass association. This vegetation occurs as a broad zone surrounding the PFP and is between the sagebrush/bluebunch wheatgrass-type and the sagebrush-bitterbrush/cheatgrass type. It differs from the sagebrush/bluebunch wheatgrass, because sagebrush plants tend to be larger in size and provide more ground cover. Spiny hopsage

and rabbitbrush may be intermingled with sagebrush shrubs. Fire can burn through this kind of vegetation, killing sagebrush, but hopsage and rabbitbrush survive burning, sending out new growth during the growing season following the fire. The general paucity of herbaceous cover also tends to favor invasion by tumbleweed, with or without fire. The sagebrush/cheatgrass and sagebrush/Sandberg's bluegrass communities provide very limited forage for wildlife.

Vegetation is removed routinely within the PFP site fence and adjacent to it for security purposes, which also reduces the fire hazard. A discussion of the impact on the PFP from loss of power due to potential range fires or other accidents may be found in Chapter 9.0, Section 9.2.

The PFP site is blanketed by a thin layer of windblown sediments. These sediments, called eolian sediment (ERDA 1975), range from fine sands and silt, which in some places blanket coarse gravel and basalt bedrock, to coarse sands, which are moved only short distances.

Water erosion on the plateau around the PFP is minor because of the minimal precipitation, high soil porosity, and lack of sufficient relief to initiate runoff.

Winds are of substantial importance because they can erode the mobile surfaces. Erodible soils (ERDA 1975), mainly Rupert Sand and Burbank Loamy Sand, exist on the plateau. The shear stress of the wind at the Earth's surface determines whether sufficient force exists to move sand grains. Where vegetation exists, the shear stress is reduced sharply and erosion is minimized. However, if the vegetation is removed by fire, construction, plowing, or other means, strong winds will erode the sandy soil (ERDA 1975). Winds are also a factor in the tumbleweed nuisance, which requires removal of accumulated tumbleweeds along fences and buildings for safety and security reasons.

Traffic routes are shown on Figure 3-2. The only road used by the general public is State Route (SR) 240, which passes within 2.5 mi of the PFP. A four-strand barbed wire fence separates the highway right-of-way and the Hanford Site. The Hanford Site is traversed by SR 240 and by the Columbia River, also shown on Figure 3-2.

There are no residents within the Hanford Site boundary. Within this boundary, only DOE personnel and contractor personnel, or other authorized personnel, are allowed to travel in areas beyond the Rattlesnake Barricade, Wye Barricade, and the Yakima Barricade (see Figure 3-2). This restriction of access allows some measure of control over exposure to offsite individuals from Hanford Site activities.

3.1.3 Population, Distribution, and Trends

The 1990 estimate of population living within a 50-mi radius of the Hanford Meteorological Station (HMS) is 376,000 (Beck et al. 1991). The HMS is used as the population reference point for the PFP because of the availability of data and its proximity: 2 mi northeast of the PFP. Figure 3-5 shows the 1990 U.S. Census populations of nearby communities with the circle of a 50-mi radius from the HMS superimposed. Population estimates

were made through the year 2040 based on 1990 census information, current birthrate trends, and an estimate of net migration into or out of the state as economic and employment opportunities change over the forecast period. The forecast does not reflect the population expansion that would result from the creation of a nuclear park or a more intensive use of nuclear energy for power generation and other purposes. It was assumed that the Hanford Site would remain under the control of the DOE and that no persons would reside within the site boundaries. The population residing in the unincorporated areas was calculated on the basis of population density in the portion of a specific census district, which lies within the area. This assumed an even distribution of population throughout the unincorporated areas of each census district. It was further assumed that the rate of population growth was the same for both incorporated and unincorporated areas. Figure 3-6 shows the distribution of population within a 50-mi radius of HMS projected by decades until the year 2040.

A seasonal increase of an estimated 2,800 migratory farm workers occurs annually in the agricultural region east of the Columbia River (Franklin County). The peak periods are May and June and during the fall harvest. Some of these workers are permanent Tri-Cities residents and most live in Pasco (Herborn 1989). See Figure 3-7 for distribution of transient populations (Supply System 1988).

3.1.4 Uses of Nearby Land and Waters

The nature and extent of present land use is presented here on the basis of arcs from the HMS. The Hanford Site vicinity map with sectors overlaid is shown in Figure 3-8. Starting from a line directly north of the HMS, the 0- to 10-mi zone between the 0° and 150° radials is a limited access area under DOE control. Land north of the river is controlled by the U.S. Fish and Wildlife Service as the Saddle Mountain National Wildlife Refuge and the Washington State Department of Game as the Wahluke Wildlife Recreation Area. Most of the zone between the 150° and 270° radials consists of the Fitzner/Eberhardt Arid Lands Ecology Reserve, which also is limited access DOE land under the control of the Pacific Northwest National Laboratory. Between the 270° radial and the starting radial, land south of the Columbia River is DOE-controlled limited access, and land north of the river is the Saddle Mountain National Wildlife Refuge. See Figure 3-9 for locations of recreational areas and refuges/reserves at the Hanford Site.

Again, starting from the 0° radial, the 10- to 20-mi zone is a continuation of the Saddle Mountain National Wildlife Refuge. Farther north, this zone includes the easternmost portion of the Wahluke Slope and the Saddle Mountains. Between the Wahluke Branch Canal and the Columbia River, the zone consists of lands in the Columbia Basin Project that are irrigated or being developed for irrigation. The area west of the river is a limited access area (the Hanford Site). There are no private industrial facilities located within the 10- to 20-mi radius of the PFP. From the 140° to the 360° radial and within the 10- to 20-mi radius, the area outside the Hanford Site is available for residential living or farming. This area is mainly unirrigated and used for grazing cattle and sheep. South and west of the Columbia River, in the vicinity of the Priest Rapids Dam, are 411 mi^2 of undeveloped and unpopulated land used for the U.S. Army Yakima Firing Range.

Northeast of Priest Rapids Dam and Reservoir is the Wahluke Slope portion of the Columbia Basin Project.

The 20- to 30-mi zone on the 0° radial is north of the Saddle Mountains and is irrigated farmland, part of the Columbia Basin Project. The area from lower Crab Creek to northwest Othello generally is undeveloped. From Othello south to the Columbia River, the land is irrigated farmland. On the west side of the river is the city of Richland. West from Richland, the 20- to 30-mi zone includes the Yakima River and the towns of Prosser, Sunnyside, Grandview, and Mabton. Land along the Yakima River is primarily in orchard use. Higher land away from the valley floor is used primarily for grazing livestock, with some land used for grain crops. At about the 270° radial, the U.S. Army Yakima Firing Range is again encountered. At 320° is the Ginkgo Petrified Forest, a state park and national landmark.

At the 0° radial, the 30- to 40-mi zone consists of undeveloped area of sagebrush and sand dunes. At 20°, the Potholes Reservoir, a recreation area surrounded by sand dunes, is located south of Moses Lake. Between 30° and 50°, this zone encompasses a major portion of the U.S. Water and Power Resources Service Columbia Basin Irrigation Project. At about the 130° radial, the Columbia River is encountered, with the city of Pasco on the north side and the city of Kennewick on the south side. South and west of Kennewick, the 30- to 40-mi zone runs south of the Horse Heaven Hills. Although this land is used primarily for dryland wheat farming, there are about 88 sections (56,320 acres) where permits have been granted for private irrigation development. Crossing the Horse Heaven Hills, the 220° to 260° zone includes part of the Yakima Valley, containing the towns of Granger, Toppenish, Zillah, and Wapato. This land is largely in orchards and truck crops, with livestock grazing at the higher elevations. Northeast of Yakima is the U.S. Army Yakima Firing Range, east of which lies irrigated farmland of the Columbia Basin Project.

At the 0° radial, in the 40- to 50-mi radius, the land is primarily rangeland with some irrigated farmland. The town of Moses Lake is in this zone at about the 20° radial. Between the 20° and 90° radials is a large portion of land planned for irrigation development as part of the Columbia Basin Project. At about 70°, between the 40- and 50-mi radius, the land is used for dryland wheat production. Between the 90° and 120° radials and extending to the 50-mi radius, the land is used for dryland wheat production. An exception is the area at the confluence of the Snake and Columbia Rivers, where private irrigation projects are under way. Land on both sides of the Columbia River below McNary Dam supports private irrigation projects totaling about 345 sections (220,800 acres). Between the 200° and 260° radials, the terrain is very rugged and, for the most part, undeveloped. At the 260° radial, the Yakima Valley commences with the city of Yakima at 270°. This is an area of both irrigated and dryland farming and cattle production. At 330°, a portion of the Wenatchee National Forest is encountered.

Recreationists, consisting of hunters, fishermen, boaters, and off-road sports enthusiasts, enjoy activities throughout various parts of the area. The primary fishing season is from June through November; the main hunting season is October through January. The heaviest use of the Columbia River area by recreationists is on weekends and holidays, usually in the early morning hours. On an average, 50 fishermen and 10 hunters are present during the weekdays east of the Columbia River. These numbers increase to about

100 fishermen and 50 hunters on weekends and holidays. Recreationists also use the Yakima River, with an estimated maximum of 50 at any time in this area. Additionally, there could be as many as 1,500 recreationists at the Horn Rapids Off-Road Vehicle Park for any given event. During peak fishing, hunting, or sports events, up to 2,550 recreationists may be located within the area. See Figure 3-7 for distribution of transient populations (Supply System 1988).

Annually, on the last weekend in July, about 30,000 to 40,000 visitors attend the Tri-Cities Water Follies, of which the major event is the Columbia Cup hydroplane boat races on the Columbia River. This event is held at Columbia Park, which is more than 25 mi southeast of the PFP.

An estimated 200,000 acre-ft of water may be taken annually for irrigation from the Columbia River in the Hanford Site vicinity (DOE 1987). This estimate is based on the best data available from the Washington State Department of Ecology. These are "paper water rights" (legal permits to limit usage) and are estimated to be twice the actual pumpage, even though not all withdrawals of water are listed. Water rights received after 1969 are not reflected, and not everyone who withdraws water has applied to the State of Washington for water rights. However, the data given are an adequate upper limit for current water usage to 40 mi downstream from the 200 East and West Areas (Rockwell 1986).

Downstream from the Hanford Site private irrigation development is extensive on both sides of the river.

3.2 NEARBY INDUSTRIAL, TRANSPORTATION, AND MILITARY FACILITIES

The PFP is located near the center of the Hanford Site in the 200 West Area. A commercial facility, U.S. Ecology, is located on land leased from the State of Washington. The U.S. Ecology site is within 5 mi of the PFP and handles radioactive low-level wastes (LLW). The nearest military facility is the U.S. Army Yakima Firing Range, located just northwest of the Hanford Site western boundary. All facilities on the Hanford Site are controlled or licensed by the DOE or the U.S. Nuclear Regulatory Commission (NRC) (see Figure 3-10).

Roads near the PFP include SR 24 and SR 240 (see Figure 3-10). These highways and the Hanford Site roads are used by many types of vehicles, including commercial trucks for deliveries of gas, diesel fuel, chemicals, and reagents. However, the separation of the roads from the PFP is such that no adverse effects from highway accidents are projected for the PFP operations.

There are no private or commercial airports within a distance of 20 mi from the PFP. The Richland Airport, nearest to the Hanford Site, is a small, general utility airport, and Kennewick's Vista Field, also a small airport, is located farther out from the site. The Tri-Cities Airport at Pasco, used by local carriers, is 33 mi from the Hanford Site. Federal and military airways within close proximity to the PFP are shown on Figure 3-41. The probability of aircraft affecting the PFP is remote and is discussed in Chapter 9.0.

There are no refineries, major oil storage facilities, munitions, or explosive storage facilities close to the PFP. The nearest natural gas

transmission pipeline is approximately 35 mi away. The considerable distance of these facilities eliminates the potential hazards to the PFP from fires and explosions.

A partial tabulation of the active nuclear areas on the Hanford Site and their location relative to the PFP is presented in Table 3-1. The SARs for the facilities identified in Table 3-1 were reviewed to determine the possible accidents at these facilities and the potential effects of such accidents on the safe operation of the PFP. It was determined that the distances of these areas and related facilities from the PFP and the engineered safeguards built into each facility provide adequate assurance that releases resulting from postulated accidents would not present a significant risk to the PFP or operating personnel.

3.3 METEOROLOGY

The following sections describe the meteorological conditions that influence the operations of the PFP.

3.3.1 Climatology

The Cascade Mountain Range to the west greatly affects the climate of the Hanford Site area. Storm tracks generally move from the Pacific Ocean across the Cascade Mountain Range and then across the Hanford Site. The orographic effect of this range helps create the moderate winters, hot summers, and the relative dryness of the Hanford Site area (Rockwell 1986).

3.3.1.1 Precipitation. Average annual precipitation is 6.26 in.; 54% of the annual precipitation occurs during November through February, whereas only 10% occurs in July, August, and September. The driest month is July with 0.15 in. and the wettest month is December with 1.03 in. (Hoitink and Burk 1995).

Total annual precipitation at the Hanford Site and the probability that the precipitation will not exceed a given amount is shown in Figure 3-11. Precipitation of 1.56 in. in a 24-hour period can be expected to occur at the Hanford Site at least once in 25 years. At the other extreme, there have been 102 consecutive days without measurable precipitation during the summer of 1919 and 172 d with only 0.32 in. (February 24 to August 13, 1968) (Stone et al. 1983).

3.3.1.1.1 Design Criteria. There is currently no specific rainfall design criteria for facilities at the Hanford Site (see Chapter 4.0, Section 4.3.11, for discussion of general design criteria utilized at the Hanford Site).

3.3.1.2 Snowfall. About 38% of all precipitation from December through February is in the form of snow. The average number of days during which there is an accumulation of as much as 6 in. of snow is four, although the 1964/1965 winter had 35, 32 of which were consecutive. Total annual snowfall, which includes all frozen precipitation, has varied from a low of 0.31 in. (1957-1958) to a high of more than 56.1 in. (1992-1993) (Hoitink and Burk 1995). The average annual snowfall is 13.2 in. The largest depth of snow on the ground at any one time was 24.5 in. in February 1916. Table 3-2 provides

snowfall statistics from 1946 through 1994. There is about a 30% probability that the depth of snow on the ground will exceed 6 in. during the winter season (see Figure 3-12).

3.3.1.2.1 Design Criteria. Facility design criteria at the Hanford Site for snowfall loading is discussed in Chapter 4.0, Section 4.3.6 and 4.3.9.

3.3.1.3 Hail and Ice. The HMS has recorded hailstones ranging in size from 0.2-in. to 0.4-in. in diameter, though hail occurs twice a year at most. Glaze ice occurs on an average of six times a year, between November and March. Rime ice occurs at higher elevations in the hills or along the banks of the Columbia River (Stone et al. 1983).

3.3.1.3.1 Design Criteria. There are currently no specific hail and ice design criteria for facilities at the Hanford Site (see Chapter 4.0, Section 4.3.11, for discussion of general design criteria utilized at the Hanford Site).

3.3.1.4 Wind. The Cascade Mountain Range serves as a source of cool air, especially during the summer months, and has a considerable effect on the Hanford Site wind regime. The drainage (gravity) wind, plus topographic channeling, causes a considerable diurnal range of speeds during the summer (see Table 3-3).

While gravity winds occur with regularity in the summer, these are seldom strong unless reinforced by frontal activity. In June, the month of highest average speed, there are fewer instances of hourly averages exceeding 31 mi/h than in December, the month of lowest average speed (see Figure 3-13 and Table 3-3).

Light winds at the Hanford Site in winter cause considerable atmospheric stagnation. December, for example, has an average of 10 days with a peak gust under 13 mi/h. By contrast, only once in 7 years does June have even one such day. During the winter, about 28% of hourly average wind speeds are less than 4 mi/h. Wind speeds are less than 4 mi/h during 19% of the year (Stone et al. 1983).

3.3.1.4.1 Design Criteria. Facility design criteria at the Hanford Site for wind loading and missile protection is discussed in Chapter 4.0, Section 4.3.1 and 4.3.4, respectively.

3.3.1.5 Fog. Episodes of fog are typically associated with low wind speeds. Wind speeds exceed 4 mi/h during only 27 of the hours in which fog is present (Stone et al. 1983).

3.3.1.5.1 Design Criteria. There is currently no specific design criteria for fog for facilities at the Hanford Site (see Chapter 4.0, Section 4.3.11, for discussion of general design criteria utilized at the Hanford Site).

3.3.1.6 Dust. This phenomena is recorded at the HMS when the visibility is restricted to 6.2 mi or less by either dust or blowing dust. The dry sand and soil of the Pasco Basin, in addition with local construction and agricultural activities, combine to generate all sources of airborne dust at the Hanford Site. Blowing dust at the Hanford Site occurs with strong winds of greater

than 18 mi/h. An average of 5 days per year has dust or blowing dust. These dust storms last an average of just over 3 hours but have lasted as long as 18 hours. Dust storms occur most frequently from March through May and also in September. The spring dust storms occur when soil is disturbed by spring agricultural activity and winds. September dust storms are related to ground breaking for winter wheat in the eastern and central part of the Pasco Basin (north and northeast of the Hanford Site). Dust storms are least frequent in August, November, and December (Stone et al. 1983).

3.3.1.6.1 Design Criteria. There is currently no specific design criteria for dust for facilities at the Hanford Site (see Chapter 4.0, Section 4.3.11, for discussion of general design criteria utilized at the Hanford Site).

3.3.1.7 Temperature. The average maximum temperatures in January and July are 38.4 °F and 91.4 °F, respectively. The average minimum temperatures for the same months are 24.0 °F and 60.9 °F, respectively. The average monthly relative humidity varies from a low of 33.2% in July to a high of 80.2% in December. The lowest winter season daily minimum temperatures range from -23 °F to 20 °F; the highest summer season daily maximum temperatures vary from 100 °F to 113 °F (Hoitink and Burk 1995).

Temperatures at the Hanford Site are colder in winter and warmer in summer than would be the case without the Cascade Mountain Range. However, other mountain ranges shield the area from arctic outbreaks, and half of all winters are free of temperatures below 0 °F. However, two winters in 50 years of record have contributed a total of 6 days with temperatures of -20 °F or below; in January through February, 1950, there were four consecutive such days. There are 6 days recorded when the maximum temperature failed to get above 0 °F. At the other extreme, in the winter of 1966-1967, the lowest temperature all season was 20 °F. Although daytime temperatures reach 90 °F or above for an average of 51 days per year, night time temperatures of 70 °F or above occur only an average of 7 days per year. The cool nights are a result of the gravity winds mentioned earlier.

3.3.1.7.1 Design Criteria. There is currently no specific temperature design criteria for facilities at the Hanford Site (see Chapter 4.0, Section 4.3.11, for discussion of general design criteria utilized at the Hanford Site).

3.3.1.8 Thunderstorms. Thunderstorms occur in every month of the year, except January and November. The thunderstorm season is essentially from April through September. The average number of thunderstorm days per year is 10; however, the total varies from a low of 3 in 1949 to a high of 23 in 1948. The largest number of thunderstorms in any single month was 8 in June 1972, July 1983, and August 1953 (Hoitink and Burk 1995). Although severe thunderstorms are rare, the Hanford Site is vulnerable to lightning strikes causing grass fires; the most notable occurrences were in August 1961, July 1963, July 1970, August 1973, and August 1984 (Rockwell 1986).

3.3.1.8.1 Design Criteria. There is currently no specific thunderstorm design criteria for facilities at the Hanford Site (see Chapter 4.0, Section 4.3.11, for discussion of general design criteria utilized at the Hanford Site).

3.3.1.9 Tornados. The formation of a severe tornado of the Midwest-type is highly unlikely under the climatologic and orographic conditions of the Pacific Northwest. There have been only two tornado funnel clouds and one small tornado (June 16, 1948) observed on the Hanford Site in the 34-year period 1945 through 1978. Although one of these touched ground, it caused no damage. The nearest reported tornado damage was in Yakima (April 30, 1957), about 45 mi to the west, and at Wallula Junction (June 26, 1958), about 50 mi to the southeast (Rockwell 1986). Only minor damage was noted.

3.3.1.9.1 Design Criteria. Design criteria for tornado winds at the Hanford Site is discussed in Chapter 4.0, Section 4.3.2.

3.3.1.10 Ashfall. Ashfall and design criteria for ashfall loading at the Hanford Site is discussed in Section 3.6.6.4.

3.3.1.11 Data Sources. The principal source of climatologic data for the Hanford Site is the HMS, with its 410-ft tower, located between the 200 East and 200 West Areas (see Figure 3-2). Elevation of the station is 733 ft above msl. This meteorological station has been collecting data since 1944. From 1912 through 1942, weather records were kept at a U.S. Weather Bureau cooperative station near the old Hanford townsite.

Wind and temperature measurements are taken at the HMS tower levels shown in Table 3-4.

Surface observations of dew point temperatures and ambient air temperature are taken every fifteen minutes about 0.25 mi east of the tower at the HMS building. Also near the building is a precipitation gauge and a pyranometer used to measure solar radiation.

3.3.1.12 Normal and Extreme Values of Meteorological Parameters. These data are given in Table 3-5.

3.3.2 Onsite Weather Forecasting and Climatology Capability

Meteorological and climatological services available from the HMS include the following:

- Emergency Response Capability--In an accidental release of radioactive material, the forecaster on duty would immediately compute a short term wind forecast for the release location. To do this, one uses wind data automatically reported every fifteen minutes by a network of 30 wind stations. Wind data are used to construct airflow charts over the Hanford Site every 15 minutes. The wind data are also continuously sent to the Unified Dose Assessment Center (UDAC). The next duty of the forecaster is to incorporate the wind data and stability category with an interactive mesoscale diffusion and transport computer model to produce computer printouts of plume positions and movement over the Hanford Site. These calculations are made for two situations: once a month as a practice run, and on request. This service can be requested 24 hours per day except on the weekend and holidays when the service is only available on the day shift. A backup generator at the HMS is available to support this forecasting capability. A manually

started backup generator is also available at the transmitter. In the case of a loss of power at the transmitter, the Hanford Patrol would be contacted to manually activate the backup generator.

- Adverse Weather Advisories--This service is provided to facilitate safe and efficient operation of the Hanford Site plants. These advisories consist primarily of winds in excess of 35 mi/h and thunderstorms; however, occasional warnings are required for drifting snow and freezing rain. Although tornadoes are seldom seen in the Hanford Site, if conditions were such that a tornado could be produced, a warning to that effect would be issued over the emergency warning system. People designated by each Hanford Site contractor are notified to take appropriate action.

- General Weather Forecasts--General weather forecasts are prepared and recorded at 0700 and 1500 hours each day. The forecasts are tailored to the requirements of the DOE and Hanford Site contractors for general work scheduling.

- Climatology--Climatologic data and analyses for the Hanford Site are provided to assess energy demands for preliminary site assessments and for the design and construction of facilities in which environmental control is essential.

One of the functions of the HMS is to monitor and record the wind speed and direction and stability data from the HMS tower. Joint frequency distribution of wind speed, wind direction (at ground and stack height 32 ft and 200 ft, respectively), and stability data (based on vertical temperature gradients; ΔT at 200 ft to 230 ft), are given in Tables 3-6 and 3-7 for the period 1983 through 1991 and is considered to be representative for the Hanford Site.

Atmospheric stability refers to the degree of turbulence in the air; when the atmosphere is thermally stable, turbulent motions are suppressed and less mixing and dilution of airborne contaminants can occur.

Figure 3-14 Sheet 1, presents an example of a wind rose for all stability classes combined. Figure 3-14 (Sheet 2) presents the wind rose pattern broken down to individual areas in the Hanford Site.

3.3.3 Short-Term and Long-Term (Routine) Dispersion Estimates

Straight-line Gaussian plume models are widely accepted and used for atmospheric dispersion estimates related to radiological and toxicological releases. These models are appropriate if the following conditions can be assumed.

- The distance from the source to the point analyzed is large compared to the size of the source. Most Gaussian plume models assume the source to be a point of zero size so that results too close to the source overestimate plume concentrations. Simple Gaussian plume models generally are not considered valid if less than about 100 ft from the source.

- The terrain is relatively flat and surface and meteorological conditions are uniform in all directions and are constant in time. The conditions at the time and place of the release completely determine subsequent transport and diffusion.

- The release rate is constant and is of relatively long duration so the plume is long enough that diffusion in the direction of travel can be neglected (i.e., transport is dominated by bulk movement of the air). This yields a continuous (not-time-dependent) model, which is not valid for short releases such as explosions or tank ruptures. A continuous model will tend to overestimate greatly air concentrations for such short release times.

The basic Gaussian plume model for atmospheric releases to onsite personnel and offsite individuals (as utilized in analyses in Chapters 8.0 and 9.0) is given by:

$$\overline{X} = Q' F_{(y)} G_{(z)} / (2\pi\sigma_y\sigma_z U)$$

where:
- $\overline{X}/Q'$ = Concentration at the receptor
- Q' = Release rate
- σ_y = Horizontal diffusion coefficient
- σ_z = Vertical diffusion coefficient
- U = Average wind speed
- $F_{(y)}$ = Horizontal off-axis correction
- $G_{(z)}$ = Vertical off-axis correction.

The x direction is downwind in the direction of transport, the y direction is transverse to the direction of transport horizontally, and the z direction is transverse to the direction of transport vertically.

The off-axis correction factors describe the decrease in concentration with increasing distance from the plume centerline. These factors are defined as follows:

$$F_{(y)} = \exp[-0.5(y/\sigma_y)^2]$$

$$G_{(z)} = \exp\{-0.5[(z-h_e)/\sigma_z]^2\}$$

where y and z are the horizontal and vertical distances to the plume axis, respectively, and h_e is the effective release height. The plume is usually assumed to be reflected by the ground. This reflection is accounted for by

placing a mirror image virtual source below the ground, producing a vertical off-axis correction of the following form:

$$G_{(z)} = \exp\{-0.5[(z-h_e)/\sigma_z]^2\} + \exp\{-0.5[(-z-h_e)/\sigma_z]^2\}$$

Two special cases are of primary interest:

1. Release at ground level and receptor at ground level on plume centerline. Therefore, $y = 0$, $z = 0$, and $h_e = 0$ leading to:

$$F_{(y)} = 1.0$$

$$G_{(z)} = 2.0$$

$$\overline{X}/Q' = 1/(\pi\sigma_y\sigma_z U)$$

2. Elevated release with receptor at ground level. Therefore $y = 0$, $z = 0$, and h_e the effective stack height leading to:

$$F_{(y)} = 1.0$$

$$G_{(z)} = 2.0 \exp[-0.5(h_e/\sigma_z)_2]$$

$$\overline{X}/Q' = \exp[-0.5(h_e/\sigma_z)^2]/(\pi\sigma_y\sigma_z U)$$

The horizontal and vertical diffusion coefficients, σ_y and σ_z, are functions of x (the transport distance to the receptor) and the atmospheric stability class (Randerson 1984) and are evaluated using empirical formulas of the form (Napier et al. 1988):

$$\sigma = Ax^B + C$$

The dispersion coefficients ($\overline{\chi}/Q'$) used in this document for calculating the population dose due to atmospheric releases were derived by the GXQ Code (Hey 1993a, 1993b). These coefficients are based on site-specific meteorology records in the form of joint frequency tables (see Tables 3-6 and 3-7) where, for each of 16 directional sectors, frequencies of occurrence of the various atmospheric stabilities as a function of wind speed are tabulated (wind data used to generate the joint frequency data presented in this chapter was collected in the 200 Areas between 1983 and 1991 at the HMS [Schreckhise et al. 1993]). For a given direction, two $\overline{\chi}/Q'$ values (for both ground level and stack level releases) are calculated for each stability and wind speed

category and weighted according to its frequency of occurrence. For acute releases from the PFP, the 99.5th percentile $\bar{\chi}/Q'$ in the direction and distance of interest is determined, while for chronic releases an annual average $\bar{\chi}/Q'$ value is determined.

The onsite and offsite $\bar{\chi}/Q'$ values for the acute ground level releases (used in the accident analyses in Chapter 9) were then adjusted to account for building wake and plume meander effects in accordance with NRC Regulatory Guide 1.145, *Atmospheric Dispersion Models for Potential Accident Consequence Assessments at Nuclear Power Plants* (NRC 1982a). Wake correction factors for the onsite and offsite locations were calculated to be 0.25 and 0.80, respectively.

For free-standing stacks (i.e., stacks at least 2.5 times the height of nearby buildings), the effective release height is defined by:

$$h_e = h_s + h_r + h_d$$

where: h_s = The physical stack height
h_r = Plume rise resulting from momentum and buoyancy
h_d = Downwash resulting from air movement around the stack.

Ground concentrations near an elevated release point (i.e., within about three hundred feet) tend to be unstable with slight changes in conditions giving large changes in the ground-level concentration. For this reason, calculated doses near an acute elevated release should be viewed as approximate estimates. To allow for this, usually no credit is taken for plume rise effects for acute elevated releases, because the conditions during such a release cannot be ensured. Average conditions over a year, however, are well known from historical data, permitting the use of a plume rise correction for calculation of chronic doses. As expected, the solutions for ground-level and elevated releases converge as the receptor distance increases and become relatively insensitive to moderate changes in effective release height beyond 1 or 2 km (about 0.6 to 1.2 mi).

3.3.3.1 Maximally Exposed Individual. The onsite maximally exposed individual (MEI) is located in the nearest normally occupied facility with the highest dose outside the PFP emergency response area. The potential offsite MEI is the hypothesized receptor at the Hanford Site boundary location that receives the highest radionuclide concentration. For long-lived isotopes (such as plutonium), these are the equivalent to the onsite and offsite locations having the greatest $\bar{\chi}/Q'$ values.

Dose consequences to the MEI are calculated for use in determining the risk (e.g., risk = consequence x probability) associated with routine and accidental releases. The chronic dose releases to onsite and offsite individuals (see Chapter 8.0, Section 8.4) utilize the dispersion coefficients ($\bar{\chi}/Q'$) calculated from joint frequency data provided by the HMS. Acute dose releases to onsite and offsite individuals are presented in the accident analyses of Chapter 9.

3.3.3.2 Population. For purposes of estimating annual population doses as a result of chronic releases (as presented in Chapter 8.0), calculations are carried out for a series of rings at varying distances from the point of release in each directional sector. The rings corresponding to the transport distances evaluated are shown in Table 3-8. The directions evaluated are the midpoints of 16 sectors, each 22.5° wide. The directional sectors are defined in Table 3-9. The sectors having the largest scaled dispersion coefficients ($\bar{\chi}/Q'$) are given in Table 3-10 for the 200 West Area. These values were chosen as the worst case for exposure (Nguyen 1995).

These dispersion coefficients are used in conjunction with a similar grid showing population within each segment (one sector of one ring) to calculate annual total, or chronic, average population doses within a 50-mi radius of the release point. Calculations of chronic dose releases to offsite population (see Chapter 8.0, Section 8.6) utilize the dispersion coefficients ($\bar{\chi}/Q'$) calculated from joint frequency data provided by the HMS. Acute dose releases to offsite population are presented in the accident analyses of Chapter 9.

3.4 SURFACE HYDROLOGY

3.4.1 Hydrologic Description

The surface water located within the boundaries of the Hanford Site consists of the Columbia River, various ditches, ponds, and trenches in and near the 100 Areas, 200 East and West Areas, and 300 Area. These are shown in Figure 3-15. Two ephemeral streams just west of the Hanford Site, Cold and Dry Creeks, may flow for a short period after a heavy rainfall or snowmelt. The Yakima River borders part of the southern boundary of the Hanford Site.

The surface hydrology of the Hanford Site has been studied extensively (Rockwell 1988). These studies include an analysis of the Columbia and Yakima Rivers, as well as extensive investigations as to the nature of a number of human-made ditches and ponds used for the disposal of low-level radioactive liquid waste, certain industrial waste, and cooling waters from various processes. *Annual Report of RCRA Groundwater Monitoring Projects at Hanford Site Facilities for 1994* (DOE-RL 1995), provides a listing of ditches, ponds, and trenches and their chemical and radiological inventories.

3.4.2 Floods

3.4.2.1 Flood History. The Columbia River, which flows through the northern part of the Hanford Site and along the eastern boundary, and the Yakima River, which flows along the southern boundary, are the dominant streams in the area. Both streams are important sources of industrial, agricultural, and domestic water for the region. The average annual Columbia River flow in the Hanford reach, based on 65 years of records, is about 120,000 ft^3/s (USGS 1985). High flowrates ranging from 250,000 ft^3/s to 450,000 ft^3/s have been recorded. During low-flow periods, flowrates typically average 60,000 ft^3/s (USGS 1985). For 57 years of records, the average annual flow of the Yakima River has been about 3,672 ft^3/s, with monthly maximum and minimum flows of 17,300 and 162 ft^3/s, respectively. Maximum Columbia River floods of historical record

occurred in 1894 and 1948, with flows of 800,000 and 740,000 ft^3/s, respectively (Wood 1954). The likelihood of floods of this magnitude recurring has been reduced by the construction of several flood control/water storage dams upstream of the Hanford Site. Normal river elevations within the Hanford Site range from 394 ft where the river enters the Hanford Site near Vernita to 341 ft where it leaves the Hanford Site near the 300 Area. The ground elevation at the PFP is 676 ft above msl.

Since 1902, there have been fewer than 20 major floods on the Yakima River. The most severe of these occurred in November 1906, December 1933, May 1948, and February 1996. Discharge magnitudes at Kiona, Washington, were 66,000, 67,689, 37,000 ft^3/s, and approximately 45,500 ft^3/s, respectively (Supply System 1981 and U.S. Army Corps of Engineers 1996). The recurrence intervals for the 1933 and 1948 floods are estimated at 170 and 33 years, respectively.

3.4.2.2 Flood Considerations. The Columbia River probable maximum flood (PMF) (the flood discharge that may be expected from the most severe combination of meteorologic and hydrologic conditions reasonably possible in the region) would produce a flow of 1,440,000 ft^3/s; flood elevations would be about 423 ft at 100-N Area and 384 ft at the 300 Area (ERDA 1976). This flood would not affect the central part of the Hanford Site (the plateau of the 200 East and West Areas), where most of the transuranic wastes and high-level wastes are now stored and which has an elevation greater than 499 ft. Similarly, waters of a 100-yr flood (459,000 ft^3/s) would have no effect on the PFP and waste disposal sites (ERDA 1975).

3.4.2.2.1 Design Criteria. PFP facilities are not required to be designed nor analyzed for flood loads, as the PFP is located outside of the PMF flood-affected zone of the Columbia River [see Chapter 4.0, Section 4.2.3, for discussion of the flood design criteria for safety class and safety significant structures, systems, and components (SSCs)].

3.4.2.3 Effects of Local Intense Precipitation on Flooding. The probable maximum precipitation (PMP) has been estimated as 11 in. in 24 hours at least once in a million years (ERDA 1975). Potential flooding of the 200 West Area has been analyzed on a local and regional basis (Skaggs and Walters 1981). The referenced analysis provides a detailed evaluation of the potential for flooding in Cold Creek. (The PFP is located within the Cold Creek Watershed.) Using procedures of the U.S. Weather Bureau (1966), maximum total precipitation was computed to be 12.43 in. over a 3-d period having a maximum 6 h rainfall of 4.52 in. (Skaggs and Walters 1981). The results of the Skaggs and Walters study show the flood would reach a maximum elevation of 645 ft above msl. The PFP, at 676 ft above msl, is above this maximum elevation for which flood protection is required.

The PFP is not within a flood plain. The area adjacent to the PFP drains to low ground, which extends in a north-to-south direction (Figure 3-16). Plant buildings are located on high ground (elevation 676 ft above msl) to the west of the low ground.

3.4.3 Probable Maximum Flood on Streams and Rivers

3.4.3.1 Precipitation Losses. For the Pasco Basin (see Figure 3-17) water balance estimates indicate precipitation of 756,000 acre-ft/yr, zero runoff and groundwater recharge of 6,000 acre-ft/yr (less than 1%) (Leonhart 1979).

3.4.3.2 Runoff Model. The total annual precipitation over the Pasco Basin is estimated at 7.6×10^5 acre-ft, averaging less than 8 in./yr. The mean annual runoff from the basin is estimated to be less than 2.5×10^4 acre-ft/yr, or approximately 3% of the total precipitation. The runoff coefficient is zero, for all practical purposes. The bulk of the remaining precipitation is assumed to be lost through evapotranspiration, with perhaps less than 1% recharging the groundwater system (Leonhart 1979).

Surface runoff from the Hanford Site to the Columbia and Yakima Rivers contributes negligibly to total gauged flows. About two-thirds of the Hanford Site drains into the Columbia River; the remaining one-third (in the western and southern portions of the site) drains into the Yakima River. The drainage divide between the Columbia and Yakima River watersheds is shown in Figure 3-18, which illustrates that the divide lies between the 200 East and 200 West Areas.

3.4.3.3 Probable Maximum Flood Flow, Water Level Determinations, and Coincident Wind Wave Activity. The Columbia River PMF, resulting in a maximum water level of 423 ft above msl, would not affect the PFP, which is at elevation 676 ft above msl.

The development of irrigation reservoirs within the Yakima River Basin has considerably reduced flood potential of the river. For example, the December 1933 flood was reduced from 84,700 to 52,965 ft^3/s at Yakima, Washington, by management of upstream reservoir storage facilities. A flood in December 1959, if it had been uncontrolled, could have reached a magnitude of 56,496 ft^3/s at Yakima, was held at 27,542 ft^3/s by the reservoir system.

Lands susceptible to a 100-year flood on the Yakima River are shown in Figure 3-19. Flooded areas near Horn Rapids could extend into the southern section of the Hanford Site; however, these waters would not reach the PFP. The Yakima River upstream from Horn Rapids is physically separated from the Hanford Site by Rattlesnake Mountain. This topographic barrier prevents potential flooding of the Yakima River from reaching the PFP.

The potential for flash flooding from the Cold Creek was discussed in Section 3.4.2.3. The maximum elevation of the flood was estimated to be 645 ft above msl. The elevation at the PFP is 676 ft above msl.

PFP facilities are not required to be designed nor analyzed for flood loads, as the PFP is located outside of the flood-affected zones of the Columbia and Yakima rivers, and of the Cold Creek (see Chapter 4.0, Section 4.2.3, for discussion of the flood design criteria for safety class and safety significant SSCs).

Any coincident wind wave activity that a flood might induce would not affect the 200 West Area, as the flood would not reach this point.

3.4.4 Potential Dam Failures (Seismically Induced)

Grand Coulee Dam has been recognized as being the only upstream dam with a storage capacity great enough to cause a flood in the event of dam failure. A study concluded that seismic damage to Grand Coulee Dam would not produce a flowrate in excess of the PMF (ERDA 1976).

3.4.5 Probable Maximum Surge and Seiche Flooding

Surge and seiche flooding (causally related to hurricane, typhoon, or similar storms) are not possible in this region. Hurricanes and typhoons are not characteristic of the Hanford Site location meteorology.

3.4.6 Probable Maximum Tsunami Flooding

Tsunami flooding is not possible in this region because of the separation and elevation of the Hanford Site location from the Pacific Ocean.

3.4.7 Ice Flooding

The Snake and Columbia Rivers occasionally have been subjected to surface freezing; however, the flow channel has remained open since the flood control dams have been in place. No effects caused by this phenomenon will influence the PFP site.

The Yakima River has been subject to ice dam flooding; however, the riverbed is at approximately the same elevation as the Columbia River, and its flood capacity is such that it cannot cause the water level to rise enough to affect the PFP site.

3.4.8 Water Canals and Reservoirs

Water canals are not located in the vicinity of the PFP. No reservoirs are directly associated with the PFP; however, until 1982, liquid discharges of cooling and rainwater were carried from the plant by the open 216-Z-19 Ditch. This ditch was located on the southeast side of the PFP and carried liquid effluents to the 216-U-10 Pond. Subsequently, liquid discharges from the PFP were routed to the 216-Z-20 Crib for disposal. Use of the ditch, pond, and 216-Z-20 Crib have been discontinued. Potentially contaminated aqueous streams from the PFP are now treated at the Low-Level Waste Treatment Facility (LLWTF) (the 243-Z/ZA Complex). These streams leave the LLWTF and go to the Treated Effluent Disposal Facility (TEDF) in the 200 East Area for discharge to the environment (see Chapter 7.0, Section 7.3.2).

3.4.9 Channel Diversion

Flow diversions in the central Washington area have occurred historically several times. The causes were (1) glacier advances and recessions, and (2) major rock slides into the Columbia River bed. The areas where these

events occurred are 60 mi north of the Hanford Site. The rock slides have caused only temporary changes in flow and no permanent flow path changes.

Flow blockage downstream caused by volcanic activity could conceivably occur. However, a blockage of over 500 ft in height would be required to affect the PFP site.

3.4.10 Flooding Protection Requirements

Because of the natural drainage capabilities of the soil and the site elevation compared with the surrounding area, no flooding protection requirements are imposed on the PFP.

Specific effects on facility structures and equipment as a result of local, intense rainfall have not been identified. Flooding of the 291-Z Building because of the maximum rainfall, for example, has not been evaluated as of 1995, but analyses of loss of ventilation for any reason indicate no radiological concerns (see Chapter 9.0).

3.4.11 Low Water Considerations

Process and sanitary water is used at the PFP and supplied by the Hanford Site Utilities Services. Water is pumped from the Columbia River through a treatment process and then to the holding tanks located in the 200 West Area at the powerhouse. Under the most extreme cases of interruption in water flow, the plant may be placed in an orderly shutdown mode in accordance with the Building Emergency Procedures. While low-water conditions may affect plant performance, they do not present an imminent threat to the plant.

3.4.12 Environmental Acceptance of Effluents

The sediments beneath the PFP site consist of a thin mantle of windblown silts and sands, which cover layers of sand and gravel up to 200 ft thick deposited by catastrophic Pleistocene floods. These sedimentary deposits have the capacity to absorb and retain radioactive contaminants from the waste streams and from accidental spills or leaks.

Because of the mild, dry climate, precipitation and evapotranspiration influence the sediment moisture content mostly in the surface 6 to 7 ft, with measurable changes occurring as deep as 40 ft (Rockwell 1978b). Even though the sorption capacity of the sediments is low, the total sorption capacity of the sediment column between waste release point and the water table is high because of the long length of the column (up to about 320 ft in the 200 East and West Areas). The high column sorption capacity and low precipitation provide excellent conditions for maximum sorption of radionuclides released to the sediments. The soil column contains gravel, silt, and sand with some clays. The clays make good filter beds, and the soil columns exhibit cation exchange capabilities of 2.5 to 10 meq/100 g of soil (ERDA 1975).

3.4.13 Chemical and Biological Composition of Adjacent Water Sources

There are no water sources immediately adjacent to the PFP.

3.5 SUBSURFACE HYDROLOGY

3.5.1 Regional and Area Hydrological Characteristics

The Hanford Site lies within the Pasco Basin, a structural and topographic low within the Columbia Plateau physiographic province. The Pasco Basin (Figure 3-20) is bound by the Saddle Mountains to the north, the Umtanum and Yakima Ridges to the west, the Rattlesnake and Horse Heaven Hills to the south, and a broad regional monocline (known locally as the Jackass Mountain monocline) to the east.

The regional geology of the Hanford Site has been extensively studied and documented (Rockwell 1979a). From a hydrologic standpoint, the area is composed of a series of confined aquifers (primarily sedimentary interbeds of the Ellensburg Formation and interflow zones within the Columbia River Basalt Group) overlain by an unconfined aquifer in the upper and middle Ringold Formation and overlying sediments of the Hanford formation. The geologic and hydrologic characteristics of the various stratigraphic horizons are summarized in Table 3-11.

Based on interpretations from available geologic data, numerous lava extrusions flowed out from extensive fissure systems and flowed across the Columbia Plateau during the late Tertiary Period. The highly fluid lavas covered the developing Pasco Basin. As basining continued, thick sections of basalt accumulated within these low regions. Because of the geometry of the flows and the erosion or deposition of various sediments between the flows within these rock units, several artesian aquifers exist (e.g., the Mabton-Priest Rapids aquifer in the Cold Creek area and the Frenchman Springs aquifer in the Quincy-Odessa area). Water recharged these aquifers about 14,000 yr ago, based on radiogenic age-dating using the radioactive ^{14}C technique.

During the late Tertiary Period (Pliocene Epoch), the number and size of fissure eruptions decreased markedly and finally ceased. Even though volcanic activity ceased, basining continued and was accompanied by a regional north-south compression. As a result of these compressional forces acting on the basalt rocks, several east-west-trending anticlinal ridges (e.g., Saddle Mountains, see Figure 3-20) were formed in the western part of the Columbia Plateau. The formation of these ridges had a significant impact on the course of the Columbia River. Where the Columbia River was able to erode the basalt at least as quickly as the anticlinal ridges formed, little change in the course of the Columbia River occurred. Where the ridges rose faster than the water was able to erode, the river was temporarily halted and lakes were formed. As basining continued, lacustrine and fluvial deposits continued to fill the Pasco Basin and covered previously deposited basalts. These sedimentary deposits comprise the Ringold Formation. The White Bluffs just east of the Columbia River and north of Richland, Washington, represent the upper portion of the Ringold Formation.

The total thickness of the Ringold Formation in the Pasco Basin is about 1,200 ft. It is characterized by clay, silt, and fine sand with some gravel lenses in the lower section, cemented gravel in the middle, and silts and sands in the upperpart of the section. The Ringold sediments are well-to-poorly sorted and show a wide range of cementation. Locally, the coarse silts, sands, and gravel possess high hydraulic conductivities and are capable of storing vast quantities of groundwater. The silty clay and silty very fine sand beds have very high porosity but yield little or no water. These deposits are considered to be impermeable under hydraulic gradients of normal magnitude. The water table over the western portion of the Hanford Site occurs near the top of the Ringold Formation. In the eastern half of the Hanford Site, the water table rises well above the Ringold Formation and saturates the lower portion of the overlying Hanford Formation.

The gravel zones in the basal and lower units of the Ringold Formation tend to form a local confined aquifer system. The upperpart of the Ringold Formation and the overlying Hanford Formation constitute the major unconfined aquifer beneath the Hanford Site.

The extent of the Columbia River downcutting that took place primarily during the Pleistocene is an influential factor in the unconfined aquifer. Significant paleochannels of high hydraulic conductivity were formed as a result of this downcutting. The nature and location of the paleochannels have been studied using data from about 3,000 wells drilled on the Hanford Site and from a gravity survey (Deju and Richard 1975).

3.5.1.1 Uppermost Confined Aquifers. The uppermost confined aquifers consist of the lower and basal units of the Ringold Formation and the uppermost sedimentary interbeds and interflow zones (ARCHO 1976). From a water supply standpoint, the only significant confined aquifer is in the Priest Rapids member of the Columbia River Basalt Group. The aquifer is about 975 ft below the surface in the 200 East and West Areas.

The Rattlesnake Ridge interbed is the uppermost confined aquifer within the basalt aquifer system. The shape of the potentiometric surface of the uppermost confined aquifer is used to obtain an approximate picture of the regional flow system (Figure 3-21). Flow lines are perpendicular to contours of equal hydrostatic head contours. Recharge into the aquifer appears to occur within the ridges and plateaus fringing the Pasco Basin, with discharge being toward the Columbia River. The eastern portion of the Hanford Site appears to be a regional discharge area for the uppermost confined aquifer.

The uppermost confined aquifer is interconnected in places to the overlying unconfined aquifer. This occurs in areas where the confining layer has been eroded or subjected to extensive warping and deformation, such as along the anticlinal axis that runs from Umtanum Ridge to Gable Mountain.

3.5.1.2 Unconfined Aquifer. The unconfined aquifer consists of sand and gravel deposits of both the Hanford and Ringold Formations. Since these materials are very heterogeneous, greater lithologic differences appear more often within a given bed than between beds. The water table represents the top of the unconfined aquifer at any given time (Figure 3-22). The aquifer bottom is either basalt bedrock or silt and clay zones of the Ringold Formation. The aquifer bottom has been determined using information from hundreds of wells drilled at the Hanford Site.

The hydraulic characteristics of the unconfined aquifer are quite variable and are summarized in Tables 3-12 and 3-13 (Rockwell 1986). The storage coefficient is not sufficiently known to plot its areal distribution; however, as a result of extensive pump testing and geologic studies, a map was developed (ARCHO 1976) from the vertically averaged hydraulic conductivity distribution for the unconfined aquifer system (Figure 3-23). A zone of high hydraulic conductivity is situated between Gable Butte and Gable Mountain and continues through the middle of the Hanford Site.

The Rattlesnake Hills, Yakima Ridge, and Umtanum Ridge to the west and southwest (Figure 3-24) are impermeable boundaries. Gable Mountain and Gable Butte, as well as other small areas of basalt, rise above the water table, distorting the groundwater flow. The Yakima River recharges the unconfined aquifer along its reach from Horn Rapids to Richland. The Columbia River represents a hydraulic discharge boundary for the aquifer. Groundwater flow and bank storage are affected by seasonal river stage fluctuations of the Columbia River.

The flow pattern that originally prevailed in the unconfined aquifer before waste discharges was primarily to the east and northeast with discharge into the Columbia River (ERDA 1975). Natural recharge occurs in the Cold Creek and Dry Creek valleys along the margin of the Rattlesnake Hills and Yakima Ridge. Groundwater flow appears to be distorted by a buried extension of Yakima Ridge, which parallels the Rattlesnake Hills for a distance of about 2 mi.

Before waste water disposal at the Hanford Site, unconfined groundwater flowed west to east across the Pasco Basin to the Columbia River. Artificial recharge has created significant perturbations in groundwater flow. The elevation of the water table beneath most of the 200 Area Plateau declined from June 1993 through June 1994. The largest change occurred in the 200 West Area where the water table dropped 3.84 ft. The declining water table in this area is caused by continued dissipation of the mound from the decommissioned U Pond. The maximum elevation of this mound, which occurred in 1984, was approximately 485 ft above mean sea level. The residual mound from U Pond appears to have shifted northward because of continuing waste water disposal to the Z-Plant Cribs (Dirkes and Hanf 1995). The water table map for the Hanford Site and outlying areas indicates that the groundwater mound beneath the 200 West Area has influenced regional groundwater flow. It contributes to steep hydraulic gradients to the east of the 200 West Area. The groundwater mound from U Pond has also increased the gradient in the gap between Umtanum Ridge and Gable Butte. However, the steep gradient in this area also results from recharge coming from the Cold Creek Valley and from the small width and shallow sediments in the gap (Dirkes and Hanf 1995).

3.5.1.2.1 Design Criteria. Facility design criteria for subsurface hydrostatic loading at the Hanford Site is discussed in Chapter 4.0, Section 4.3.10.

3.5.1.3 Unsaturated Zone. On the Hanford Site, the thickness of the unsaturated zone varies from 0 to 350 ft.

During the period August 1, 1973, through July 31, 1974, the Hanford Site experienced 170% of normal rainfall. At a field test site located south of the 200 East Area, where rainfall moisture penetration is measured routinely,

this excessive rainfall penetrated about 8 ft into the sediments. Moisture from rainfall during this period appears to have evaporated to the atmosphere. The data indicate that the loss of moisture by evaporation is greater than that gained through precipitation, forming a desiccated zone at the near-surface during the summer months (ARCHO 1975). The Hanford Site sediments, below a depth of about 30 ft, are essentially dry.

3.5.2 Plutonium Finishing Plant Site Hydrogeological Characteristics

Four major stratigraphic units underlie the PFP (discussed in Section 3.6): (1) the basalt of the Columbia River, which forms the bedrock beneath the area; (2) semiconsolidated sediments of the Ringold Formation, which directly overlie the bedrock; (3) unconsolidated eolian silt; and (4) unconsolidated sand, silt, and gravel (collectively termed glaciofluvial sediments) which directly overlie the eolian silt.

The surface of the Columbia River Basalt beneath the PFP lies at an elevation of 145 ft above msl. Beneath the PFP, both the lower and upper Ringold units are missing. The middle Ringold unit is approximately 415 ft thick. Although the middle Ringold unit consists predominantly of pebbles and cobbles, it contains a few sand lenses up to 20 ft thick. Early Palouse soil (wind-deposited silt) occurs beneath the PFP between elevations of 560 and 585 ft above msl. They are overlain by 90 ft of a coarse-to-medium glaciofluvial sand.

The water table is found beneath the PFP in the middle Ringold Formation. Initially the water table beneath the PFP was at 400 ft above msl. The elevation of the water table surface in this area has been influenced by water discharged to surface ponds and cribs since the startup of the Hanford Site project. After deactivation of the Reduction Oxidation (REDOX) Chemical Processing Plant, the rise in the water table stopped and it began to recede. The elevation of the water table rose again with the start of cooling water discharge from the 242-S Waste Evaporator-Crystallizer, which is currently shut down. The water table beneath PFP currently ranges from approximately 454 to 456 ft above msl (Hartman et al. 2000).

Figure 3-25 shows the locations of test wells used for monitoring water levels in the 200 West Area and around the PFP. There are no wells at the PFP in use as a source of drinking water. Figure 3-26 shows a sample hydrograph for a typical well structure near the PFP. Chemical monitoring of the groundwater is performed near the PFP [see *Hanford Site Groundwater Monitoring for 1994* (Dresel et al. 1995) for details and results of groundwater monitoring for chemicals and radionuclides in the Hanford Site]. As a result of this monitoring effort, it has been discovered that CCl_4 is present in the groundwater around the plant. Figure 3-27 shows sample results of the available data for this compound (Dirkes and Hanf 1995). During the Plutonium Reclamation Facility (PRF) operation, CCl_4 was a component of the solvent for the extraction columns. The current processes active at the PFP do not use CCl_4, and all of the drums of CCl_4 have been removed. Groundwater remediation activities on the CCl_4 began in 1992 and are continuing.

The only potential pathways for groundwater contamination to enter the unconfined aquifer from the PFP are indirect washing of potentially contaminated soils in the french drains by non-contaminated steam condensate

discharges and/or accidental releases. Located under the PFP, this aquifer has a low transmissivity and a low hydraulic conductivity. As a consequence, migration of radionuclides (such as those from past disposal practices) to the water table would be slow. The total hydrological load resulting from operating PFP from 1977 to 1985 amounted to 72 x 10^8 gal. The 216-Z-20 Crib stream formerly serviced the PFP to collect waste water. A radionuclide inventory of the crib is provided in *Westinghouse Hanford Company Environmental Surveillance Annual Report 200/600 Areas*, Calendar Year 1988 (Elder et al. 1989). For a discussion of current waste discharges from the PFP, see Chapter 7.0.

Wells are currently sampled in the vicinity of PFP according to the *Environmental Monitoring Plan*, DOE/RL-91-50 (DOE-RL 1997).

The 216-Z-21 Basin received demister and cooling water from the PFP. Environmental surveillance results for the basin are shown in (Elder et al. 1989).

Wastewater streams from the PFP no longer flow to the 216-Z-20 Crib or 216-Z-21 Basin but are now directed to the LLWTF and/or the TEDF. For discussions of the LLWTF and the TEDF, refer to Chapter 7.0. For discussions of wastewater streams, refer to Chapter 5.0.

3.5.3 Contaminant Transport Analysis

There are no normal or consequential off-normal radiological events caused by the PFP that would burden the groundwater. Laboratory sorption studies and the observed depth distribution of plutonium beneath various cribs, ditches, and ponds at the Hanford Site indicate that there is very little mobility in Hanford soils and sediments. However, mobile forms of plutonium have been reported at other DOE sites. Infrequent and low amounts of precipitation, the fact that the majority of plutonium is in a dry powder form, and the hazardous spill reporting and cleanup policies of the Hanford contractors toward plutonium spills, reduces the probability of current releases of plutonium from reaching the groundwater.

Kasper describes the distribution of plutonium in sediments beneath the 216-Z-12 Crib, which was used to support operations at the PFP (Kasper 1982). Plutonium activity decreased rapidly with depth, and was essentially equal to background (less than 1 ρCi/g) at 10 m (about 30 ft) below the crib. Groundwater in nearby wells showed no detectable alpha activity (less than 0.017 ρCi/mL). If plutonium from the PFP were spilled on the ground, the contaminated soil would be removed and taken to an appropriate disposal site. Soil removal is the standard decontamination procedure for such spills.

Spills of hazardous materials, such as coolants and acids, may occur at the PFP, however, these spills can be minimized by operator or maintenance personnel actions. These spills also would be removed with contaminated soil. Implementation of the hazardous spill reporting and cleanup policies of the Hanford contractors inhibits spills of small volumes of hazardous materials from affecting groundwater. Solid Waste Handling Operations personnel are trained and responsible for hazardous spill cleanup involving such things as coolants and acids. Reporting requirements for spills are followed in accordance with DOE Orders 232.1 (DOE 1995b) and 5400.1 (DOE 1990), and

Reporting Occurrences and Processing Operations Information, HNF-PRO-060, and *Identifying and Resolving Unreviewed Safety Questions*, HNF-PRO-062.

3.6 GEOLOGY AND SEISMOLOGY

3.6.1 Basic Geologic and Seismic Information

The geology of the Hanford Site region is well documented (Supply System 1981; JABE 1970, 1971; DOE 1988; NRC 1982c). The PFP site is located on the glaciofluvial deposits at an elevation of 676 ft above msl. The glaciofluvial deposits at the PFP site are underlain by sediment of the Ringold Formation from about 550 ft above msl to basalt at about 125 ft above msl.

The thickness of the basalt exceeds 10,000 ft on Rattlesnake Mountain; however, the total thickness at the PFP site is unknown but assumed to be roughly the same.

Seismic investigations and evaluations for the PFP and other Hanford Site activities have been summarized and reported by John A. Blume and Associates (JABE 1970) and others (Supply System 1981, Rockwell 1979b).

Two of the largest historical earthquakes in the region were the Umatilla, Oregon, earthquake in 1893, with estimated Modified Mercalli (MM) intensity VII, located 33 mi southeast of the Hanford Site, and the Milton-Freewater, Oregon, earthquake of 1936, with estimated MM intensity VII, located 57 mi southeast of the Hanford Site (JABE 1970). Calculations indicate that the Umatilla earthquake produced a maximum ground acceleration of approximately 0.03 g at the Hanford Site (JABE 1970).

A large earthquake that reportedly occurred on December 15, 1872, in the Northern Cascades-Okanogan area was the subject of a detailed investigation by the Supply System (Supply System 1977a). The results of the investigation did not pinpoint the epicenter but located it in the Northern Cascades-Okanogan area, over 94 mi from the PFP site. The earthquake was estimated to be at an MM intensity VIII, which was estimated to have produced an MM intensity at the PFP site of IV to V.

The primary earthquake-generating structures considered to be capable are the Rattlesnake-Wallula Alignment and the Gable Mountain/Gable Butte structure (Section 3.6.1.2.1).

Evaluation of the earthquake frequency and magnitude data presented within this chapter resulted in the design response spectra presented in the site-wide standard, SDC 4.1, Revision 12, *Standard Design Criteria Architectural-Civil, Design Loads for Facilities* (DOE-RL 1993). The design response spectra for the design-basis earthquake (DBE) is then applied to the design of safety class and safety significant SSCs. See Chapter 4.0, Section 4.2.5, for detailed discussions of the seismic design criteria.

3.6.1.1 Local Topography. Contours within a 50-mi radius of the PFP are shown in Figure 3-28. The topography around the PFP basically slopes downward to

the north, south, and west and slopes slightly up to the east. Cross sections showing profiles of the ground surface are presented in Figure 3-29.

3.6.1.2 Regional Geology. The Hanford Site is situated within the Columbia Plateau physiographic province, characterized by the occurrence of a thick sequence of tholeitic basalts varying significantly in topographic expression as well as structure. The Columbia Plateau physiographic province is bordered by the Northern Rocky Mountains physiographic province to the north and east, the Basin and Range physiographic province to the south, and the Cascade physiographic province to the west (Figure 3-30).

The regional geology is dominated by Cenozoic volcanic rocks and structures. A generalized geologic map of the region is shown in Figure 3-31. A regional tectonic map is shown in Figure 3-32. The major regional geologic provinces are described in the following subsections.

3.6.1.2.1 Columbia Plateau Physiographic Province. The Columbia Plateau physiographic province can be subdivided into several smaller physiographic subprovinces: Columbia Basin subprovince (sometimes referred to as the Columbia Plateau), the Blue Mountains subprovince, and the Harney-Snake River Plateau subprovince (Dowden et al. 1975).

Columbia Basin Subprovince. The interior lowland portion of the Columbia Plateau, represented by a broad geologic and structural basin, is referred to as the Columbia Basin physiographic subprovince.

The major topographic relief forms are several east-to-southeast-trending ridges on the western side. The Frenchman Hills, Saddle Mountains, Horse Heaven Hills, Rattlesnake Hills, Yakima Ridge, and Umtanum Ridge are surface expressions of anticlinal folds of Tertiary Columbia River basalts and sedimentary interbeds. Within the Hanford Site, Rattlesnake Mountain, Yakima Ridge, and Umtanum-Gable Mountain Ridge represent an eastward-to-southeastward continuation of the ridge system.

The PFP is in the Pasco Basin, one of several structural subbasins within the Columbia Basin (Figure 3-33). The Columbia Basin contains the Channeled Scablands formed during Pleistocene glaciation.

The Cordilleran Ice Sheet extended into northern Washington, but its maximum extent was north of the Hanford Site. Ice-dammed lakes formed in northern Idaho and western Montana when ice lobes filled major drainage valleys. The failure of these dams resulted in multiple, catastrophic flood as the water spilled across the Columbia Basin subprovince. Maximum discharge through scabland channels has been estimated to be as much as 7.52×10^6 ft^3/s (USGS 1973). These floods eroded the basalt, Ringold and Palouse Formations, forming large coulees and thick sequences of glaciofluvial sediments (Washington 1959).

The Columbia Basin is a broad structural basin that was downwarped while lavas were periodically being extruded. The region continued to deform, forming anticlinal ridges. The Columbia Basin contains a thick sequence of Miocene basalt flows with intercalated sedimentary interbeds overlain by Pliocene-Pleistocene lacustrine and fluvial sediments, Pleistocene glaciofluvial sediments, and Holocene alluvium, colluvium, and eolian deposits.

The eastern portion of the Columbia Basin consists of rolling hills mantled by the Palouse loess derived from degradation of Quaternary sediments from the west-southwest and northwest.

The Columbia Basin subprovince is drained by three major rivers: the Yakima River and its tributaries drain the southwestern portion, the Columbia River and its tributaries drain the central and northern portion, and the Snake River and its tributaries drain the southeastern portion.

Blue Mountains Subprovince. The Blue, Ochoco, and Wallowa Mountains all occur in this subprovince and contain elevated plateau basalts similar to those of the Columbia Basin, as well as older rocks that have become exposed by erosion. Alpine glaciers were present in the Wallowa Mountains during the Pleistocene.

The structure and topography of this subprovince, which lies mostly in northeastern Oregon, have more in common with the Northern Rocky Mountains physiographic province than with the Columbia Basin subprovince. The mountains rise above the Columbia Basin subprovince to the north and the Harney-Snake River Plateau subprovince to the south. The Snake River crosses the eastern portion through deeply entrenched gorges. The eastern portion is bordered by the Idaho Batholith subprovince of the larger Northern Rocky Mountains physiographic province.

The Blue Mountains subprovince is a northeasterly trending complex of deformed Paleozoic and Mesozoic sediments and intrusive Cenozoic rocks that lie south of the Columbia Basin subprovince. The structure generally is described as an asymmetric anticline with a steep northern flank and gently dipping southern flank. Some of the region is covered with basalt that has been elevated and deformed by continued orogenic activity. Resulting erosion has stripped much of the younger basalts and exposed Paleozoic and Mesozoic rock not found in the Columbia Basin. The present topography is a result of major Pliocene deformation and Quaternary erosion.

Harney-Snake River Plateau Subprovince. The Harney region lies south of the Blue Mountains and is a high plain with little local relief, except for volcanic craters that are mostly Quaternary in age. Internal drainage is characteristic of this region.

This region extends from the Cascades to the Steens Mountains in southern Oregon. It is similar to the Columbia Basin in that it is dominated by basalt flows and sedimentary interbeds. The region lacks the fluvial and eolian overburden found in the Columbia Basin.

The Snake River Plateau region lies beyond the 200-mi radius.

3.6.1.2.2 Northern Rocky Mountains Physiographic Province. The Northern Rocky Mountains are subdivided into the Okanogan Highlands subprovince, the Idaho-Montana Rocky Mountains subprovince, and the Idaho Batholith subprovince.

Okanogan Highlands Subprovince. This subprovince lies north of the Columbia Basin subprovince of the Columbia Plateau. The southern boundary is where the Columbia River Basalt laps onto the highlands. It is made up of north-south-trending mountains between the Cascade Mountain Range

physiographic province to the west and the Idaho-Montana section of the Northern Rocky Mountains physiographic province to the east. The region slopes toward the south with stream drainage into the Columbia Basin. The Okanogan Highlands molded by Pleistocene glaciation have been highly dissected by fluvial erosion.

This subprovince can be divided into two geologic regions (USGS 1970). East of the Columbia Basin the region is composed of Precambrian Beltean rocks and lower Paleozoic rock primarily composed of quartzite, phyllites, and carbonates. This portion of the highlands has been folded and faulted during several periods of deformation and was intruded by granitic intrusions of British Columbia. The folds of this belt are cut by pre-Tertiary faults.

The area west of the Columbia River is composed of graywacke, greenstone, slate, chert, conglomerates, and limestone. The sediments have been intruded by late Mesozoic quartz monzonites and granodiorites. Tertiary volcanic rock uncharacteristically caps the older rocks. The western portion contains north-south-trending, high-angle, normal faults that have preserved the Tertiary rocks by downfaulting into older crystalline rocks.

Idaho-Montana Rocky Mountains Subprovince. The mountains of this subprovince of the Northern Rocky Mountains physiographic province have a north-northwest fabric and are drained by the Clark Fork River, Kootenai River, Pend Oreille River, and other tributaries of the Columbia River. The subprovince was glaciated by both continental and alpine glaciers. The flood waters that formed the Channeled Scablands of the Columbia Basin had their origin here when ice blockage formed the glacial Lake Missoula.

This subprovince is northeast of the Columbia Basin and primarily consists of an extensive segment of Precambrian crystalline and sedimentary rocks. The dominant rock types are quartzites, slates, and argillites of the Belt Supergroup. Major deformation and mountain building took place during the Mesozoic.

Idaho Batholith Subprovince. This subprovince of the Northern Rocky Mountains province lies east of the Blue Mountains and is drained by the Salmon and Clearwater Rivers, which flow into the Snake River.

The area lies southeast of the Columbia Basin and south of the Idaho-Montana Northern Rocky Mountains. The most prominent rock types are quartz monzonites and granodiorites with some granites. The main batholithic intrusion took place during the Cretaceous Period.

3.6.1.2.3 Cascade Mountain Range Physiographic Province. The Cascade Mountain Range is bordered by the Columbia Plateau and Northern Rocky Mountains physiographic provinces on the east and the Pacific Border physiographic province on the west. This province is divided into two subprovinces, the Northern and the Central, shown in Figure 3-30. In Washington State, the northern part of the range is referred to as the Northern Cascade Mountain Range. In Oregon, the Cascades are divided into the Western Cascade Mountain Range and the High Cascade Mountain Range, which extends into Washington State. Prominent Quaternary stratovolcanos of the High Cascades are Mt. Hood, Mt. Rainier, Mt. Adams, and Mt. St. Helens. Many glaciers are present on the high peaks of the Cascades. The Columbia River cuts across the Cascade Mountain Range at the Washington-Oregon border.

This north-south trending morphologic geotectonic unit extends from southern British Columbia to northern California along the western boundary of the Columbia Basin. The broad up-arching occurred normal to a north-south axis during late Pliocene and early Pleistocene time. The uplift increased to the north, reached a maximum in the North Cascade near the Canadian border, and decreased to the south. Quaternary volcanic activity has built large stratovolcanic cones that dominate the southern portion of the range and decrease in number to the north. The High Cascades of Oregon and Washington States are composed of coalescing Pliocene shield volcanoes capped with Quaternary stratovolcanos. The Western Cascades of Oregon extend the length of Oregon and into southern Washington State and are composed of slightly to moderately deformed rocks of Eocene through Miocene age. The Northern Cascades include the part of the range north of Snoqualamie Pass and are dominated by pre-Cenozoic igneous and metamorphic rocks.

The geology of the North Cascades is strongly influenced by large, steeply dipping faults of late Mesozoic, early Cenozoic age. The crystalline core is composed of deformed schists and gneisses and is flanked by younger sedimentary and volcanic rocks. In general, the oldest rocks are the most strongly deformed.

3.6.1.2.4 Pacific Border Physiographic Province. The Pacific Border physiographic province (USGS 1970) includes the Puget Sound-Willamette Lowlands, the Coast Range, and the Olympic Mountains subprovinces.

Puget Sound-Willamette Lowlands Subprovince. This lowlands subprovince extends from Eugene, Oregon, to Vancouver, British Columbia. The northern part, which lies in general between the Cascade Mountain Range and the Olympic Mountains, was modified during the Pleistocene by the Puget Sound ice lobe. The southern portion of the Puget Sound-Willamette Lowlands is drained by the Willamette River and contains fluvial and glaciofluvial valley fill.

The structure of this subprovince is a broad downwarp with transverse-trending faults and folds. Rock outcrops are closely related to the Tertiary rocks of the nearby Cascade and Coast Range Provinces. The lowland contains thick deposits of Quaternary fill.

Olympic Mountains Subprovince. Included in this subprovince are the Olympic Mountains of Washington State. The Olympics are higher, wider, and more rugged than the Oregon Coast Range, and many alpine glaciers are found there.

Coast Range Subprovince. The Coast Range extends about 600 mi along the Pacific Coast of Washington and Oregon. The anticlinorium in the Coast Range south of the Olympic Mountains is Miocene and Pliocene in age.

The Coast Range of Washington and Oregon extends about 600 mi from the Klamath Mountains of southwestern Oregon to the Olympic Mountains west of the Strait of Juan de Fuca in northwestern Washington. Tertiary eugeosynclinal sediments are exposed in the core of the Olympic Mountains and the Coast Range, the oldest of which are low-grade metasediments, argillites, and graywackes. The flanks of the Olympics are made up of marine basalts and marine sedimentary rocks of Eocene and Miocene age. The anticlinorium in the Coast Range south of the Olympic Mountains is Miocene and Pliocene in age.

3.6.1.3 Hanford Site Geology. The Hanford Site is located in the Pasco Basin, a structural and topographical depression within the Columbia Plateau. The terrain of the central and eastern parts of the site is relatively flat. The central part of the Hanford Site, including the 200 East and West Areas plateau, has undergone minimal erosion since deposition of the Hanford Formation sediments by glacial flood waters about 13,000 yr ago.

The Pasco Basin (Figure 3-17) is one of several structural and topographic basins within the western Columbia Plateau. The Pasco Basin is partly surrounded by large anticlinal ridges (the Yakima Folds) that developed during Miocene and Pliocene time. The Saddle Mountains form the northern boundary of the Pasco Basin; Umtanum Ridge and Yakima Ridge form the western boundary; Rattlesnake Hills and Horse Heaven Hills form the southern boundary; and a broad zone of gradually increasing westward dip forms the eastern boundary. Umtanum Ridge and Yakima Ridge plunge eastward, decrease in relief, and die out within the basin interior (Rockwell 1979a).

The Pasco Basin occupies about 2,000 mi^2 between 46°00' and 45°50' N. latitude, and 119°00' and 120°20' W. longitude. It is a semiarid steppe with a sparse covering of vegetation, as described in Section 3.1.2. Detailed descriptions of the climate, soil, terrain, and other aspects of the geography of the basin are in reports that describe the Hanford Site environment (ERDA 1975; Rockwell 1978a; DOE 1986, 1988).

The Pasco Basin is underlain by a bedrock section of the Columbia River Basalt Group at least 4,800 ft thick and in places greater than 10,000 ft. This bedrock section is overlain by 0 to approximately 700 ft of fluvial, lacustrine, and glaciofluvial sediments of Pliocene and Pleistocene age, with the greater sediment thicknesses in the synclinal positions in the basin interior. Volcaniclastic sedimentary layers are interbedded between the basalt flow in the upperpart of the bedrock section. Many of the basalt flows throughout the bedrock section are apparently blanket-like and extend laterally as single rock-stratigraphic units (and time-stratigraphic units) across the Pasco Basin and beyond; other flows are less extensive, although still blanket-like, and pinch out within the basin. A few flows in the upperpart of the section were emplaced as valley fills and are restricted in their lateral extent (Rockwell 1979a).

Yakima Folds bound the Pasco Basin on the north and south and plunge eastward into the basin from the west (Figure 3-34). Structural deformation that formed the Yakima Folds was occurring during deposition of the anticlines are generally broad, open folds. Drill holes and geophysical surveys reveal that most subsurface structures in the central Pasco Basin appear to be extensions of the Yakima Folds and their associated second-order structures, but a few subsurface structures might be related to northwest-trending structures that appear to crosscut the east-west-trending Yakima Folds (Leonhart 1979).

3.6.1.3.1 Stratigraphy and Lithology. Five major basalt units underlie the Pasco Basin: Pre-Columbia River Basalt Group, Columbia River Basalt Group, Ellensburg Formation, Ringold Formation (including the Palouse Soil), and Hanford Formation. These major rock units are locally mantled by surficial sediments. All major rock units crop out within the Pasco Basin except for Pre-Columbia River Basalt Group rocks, although they are partially penetrated in borehole RSH-1 at depths below about 4,000 ft. Formal rock

stratigraphic nomenclature used in the Pasco Basin is shown in Table 3-14 (Rockwell 1979a). The surface of the basalt is given in Figure 3-34 (Rockwell 1979b). Generalized geologic cross sections of the Pasco Basin are given in Figure 3-35.

No subbasalt rocks are exposed within the Pasco Basin so knowledge of subbasalt rocks is limited to studies along the margin of the Columbia Plateau as well as a few deep boreholes and surveys of the interior (DOE 1988). Rock types, of varying ages, surround the plateau. These subbasalt units are inferred to represent possible correlative sequences of sedimentary and volcaniclastic rock beneath the Columbia River Basalt. Recent reports (DOE 1988) estimate that Pasco Basin basalt is greater than 10,000 ft thick, subbasalt sedimentary rock is about 20,000 ft thick, and basement rock is about 6 mi deep.

1. Pre-Columbia River Basalt Group Rocks--The deep-seated, crustal rocks of the Pre-Columbia River Basalt Group are interpreted from geophysical data and from one deep borehole. The geophysical techniques included an unreversed, north-south refraction profile across eastern Washington, seismic modeling (USGS 1978), and magnetotelluric surveys (Rockwell 1979b). The borehole data are from RSH-1 drilled by Standard Oil Company of California on the south slope of Rattlesnake Mountain.

   Results from these surveys and borehole data indicate a deep-seated crystalline basement, possibly of granite origin, overlain by a 3,000- to 6,000-ft-thick section of sedimentary rocks. A volcanic rock sequence is interpreted to overlie the sedimentary rocks (Rockwell 1979a).

2. Columbia River Basalt Group Rocks--Lavas of the Columbia River Basalt Group on the Columbia Plateau (Figure 3-17) comprise a tholeitic flood-basalt province of moderate size covering an area of about 63,000 mi^2 and having an estimated volume of about 41,000 mi^3 (DOE 1988). The plateau is both a structural and topographic depression with its lowest elevation in the center of the province, the approximate location of the Pasco Basin (see Figures 3-30 and 3-35). Here, the accumulation of flows of the Columbia River Basalt Group and interbedded sediments attain their maximum known thickness (DOE 1986).

   The Columbia Plateau is the Earth's youngest recognized flood-basalt province. It was formed between 16,500,000 and 6,000,000 yr ago (American Journal of Science 1974; USGS 1977b), when large volumes of lava were erupted from north-northwest-trending linear vent systems now preserved as dikes (American Journal of Science 1961). Individual Columbia River basalt flows are voluminous, generally 2 to 6 mi^3, with a maximum known volume of 145 mi^3. Flows range in thickness from a few inches to about 300 ft, with an average thickness of 90 to 120 ft. The thickest flows are generally caused by ponding in pre-basalt valleys, in structurally controlled basins that developed during volcanism, or in narrow canyons previously eroded into older flows (Rockwell 1980).

The Columbia River Basalt Group in the Pasco Basin consists of three formations: Grande Ronde Basalt, Wanapum Basalt, and Saddle Mountains Basalt (Figure 3-17). Detailed reports of the stratigraphic and lithologic descriptions of the Grande Ronde Basalt, Wanapum Basalt, and Saddle Mountains Basalt are found in (Rockwell 1979a) and (Swanson et al. 1979).

3. Ellensburg Formation--Within the upperpart of the basalt sequence, sedimentary materials are increasingly prevalent upward, beginning with Vantage sandstone (Rockwell 1979a). These volcaniclastic materials include tufts and tufaceous sediments of many kinds, now partly altered to clay. Virtually every basalt flow above the Vantage sandstone horizon is capped at one site or another by stream-deposited sediments. The extent and thickness of these interbedded sediments generally increase upward in the section and are more extensive in the western portion of the Columbia Plateau. The lower beds tend toward rock types common to the Okanogan Highlands, southern British Columbia, and the North Cascades. The upper beds show an increasing abundance of volcanic debris, referred to as the Ellensburg Formation.

   Approximately 15,000,000 yr ago, the ancestral Columbia River was crossing central Washington, laying down trains of gravel, sands, silts, and clays comparable to today's Columbia River sediments. As the basalt flows advanced upon the river, it returned by gravity to the basin center, leaving its sediment trains as a mark of earlier courses. East of the current course, river sediments are virtually nonexistent between basalt flows, attesting to the shift exclusively westward from the current basin center.

4. Ringold Formation--The Ringold Formation was deposited in response to a flattening of the gradient of the Columbia River, perhaps related to the uplift of the Horse Heaven Hills, and consequent deposition of the sediments carried. Previously, deformation of the basin was accompanied by basalt flow extrusion into the topographically low areas. Cessation of flows about 6,000,000 yr ago permitted the deposition of a continuous sequence of sediments. Initially, these were blends of upriver rock types derived from the North Cascades and the Okanogan Highlands, with volcanic debris, largely of andesitic composition, from the central and southern Cascades. These latter sediments were transported to the Pasco Basin by the ancestral Yakima and related rivers. With time, the composition of the sediments being deposited in the Pasco Basin became more and more that of the Okanogan rock type.

   The beginning of anticlinal uplift, especially to the west and slightly before the eruptions of the latest basalt flows, locked the Columbia River into the Pasco Basin and halted the east-to-west migration. Somewhat later, uplift of the Horse Heaven Hills resulted in a continuously rising base level for the river and the deposition of sediment.

   The Ringold Formation ranges in thickness from about 350 to 700 ft and is subdivided into four units, principally on the basis of

texture (DOE 1988). These units are the basal Ringold unit and the lower, middle, and upper units.

These fine-grained sediments are considered to be the equivalent of the Palouse soils (loesses) of eastern Washington and western Idaho. The climate during the period was probably comparable to that of today, with effective wind transport and deposition of sediment (General Electric 1970).

5. Plio-Pleistocene Unit--This is a locally derived unit, probably of early Pleistocene or latest Pliocene age, overlying the Ringold Formation over much of the western Pasco Basin. The Plio-Pleistocene unit appears to correlate with other widestream alluvial sequences present near the base of the basaltic ridges that bound the Pasco Basin on the north, west, and south (DOE 1988).

6. Early "Palouse" Soil--Overlying the Plio-Pleistocene unit is a fine-grained, sand-to-silt unit of mostly eolian origin, differentiated from the overlying slack water flood deposits (DOE 1988).

7. Hanford Formation--The Ringold Formation and the basalts and sedimentary interbeds were eroded and truncated by normal flow of the Columbia River and by multiple floods that occurred when ice dams breached during the Pleistocene. These ice-dammed glacial lakes released catastrophic torrents. The floods scoured the land surface of the Hanford Site, leaving a network of buried channels filled with the outwash and gravel.

   The glaciofluvial sediments were deposited in the Pasco Basin on the basalt and Ringold Formation. These sediments can be divided into the coarser sands, gravel, and boulders and are referred to as the Pasco Gravel; the fine-grained sand and silt units are called the Touchet Beds.

   The Touchet Beds represent low-energy deposits in glacial Lake Lewis, which formed when flood waters were backed up behind the Wallula Gap constriction. The Pasco Gravel represent higher energy deposition in areas of more rapid water flow. In general, the Touchet Beds are found in the margins of the basin and the Pasco Gravel in and near the center of the basin. The characteristic variability of sediment size and degree of sorting within the "gravel" unit can be attributed to changes in water velocity and water level that occurred during the flooding process. The thickness of the Hanford Formation varies significantly within the basin, with the thickest occurrence in the region of buried channels.

8. Volcanic Ash Deposits--Several volcanic ashfalls were deposited in the late Pleistocene and Holocene over the Pasco Basin sediments. The thin, widespread ash associated with the last major ashfall was identified as the Mt. St. Helens Set S (USGS 1977a) and dated by radiocarbon at 13,000 yr before present (BP). Younger ash, such as that from Mt. Mazama (6,600 yr BP) and Glacier Peak (12,000 yr BP), has been found in the basin where the environment was favorable for preservation. The latest ashfall to be deposited in the Pasco Basin

is from the May 18, 1980, eruption of Mt. St. Helens and is discussed in Section 3.6.6.

9. Eolian Deposits--Loess and sand dunes mantle the surface of the Pasco Basin. These deposits are primarily reworked sediments of the Hanford Formation. The thickness of the windblown sediments varies considerably, ranging to greater than 50 ft in some dunes.

3.6.1.3.2 Geologic Features of the Pasco Basin. The Pasco Basin is defined on the north by the Saddle Mountains, on the south by the Rattlesnake Hills and Rattlesnake-Wallula Alignment, on the east as the junction between the Yakima Fold Belt and Palouse subprovinces (which generally coincides with the Ice Harbor dike system and Jackass anticline/monocline) and on the west by the Hog Ranch-Naneum Ridge anticline. An index map to the structural features is presented in Figure 3-36.

Summaries of the geologic mapping that has been conducted in the Pasco Basin and adjacent regions can be found in reports published by the Supply System and Rockwell (Supply System 1981, Rockwell 1979a).

1. Anticlinal Features

- Saddle Mountains--The Saddle Mountains is a broad anticlinal uplift that trends generally east-west for 68 mi and forms the northern boundary of the Pasco Basin. Two dominant structural features associated with the Saddle Mountains are the Saddle Mountains anticline and the Saddle Mountains fault, although the complex geometry of the anticline has resulted in other secondary anticlines, synclines, and monoclines that parallel the main trend of the structure. The Saddle Mountains fault is either a reverse or thrust fault that has an unknown dip angle. Although the fault generally parallels the Saddle Mountains anticline, it does not appear to have the same length and may not extend east of Smyrna Bench. At least 1.9 mi of crustal shortening resulting from horizontal compression has been measured on the Saddle Mountains fault on the west side of Sentinel Gap.

- Umtanum Ridge--The Umtanum Ridge-Gable Mountain structural trend is a segmented anticlinal ridge extending for a length of 85 mi in an east-west direction. This structure consists of five segments defined on the basis of changes in style of deformation and orientation of fold segments. From the west, Umtanum Ridge can be divided into three segments, the easternmost segment of these three segments plunging eastward and joining the fourth segment, the Gable Mountain-Gable Butte structure, just east of the western boundary of the Hanford Site and south of the Vernita Bridge. The fifth segment, the Southeast Anticline segment, trends southeast off the eastern boundary of the Gable Mountain-Gable Butte segment. The Gable Mountain-Gable Butte and Southeast anticline segments have considerably less structural relief than the Umtanum Ridge structural segments.

- Umtanum Ridge Segments--The three Umtanum Ridge segments trend for about 50 mi in a northwesterly direction. In general, Umtanum Ridge is an asymmetrical, north vergent to locally overturned, anticline with a major thrust to high-angle reverse fault on the north side. West of the Priest Rapids Dam site, the Umtanum fault may include as many as three imbricate thrust slices in which the basalt is folded, overturned, and faulted over the relatively undeformed Mabton interbed. The Umtanum fault juxtaposes vertical Frenchman Springs flows over nearly horizontal Priest Rapids flows. Results from drilling suggest that this fault dips southward under the ridge at 30° to 40° although it could be as high as 60°. Continuity of the fault eastward toward Gable Mountain cannot be established by exposure; however, decreasing structural relief suggests that fault displacement also decreases. The Umtanum fault is interpreted to die out 7 mi east of Priest Rapids Dam.

- Gable Butte-Gable Mountain Segment--Gable Mountain and Gable Butte are two topographically isolated, anticlinal ridges that provide the only extensive outcrops in the central Pasco Basin. Gable Mountain and Gable Butte are composed of a series of northwest trending, doubly plunging, in echelon anticlines, synclines, and associated faults. The folds are second-order folds within the closure of the first-order Umtanum Ridge anticline. Faults have been mapped on Gable Mountain.

- Yakima Ridge--The Yakima Ridge uplift extends from west of Yakima, Washington, to the center of the Pasco Basin, where it forms the southern boundary of the Cold Creek syncline. The eastern most surface expression of the Yakima Ridge uplift is represented by an anticline that plunges eastward into the Pasco Basin. A north-dipping reverse fault occurs south of the main ridge along the southeastern end of the exposed part of Yakima Ridge. The reverse fault parallels the main trend of Yakima Ridge.

  The eastern extension of Yakima Ridge occurs beneath supra-basalt sediments with only a few exposures. There are two predominant trends in the potential-field data over the buried part of the structure: a northwest and an east-west trend. The east-west trend coincides with the subsurface extension of Yakima Ridge and is interpreted to be a westerly plunging anticline that has had little erosional modification. The northwest trend is smaller in scale and does not appear to be related to the larger features. It appears more likely to be related to cross folds or cross faults on Yakima Ridge. A fault in the Frenchman Springs Member of the Columbia River basalt was penetrated in a borehole along one of the northwest trending potential-field anomalies.

- Rattlesnake Hills--The Rattlesnake Hills uplift, in conjunction with the Rattlesnake-Wallula alignment, forms the southern boundary of the Pasco Basin. The Rattlesnake Hills extend from near Yakima, Washington, on their west end, easterly to Snively Basin, where they abruptly terminate against the Rattlesnake-

Wallula alignment. The Rattlesnake Hills uplift is an asymmetrical anticline that has been faulted. It has a steeply dipping north limb and more gently dipping south limb. At the eastern end of the Rattlesnake Hills is Snively Basin. The fold geometry of Snively Basin is more complex than any other Yakima Fold. Several thrust faults are present that may connect with faults associated with Rattlesnake Mountain.

- The Rattlesnake-Wallula Alignment--The Rattlesnake-Wallula Alignment is composed of two structural elements in the Pasco Basin: the Rattlesnake Mountain uplift and "The Rattles." The southeastern extension of this alignment is the Wallula Fault Zone. The Rattlesnake-Wallula Alignment is the southeastern part of the Cle Elum-Wallula disturbed zone.

- Rattlesnake Mountain--Rattlesnake Mountain forms the northwestern part of the Rattlesnake-Wallula Alignment in the Pasco Basin. The geometry of the structures associated with the Rattlesnake-Wallula Alignment are asymmetrical, anticlinal ridges that have high-angle reverse or thrust faults along their steep northern flanks. Several faults are associated with Rattlesnake Mountain, including the Rattlesnake Mountain Fault Zone. The Rattlesnake Mountain Fault Zone consists of at least two faults that lie along the northeast flank of Rattlesnake Mountain within and parallel to the hinge area of the Rattlesnake Mountain anticline.

- The Rattles--A series of anticlines that extend southeast of Rattlesnake Mountain along the Rattlesnake-Wallula alignment are informally referred to as "The Rattles." They include Red Mountain and Badger Mountain and merge with the eastern segment of the Horse Heaven Hills near Wallula Gap. At the gap, their trend merges with the Wallula Fault Zone. Faults subparallel to the northwest trend of these ridges are found along some of the hills.

- Wallula Fault Zone--The Wallula Fault Zone extends from the eastern limit of "The Rattles," near Wallula Gap, southeastward along the north side of the Horse Heaven Hills to the vicinity of Milton-Freewater, Oregon, where the zone intersects the Blue Mountains. The zone is up to 1,080 ft wide and contains brecciated basalt and clay gouge. The fault dips steeply to the south. The fault is a reverse or oblique-slip fault, youngest movement of which was dominantly right lateral. The age of faulting on the Wallula Fault near Warm Springs Canyon in Oregon has been postulated as Quaternary. Tectonic breccias are overlain by undisturbed late Plesitocene Touchet Beds (approximate age 13,000 yr) and loess. Data from trenching support an interpretation that faulting may be as young as Quaternary, but older than glaciofluvial Touchet Beds (Woodward-Clyde Consultants 1981). Trenches across the Wallula Fault were also studied (Gardner et al. 1981). They found that faulted basalt of the Ice Harbor Member is overlain by undisturbed glaciofluvial gravels and Touchet Beds, leading to the conclusion that the last fault movement took place between

Ice Harbor time (8.5 M yr BP) and the latest cataclysmic flooding (13,000 yr BP).

2. Synclinal Features

   - Pasco Syncline--The Pasco syncline is located in the southeastern part of the Pasco Basin. It is bounded by The Rattles of the Rattlesnake-Wallula Alignment on the south and by the Palouse Slope on the north and east. The syncline is a broad, gentle, low-amplitude, long-wavelength, northwest-trending fold. The Pasco syncline loses definition in the Wye Barricade depression, which is a relatively broad and flat structural depression.

   - Cold Creek Syncline--The Cold Creek syncline lies between the Umtanum Ridge-Gable Mountain uplift and the Yakima Ridge uplift. The Cold Creek syncline is an asymmetric and relatively flat-bottomed structure. Its amplitude is greater and wavelength is shorter west of the Hanford Site. The Wye Barricade depression marks the southern extent of the Cold Creek syncline.

     The Yakima Barricade geophysical anomaly occurs on the west side of the Hanford Site on the south flank of the Cold Creek syncline. Two boreholes, drilled across the geophysical gradient, constrain its location and characteristics (boreholes DH-27 and DH-28) and indicate that the top of the Pomona Member (12 M yr BP) increases in elevation from about 70 ft on the east in borehole DH-28 to 234 ft on the west in borehole DH-27, suggesting 244 ft of relief over a relatively short distance of 2,600 ft.

     The overlying Elephant Mountain Member (10.5 M yr BP) apparently pinches out in an east-west direction across the feature. Relief on top of the basalt and lower Ringold unit is 145 ft and 100 ft, respectively. The top of the next younger unit, the middle Ringold, appears to be undeformed across the feature.

     The present data suggest that this feature is either a steeply dipping fold or a high-angle fault that formed during the late Miocene to early Pliocene. The top of the middle Ringold unit (age 5 M yr BP) appears undeformed, suggesting that vertical movement along this feature may have ended by late Pliocene.

3. Late Miocene to Pliocene Sedimentary Deposits--Suprabasalt sediments were deposited in most synclinal valleys of the Yakima Fold Belt and within other structural basins on the Columbia Plateau during the late Neogene (late Miocene to Pliocene time). Each synclinal basin on the Columbia Plateau is relatively unique compared to the other basins of the Plateau.

4. Quaternary Deformation--There is very little direct field evidence to indicate Quaternary deformation in the Columbia Plateau. Four areas of suspected Quaternary faulting have been documented: (1) the central Gable Mountain fault in the Pasco Basin, (2) the Toppenish Ridge fault in the Yakima Valley, (3) the Union Gap fault in Ahtanum Ridge, and (4) the Cle Elum-Wallula Alignment. The closest location to the PFP site is the central Gable Mountain. Evidence has been found that suggests Quaternary movement on the central Gable Mountain fault (see Section 3.6.2) (Puget Sound Power and Light Company 1982). This evidence includes faulting of glaciofluvial deposits, which were dated at 13,000 yr BP or older, and offsets of as much as 2.6 in.

   Fractures in these deposits are continuous with a reverse fault in the underlying Columbia River basalt along which progressively older units are increasingly offset. However, an alternative, nontectonic interpretation attributes the youngest observed offset to rapid hydrostatic loading and unloading that occurred during cataclysmic flooding (Puget Sound Power and Light Company 1982).

   A zone of nearly 100 surface ruptures on Toppenish Ridge is interpreted as representing late Quaternary tectonic deformation. These surface ruptures occur along a 20-mi portion of the ridge, between its crest and the base of its northern limb. The total width of the zone varies from 0.3 to 1.4 mi.

   Individual scarps are approximately parallel to the ridge trend, and range from 0.06 to 1.9 mi in length. Dip-slip separations on individual ruptures do not exceed 13 ft. Carbon-14 dates of organic material sampled from sag ponds associated with these fault zones are 505 ±160 yr and 620 ±135 yr.

   A third fault inferred to be of Quaternary age was exposed during highway construction near Union Gap, Washington, on Ahtanum Ridge. At this location, a high-angle reverse fault offsets Yakima River terrace gravels by at least 23 ft and results in the juxtaposition of the Ginkgo flow (Frenchman Springs Member, Wanapum Basalt) against the gravels (Supply System 1981). There is no reliable date for these terrace gravels, but it is believed that they are Pleistocene. The fault zone is capped by undeformed slack-water cataclysmic flood sediments dated elsewhere at 13,000 yr BP, indicating that the last movement of the fault occurred before that time.

   Evidence for Quaternary deformation has been reported for 14 localities either in or directly associated with the Cle Elum-Wallula disturbed zone (Supply System 1981). The areas closest to the Hanford Site include the following:

   1. Little Dry Creek fault south of Milton-Freewater, Oregon
   2. Buroker fault east of Milton-Freewater, Oregon
   3. Unnamed fault south of Umapine, Oregon
   4. Wallula Fault Zone east of Warm Springs Canyon, Oregon

5. Wallula Fault Zone near Wallula Gap, Washington
6. Wallula Fault Zone near Finley Quarry, Washington.

The last three localities lie along a 12-mi segment of the Wallula Fault Zone. No definitive evidence for Quaternary deformation has been reported northwest of the Finley Quarry location; however, the geomorphic expression and the continuity with the Wallula fault zone suggest Quaternary movement. The lack of evidence for Quaternary deformation farther northwestward along the Cle Elum-Wallula disturbed zone may result from the absence of a well-preserved stratigraphic record.

3.6.2 Vibratory Ground Motion

3.6.2.1 Geologic Conditions of the Site. The thick sequence of Columbia River Basalt masks the pre-basalt history of the Pasco Basin. The basalts are Miocene in age. An age of 6,500,000 to 16,500,000 yr has been inferred from radiogenic ages of basalts that crop out in the region (American Journal of Science 1974, USGS 1977b).

The Ringold Formation was deposited during Pliocene time. It was suggested that deposition continued into the Pleistocene, but later works (UW 1973) show evidence for termination of sedimentation in the latest Pliocene.

During the Pleistocene, glacial Lake Missoula floods scoured the area north and east of the Hanford Site, and glaciofluvial action put down thick deposits in the Pasco Basin.

3.6.2.2 Underlying Tectonic Structures. No unusual structures lie under the PFP site. The descriptions are given in Sections 3.6.1.1 and 3.6.1.2.

3.6.2.3 Behavior During Previous Earthquakes. Adverse behavior of the surficial geologic materials (i.e., soils) or the local bedrock during previous earthquakes has not been reported. A review of isoseismal maps indicates that ground motion corresponding to an earthquake of MM intensity VI is the largest projected (i.e., extrapolated) to have been felt at the Hanford Site (Supply System 1974). Such motion is perceptible but generally causes no adverse behavior of natural geologic materials.

3.6.2.4 Engineering Properties of Underlying Materials. The PFP is founded on glaciofluvial, medium-to-coarse sand and gravelly coarse sand known locally as the Hanford formation. This material is essentially dry, containing 2% moisture by weight--well above the water table--and about 120 ft thick (Tallman et al. 1979). Underlying the Hanford Formation is a sequence of sandy gravel and gravelly coarse sand that is part of the Ringold Formation. Ringold sediments overlie basalts and sedimentary interbeds of the Columbia River Basalt Group and Ellensburg Formation.

3.6.2.5 Earthquake History. The Columbia Basin, including the smaller structural unit, the Pasco Basin, is an area of low seismicity in which moderate level earthquakes (MM intensity less than or equal to VII) have occurred. While the historical record of earthquakes is relatively brief, it is sufficiently long to indicate that this area of eastern Washington

has experienced fewer earthquakes and of generally lower level than areas in the Puget Sound-Willamette Lowlands of western Washington or the Rocky Mountains. The Pasco Basin contrasts markedly with zones of higher seismicity to the west and east. A summary of eastern Washington earthquakes is presented in Tables 3-15a and 3-15b. These earthquakes attenuated rapidly eastward, so that the maximum known MM intensity in the vicinity of the Hanford Site was less than or equal to IV (Supply System 1981, DOE 1988, Weston 1977, UW 1992, UW 1993, UW 1994, UW 1995).

A network of seismographs was established in eastern Washington and has been operational since March 1969. Without this dense network of recorders, most events that have been recorded would have gone undetected. Some spatially and temporally restricted earthquake swarms have been felt, but the distribution of earthquakes generally indicates that stress is low, infrequent, and not concentrated in planar zones suggestive of discrete fault activity.

A large earthquake occurred at about 10:40 p.m. (universal time) on December 15, 1872, in a sparsely populated area of northern Washington and southern British Columbia. Because of scarce data, details of this earthquake are not well established. Research was conducted (Supply System 1977a) to determine the epicenter and epicentral intensity of this earthquake, along with any possible relationship to the geologic structure. This research was undertaken in the preparation of preliminary safety analysis reports and amendments thereto for several commercial light-water reactor units to be located on the Hanford Site. The research included detailed geologic mapping in the epicentral area, as well as in the region, analysis of imagery, compilation and review of contemporary accounts of this earthquake, geophysical investigations, development of a plate tectonic model for the Pacific Northwest, and analysis of both macroearthquakes and microearthquakes (Supply System 1977a, 1977b; Shannon and Wilson 1977b; Weston 1977).

Because the December 15, 1872, earthquake is of potential significance to the proposed Hanford Site nuclear generating stations, a number of hearings and reviews were conducted following submittal of a geologic evaluation on structures in the Columbia Plateau (Shannon and Wilson 1977a). Joint hearings involving members of the Supply System, Portland General Electric, Puget Sound Power and Light, the NRC Advisory Committee on Reactor Safeguards, and the U.S. Geological Survey (USGS) were conducted. As a result of these meetings and reviews of new information on the 1872 earthquake, the USGS and the NRC reevaluated the geology and seismology pursuant to the design of these proposed nuclear facilities. The USGS concluded that: (1) the 1872 earthquake was probably of MM intensity IX because of the numerous landslides reported; (2) an earthquake similar to the 1872 event will not occur in the Columbia Plateau but could occur along the northern margins of the plateau; and, (3) a 0.25g zero-period horizontal ground acceleration was appropriate for design of the Supply System WNP-1 and WNP-4 nuclear power plants.

The NRC concluded that: (1) the Columbia Plateau is a unique tectonic province within the context of ERDA (1975) and is distinct from the area in which the 1872 earthquake occurred; (2) an event similar to the 1872 earthquake need not be considered near Supply System WNP-1 and WNP-4; (3) a zero-period horizontal ground acceleration of 0.25g was appropriate for design of WNP-1 and WNP-4, as stated in the safety evaluation report (NRC 1975); and (4) the 1872 earthquake should be considered a "strong MM intensity VIII," based

on the absence of evidence, other than landslides (which have occurred at much lower intensities).

While many details relating to the 1872 event remain uncertain, the recent investigations indicate that this event was generated at least 140 mi northwest of the Hanford Site in a sparsely populated area that is geologically different from the Columbia Basin. The epicentral intensity was probably MM VIII, but the Hanford Site apparently experienced effects corresponding to a maximum MM VI (NRC 1975). Geologic investigations indicate that surface faulting apparently did not occur during this earthquake. Therefore, the potential for recurrence of a similar-sized event and the potential for surface faulting during an earthquake in the Columbia Basin seem low.

3.6.2.6 Correlation of Epicenters with Geologic Structures. No well-defined relationship exists between macroseismicity and geologic structure in the Columbia Basin or anywhere in the region of the Hanford site.

The July 16, 1936, MM VII Milton-Freewater earthquake occurred 30 mi east of the area where the extensions of the northwest trending Horse Heaven Hills and Rattlesnake-Wallula structures merge, along with the projected extension of the Wallula Gap fault. The northeast trending Hite fault also occurs in this area. Ground rupture was reported in the epicentral area and near Wallula Gap. Both areas are underlain by thick sequences of unconsolidated sediments. The nature of these reports suggests nontectonic deformation, especially along the edges of slopes artificially excavated for a highway and a railroad. Several aftershocks of this earthquake suggest that the plane of rupture was oriented northeast, an alignment that agrees with that of the Hite fault and the Blue Mountains anticline. The sensed area and isoseismals also display an elongation in a northeasterly direction (Supply System 1974). It is not certain whether this earthquake occurred along any of the mapped structures in the area. Since it is the only recorded MM intensity VII or greater earthquake within a 72-mi radius of the Hanford Site, it is unique.

With one exception, neither macroearthquakes nor microearthquakes appear to align along any of the northwest trending zones of steep slope on the north sides of these anticlines. The MM V-VI earthquake on November 1, 1918, near the town of Corfu, Washington, apparently occurred in a position to the north of the Saddle Mountains anticlinal axis (Supply System 1981).

Microearthquake activity that has been monitored continuously in the Columbia Basin since March 1968 (first by the USGS and later by the University of Washington with an expanded network) indicates:

- Low levels of stress release
- Shallow focal depths (less than or equal to 50 mi)
- No obvious relationship to any mapped geological structure.

Swarm activity has been recorded at Wooded Island, and events have been clustered in time within controlled zones. Unlike the situation in California, where segments of the Hayward, San Andreas, and Calaveras faults are clearly delineated by microearthquakes, there is no clustering, concentration, or alignment of microearthquake epicenters along any of the mapped northwest-trending structures in the Columbia Basin.

On the basis of probable geomorphic expression in the Touchet Beds (12,000 yr old) a fault extending 5 mi from VanSycle Canyon across the Columbia River to Yellepit Station is considered to be a capable fault (Brown 1968). The north side of this fault, known as the Wallula Gap fault, has moved down, displacing stratigraphic horizons greater than 1,000 ft (AGU 1977). There is no displacement or geomorphic expression of the fault in Holocene loess deposits. No earthquakes are known to have occurred along the fault.

3.6.2.7 Identification of Capable Faults. Four faults on Gable Mountain--the "south, central, west" faults and the "north-dipping reverse fault,"--and the Rattlesnake Mountain fault are assumed capable by the NRC using the definition in Appendix A to 10 CFR 100 (NRC 1982b).

3.6.2.8 Description of Capable Faults. The central fault is interpreted as a tear fault that developed along with the growth of Gable Mountain anticline. The fault strikes northeast-southwest and dips to the southeast with a length of about 2 mi. The central fault dies out to the northeast and southwest in the hinge zones of the east Gable Mountain anticline and west Gable Mountain anticline, respectively. Glaciofluvial deposits (13,000 to 19,000 yr BP) are displaced about 2.6 in. or less over a length of about 1,100 ft (Puget Sound Power and Light Company 1981). Long-term displacement rates are low (2.0×10^{-4} in./yr). The youngest movement is greater than 13,000 yr BP.

The south fault is an east-west trending reverse fault that dips south and has a length between 1,700 ft and 4 mi. Displacement of glaciofluvial deposits has not been observed; however, slickensides in clastic dikes derived from these deposits suggest minor dip-slip displacement since dike emplacement. Apparent accumulative dip-slip displacement has been no more than 50 ft in the last 11M yr.

The north-dipping reverse fault occurs on the south side of Gable Mountain and is probably a back-limb thrust fault. It has been traced for 2,000 ft in an east-west direction but may be as long as 4 mi in length. Apparent maximum cumulative displacement has been 380 ft in the last 11M yr. Displacement of glaciofluvial deposits has not been observed.

The west fault is a 0.5-mi-long normal fault striking northeast and dipping to the west. This fault is interpreted as a short tear fault, which formed in response to folding in the west Gable Mountain anticline hinge area. Apparent cumulative dip-slip displacement has been 15 ft over the past 11M yr; no displacement of glaciofluvial sediments has been observed.

Two faults were recognized in corehole DB-10 on the south side of Gable Mountain during drilling to delineate the extent of the echelon folds on Gable Mountain (Rockwell 1979a). Subsequent drilling by Golder Association constrained the upper fault to about 0.5 mi in length with a north-south strike and a 25 to 45° dip to the west (Puget Sound Power and Light Company 1981). Vertical stratigraphic throw has been about 165 ft over the past 11 to 13M yr. Altogether, no age determination of last movement was made. This fault was interpreted to be independent of Gable Mountain faults (Puget Sound Power and Light Company 1981).

The Rattlesnake Mountain fault, about 8 mi south of the PFP site, is also assumed to be capable (Farooqui and Thoms 1980). There is no known Quaternary

movement along this portion of the Rattlesnake-Wallula Alignment. Quaternary movement is possible southeast of Rattlesnake Mountain along a splay of the Wallula Fault at Finley Quarry (Farooqui and Thoms 1980). This exposure is a 33-ft-wide fault zone on the northern flank of one of the doubly plunging anticlines that lie along the Rattlesnake-Wallula Alignment. The fault juxtaposes colluvium of unknown age against older Miocene basalt along a high-angle reverse fault. Younger colluvium and loess overlying the fault are not displaced. These younger sediments are overlain by two caliche soil horizons, the higher of which was dated at least 70,000 yr (Woodward-Clyde Consultants 1981), indicating that the displacements occurred more than 70,000 yr ago.

3.6.2.9 Maximum Earthquake. There are four accepted sources for earthquake generation that could cause ground vibrations at the PFP site large enough for specific evaluation (NRC 1982b).

- A swarm-type of earthquake occurring in the basalt with a Richter magnitude of 4.0.
- A surface-wave magnitude 6.5 event occurring at the closest distance to the PFP from the Rattlesnake Mountain Fault, about 8 mi.
- A floating-type of earthquake, not associated with any known geologic structure. Such an event would be the largest known to have occurred in the tectonic province where the PFP is located. It would be a Richter magnitude 5.75 event assuming the 1936 Milton-Freewater earthquake is in the same tectonic province as the Pasco Basin.
- A surface-wave magnitude of 5.0 ± 0.5 earthquake on the north dipping Gable Mountain Fault. This fault is the largest and closest assumed capable structure at Gable Mountain. The distance to the PFP site is about 3 mi.

3.6.2.10 Design Basis Earthquake. The design response spectra for the DBE for Safety Class and Safety Significant nonreactor nuclear facilities is generated from the time histories of the seismology of the region (DOE-RL 1993). See Chapter 4.0, Section 4.3.5, for detailed discussions of the seismic design criteria.

3.6.2.11 Operating Basis Earthquake. See Chapter 4.0, Section 4.3.5, for discussion of the seismic design criteria for Safety Class and Safety Significant nonreactor nuclear facilities.

3.6.3 Surface Faulting

No evidence of surface faulting or potential for surface fault manifestations has been found on the PFP site.

3.6.4 Stability of Subsurface Material

3.6.4.1 Geologic Features. Geologic features at the PFP site are discussed in Section 3.6.1.2.1 and in Section 3.6.2.

3.6.4.2 Properties of Underlying Materials. The Ringold Formation at the PFP site is covered by about 100 ft of glaciofluvial gravel and associated sediments, informally called the Hanford Formation. The Hanford Formation gravel and sediments are compact, locally uncemented deposits of Pleistocene times. The Hanford Formation was laid down by glacial meltwaters and the glacial Lake Missoula floods between about 100,000 and 10,000 yr ago. The soils within the upper 100 ft at the PFP site are predominantly dense, fine-to-coarse sands with admixtures of silt and pebbles (Tallman et al. 1979).

3.6.4.3 Soil and Rock Characteristics. Seismic surveys of the PFP site were conducted to determine shear and compressional wave velocities and to develop data on the dynamic properties of the foundation soil (URS/JABE 1980). A generalized geological cross section is presented in Figure 3-37.

3.6.4.4 Excavations and Backfill. Excavations and backfill were completed for construction under the Uniform Building Code (UBC 1946), using Hanford specification HW-3259 (Giffels and Vallet 1948). The safe bearing value of the soil is 9000 lb/in^2. All excavation was done within the building lines and as required to a point 5 ft beyond the building lines to accommodate the work of all trades. Excavation for wall, column, pier, and other footings was carried to a suitable bearing area approved by the construction engineer. The depth of exterior footings was not less than 2 ft 6 in. below finish grade line. All concrete footings were carried to soil at least 1 ft below the existing ground line, or to undisturbed soil, but always to depths as shown on foundation plans (the preceding was taken from the 234-5Z Building foundation plan, H-2-16008).

All backfilling required for completion of the work included filling to a point approximately 5 ft outside the lines, of any structure. For filling and backfilling outside of building lines, suitable excavated material or material borrowed on the site was used. Backfill material inside of the PFP, against walls, over column footings, and fill under slabs was sand or uniformly graded gravel, 100% of which passed through a 1-in. mesh screen. No backfilling was performed on frozen surfaces.

Backfilling was placed in layers not over 12 in. thick by loose measurement. All backfill material was tamped using air tampers.

Excavating and backfilling are not now common practices at the PFP and, when conducted, are performed by construction personnel using approved procedures. Compaction criteria for any new engineered backfill is now specified to be in accordance with *Standard Specification for Road, Bridge and Municipal Construction* (WSDOT 1994).

3.6.4.5 Groundwater Conditions. The stability of the water table is discussed in Section 3.5.2.

3.6.4.6 Response of Soil and Rock to Dynamic Loading. Data on the dynamic properties of the PFP founding materials have been reported (URS/JABE 1980). A site-specific response spectrum was developed, based on specific density of site materials of 1.84 and a representative shear wave velocity of 1,200 ft/s. Also, the soil and rock are similar in properties to those underlying nearby sites for nuclear power plants, for which extensive analytical data are available (Supply System 1981, Puget Sound Power and Light Company 1981).

3.6.4.7 Liquefaction Potential. The water table is at a depth of about 200 ft beneath the PFP site. This fact, plus the dense, coarse nature of the underlying materials, precludes a potential for liquefaction.

3.6.4.8 Earthquake Design Basis. The major PFP buildings were designed and built over the period of 1946 through 1982. Applicable design criteria for the period were used. The specific criteria for each of the major buildings are discussed in Section 5.2 and summarized in Table 5-2.

3.6.4.9 Static Analysis. At the time of original design and construction (1947 to 1949) formal static analysis of the subsurface material, as currently required, was not performed. Evaluations consistent with UBC 1946 were performed. The subsurface conditions were found to be compliant and construction was completed. During the past 40 yr of operation there has been no indication of settlement or subsurface instabilities.

3.6.4.10 Criteria and Design Methods. For principal design criteria and design methods at the Hanford Site see Chapter 4.0, Section 4.3.5.

3.6.4.11 Techniques to Improve Subsurface Conditions. The subsurface conditions are stable. No improvements to subsurface conditions were attempted. Construction was satisfactorily completed.

3.6.5 Slope Stability

The PFP site reveals no near or adjacent slopes whose failure (instability) might constitute a hazard. Moreover, the soils at the site are typically granular and, hence, relatively resistant to failure due to sliding.

3.6.6 Volcanic Action

3.6.6.1 Volcanoes of the Cascade Mountain Range. There are several major volcanoes in the Cascade Mountain Range west of the PFP site (Figure 3-38). The closest is Mt. Adams about 100 mi distant; the most active is Mt. St. Helens about 130 mi west-southwest of the Hanford Site. Because most volcanic activity is confined to the immediate area of the volcano, mud flows, avalanches, pyroclastic rock flows, lava flows, and shock waves that may be associated with such activity do not pose a hazard to the Hanford Site. The only potential hazard to the site is ashfall resulting from a major eruption of one of these volcanoes (Supply System 1981).

3.6.6.2 Ash History for Hanford Site. The stratigraphic record of tephras in the Pasco Basin suggests that the only primary product of Cascade Mountain Range volcanism that may be expected to reach the Pasco Basin during the next 10,000 yr is air-fall tephra. The USGS made a similar assessment for the Supply System WNP-2 nuclear power plant site (Woodward-Clyde Consultants 1981).

The hazard posed by any particular Cascade volcano to the PFP site is dependent on the probability of renewed eruptive activity and amount of air-fall tephra. Sarna-Wojcichi et al. (1980) have estimated an annual probability of 10^{-4} to 10^{-5} for eruption of some Cascade Mountain Range volcanoes based on the frequency of occurrence of various ejecta during a

given interval of geologic time. Some of the volcanoes, such as Mount St. Helens, are known to erupt more frequently, and the stratigraphic record may not provide complete information on the frequency of eruptions but rather may reflect only the relatively large eruptive episodes (Sarna-Wojcichi et al. 1980).

The amount of air-fall tephra that may reach the Hanford Site depends on the volume of material erupted, the tephra characteristics, and the distance of the Hanford Site from the source. Dispersal patterns of ejecta from eruptions are determined by the wind direction and velocity and the altitude to which the ash cloud rises.

Varying amounts of ash were deposited across the Columbia Plateau during the May 18, 1980, eruption of Mt. St. Helens. About 0.3 in. of ash was deposited at the Hanford Site meteorological tower. The Hanford Site was not in the main path of the ash cloud and received only a fraction of ash compared with locations to the north that were located directly in the path of dispersing winds (Sarna-Wojcichi et al. 1980).

3.6.6.3 Ash Densities and Depth Comparisons. Studies of the impact of ashfalls associated with volcanic eruptions indicate that the density and the depth of the ash are important. Sarna-Wojcichi of the USGS indicates that there are great variations in depth just from the settling of ash from air currents and other natural means (Sarna-Wojcichi et al. 1980). For example, the depth of ash at Pullman, Washington, from the Mt. St. Helens, May 18, 1980, eruption measured 0.4 in. shortly after the event but less than 0.15 to 0.2 in. in depth after 1 d. Because of the potential effect of roof loading on structures, the density of the ash is an important parameter to consider in an ashfall event.

The actual ash densities observed from the Mt. St. Helens eruption on May 18, 1980, are shown in Figure 3-39. At a distance equal to that of the PFP from the volcano (130 mi), the apparent density would be about 31 lb/ft^3. With natural settling, this can increase to 62 lb/ft^3 with a corresponding decrease in depth. The density of the ash varies greatly with other conditions. For example, Sarna-Wojcichi indicated that the ash that fell during the later eruptions of Mt. St. Helens and was exposed to rain and subsequently dried out experienced an increase in density to 74 lb/ft^3 when compared with other densities shown in Figure 3-39 (Sarna-Wojcichi et al. 1980).

3.6.6.4 Volcanic Design Basis Ashfall. The following sections describe characteristics of the PFP design basis event.

3.6.6.4.1 Particle Size and Distribution of Ash. Particle size and distribution from a volcanic ash eruption normally vary with the distance from the volcano and the relative wind speed. The particle size generally decreases with increased distance from the volcano, reflecting settling of the coarse material near the source. Different winds at the time of the event could cause different settling rates than occurred during the May 18, 1980, eruption of Mt. St. Helens and could change the particle size distribution of the ash. For the design basis ashfall event a particle distribution was developed as listed in Table 3-16.

3.6.6.4.2 Abrasive Characteristics of Ash. The abrasive characteristics are determined by the main minerals in the ash. These main minerals, in order of decreasing abundance are: plagioclase feldspar (andesite), orthopyroxene (hypersthene), titanium-bearing magnetite, and glass. This mixture is very abrasive and may cause accelerated wear and damage to mechanical moving parts.

3.6.6.4.3 Chemical Composition of Ash. The chemical constituents in the ash may vary with each volcanic eruption, depending on whether old material or new volcanic material was being erupted and also on the distance from the volcano. Using the results obtained for the May 18, 1980, event (Long 1980), an estimated composition for the design basis ashfall event was developed and is shown in Table 3-17.

3.6.6.4.4 Composition of Water-Soluble Constituents. Reports by many observers on the ashfall from Mt. St. Helens on May 18, 1980, indicate that the dry ash was mildly corrosive. Leaching studies of the ash were conducted to determine what species would dissolve when the ash came into contact with water. These experiments showed no acidity. In fact, some of the samples increased in pH. Although this would appear to be a discrepancy, adding water to the sample may have caused any acids in the ash to react with the bulk of the ash.

The water-soluble constituents for the design basis ashfall event and a comparison with soil are given in Table 3-18 (Fruchter et al. 1980).

For the design basis ashfall event, the dry ash should be considered mildly corrosive to metals.

3.6.6.4.5 Ash Drift Characteristics. The characteristics of the ash from the standpoint of drifting will be very similar to that of snow. The density of the ash is much greater, which requires stronger winds to cause movement.

3.6.6.4.6 Ash Electrical Properties. The ash has the following properties.

- Resistivity--Dry ash resistivity equals 1 x 10^8 mohm/cm.

  NOTE: Volcanic ash is about 5 to 10 times more conductive than dirt from the Yakima Valley. However, for a material normally to be considered conductive, the range would be from 10^4 to 10^5 ohm-cm.

- Conductivity--Aqueous extract, 1:1 ash/water by volume, conductivity equals 2.99 mohm/cm. Resistivity of aqueous extract equals 334 ohm-cm.

  NOTE: In samples taken of May 18, 1980, Mt. St. Helens eruptions, a considerable variation in conductivities within any one sample was observed because of the inherent heterogeneity of each ash sample.

- Equivalent Salt Deposit Densities--The severity of contamination is generally quantified in terms of Equivalent Salt Deposit Densities (ESDD). Since volcanic ash dissolves slowly, it will retain its

conductive nature over a longer period of time. In Table 3-19, volcanic ash is compared to the equivalent salt found in soil (Nellis and Hendrix 1980).

In making a comparison of severities of contamination on insulators, the Institute of Electrical and Electronic Engineers has established ESDD ranges to categorize the severity of contamination (see Table 3-20).

The volcanic ash would be in the heavy severity range for electrical insulators.

3.6.6.5 Design Basis Ashfall. A volcanic ashfall is considered to be a potentially occurring natural phenomenon in the category of tornado and earthquake. Early design criteria did not account for ashfall specifically from volcanic activity but did consider roof loading. The design basis ashfall was added to the Hanford Site design criteria following the May 18, 1980, eruption of Mt. St. Helens (Table 3-21).

The basis for evaluation is an assumed eruption of Mt. Adams (100 mi from the Hanford Site) in a similar manner to that which occurred at Mt. St. Helens.

The probability of a volcanic eruption of Mt. Adams is indeterminable, but it was chosen because it is closest of the volcano peaks to the Hanford Site. Southwesterly winds, could easily make the Hanford Site a target for ashfall with wind conditions similar to the St. Helens eruption, and its physical construction is very similar to Mt. St. Helens. Mt. St. Helens or Mt. Rainier, based on past history, have a higher probability of eruption; however, Mt. Adams, because of location, is the worst case.

While the Hanford Site is distant enough to avoid danger from the immediate eruption (i.e., the stone wind or avalanche), ashfall does present a problem as it did on May 18, 1980, during the eruption of Mt. St. Helens.

With winds to the northeast, the ash flow would be directly toward the PFP, as shown in Figure 3-40. For a total ashfall duration of 20 h, with a decreasing rate after the first 6 h, the ash accumulation would be as follows:

Average ashfall: 3 in./20 h = 0.15 in./h.

For the purpose of this scenario, the ash will be dry in form with the only compaction caused by its own weight, which is dependent on the depth of accumulation.

Ash causes three immediate concerns to the PFP management. The ash is extremely abrasive to any exposed mechanical equipment, ash may cause pluggage problems with the ventilation system, and heavy accumulations on top of the facility may exceed roof loading limits.

In the event of ashfall at the PFP, most exterior equipment that would be exposed to the abrasiveness of the ash would be shut down, including the vehicles such as the process and sample trucks. Ashfall accumulations of 1 to 2 in. can be washed at the ventilation intakes by turning the wet cell washers on full and maintaining clean water in the spray pans. However, for

heavier ashfalls it would be advisable to shut down the normal ventilation, leaving the wet cell washers on, and rely on natural circulation for ventilation through the facility exhaust stack until the ashfall is over. It may become necessary for the PFP personnel to clear the roof of ash before excessive buildup occurs. This effort requires special safety precautions and includes protective clothing and respiratory protection and is included in the plant emergency planning for response to volcanic eruption.

3.6.6.5.1 Design Criteria. Facility design criteria for ashfall loading at the Hanford Site is discussed in Chapter 4.0, Section 4.3.6 and 4.3.9.

LOCATION AND HISTORY

PRESENT LOCATION 25 mi NW OF RICHLAND, WASHINGTON
LATITUDE 46°34'N; LONGITUDE 119°36'W. ELEVATION 733 ft
OBSERVATIONS FROM 1913 TO 1944 WERE BY UNITED STATES WEATHER BUREAU COOPERATIVE OBSERVERS AT A SITE ABOUT 10 mi ENE OF PRESENT LOCATION. BETWEEN 1944 AND 1975, OBSERVATIONS HAVE BEEN MAINTAINED ON A 24 hr-A-DAY BASIS BY THREE DIFFERENT GOVERNMENT CONTRACTORS

78901048.247
W-021-3

EXTREME AVERAGES OR TOTALS AND YEAR OR SEASON OF OCCURRENCE

1912-1975 TEMPERATURE AVERAGES (°F)		
HIGHEST ANNUAL	56.2	1958
LOWEST ANNUAL	39.2	1929
HIGHEST WINTER (D-J-F)	41.1	1933-34
LOWEST WINTER	24.7	1948-49
HIGHEST SPRING (M-A-M)	58.2	1947
LOWEST SPRING	48.0	1956
HIGHEST SUMMER (J-J-A)	78.2	1958
LOWEST SUMMER	70.3	1954
HIGHEST FALL (S-O-N)	59.9	1963
LOWEST FALL	49.6	1946
1912-1975 PRECIPITATION TOTALS (IN.)		
GREATEST ANNUAL	11.45	1950
LEAST ANNUAL	3.26	1967
SNOW, ICE PELLETS (SLEET)		
GREATEST SEASONAL	43.6	1915-16
LEAST SEASONAL	0.3	1957-58
1946-1975 WIND SPEED AVERAGE (mi/hr)		
HIGHEST ANNUAL	8.3	1968
LOWEST ANNUAL	6.3	1957
1946-1975 RELATIVE HUMIDITY AVERAGE (%)		
HIGHEST ANNUAL	57.9	1950
LOWEST ANNUAL	46.4	1963
1946-1975 SKY COVER AVERAGES (SUNRISE TO SUNSET, SCALE 0 - 10)		
HIGHEST ANNUAL	6.4	1966
LOWEST ANNUAL	5.1	1949
1953-1975 SOLAR RADIATION AVERAGE DAILY TOTAL (LANGLEYS)		
HIGHEST ANNUAL	390	1973
LOWEST ANNUAL	357	1967

[a] Wind speed (m/s) classification as follows:

< 1.8	=	0.89
1.8 - 3.6	=	2.7
3.6 - 5.8	=	4.7
5.8 - 8.5	=	7.2
8.5 - 11	=	9.8
11 - 14	=	13
14 - 17	=	16
> 17	=	19

[b] Atmospheric stability classification (from NRC 1974) (Pasquill Category)

extremely unstable	=	A
moderately unstable	=	B
slightly unstable	=	C
neutral	=	D
slightly stable	=	E
moderately stable	=	F
extremely stable	=	G

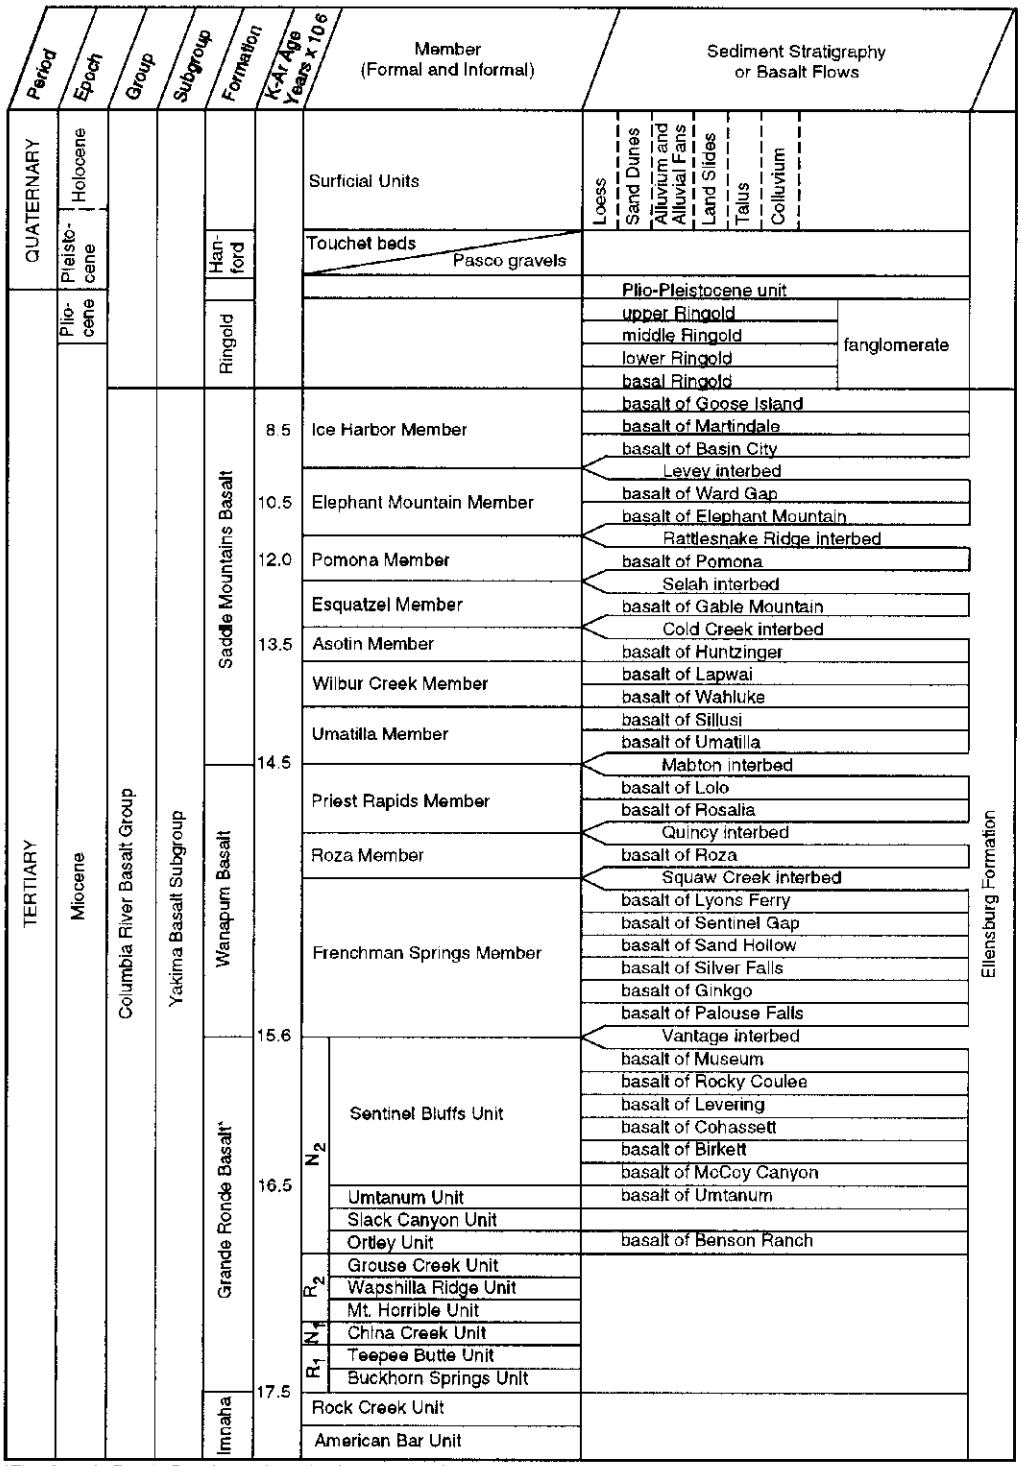
Table 3-11. Geologic and Hydrogeologic Characteristics of the Pasco Basin.

Geologic Time Scale			Geologic Characteristics				Hydrogeology	
Era	Period	Epoch	Radiogenic Date, Years Before Present	Stratigraphic Unit	Bed or Flow Unit	General Lithologic Character	Average Thickness (ft)	Hydrologic Character	Aquifer
Cenozoic	Quaternary	Holocene	6,600 — 10,000	Alluvium Colluvium and Eolian Sediments		Sands, silts, gravels, and clays modified by wind erosion	Dunes to 50	Occur everywhere above the water table	Dry
		Pleistocene	12,500	Glaciofluvial Sands and Gravels (Hanford Formation)	Touchet Silts	Fine-grained facies of the glacio-fluvial deposits. Bedded in quiet water	0 - 400	Occur above the water table, except between the high terrace plateaus and the Columbia River. Has very high transmissivity and storage	Occasionally an unconfined aquifer or dry
			>12,000		Pasco Gravels	Predominantly coarse-grained gravels. Cobbles and sands with cut-and-fill structure			
			<18,000		Palouse Soil	Calcareous sand and silt Eolian deposit mainly derived from Ringold Formation	0 - 80	Above water table when present	Dry
			40,000 — 1,000,000	Ringold Formation	Upper Ringold	Locally capped by Caliche. Mostly well-bedded fluvial silts and sands with some gravels	0 - 400	Sands and gravel beds have very high hydraulic conductivity and storage. Some beds of silty clay or clay are essentially impermeable	Local confined and unconfined aquifer
					Middle Ringold	Sands and gravels, well sorted, compact, but variably cemented	0 - 400		
					Lower Ringold	Silts and clays with interbedded gravels and sands. Clay is characteristically blue, but may be green, brown, or tan	0 - 400		Aquitard
	Tertiary	Pliocene	4,000,000 — 5,500,000		Saddle Mountains	Basalt flows with interflow zones. Several sedimentary interbeds or Ellensburg Formation are present	900	Flows are dense with low-hydraulic conductivity. Interflows and interbeds have higher hydraulic conductivity and transmissivity	Confined aquifers
		Miocene	11,000,000 — 15,000,000	Columbia River Basalt Group	Wanapum	Basalt flows with interflow zones. Few interbeds of Ellensburg Formation are present	1,000		
					Grande Ronde	Basalt flows with interflow zones. Interbeds of Ellensburg Formation are infrequent and very thin when present	3,000		

78810021.78

W-021-8 8/96

Table 3-12. Hydraulic Conductivity of Unconfined Aquifer.



Interval tested (formation)	Hydraulic conductivity (ft/d)
Hanford	500 to 20,000
Hanford and Ringold	100 to 1,000
Ringold (including clay)	1 to 200

Table 3-13. Transmissivity of Unconfined Aquifer.

Region	Transmissivity (ft^2/d)
North of Gable Butte and Gable Mountain	4,000 to 25,000
On the flank of Gable Butte and Gable Mountain and along Paleochannels	40,000 to 600,000
Other areas of the Hanford Site	2,000 to 40,000

NOTE: Storage coefficient ranges from 0.05 to 0.15 throughout the Hanford Site.

Table 3-14. Pasco Basin Stratigraphic Nomenclature.

*The Grande Ronde Basalt consists of at least 120 major basalt flows. Only a few flows have been named.
N_2, R_2, N_1 and R_1 are magnetostratigraphic units.

December 17, 1995	15:01:47.90	3.1	47.595° N. 120.219° W	12.42	-
December 27, 1995	22:52:54.84	3.1	46.778° N. 122.829° W	0.15	-

[a]Unless otherwise noted, all magnitudes are coda-length magnitudes.
MB = Body-wave magnitude.
ML = Local (Richter) magnitude.
NOAA = National Oceanic and Atmospheric Administration.

Table 3-16. Hanford Site Ashfall Particle Size Distribution.

Fraction (wt%)	Particle size (μm)
5	>150
64	75 - 150
5	45 - 75
24	20 - 45
1	3.5 - 20
1	<3.5

Table 3-17. Chemical Composition of Ash.

Major compound	Composition (%)
SiO_2(not free silica)	60.3
Al_2O_3	16.4
Fe_2O_3	5.61
CaO	5.55
Na_2O	4.83
MgO	2.77
K_2O	1.56
TiO_2	0.85
P_2O_5	0.46
MnO	0.087
Trace element	**Composition (ppm)**
Boron	34
Sulfur	1,100
Chlorine	500
Vanadium	127
Chromium	31
Cobalt	19
Nickel	27
Copper	41
Zinc	56
Gallium	8
Arsenic	2.6
Selenium	1
Bromine	1
Rubidium	27
Strontium	510
Yttium	12
Zirconium	160
Niobium	5.7
Molybdenum	4.4
Cadmium	4
Barium	--
Mercury	0.0070
Lead	6

NOTE: These were used as input data for the ashfall design basis for the Hanford Site.

Table 3-18. Water-Soluble Ions in Volcanic Ash.

Ion	Concentration (ppm)	Soil (ppm)
Cl^-	400.0	1.9
No_3^-	20.0	2.5
SO_2^-	750.0	2.2
Aluminum	0.25	1.8
Barium	0.18	0.03
Calcium	290.0	6.2
Iron	0.09	2.4
Potassium	40.0	1.4
Magnesium	38.0	2.0
Manganese	5.8	0.05
Sodium	210.0	4.6
Silicon	11.0	20.0
Strontium	1.6	0.02
Titanium	0.01	0.01
Zinc	0.3	0.4

Table 3-19. Equivalent Salt Deposit Densities.

Sample matrix	Equivalent salt for 100-m^2 sample (mg)	ESDD* (mg/cm^3)
Volcanic ash	132	0.40
Soil	20	0.06

*Calculated for a 3-mm ash layer uniformly deposited on an insulator surface. The ESDD is defined as the equivalent amount of salt (NaCl) that would yield the same conductivity as the contaminant (volcanic ash) in the same volume of water.

Table 3-20. Equivalent Salt Deposit Densities Severity Range.

ESDD (mg/cm^3)	Severity
0.0 to 0.03	Very Light
0.03 to 0.06	Light
0.06 to 0.10	Moderate
0.10 and up	Heavy

Table 3-21. Ashfall Loading Variables.

Ash depth		Ash density		Ash loading
in.	Condition	lb/ft^3	Condition	lb/ft^2
4.5	Uncompacted	72	Dry, loose	27
3	Compacted	96 101	Dry, compacted Wet, compacted	24* 25.5

*SDC 4.1, Rev 12 (DOE-RL 1993), specifies 24 lb/ft^2 as the design basis ashfall loading.

PLUTONIUM FINISHING PLANT
FINAL SAFETY ANALYSIS REPORT

CHAPTER 4.0

PRINCIPAL DESIGN CRITERIA

FEBRUARY 2001

This page intentionally left blank.

PREFACE

Revision 2 of Chapter 4.0 of the Plutonium Finishing Plant (PFP) Final Safety Analysis Report (FSAR) includes modifications for the following:

- Changing the terminology for the back-up power systems to standby power systems
- Change the Building 232-Z and Building 241-Z stack cams from safety class to safety significant designation
- Incorporation of the Magnesium Hydroxide Precipitation Process
- Incorporation of the Bagless Transfer System

Other minor changes include editorial changes and additional clarifications.

It is noted that various sections of Chapter 4.0 present information concerning plutonium-bearing solution stabilization operations using the Production Vertical Denitration Calciner located in the RMC Line and the Laboratory Prototype Calciner located in the Plutonium Process Support Laboratories. Operation of either the production calciner or the laboratory calciner for solution stabilization is not authorized at this time. If necessary, the related portions of Chapter 4.0 will be updated prior to initiation of operations.

The new packaged boilers operated by Johnson Controls, Inc. which provide steam to the PFP were previously incorporated in the FSAR. This included switching the emergency exhaust fans from those which are steam-driven to those which are connected to the standby power system. However, the conversion from using steam-driven fans to standby power driven fans has not been fully implemented. The emergency exhaust fans are currently run by the new steam supply system installed under the Hanford energy conservation program. Electrically-driven emergency exhaust fans are planned to be connected to the diesel-generator standby power supply at some future date. The emergency exhaust fan functions are unchanged from that described in the FSAR regardless of the type and source of power.

The significant areas of change in Revision 2 are indicated by vertical bars in the margin of each page.

This page intentionally left blank.

4.0 PRINCIPAL DESIGN CRITERIA

The Plutonium Finishing Plant (PFP) (originally referred to as the 234-5 Building) was conceived and designed under Project C-198 before 1948 and its construction was completed in 1949. Additional facilities have been designed and constructed from 1949 to the present (the latest major building being the 243-Z Building, finished in 1994). In each case, the facilities were designed in accordance with the codes and standards of the time. The history of the available codes, standards, and guides are shown in the design and construction time line (Figure 4-1). For many of the older facilities, it is not practical to define the original design criteria used, as the design specifications for these facilities were not properly or consistently documented during that time period. Additional information concerning the design and construction dates of specific buildings is presented in Chapter 5.0.

The original PFP design criteria are assumed to be based on DuPont design criteria for explosives-manufacturing plants. It is assumed that following the change of the Hanford Site contractor from DuPont to General Electric (G.E.) in 1945, G.E. Hanford Company retained much of the personnel and design philosophies of DuPont and used these resources in the design and construction of the original PFP facility (the 234-5Z Building).

The U.S. Department of Energy (DOE) Order 5481.1B, *Safety Analysis and Review System* requires that an evaluation of facilities be made against current DOE design criteria (this order is currently undergoing the process to be canceled; DOE Orders 420.1 and 5480.23 would serve as compliance documents for evaluation of facilities). Current principal design criteria, for existing structures, systems, and components and for the purposes of this final safety analysis report (FSAR), are defined as those criteria contained within DOE Order 6430.1A, *General Design Criteria*. New structures, systems, and components will be designed and evaluated in accordance with HNF-PRO-097, "Engineering Design and Evaluation". This order also requires adherence to other applicable DOE orders (e.g., 5480 series) and to other national codes and standards.

4.1 DESIGN CRITERIA CONFORMANCE

The PFP was evaluated against the design criteria of DOE Order 6430.1A using a methodology similar to the Systematic Evaluation Program (SEP) developed through the U.S. Nuclear Regulatory Commission (NRC), for principal design criteria with an emphasis on safety-related design criteria. The SEP was developed by the NRC in cooperation with commercial reactor operators to evaluate older operating nuclear facilities that were designed and built before the establishment of DOE Order 6430.1A. The SEP thereby allowed safety design reviewers to confirm and document a facility's safety design relative to DOE Order 6430.1A safety design criteria. The selected criteria approved by Westinghouse Hanford Company (Westinghouse Hanford) management for incorporation into this FSAR included all Section 99 elements and those special elements in Section 1300 which referred to plutonium handling, storage, or processing. These criteria were structured to the Regulatory Guide 3.39 (NRC 1986) requirements.

Evaluation of the PFP conformance to DOE Order 6430.1A is provided in *Preliminary Evaluation of PFP Conformance to DOE Order 6430.1A General Design Criteria* (WHC 1990). Conformance to these safety criteria ensures that the operation of the PFP will not contribute to an unacceptable onsite or offsite consequence. The nonconforming items are evaluated in Attachment II of WHC (1990). The attachment also notes Chapter 9.0 evaluations if a potential onsite/offsite consequence issue is involved.

This engineering study was a preliminary assessment of the PFP conformance to DOE Order 6430.1A, required by DOE Order 5481.1B. The assessment evaluated conformance of the PFP to design criteria having a potential safety boundary impact. The following two assessments were made of the PFP in this study.

- An initial conformance assessment identified conforming, nonconforming, and not applicable items, categorized their safety implications and consequences, and set a confidence level for these decisions.

- A further assessment evaluated nonconforming items for acceptance or upgrading. Best engineering judgement was used in evaluating nonconforming items to ensure that deviations from general design criteria did not compromise the PFP safety boundary. In many instances, the rationale for acceptance or upgrading was based on safety analysis techniques defined in WHC-CM-4-46, *Safety Analysis Manual*. Approved risk acceptance criteria are defined for offsite and onsite consequences resulting from routine operations, abnormal events, and design basis accidents (DBAs) for both radioactive and toxic chemical releases. However, nonconforming items that adversely impact facility workers or ground water/soil contamination did not have approved risk acceptance criteria. Best engineering judgement was used to evaluate these kinds of impacts.

4.1.1 Nonconformance to Design Criteria

Existing facilities (such as the PFP) that cannot be shown to conform with the design requirements contained in DOE-RL (1993) may be evaluated to the site-specific and less conservative natural phenomena hazards defined in WHC-SA-0606A *Natural Phenomena Hazards, Hanford Site, Washington* (Tallman 1989). If evaluation using site-specific natural phenomena hazards cannot show an existing facility to be in conformance with the acceptance criteria, then the methods for evaluating existing structures defined in *Design and Evaluation Guidelines for Department of Energy Facilities Subjected to Natural Phenomena Hazards*, UCRL-15910 (Kennedy et al. 1990) may be used. Potential options for existing facilities include the following:

- Conducting a more rigorous evaluation to reduce conservatism that may have been introduced by simplified evaluation techniques; alternatively, a probabilistic assessment of the facility may demonstrate that the performance goals for the facility may be met

- Strengthening the facility to provide resistance to hazard effects that meet the guidelines

- Changing the use of the facility, provided there is an adequate technical basis, so that the facility falls into a hazard category governed by less stringent requirements.

If an existing facility is close to meeting the guidelines, a slight increase in the annual risk to natural phenomena hazards may be allowed for less than 20 yr. Hazard exceedance probabilities of twice the recommended values may be used for wind and seismic loads, or alternately, permitting calculated inelastic demand to exceed capacity by no more than 20% may be allowed. Relief for flood evaluation is not permitted. Earthquake and wind loads for the reduced hazard probabilities may be obtained from Tallman (1989).

In general, PFP facilities found to be nonconforming to specific DOE 6430.1A design criteria were found acceptable as is based on (1) showing that the nonconformance is low risk by use of relevant analysis scenarios and consequences performed for the nonconforming facilities, and (2) operational safety requirements necessary to maintain the plant safety envelope (WHC 1990).

All modifications and upgrades identified in WHC (1990) have been either completed or determined by further evaluation to be unnecessary.

4.2 PURPOSE OF PLANT

The primary purposes of the current PFP complex are listed below:

- Plutonium material shipping/receiving/storage
- Remote Mechanical A (RMA) and Remote Mechanical C (RMC) Line operations
    - Reactive plutonium-bearing material stabilization
    - Plutonium-bearing solution stabilization using the Production Vertical Denitration Calciner
    - Other RMA and RMC Line processes
- Laboratory support
- Facility cleanout operations
- Radioactive waste handling.

Various plutonium-bearing materials were produced during previous PFP operations. This inventory of plutonium is in the form of pure and mixed oxides, fluorides, metal, polycubes, oxalates, silicates, and organic-based sludges and residues. Reactive plutonium-bearing material must be stabilized before long-term storage to prevent the formation of excessive hydrogen or nitrated organic compounds. Plutonium stabilization is conducted in selected gloveboxes in the 234-5Z Building. The principal plutonium material storage vaults are in the 2736-Z Building, and shipments (oxide or metal forms) are prepared or received in the 2736-ZB and 2736-ZC facilities. Nitrate solution

storage is provided in the 234-5Z Building. Developmental work involving plutonium materials is conducted in the laboratories within the 234-5Z Building.

4.2.1 Plant Feed

The feed for the stabilization processes comes from material stored in the plant. This material is composed of by-product from former production campaigns, research scrap, and shipments received from offsite. The isotopic distribution of the PFP plutonium inventory is documented in *Technical Basis for Characterization of Plutonium for PFP Safety Analyses* (Crowe and Szempruch 1994). The PFP may receive additional onsite or offsite shipments of plutonium-bearing materials for storage.

The original PFP mission was to supply plutonium metal for national defense. Plutonium metal was processed at the PFP and shipped in large quantities during the 1950's and 1960's. Virtually all of this plutonium is characterized as containing nominally 6% or less of the ^{240}Pu isotope. Similar metal production was done for several years in the 1980's.

In the 1960's, the PFP plutonium processing changed. Demands for plutonium metal declined while research in power technology indicated that plutonium oxide could be used as fuel. Later research demonstrated how to use plutonium oxide as a fuel for breeder reactors. The predominant product form from the PFP changed from a single, metallic piece (weighing about 2 kg) to a fine, powder oxide. Demands for the oxide powder increased from grams for research to thousands of kilograms for reactor fuel. In the late 1960's and 1970's, the PFP processed almost all of the plutonium oxide used in this country, including thousands of kilograms for Fast Flux Test Facility (FFTF) reactor cores.

Production strategies for the oxide dictated scheduling between metal production campaigns. They also included a degree of overproduction to allow for process losses, out-of-specification product, and requests for kilogram quantities of plutonium oxide for research efforts. Storage of production overrun materials became common.

The completion of the Plutonium Reclamation Facility (PRF) in the 1960's provided the PFP with plutonium scrap recovery capability. Plutonium scrap from military applications as well as from commercial and breeder reactor research was returned to the Hanford Site for the recovery of plutonium. Because the Hanford Site was the DOE scrap-management site and the envisioned supply site for DOE breeder reactor fuel, the PFP received virtually all plutonium with greater than 6% ^{240}Pu content from both domestic and foreign sources. The scrap, which had a wide variety of chemical and physical forms, was added to the growing inventory of plutonium metal and oxide stored at the PFP.

During the 1960's and 1970's, other changes occurred that ultimately impacted isotopic composition of the plutonium stored at the PFP. The declining demand for plutonium metal caused N Reactor production to change from nominal 6% ^{240}Pu to nominal 12% ^{240}Pu. The 12% ^{240}Pu material was used for breeder reactor research and FFTF cores. Commercial nuclear reactors and some government experimental reactors produced plutonium with higher ^{240}Pu content.

Changes in production demands and capabilities at other DOE sites caused large segments of the DOE inventory to be relocated. The inventory was shipped to the PFP because of available storage space and anticipated breeder reactor program needs. Plutonium handling or processing of 15% to 18% ^{240}Pu material was not uncommon, and some small lots in excess of 40% ^{240}Pu were processed at the PFP. This material is part of the current inventory of thousands of containers in storage vaults.

The current plutonium inventory is a collection of individual items and not a continuous spectrum of a single product line. The plutonium in each inventory container is unique because of its creation in a particular reactor environment and its chronological history of processing and storage. Individual containers may have similar plutonium isotopic distributions because they have a common history, were part of a common process blend lot, or purely from coincidence.

The present plutonium inventory at the PFP comprises more than 8,000 items. Accountability methods and records requirements over the years have changed. This has resulted in an inventory database that ranges from detailed isotopic information for some items to only the total plutonium mass and an indication of ^{240}Pu content for others. The present PFP plutonium inventory shown in Table 4-1 was derived from current inventory records. For cases in which the database did not contain isotopic information, the plutonium material accountability personnel provided an estimate of the total inventory of each isotope. Past laboratory data and hard copy records were used to determine an estimate of the isotopic content of each package. Estimates and professional judgements were used to assign isotopic values to materials of common origin or process lot. The plutonium inventory was separated into groups, or "bins," based on the percent of ^{240}Pu. The bins typically spanned a 3% range.

The isotopic distribution of the current plutonium inventory determined as described above is shown in Table 4-2. Some 400 kg of plutonium in clad nonirradiated FFTF fuel pins and assemblies is not included in the table because this material is relatively "clean" (lower activity) and is not considered dispersible. Inclusion of the plutonium from the FFTF fuel in the database would reduce the calculated unit doses and, from the standpoint of safety analysis, would not be conservative. In addition, EBR II reactor spent fuel stored in the 2736-ZD vault is not included as dispersible inventory in the table.

Nondestructive analysis (NDA) of shipments and periodic vault inventory verifications have been performed at the PFP for more than a decade using gamma spectroscopy to determine isotropic concentrations of plutonium. The vault verification program includes randomly selecting a number of items from the inventory and nondestructively verifying contents. The shipping NDA measurements verify the composition of material shipped into and out of the PFP. Additional measurements are made for items created during PFP operations. In all, about 4,700 items have been measured during the past 8.5 yr. The results of these measurements have been maintained by the PFP laboratory analysts in a historical database.

This database, referred to in this document as the NDA verification database, validated the inventory estimate and assessed the distribution of individual isotopes and their net effect on calculated potential doses in

safety analyses; however, because the database is a record of "all" measurements, it includes duplicate measurements and counts of standards made for quality control purposes. These data were deleted from the database before use in this evaluation because they do not represent items in the inventory. Some of the database items were analyzed when shipped in and again when shipped out. Counting these items in the estimate is not appropriate because these items no longer are in the inventory, therefore, they were deleted from the database. The plutonium isotopic distribution of the NDA database is shown in Table 4-2. The remaining mass of plutonium and number of items measured are also shown in Table 4-2, columns 2 and 3. The correspondence between the NDA verification database and the current PFP inventory is shown in the comparison of the isotopic composition of the individual bins in Table 4-1 and 4-2.

4.2.2 Plant Product and Byproducts

The only product generated by active PFP processes is stabilized plutonium-bearing material. This material is handled, packaged, and stored in accordance with process descriptions contained in Chapter 6.0, Sections 6.1, 6.3, and 6.4.

Former products of the PFP processing facilities were: (1) the purified plutonium nitrate from PRF, which was sent primarily to the RMC Line, (2) plutonium metal (weapons grade) from the RMA and RMC Line, and (3) plutonium oxide powders from the RMA Line. The specifications for these products are shown in Table 4-3.

4.2.3 General Plant Functions

The PFP functions are as follows:

- Perform stabilization of reactive plutonium-bearing materials
- Perform stabilization of plutonium-bearing solutions
- Manage the plutonium inventory at the Hanford Site including receipt, analysis, storage, and shipment
- Conduct development work involving plutonium material.

Utilities and support functions are discussed in Chapter 5.0. The process systems are described in Chapter 6.0. Effluent and waste handling functions are discussed in Chapter 7.0.

4.3 STRUCTURAL AND MECHANICAL SAFETY CRITERIA

The building structures and mechanical systems at the PFP were designed by the Architect and Engineer before today's stringent requirements for resistance to natural force events. Construction for the 234-5Z, 241-Z, 291-Z, and 2902-Z (water tower) Buildings began in 1948. The design requirements of this time period considered static loads, vertical live loads,

and dead loads. During this period, the Hanford Site was designated as a low intensity, minimum occurrence earthquake zone.

From 1949 to 1968, the Hanford Site chemical processing (CP) structures were designed for static, vertical live, and dead loads in accordance with the UBC, which included seismic provisions (see Chapter 5.0, Section 5.2, for more details on the original design criteria of specific PFP buildings). Lateral wind forces related to areas and lateral earthquake forces related to the mass of structures were specified according to the UBC provisions that designated the Hanford Site as seismic zone 2.

Since 1973, critical structures, facilities, and equipment at the Hanford Site have been designed and/or analyzed for the combination of dead, live, and operating loads plus seismic forces from a maximum credible earthquake, as defined in Section 4.3.5.

The current criteria for natural phenomena design are presented in this section as the appropriate design basis for evaluating existing facilities and future modifications and additions. DOE Order 6430.1A states in Section 0101-1 that for existing facilities, original design criteria apply to the structure in general and that modifications are to comply with current criteria. The ability of existing facilities to withstand the stresses derived from current design loading criteria (or the consequence of failure to do so) is detailed in Chapter 5.0, Section 5.2.

General criteria for structural and mechanical safety are defined in DOE Order 6430.1A.

4.3.1 Wind Loading

The PFP is classified as a high-hazard nonreactor nuclear facility in accordance with Kennedy et al. (1990). Wind design criteria are in accordance with *Hanford Plant Standard, Standard Arch-Civil Design Criteria*, "Design Loads for Facilities," SDC 4.1, Revision 12 (DOE-RL 1993). Evaluation methodology and site-specific criteria are obtained from Kennedy et al. (1990). The Hanford Site is considered Exposure Category C with an importance factor of 1.0. See Chapter 5.0, Section 5.2, for a discussion of specific building wind loading criteria.

4.3.1.1 Design Wind Velocity. The original design criteria did not utilize a design wind velocity but defined a resultant applied force in pounds per square feet. The current criteria comes from DOE-RL (1993) and Kennedy et al. (1990). The current criteria from DOE-RL (1993) is as follows.

- Nonreactor safety class 1 (Kennedy et al. 1990) structures, systems, and components (SSCs) (now referred to as Safety Class SSCs) are designed for wind loads in accordance with ASCE 7-88. High-hazard facilities as defined in Kennedy et al. (1990) are designed to a wind having an annual probability of 1×10^{-4}.
- Fastest-mile speed at a height of 10 m = 90 mi/h.

4.3.1.2 Basis for Wind Velocity Selection. The basis for the 90-mi/h design wind velocity identified in Section 4.3.1.1 is Kennedy et al. (1990),

Table 5-e, "Recommended Basic Wind Speeds for DOE Sites." This correlates with the wind history described in Chapter 3.0, Section 3.3.1.

Compliance with design criteria is analyzed in Section 5.2 and in Chapter 9.0.

4.3.2 Tornado Loadings

Analysis of the effects of the design basis tornado (DBT) on nonreactor nuclear facilities (such as the PFP complex) is not required based on current design criteria stated in DOE-RL (1993).

- The design basis wind velocity is a function of the Safety Class of the structures. ". . .according to probabilistic hazards studies, the controlling load for nonreactor structures at the Hanford Site is from extreme wind."

- Nonreactor Safety Class 1 structures, systems, and components (now Safety Class SSCs) are to withstand the effects cited previously for reactor facilities with three exceptions: (1) Safe Shutdown Earthquake (SSE) is identified as the Design Basis Earthquake (DBE), (2) Operating Basis Earthquake (OBE) is not required, and (3) DBT is replaced by Design Basis Wind.

This correlates with Kennedy et al. (1990), Section 5.2.4 and Table 5-1, which states that the Hanford Site should be designed for extreme wind and not tornado.

4.3.3 Water Level (Flood) Design

There is no possibility of PFP structural failures due to high flood water level. Therefore, the calculation of dynamic water force design loads due to maximum flood level is not necessary.

The lowest elevation within the PFP complex (bottom of the tunnel level in 234-5Z Building) is approximately 666 ft above mean sea level (msl). The probable maximum flood level of the Columbia River at the 100-N Reactor site would be at an elevation of 423 ft. In addition, the probable maximum 24-h precipitation of 11 in. during a million-year period would not result in any flooding due to the natural drainage of the soils (see Chapter 3.0, Sections 3.4.2 and 3.4.3 for details).

4.3.4 Missile Protection

The original designs of the 234-5Z, 232-Z, 236-Z, 241-Z and 242-Z Buildings did not incorporate criteria for missile protection. The design of the 2736-Z and 2736-ZB Buildings incorporated criteria for wind generated missiles. The only other source of externally generated missiles is the gas storage bottles located outside the 234-5Z Building, but within the 2734-Z structure designed for that purpose.

No significant potential for internally generated missiles has been identified except in the 236-Z and 234-5Z Buildings.

4.3.4.1 Missile Barriers and Loading. Those PFP buildings that contain plutonium inventory have been evaluated for extreme-wind and/or tornado-generated missiles are identified in Chapter 5.0, Section 5.2, and Chapter 9.0, Section 9.2.5.

The 236-Z process cell wall (2-ft-thick concrete) design is based on radiation protection but is sufficiently thick to provide missile protection from very low probability deflagration in the concentrators located in the cell. Other deflagrations considered capable of generating missiles involve flammable gas cylinders.

4.3.4.2 Missile Selection. The criteria for extreme-wind generated missiles are provided in DOE-RL (1993) as follows:

- Missile (horizontal)--2-in. by 4-in. plank, weight 15 lb, velocity 50 mi/h (73.5 ft/s), 50-ft maximum trajectory height
- Vertical missile velocity is 2/3 of the missile horizontal velocity.

The gas bottle missile is considered a standard high-pressure gas bottle for analysis purposes.

4.3.5 Seismic Design

This section presents the generic seismic design criteria relevant to the PFP structures. Chapter 5.0, Section 5.2, presents building-specific discussion of the seismic design and analyses performed on major PFP structures.

Original Criteria. Original seismic design criteria for the PFP facilities are assumed to be based on UBC requirements applicable at the time of construction or modification at both the Hanford Site and at the General Electric Laboratory at Schenectady, New York. The 234-5Z, 241-Z, 2902-Z, and 291-Z Buildings are assumed to have been designed in accordance with the UBC of 1946. The 232-Z, 236-Z, and 242-Z Buildings are assumed to have been designed in 1959 and 1960 in accordance with applicable Hanford Plant Standards and the UBC of 1958 and 1961. The 2736-Z Building is assumed to have been designed in 1969 in accordance with Hanford Plant Standards, general criteria for the storage of plutonium (Brecke 1969) and the UBC of 1967. The 2736-ZB complex is assumed to have been designed in 1979 in accordance with *General Design Criteria, Plutonium Facilities* (ERDA 1974), Hanford Plant Standards and the UBC of 1976. Facility additions and alterations since June 1981 have been designed in accordance with DOE Order 6430, 6430.1, or 6430.1A, as applicable, DOE Order 5480 series and Hanford Plant Standards (DOE-RL 1993).

Current Criteria. Each PFP structure is placed into the applicable facility use category based on the function of the structure in accordance with UCRL-15910 (Kennedy et al. 1990). Based on the facility use category descriptions given in Kennedy et al. (1990), the PFP confinement structures are classified as High Hazards Facilities. It should be noted that

UCRL-15910, "High Hazard Category," is equivalent to DOE Order 6430.1A, "Nonreactor Safety Class 1." The performance goal for High Hazard Category structures is to provide very high confidence that radioactive materials are confined during and following a natural phenomena hazard occurrence. Maintaining confinement of hazardous materials requires that damage be limited in confinement barriers such that they remain functional. Structural members and components should not be damaged to the extent that breach of the building envelope is significant. Hanford Site procedure HNF-PRO-704, *Hazard and Accident Analysis Process*, provides the necessary guidance to determine the safety categorization of SSCs (Table 4-4). These safety SSCs are then used to determine the applicable and relevant design criteria (Table 4-5).

Current seismic design criteria for evaluation of the PFP facilities are based on DOE-RL (1993) and Kennedy et al. (1990). Additional DOE orders and national consensus codes and standards applicable to the PFP buildings are presented in Table 4-5.

Criteria for the safety categorization of SSCs are found in Section 4.4.

4.3.5.1 Input Criteria. Seismic hazard models for the Hanford Site is presented in *Evaluation of Seismic Hazard for Non-Reactor Facilities at Hanford Reservation, Hanford Washington* (Woodward-Clyde 1989). This study is used to characterize the earthquake hazard at the Hanford Site by use of a frequency plot that gives the return period or annual probability of exceedance of different peak ground accelerations of the site. These curves were derived from a combination of recorded earthquake data, estimated earthquake magnitudes of known events for which recorded data are not available, review of local geological investigations, and use of expert judgment by seismologists familiar with the region (see Chapter 3.0, Section 3.6 for details of these data).

4.3.5.1.1 Design Response Spectra. For nonreactor nuclear safety class SSCs the safe shutdown earthquake (SSE) is identified as the design basis earthquake (DBE), and design for the operating basis earthquake (OBE) is not required in DOE-RL (1993). The Hanford Site design/evaluation earthquake response spectra for the design ground motion of the DBE are shown in Figure 4-2. These response spectra are applied for the horizontal direction in the free field at the top of the ground surface. The maximum free-field surface acceleration is 0.20 g for Safety Class 1 SSCs (now Safety Class SSCs) (see Figure 4-2), and 0.12 g for Safety Class 2 SSCs (now Safety Significant SSCs) (see Figure 4-3). For vertical motion, the response spectra are taken at approximately two-thirds of the response spectra for the horizontal motion over the entire range of frequencies (DOE-RL 1993).

4.3.5.1.2 Design Response Spectra Derivation. The design/evaluation spectra generally have the shape shown in Figure 4-2. This shape is similar to that for an actual earthquake, except that peaks and valleys that occur with actual earthquake spectra are smoothed out. Also, the design/evaluation spectra include motions from several potential earthquakes such that they are broader in frequency content than spectra computed for actual ground motion. Such simplified spectra shapes are necessary in order to provide practical input for seismic analyses. Because the design/evaluation spectra are smoothed and broadened relative to actual earthquake spectra, a design/evaluation spectrum tends to be a conservative representation of actual earthquake amplification that might occur (DOE-RL 1993). The DBE response spectra shape

is the median Newmark and Hall response spectra for a sediment site (Newmark and Hall 1978). The earthquake records, damping value comparisons, and the system period intervals at which the spectra values were calculated are discussed in N. M. Newmark Consulting Engineering Service (1973).

Acceleration sensitive equipment such as relays, contactors, motor starters, and switches that require functional operability during a seismic event must also be evaluated with mounting point spectra that accommodate small-magnitude near-field high-frequency earthquake spectra (see Figure 4-4) (DOE-RL 1993). The critical damping values used for seismic natural phenomena hazard analyses of the PFP Safety Class 1 and 2 (now referred to as Safety Class and Safety significant) structures in analyses prior to 1996 are provided in Kennedy et al. (1990) and are presented in Figures 4-2 and 4-3. These critical damping values conform to *Damping Values for Seismic Design of Nuclear Power Plants*, Nuclear Regulatory Commission Regulatory Guide 1.61 (NRC 1973).

Building-specific discussions of analyses are presented in Chapter 5.0, Section 5.2.

4.3.5.2 Seismic System Analysis. The seismic system analysis applicable to SSCs within the PFP complex is described in Kennedy et al. (1990). Kennedy et al. (1990) provides guidance and criteria for design of facilities or evaluation of existing facilities to ensure that DOE facilities are adequately constructed to resist the effects of earthquakes. These guidelines generally provide procedures for the evaluation of facility response to hazard loads and an assessment of whether or not a computed response is permissible.

Numerous static and dynamic seismic analysis methods have been used in the design and evaluation of the PFP facilities. The performance of a facility subjected to a natural phenomena earthquake hazard depends not only on the level of hazard selected for design or evaluation, but also on the degree of conservatism used in the design or evaluation process. Conservative, simplified design or evaluation approaches are well established, extensively documented, and commonly practiced. Median design or evaluation approaches are currently controversial, not well understood, and seldom practiced. Less conservative, more exact/rigorous dynamic analyses are well documented and are often, by necessity, used in the evaluation of existing facilities. For instance, preliminary (conservative) seismic analysis of the 234-5Z Building indicated that the DBE motions might produce nonlinear response and possible structural distress. It was recognized, however, that the building had considerable capacity to resist DBE loads in the nonlinear range. Therefore, a rigorous linear and nonlinear finite element seismic analysis was performed. This analysis demonstrated that the 234-5Z Building was capable of resisting DBE motions without collapse (Price 1989).

Seismic analysis/design information specific to major PFP structures is presented in Section 5.2.

4.3.5.3 Seismic Subsystem Analysis. The seismic analysis applicable to the PFP subsystems (such as equipment and piping) is described in UCRL 15910 (Kennedy et al. 1990). Special considerations of the seismic resistance capacity of equipment and piping are provided in DOE Order 6430.1A.

Because the PFP facilities house hazardous operations and materials, the seismic adequacy of equipment and piping is as important as that of the building. As part of the DOE Natural Phenomena Hazards Project, practical guidelines for the support and anchorage of many equipment items that are likely to be found in DOE facilities have been developed. These guidelines primarily address equipment strengthening and upgrading to increase the seismic capacity of subsystems in existing facilities.

A brief, general discussion of factors to be considered in the design or evaluation of equipment, piping, and other nonstructural elements is presented in the following (DOE Order 6430.1A).

- Equipment or piping supported within a structure respond to the motion of the structure rather than the ground motion. Equipment supported on the ground or on the ground floor within a structure experiences the same earthquake ground motion as the building.

- Equipment or piping supported at two or more locations within a structure are stressed due to both inertial effects and relative support displacements.

- Equipment or piping may have either negligible interaction or significant coupling with the response of the supporting structure. With negligible interaction, only the mass distribution of the equipment should be included in the model of the structure and the equipment may be analyzed independently. With strong coupling, or if the equipment mass is 10% or more of the structure story mass, the equipment should be modeled along with the structure model.

- Many equipment items are inherently strong enough to remain invulnerable to earthquakes, if adequately anchored.

- Elements attached to the floors, walls, or ceilings of a building (e.g., mechanical equipment, ornamentation, piping, nonstructural partitions) respond to the motion of the building in much the same manner that the building responds to the earthquake ground motion. However, the building motion may vary substantially from the ground motion. The high-frequency components of the ground motion tend to be filtered out at the upper levels in a building, while the components of ground motion that correspond to the natural periods of vibrations of the building tend to be magnified. Elements that are rigid and rigidly attached to the structure will experience forces in the same proportion to the mass as the forces on the structure. Elements that are flexible and have periods of vibration close to any of the predominant modes of the building vibration will experience forces in a proportion substantially greater than the forces on the structure.

In summary, the seismic evaluation of equipment and piping necessitates the development of floor response spectra representing the input excitation. Once seismic loading is established, seismic capacity is determined by analysis, testing, or through the use of seismic experience data.

An evaluation of all applicable safety SSCs in the PFP complex to the Hanford Site DBE is documented in Ocoma et al. (1988).

Additional seismic analyses of PFP SSCs are discussed in Chapter 5.0, Section 5.2.

4.3.6 Roof Loads

Current dead, live, snow and volcanic-ashfall loading criteria are provided in DOE (1993). In summary, the current loading criteria are as follows.

- Dead loads - Consideration shall be given to provide for an additional roof load of 10 to 20 lb/ft^2 to accommodate future ceiling and roof equipment loading for all categories of SSCs.

- Live loads - Roof live loads shall be in accordance with ASCE 7-88 (ASCE 1988) for all categories of SSCs.

- Snow loads - Snow loads shall be in accordance with ASCE 7-88 (ASCE 1988). Fifteen lb/ft^2 shall be used as the ground snow load, but in no case shall roof loads be designed for less than 20 lb/ft^2 snow load for all categories of SSCs. In accordance with UBC, snow loading is not to be combined with roof live loads. SSCs outside of structures are to be designed for snow loads.

- Volcanic-ashfall loads - All new SSCs and modifications or additions to existing Safety Class 1 SSCs (now referred to as Safety Class SSCs) are required to meet the design ashfall criterion of 24 lb/ft^2. Additional load for ashfall is not required for Safety Class 2, 3, or 4 SSCs (Safety Significant SSCs). Ashfall loads are to be combined with snow or roof live loads.

4.3.7 Soil Loads

Subsurface conditions of the PFP were determined by approved field and laboratory means that adequately disclose soil and groundwater conditions (URS 1980). Data and other information obtained from prior subsurface investigations were used, supplemented by additional investigations at the specific location as deemed necessary by design professionals (DOE 1993). A bibliography and brief summary of geotechnical studies performed at Hanford (which includes a summary of a geotechnical investigation of the PFP site) has been documented in WHC-SD-GN-ER-30009, *Bibliography and Summary of Geotechnical Studies at the Hanford Site* (Giller 1992).

4.3.7.1 Soil Load Criteria. Soil load criteria for Safety Class 1, 2, and 3 SSCs (now referred to as safety class, safety significant,and general services SSCs) are presented in DOE-RL (1993). In summary, this document states that the effect of dynamic earth pressures shall be considered in the design of Safety Class 1 and 2 (now referred to as safety class for all Safety Class 1 and some Safety Class 2) below-grade SSCs. Safety Class 3 (now referred to as safety significant) SSCs are not required to be evaluated for dynamic soil loads. These dynamic soil properties for the PFP site are identified in Giller (1992) and are presented in Figure 4-5.

For non-safety category SSCs, the allowable soil pressure from the UBC may be used for design where precise soil bearing information is not available. These values are considered to be acceptable for undisturbed soil.

4.3.8 Process Equipment Derived Loads

The design codes and standards for modified or new SSCs (except piping system modifications will be done to the code-of-record) in the PFP complex are identified in Table 4-5. The codes and standards originally applied (code-of-record) to a facility or an SSC will continue to apply for maintenance activities until the facility or SSC is modified (WHC-CM-4-46).

Structural and piping acceptance criteria used for seismic analyses and all component modifications are contained in DOE-RL (1993) and Kennedy et al. (1990) and are also identified in Table 4-5. The safety categorization of components of gloveboxes and process equipment that were not known were conservatively assumed to be Safety Class 1 (now Safety Class).

The impact of accidents and natural forces events on the confinement barriers is analyzed in Chapter 9.0, Section 9.2.

4.3.9 Combined Load Criteria

The original combined loads criteria combined static, vertical live and dead loads, and wind loadings.

Current criteria for load combinations are provided in DOE (1989) Paragraphs 0111-99.0.4 and 0111-99.0.8. More specific criteria for combinations of designed loads are provided in DOE-RL (1993) and are summarized below.

- Load combinations and allowable stresses for load conditions that include live load, dead load, snow load, and normal operating loads for all SSCs are stipulated in the UBC.

- Load combinations and allowable stresses for load combinations that include normal operating loads and natural phenomena hazard loads of extreme wind, earthquake, flood, and ashfall for all SSCs shall be in accordance with UCRL-15910 (Kennedy et al. 1990) and its reference documents.

- Application of these load combinations and acceptance criteria for supports and anchorage of SSCs is appropriate except that the absolute sum of loads shall be used. For the design of supports and anchorage of piping systems in new facilities, the use of a capacity of half of the allowable shall be considered. For subsequent evaluations of these supports in new facilities for the purpose of documenting as-built conditions and for the evaluation of supports in existing facilities, the allowable capacity shall be used.

Structural specifications for the PFP facilities are discussed in Chapter 5.0, Section 5.2.

4.3.10 Subsurface Hydrostatic Loading

Based on the siting criteria, no subsurface hydrostatic loading calculation is necessary. The water table under the PFP complex is at an elevation of 460 ±10 ft, although standard calculational methods for foundations assume total flooding for design purposes (see Chapter 3.0, Section 3.5, for more details concerning the subsurface hydrostatic characteristics of the Hanford Site). The bottom of the tunnel level in the 234-5Z Building is at an approximate elevation of 666 ft msl and is the lowest structural elevation in the complex.

Since an almost 200-ft elevation difference exists between the water table and the lowest structural point, subsurface hydrostatic loading is neither credible nor applicable.

4.3.11 General Criteria

General criteria for structural and mechanical safety are defined in DOE Order 6430.1A. Additional design criteria guidance for safety SSCs is provided in HNF-PRO-704 and also in Table 4-5.

4.4 SAFETY PROTECTION SYSTEMS

4.4.1 General

Siting selection of the PFP facility imposes no special design considerations other than those normally required for this type of plant.

The PFP process activities require special safety considerations in facility process equipment design. Potential hazards of normal process activities are discussed in Chapter 6.0.

There are no specific criteria to safely shut down the facility. Emergency ventilation blowers are actuated following loss of normal ventilation power. In all cases analyzed in this FSAR, temporary loss or shutoff of power to processing facilities results in a safe shutdown condition.

4.4.2 Protection by Multiple Confinement Barriers and Systems

At a nuclear facility, physical confinement barriers must be established to prevent an uncontrolled release of radioactive material to the environment and to prevent or mitigate the spread of contamination within the facility. These barriers are required between the environment and the areas of a nuclear facility that contain and/or have the potential to contain radioactive material. Such physical barriers (e.g., facility layout, primary and secondary process equipment systems and components, enclosures, ventilation and filtration systems) are referred to as confinement systems. This section provides the applicable criteria selected from DOE Order 6430.1A, required for the design, construction, and implementation of the confinement systems. See

Chapter 5, Section 5.2 and 5.4.1, and Chapter 8, Section 8.3, for details of the confinement in use at the PFP.

4.4.2.1 Confinement Barriers and Systems. The original criteria for the PFP facilities relied upon several layers of confinement barriers and systems to prevent and mitigate any potential uncontrolled release of radioactive material within the facilities and to the environment. The barriers are primarily the physical location of the facilities within the PFP complex, each facility's internal arrangement, enclosures that provide containment for the equipment, equipment that provides containment for the process, and the access barriers. The systems are primarily the multiple ventilation systems for maintaining positive pressures and flows from areas with minimum potential for containing radioactive material to areas with lower pressures and exhaust filters for containment of airborne particulates, administrative and access controls, and instrumentation to indicate potential breach of confinement.

The confinement design used for the PFP was influenced by many factors, including the type of material and inventory being confined, the type of process and design of the process system(s), the confinement of the process systems (e.g., canyons, gloveboxes, vaults, etc.), system interactions and dependencies (e.g., fire protection, ventilation, and emergency power sources), and facility siting.

The general concept of confinement for the PFP facilities features a system of primary, secondary, and tertiary confinement boundaries to minimize a release of radioactive material to the environment. The number of confinement barriers used, e.g., primary and secondary and/or primary alone, is based on the quantity of material at risk. For the purpose of the PFP facilities, these confinement boundaries are defined as follows.

1. Primary confinement--Primary confinement consists of barriers, enclosures, gloveboxes, piping, vessels, tanks, etc., that contain plutonium. The principal function of primary confinement is to prevent release of plutonium to areas other than where processing operations are normally conducted.

2. Secondary confinement--Secondary confinement consists of barriers and associated ventilation systems that confine potential release of hazardous material from primary confinement. Because plutonium processing in the PFP is normally conducted in gloveboxes (the primary confinement), the operating area boundary and the ventilation system serving the operating area serve as the secondary confinement system.

3. Tertiary confinement--Tertiary confinement is provided by the building walls and other outer structures of the facility. For some of the DBAs, it represents the final barrier to the potential release of hazardous material to the environment; for others (such as for high wind loads), it is the barrier protecting the rest of the facility from damage.

Current criteria for this facility are defined in *General Design Criteria* (DOE Order 6430.1A), *Environment, Safety, and Health Program for DOE Operations at RL* (DOE-RL Order 5480.1A), and the section(s) of DOE-RL (1994) pertaining to confinement barriers and systems. These orders contain

(1) criteria for confinement barriers, (2) design criteria for enclosures and equipment, and (3) guidelines for ensuring that as low as reasonably achievable (ALARA) objectives are utilized. DOE Order 6430.1A specifies selected ALARA objectives to be used in the design of confinement barriers and systems. These criteria and objectives ensure that the lowest practical levels of releases from the operation of the plant, the protection of the workers, the protection of the public, and the protection of the environment are maintained (see Chapter 8, Section 8.1, for details).

4.4.2.2 Ventilation Offgas. Criteria from DOE Order 6430.1A for ensuring capacity standards for normal and abnormal conditions, zone interface flow velocity and differential pressure (DP) standards, the flow pattern, and ensured continuity of operation under accident conditions and special control instrumentation include the following:

- Airflow patterns and velocity with respect to contamination control
- Minimum negative pressures at key points in the system to maintain proper flow control
- Interaction of offgas systems with ventilation systems
- Minimum filter performance with respect to particulate removal efficiency and maximum pressure drop
- Minimum performance of other radioactivity removal equipment
- Minimum performance of dampers and instrumented control
- Ensured continuity of operations under all credible operating conditions.

There is a distinct difference in zone definitions between that cited in the following set of criteria and that which is actually used throughout the PFP facilities; with the exception of PFP 2736-ZB Building. The PFP employs a reverse nomenclature for the zone definitions, compared to zones as defined in current criteria (i.e., the criteria assume that zone 1 is the zone of highest contamination [e.g., process enclosures, offgas systems], which correlates to the PFP zone 4). The PFP zone 1 normally does not have the potential for contamination (e.g., lunchrooms, administrative office areas, etc.), which correlates to the criteria in zone 4.

The zone definitions for the 2736-ZB Building adhere to current criteria, not the reverse nomenclature of zone definition as maintained in all other PFP facilities. Zone definitions are addressed in more detail in Chapter 5.0, Section 5.4.1.

Additional applicable criteria for ventilation and offgas systems are discussed in Chapter 8, Section 8.3.3.

4.4.3 Protection by Equipment and Instrument Selection

The original design criteria for equipment and instrumentation at the PFP were to provide operating safety, process control, and historical records.

Some of the original equipment and instrumentation were intended to serve more than one of these three functions.

Current criteria for this facility are defined in DOE Order 6430.1A. Refer to Section 4.4, for specific safety systems and related equipment.

Additional protective equipment requirements specific to the Hanford Site are defined in various site contractor procedures including HNF-PRO-704.

Current criteria for general instrumentation and control systems were selected to provide facility and environmental safety protection. An evaluation of these systems is provided in Chapter 5.0. Instrumentation and control systems that monitor or control safety class SSCs are safety classified according to HNF-PRO-704.

4.4.4 Nuclear Criticality Safety

This section describes the criteria used for establishing acceptable criticality safety control (CSC) and outlines the engineered and administrative controls used for prevention of criticality accidents.

The CSC criteria are established in HNF-PRO-537, *Criticality Safety Control of Fissionable Material*, HNF-PRO-334, *Criticality Safety General Requirements*, and DOE Order 5480.24, *Nuclear Criticality Safety*.

The criticality safety program applies to all processing, transfer operations, transport, and storage activities involving fissionable material.

A facility classification system is established in HNF-PRO-334. Under this system, the PFP is classified as a fissionable material facility and subject to all of the elements of the criticality safety program.

4.4.4.1 Control Methods for Prevention of Criticality. The following types of CSC are incorporated into the design, operation, and administration of the PFP, as required, based on the criticality safety evaluation (CSE).

1. Mass controls--Restrictions on the quantity of fissionable material permitted in individual units or in the total configuration.

2. Volume controls--Restrictions on fissionable material volumes, or container and vessel volumes; restrictions may be specific to compositions.

3. Geometry controls--Dimension and shape restrictions on equipment design provide inherently "geometrically safe" or "geometrically favorable" containers and vessels for fissionable materials. Includes floor areas allowed for leakage accumulations and geometrically favorable drain heights ("criticality drains").

4. Density controls--Restrictions on permitted concentrations of fissionable material dissolved or dispersed in another medium.

5. Areal density control--Restrictions on allowed fissionable mass per unit area of a large slab, as for the bottom of a glovebox or floor.

6. Enrichment controls--Restrictions on maximum relative fraction of fissionable isotope constituents in total heavy metal (U+Pu) concentration.

7. Moderation controls--Restrictions on allowed range of hydrogenous-material density relative to fissionable material density in moderator/fissionable mixture (H/X ratio) or on the total amount of moderating materials allowed.

8. Controls on material compounds and form--Restrictions on allowed composition (e.g., nitrates, oxides) and allowed physical state (e.g., metallic, salt-crystal, powder, solution) for fissionable materials at particular process stages, workstations, or storage locations.

9. Piece-count controls--Restrictions on the number of fissionable units or moderator units in a glovebox or array.

10. Interaction controls--Restrictions to minimize potential neutron interactions between various units, vessels, containers, and accumulations of fissionable materials; includes controls on spacing, arrangement, and/or shielding.

11. Reflection controls--Restrictions on the composition and/or configuration of reflector materials in proximity to fissionable configurations.

12. Absorber controls--Requirements defining need for solution concentration, distributions, minimums, and required permanence of neutron absorbers (such as boron and cadmium) used for criticality safety purposes.

13. Flow controls--Requirements for designed features or operational procedures that exclude or restrict the rate of flow of solutions in process pipelines. This category includes:

    - Nuclear blanks--Temporarily remove pipe sections
    - Inline orifices--Limit the maximum potential flow rate.

14. Placement or displacement controls--Requirements for fixtures or barriers that prevent positioning of fissionable units in particular locations or prevent motions of units from designated positions.

15. Chemistry controls--Restrictions on concentrations or specifications of the makeup of process chemicals incorporated with the fissionable materials in the processing streams. These controls are to ensure the intended physical and chemical forms of the fissionable material, to prevent material buildup (such as precipitation or internal refluxing in a solvent extraction column), and to ensure control of fissionable material concentration.

4.4.4.2 Error and Contingency Criteria. Criticality prevention is based on the double-contingency principle that at least two unlikely, independent, and concurrent changes or contingencies must occur before criticality is possible.

Therefore, no single accident or error in process conditions can result in criticality. Judgment is required in determining whether two events are related and, consequently, whether they represent two contingencies or a single contingency. For example, exceeding storage limits and then flooding an area would constitute two independent events; however, fire and flooding from an automatic sprinkler system would be considered a single event. Anticipated or expected events are not considered contingencies but are analyzed as part of the base condition or as part of a single contingency based on multiple errors.

In evaluating compliance with the double-contingency principle, the CSE must show that an acceptable margin of subcriticality will be retained after any foreseeable contingency, including allowance for calculational bias and statistical uncertainty.

The application of these criteria to facility operations is covered in Sections 6.2.9, 6.3.9, 6.4.1.9, and 6.5.1.9.

4.4.4.3 Verification Analysis. The design or modification of processes, systems, and equipment for handling of fissionable material receives independent nuclear criticality safety (NCS) review, analysis, and approval. This includes equipment and systems whose performance affects NCS (e.g., fire sprinkler systems in areas containing fissionable materials). The Quality Assurance (QA) organization independently verifies equipment dimensions and installations that are essential to criticality safety.

Analytical techniques that are used to determine criticality safety limits are validated by comparison of calculated values with the results of criticality experiments in accordance with ANSI/ANS 8.1, *Nuclear Criticality Safety in Operations with Fissionable Materials Outside Reactors*. The CSEs are documented and independently reviewed in accordance with ANSI/ANS 8.19, *Administrative Practices for Criticality Safety*.

4.4.5 Radiological Protection

The radiation exposure of Hanford Site employees, visitors, and members of the general public originating from PFP operations are to be controlled to levels that are ALARA. The HSRCM-1, *Hanford Site Radiological Control Manual* (DOE-RL 1994), HNF-PRO-159, *ALARA Program Description* and HNF-PRO-1618, *ALARA Management Commitment Policy* describe the organizational structures and the methods for controlling and ensuring that human exposures to hazardous substances and conditions are maintained ALARA.

The PFP Safety organization conducts periodic assessments and appraisals of PFP operations. These provide independent radiological control assessment to ensure that the applicable radiological safety standards are being followed and comply with DOE orders.

The design philosophy used throughout PFP is based on the conservative premise that any exposure of personnel to possible internal plutonium depositions should be avoided, if at all possible. All new and modified facilities/systems/equipment are designed in accordance with accepted radiological design principles, including ALARA. The process equipment was designed to provide total containment of airborne activity, completely

separating the atmospheres exposed to possible plutonium contamination from air breathed by operating personnel. Since operations performed in the different building spaces have varying potentials for external contamination spreads, a high degree of compartmentalization has been provided to isolate various spaces in the event of a contamination incident.

The general design criteria are those specified in DOE Order 6430.1A. In some cases more restrictive criteria, specified in Hanford Site Contractor guides and policies and DOE control manuals, are applicable.

Specific design recommendations of the PFP have evolved as a result of past operating experience. Lead plate shielding, lead glass panels, and lead-loaded gloves are used in gloveboxes to reduce whole-body and extremity exposures. Gloveboxes are used in cases where handling of bare material is required. Examples of other design recommendations are as follows.

- Ventilation systems should be designed to ensure control of airborne contaminants even if normal airflow patterns may be disrupted such as an open access port. This system also must maintain airflows from lowest to highest contamination potential and filter all exhaust from zones 3 and 4 to ensure minimal escape of radioactive materials.

- Gloveports should be strategically located to permit quick servicing of glovebox equipment.

- Interior surfaces of gloveboxes should be designed to minimize material buildup.

- Operation and control of certain process equipment, valving, and material transfers should be remote from the glovebox interior, thereby reducing extremity and whole-body exposure.

- A vacuum cleaning system should be used in certain gloveboxes for removal of residual powders. This would reduce exposure to operations and maintenance personnel.

- Supply airflow in radiation zones within process area should be from ceiling to floor to maintain clean air in the breathing zone.

- Sargent™ gloveports should be used on certain gloveboxes to provide a greater degree of containment during glove change activities than conventional gloveports.

- Air sampling, radiation monitors, and communications systems should be provided to assist in controlling the release of radioactivity to the environment and providing notification of an off-normal situation at the facility. All of the monitors should have local alarms while some also should have remote alarming features.

- Radioactive materials within the process areas should be confined as close to the point of origin as practicable through the use of HEPA filters installed on the exhaust ducts of hoods and gloveboxes.

See Chapter 8 for details of the radiation protection program and associated systems.

4.4.5.1 Access Control. Multiple barriers (also referred to as "access control zones") limit access to radiation areas to only fully qualified workers. These barriers afford enhanced radiation protection, contamination control, and physical security.

General access control criteria are provided in DOE Order 6430.1A. Other specific criteria are listed below.

- The area within the site boundary is enclosed by an agricultural-type fence (minimum of three strands of barbed wire on metal posts) and posted to legally prohibit trespassing.

- For effluent control purposes and protection of the general public, and in accordance with *10 Code of Federal Regulations* (CFR), Part 100.3(a), the area within this boundary fence is considered an "exclusion area."

- Adequate emergency exits are provided. All locking personnel emergency doors are equipped with panic hardware on the inside and alarms that sound when opened.

The HSRCM-1, Part 3 (DOE-RL 1994), specifies that access to any controlled area where radioactive materials or elevated radiation fields may be present are clearly and conspicuously posted. The HSRCM-1 (DOE-RL 1994) defines four levels of radiation areas and five levels of contamination areas that must be posted (see Table 4-6).

4.4.5.2 Shielding. Shielding criteria considered here are applicable to radiation protection utilized at the PFP.

- General--The plutonium facility is designed to minimize personnel exposure, provide adequate radiation monitoring and alarm systems, and accommodate health physics activities. Physical safeguards (e.g., remote handling, equipment layout, shielding) provide primary radiation protection assurance; secondary radiation protection is provided by administrative controls.

- Shielding design--Shielding is designed to meet the exposure goals set forth in 10 CFR 835, Subpart C, "Standards for Internal and External Exposure," (DOE 1993) consistent with ALARA. The PFP also complies with HSRCM-1 (DOE-RL 1994) administrative control levels, which are more restrictive than the requirements identified in 10 CFR 835. See Chapter 8, Section 8.3.2, for details.

- ALARA--Analyses require evaluation of the cost of radiation reduction in dollars per man-rem and limits reduction to a reasonable cost.

Concrete, lead, leaded glass, masonite, polycarbonate/acrylic, and water are the principal shielding materials used in plutonium handling areas throughout the PFP complex.

4.4.5.3 Radiation Monitoring Systems. Radiation detection and alarm instrumentation is provided to warn plant personnel of significant increases in radiation levels of airborne contamination in normally accessible spaces and of above-normal amounts of radioactivity released in effluents.

The guidelines for placement and sampling intervals of fixed head samplers (FHS) and continuous air monitors (CAM) are based upon *Hanford Site Radiological Control Manual*, HSRCM-1 (DOE-RL 1994). These requirements specify that the monitoring systems are placed at strategic locations to detect and evaluate airborne contamination at workstations. These monitoring systems are required for sampling airborne contamination levels that may exceed 10% of the applicable derived air concentration (DAC) guides. Primarily, these monitoring systems consist of FHSs and alpha CAMs (See Chapter 8, Sections 8.3.4 and 8.3.5, for details of the radiation detection and alarm instrumentation system).

The gaseous effluent from the PFP complex are monitored by CAMs with local and remote alarm capability and record samplers. The liquid effluent monitors are designed with a record sampler. The alarm set points for these effluent monitors are well below release criteria to provide early warning of effluent releases. See Chapter 8.0, Section 8.3.5, for discussion of alarm set points for CAM systems. See Chapter 7.0, Section 7.2, for additional details of the effluent monitors.

The criticality alarm system (CAS) radiation detection equipment installation is based upon American National Standards Institute (ANS)/American Nuclear Society (ANS) Standard 8.3 as implemented by *Criticality Safety General Requirements* (HNF-PRO-334), *Definition and Means of Maintaining the Criticality Detectors and Alarms Portions of the PFP Safety Envelope* (HNF-SD-CP-SDD-003), and *Nuclear Alarm Manual for the Plutonium Finishing Plant* (HNF-IP-1115). See Chapter 8.0 Section 8.3.4 for discussion of the CAS system.

Survey instruments are located throughout radiation areas within the PFP complex where radioactive materials are processed, handled, transported, or stored as required in DOE Order 6430.1A. The PFP uses radiation detection instrumentation designed for survey of personnel, equipment and process areas. These instruments provide both audible and gauge or dial outputs when contamination is detected. These instruments play an important role in contamination control and personnel safety.

4.4.6 Fire and Explosion Protection

4.4.6.1 Original Criteria. The original design criteria for the PFP fire protection systems were based primarily on their action in relation to the plutonium product. Systems were designed and components selected to minimize the spread of product and prevent displacement of materials.

The current fire protection philosophy in all the buildings used for the process, handling, or storage of plutonium products minimizes the amount of combustible material to the extent practicable within the structures and in the operation of the plant (see Chapter 5, Sections 5.2 and 5.4.11). In addition, the number, type, and location of ignition sources is carefully

controlled. Criteria related to limitation of product spread and displacement (criticality potential) continue to be important.

4.4.6.2 Current Criteria. DOE Order 6430.1A embodies general criteria for design and construction of DOE facilities. Criteria in DOE Order 6430.1A are given for fire and explosion protection.

4.4.6.3 Additional Criteria. The DOE Order 5480.7A, *Fire Protection* (which has been replaced by DOE Order 440.1 and so is currently being removed as a compliance order for the site contractor) defines criteria for an "improved risk" level of fire protection sufficient to attain DOE objectives. The following criteria apply to the design of fire protection systems.

4.4.6.3.1 Public Safety and Hazards to Life. These criteria are directed toward having no threats to the public health and welfare and no undue hazards to life from fire.

The procedures *Fire Protection Program Overview*, (HNF-PRO-340), *Fire Protection Policy Statements* (HNF-PRO-341), and *Responsibilities* (HNF-PRO-342) provide guidance so that buildings comply with the Life Safety Code (NFPA 101) and DOE Order 5480.7A, and therefore meet the intent of OSHA requirements. Where noncompliance with some "Life Safety Code" provisions may be required for public safety, as with containment structures, additional protective systems are maintained.

The following restrictions are intended to reduce potential for fast-spreading fires:

- Materials of unusual fire characteristics, such as exposed urethane foams, are prohibited for interior finish
- Materials developing large quantities of toxic products of combustion are prohibited for interior finish
- Where hazardous materials (such as flammable liquids or explosives) are used, special protection features are installed.

The facility containment systems are designed to preclude an offsite release of hazardous amounts of toxic materials under maximum credible fire conditions.

Exhaust and ventilation systems, including filters, are protected or isolated from the effects of a credible fire to the extent that hazardous amounts of toxic materials or combustion products will not escape.

Natural or artificial means of controlling liquid runoffs from a credible fire are provided so that contaminated or polluting liquids will not escape the site, including potentially contaminated water resulting from fire fighting operations.

4.4.6.3.2 Unacceptable Program Delays. The design of the facility is such that the maximum credible fire will not result in loss of use of a vital facility for longer than an acceptable shutdown period as defined by the program senior official.

4.4.6.3.3 Property Damage Limitation. Property damage is limited in accordance with the following three categories.

- Category 1--When the maximum possible property loss is in the range of $1,000,000 to $25,000,000, an automatic fire protection system shall be provided that will limit the probable loss to the lower figure.

- Category 2--When the maximum possible property loss is in the range of $25,000,000 to $50,000,000, a redundant protection system is provided, even in the failure of the primary system, that should limit the loss to the lower figure.

- Category 3--When the maximum possible property loss exceeds $50,000,000, redundant systems are provided as in 1 and 2, above, and a failure-proof type of fire protection system, such as blank walls or physical separation, is provided to limit the maximum property loss to $75,000,000.

4.4.6.3.4 Higher Standard of Protection. A higher standard of protection, usually including some form of automatic protection, is justified by certain additional considerations. In general, probable loss should be limited to $250,000 in such cases. The following points should be considered in evaluating the need for automatic fire extinguishing systems:

- Vital property (including contents) that may have long lead time for replacement, significant public visibility, or sensitivity

- Effect on current process

- Favorable cost versus benefit ratios

- Effect of a facility on an adjacent or included facility

- Future increased risk or conversion to other uses.

4.4.6.3.5 Essential Elements of an Improved Risk Facility. An improved risk facility is characterized by a sufficiently high level of fire protection to fulfill requirements for insurability by the Factory Mutual System, industrial-risk insurers, or other private industrial fire insurance companies that limit their underwriting to the best protected class of industrial risks. A basic requirement is the provision of automatic fire extinguishing systems in all areas subject to serious property damage or business interruption losses as a result of fire. The primary requirement for qualifying for an improved risk rating is tangible evidence of continuing sincere interest by management and employees in minimizing losses from fire and related perils.

The DOE facilities qualifying as improved risks will incorporate the following physical improvements and internal programs and maintain records for appraisal of the programs.

1. Review of plans before contemplated construction to ensure adequacy of fire risk appraisal and protection and follow up review to ensure that fire protection features are provided.

2. Regular self inspections, tests, fire loss potential reviews, and appraisals to identify the nature, location, and severity of fire risks (injuries, dollar loss, programmatic interruption, release of toxic and radioactive materials) as well as to determine adequacy of fire loss control devices and activities.

3. Periodic audits by outside fire protection authorities such as contractor facility appraisals by field fire protection engineers.

4. Plans, procedures, devices, and trained personnel adequate to permit controlling any credible fire emergency that may arise at the facility.

5. Limitation by physical means (e.g., geographic isolation, fire walls, fire doors, draft barriers) of areas that can be directly damaged in the event of a single fire.

6. Quality construction that, in most cases, is defined as fire resistive or noncombustible type buildings with segregation or isolation of particularly hazardous operations.

7. Enclosures of adequate fire resistant construction for stairways, elevators, ducts, and other openings coupled with fixed or manual devices (such as self-closing doors or dampers, draft stops, or water curtains) to control or limit both vertical and horizontal fire spread potentials.

8. Protection of special hazards by isolation, segregation, or use of special fire control systems (e.g., automatic sprinklers, inert gas flooding, explosion suppression) together with devices (e.g., relief valves, filters, roof hatches, scuppers, blast walls) for limiting or controlling damage potentials of fire, hazardous smoke, gases, and water runoff, or other occurrences that may reasonably be anticipated during a fire emergency.

9. Adequate, reliable fire protection water supplies and distribution systems coupled with adequate hydrants, inside standpipes, and other devices to facilitate use of such water during fire emergencies.

10. Adequate automatic and manual means for detecting and reporting incipient fires, including, but not limited to, watchman service.

11. Adequate sprinkler protection for all combustible construction or occupancies where potential losses exceed departmental criteria.

Currently the PFP does not fully comply with all criteria established for an improved risk facility. Project B-631 was initiated to rectify the existing deficiencies. The duct level is now fully covered by automatic sprinklers. New fire-rated doors were installed where needed. In addition, a major upgrade was done on the fire alarm system to provide supervisory capability and ensure spare parts availability. Project B-631 was completed in 1995.

4.4.7 Materials Handling and Storage

4.4.7.1 Fuel Handling and Storage. In addition to plutonium-bearing materials, spent nuclear fuel and unirradiated fuel are stored at the PFP. Spent nuclear fuel is contained in three EBR-II storage casks that are stored in the 2736-ZD Building (refer to Chapter 5.0, Section 5.2.8.5, for a description of the 2736-ZD facility). All necessary shielding and containment is provided by the casks themselves. The EBR-II casks were relocated from a Hanford Site solid waste management burial ground to 2736-ZD to use security measures in place at the PFP to comply with DOE Order 5632.1C, *Protection and Control of Safeguards and Security Interests*.

Unirradiated FFTF fuel is temporarily stored in vault 192-A. The fuel consists of driver fuel assemblies (DFAs) stored in radial reflector shipping containers (RRSCs) and fuel pins stored in Model 60 shipping containers.

Criteria for handling and storage of the plutonium feed and product materials are discussed in Section 4.3.7.3.

4.4.7.2 Radioactive Waste Treatment. The criteria pertinent to the design and operation of radioactive waste treatment facilities are from DOE Order 6430.1A.

Radioactive waste generated at the PFP is either transferred as a liquid to the underground liquid storage tanks via the 241-Z facility or packaged as solid waste for interim or long-term storage. Guidelines and requirements applied to facility design and operation are listed below.

1. Facility design ensures that all ventilation air and gaseous effluents are exhausted through a ventilation system designed to remove particles (see Chapter 5.0, Section 5.4.1, Chapter 7.0, Section 7.1, and Chapter 8.0, Section 8.3.3., for more details).

2. All exhaust ducts (or stacks) that could contain plutonium provided with two monitoring systems. One system is a CAM type and the other is an FHS. Each monitoring system is powered by the same energy source as the motive power for the effluent exhaust or be connected to a standby power source (see Chapter 5, Sections 5.4.1 and 5.4.10, Chapter 7.0, Section 7.1, and Chapter 8.0, Sections 8.6.1 and 8.8, for more details).

3. All liquid industrial wastes are collected and transferred to liquid waste treatment systems. Provisions are made for retention systems for potentially contaminated waste streams (see Chapter 7.0, Section 7.2, for more details).

4. Process waste storage tanks and transfer lines are designed and constructed so that they are fully inspectable and so that any leakage will be detected and contained before escape to the environment (see Chapter 5.0, Section 5.4.9, and Chapter 7.0, Section 7.2, for more details).

5. Federal, state, and local codes regarding discharge of sanitary wastes are met. There are no interconnection between the sanitary waste systems and the plutonium handling area. The sanitary waste

is sampled for radioactivity (see Chapter 5.0, Section 5.4.9, and Chapter 7.0, Section 7.2, for more details).

6. Consideration is given to converting liquid wastes to solid forms (see Chapter 7.0, Section 7.5).

Additional guidance for control of radioactive wastes is given in HSCRM-1 (DOE-RL 1994), HNF-PRO-455, *Solid Waste Management*, and HNF-PRO-456, *Water Quality Program*.

4.4.7.3 Storage Facilities. Plutonium storage facilities are designed per DOE Order 6430.1A to provide confinement of radioactive materials under normal operations, anticipated operational occurrences, and DBA conditions. The design ensures that releases to the environment do not exceed the guidelines outlined in the DOE Order 5400 series. Additional guidance is given in HSRCM-1 (DOE-RL 1994).

Guidelines and requirements applied to facility design and operation are listed below.

1. Plutonium containers in which gas buildup can occur are designed to prevent leakage of gas over the maximum storage period or are vented to prevent an accumulation of explosive gases; however, such venting must not permit spread of contamination.

2. The maximum allowable self-heating (decay heat) for the containers are specified, as well as the design requirements for cooling (in terms of the required vault ambient temperature, active cooling systems, etc.).

3. Plutonium-bearing or -contaminated material are packaged in a closed metal container. Combustibles within the container shall be minimized.

4. Provisions are made to periodically monitor and check storage facilities and containers to ensure continued integrity of containment.

5. When required by the form or hazard potential of the stored material, provisions are made to monitor for contamination or loss of primary containment upon entering the plutonium storage facility.

6. Criteria for determining the suitability of plutonium containers (such as external and internal corrosion rate) are developed and documented. All containers are periodically inspected against these criteria. The time between inspections may vary depending upon container quality and type.

4.4.8 Industrial and Chemical Safety

Design criteria governing industrial safety are specified in DOE Order 6430.1A. Many of these safety considerations overlap those discussed in Section 4.3.5. Electrical services design criteria have not been included because NRC Regulatory Guide 3.39 (NRC 1986) does not include these criteria

in Chapter 4. However, the Preliminary Evaluation of PFP Conformance to DOE Order 6430.1A *General Design Criteria* (WHC 1990) does evaluate electrical services design criteria.

Industrial and chemical safety is ensured by virtue of a rigorous safety program in effect at the PFP. Industrial hazards encountered during plutonium handling operations that do not lead to an engineering solution are controlled in accordance with HNF-MP-003, *Integrated Environment, Safety and Health Management System Plan* and are described in Chapter 6.0. Other requirements and recommendations are listed below.

1. Fire protection and alarm systems are incorporated into the facility to protect operating personnel. Life safety code requirements of NFPA 101 are used in the layout of the building walls, doors, stairwells, and other access features (*Life Safety Code*, NFPA 101) (see Sections 4.3.6 and 5.4.11).

2. Electrical systems are designed in accordance with the *National Electrical Code* (NFPA 70).

3. Compressed gas system designs minimize hazards to building personnel. Pressure relief systems are provided which relieve to the HVAC exhaust or outside. Flammable air systems relieve only to the outside of the facility to limit the possibility of an explosion inside the facility. The use of compressed gas cylinders within buildings are limited to those situations in which piped systems are impractical. Installations met the requirements of WHC-CM-4-40 and WHC-CM-1-10 and meet the current requirements of HNF-PRO-087, *Storing, Using and Handling Compressed Gases.*

4. Valves, dampers, and electrical switches used for system shutoff and subsystem isolation provided with visual indicators for component status and with features to permit the use of mechanical locking devices to facilitate "lock and tag" operations.

5. Piping systems are labeled to indicate the contents and normal flow directions of the fluids.

6. Elevators are designed in accordance with ANSI A17.1, *Safety Code for Elevators, Dumbwaiters, and Escalators.*

7. Pressure systems are designed in accordance with ANSI B31.1, *Power Piping.*

8. Equipment containing PCB are not specified for use in the facility.

9. Piping system design and materials selection are based upon fluids to be conveyed, operating pressure of the system, corrosive nature of the fluids, and hazards posed to operations and maintenance personnel. While metal piping systems are generally preferred, glass, ceramic, and plastic piping systems may be acceptable for certain use, but only in accordance with the requirements of the Uniform Plumbing Code and/or ANSI B31.1.

10. Features are provided in the design to safely handle and store working amounts of required chemicals. Bulk quantities of chemicals are stored in a separate facility designed explicitly for bulk chemical storage as required by industrial safety practices. Controls for personnel protection as required by Hanford Site contractor procedures and the Occupational Safety and Health Administration requirements (i.e., 29 CFR 1910.1200) are imposed if hazardous chemicals are used. Disposal of chemicals are in accordance with WAC-173-303, *Dangerous Waste Regulations*, and Chapter 7.0, Section 7.3.

11. Oxygen monitoring equipment with alarms to alert personnel are provided in areas where oxygen deficiency potential exists.

12. The design of lifting and rigging equipment are in accordance with the requirements of DOE-RL-92-36, *Hanford Site Hoisting and Rigging Manual* (DOE-RL 1992). Appropriate requirements are applied to the design, operation and maintenance of overhead cranes and hoists.

13. Industrial noise protection for employees are in accordance with the requirements of Hanford Site contractor procedures.

14. Nonflammable hydraulic, lubricating, cooling, etc., fluids are used in plutonium handling areas.

15. Physical barriers for isolation between incompatible chemicals, materials, and processes are provided.

4.5 CLASSIFICATION OF SAFETY STRUCTURES, SYSTEMS, AND COMPONENTS

This section describes the criteria for the identification and safety classification of SSCs.

DOE Order 6430.1A states that special facility SSCs are to be designed, fabricated, erected, and tested to standards and quality commensurate with the hazards and potential consequences associated with both the facility and the role of each SSC in mitigating the consequences of DBAs. These items shall be identified as safety class items. Safety class items are SSCs, including portions of process systems, whose failure could adversely affect the environment or the safety and health of the public. Specific aspects of safety class criteria are discussed in DOE Order 6430.1A.

The PFP uses more stringent criteria for the identification and designation of safety class SSCs, as outlined in HNF-PRO-704. DOE Order 5480.23 requires that facilities identify safety class and safety significant SSCs and these identified SSCs are reported under DOE Order 232.1, *Occurrence Reporting and Processing of Operations Information*.

4.5.1 Definition of Safety Structures, Systems, and Components

HNF-PRO-704 uses the two general designations of safety SSCs listed below.

- Safety class SSCs--prevent or mitigate the release of hazardous materials to the public that would otherwise exceed the offsite radiological risk guidelines, or prevent accidental nuclear criticality.

- Safety significant SSCs--prevent or mitigate releases of radiological materials to onsite workers and toxic chemicals to the offsite public and onsite workers. This includes barriers that are judged to contribute substantially to defense-in-depth independent of quantitative analysis. Safety significant also describes worker safety SSCs that protect the facility worker from serious injury due to hazards not controlled by institutional safety programs.

4.5.1.1 Safety Structures, Systems, and Components Criteria. Designation of safety SSCs is done by use of criteria presented in HNF-PRO-704. A listing of these criteria is provided in Table 4-4. The methods and procedures for identifying safety class and safety significant SSCs are presented in HNF-PRO-704.

4.5.2 Design Criteria

Guidance for the replacement and modification of existing safety class SSCs to safety SSCs, as well as design criteria that apply to new SSCs to determine whether such SSCs are safety class, is provided in HNF-PRO-704. The codes and standards that should be addressed to determine applicable and relevant requirements are provided in Table 4-5 (note that only the applicable and relevant portions of any specific code or standard are to be applied to the design process).

Deviations to DOE Order 6430.1A design criteria are justified in the following manner (HNF-PRO-704):

- Evaluate and document in safety documentation that requires the DOE Richland Operations Office (DOE-RL) approval, except where Section 0101-2 requires DOE Headquarters (DOE-HQ) approval

- Substantiate design deviations in the safety equipment list (SEL)

- Document in the applicable functional design criteria, or in accordance with the exceptions process of HNF-PRO-116, where advance planning and approvals are warranted.

4.5.3 Requirements

1. SELs are used to identify:

   - The safety SSCs and their designations

   - The safety functions maintained or performed by the safety SSCs

   - The SSC design attributes required to perform or maintain their safety functions

- Configuration identifiers
- Calculations and reference documentation used for safety SSC identification and designation.

2. Safety SSCs that fall into more than one category are assigned to the highest applicable classification.

3. Documents that define or change the design bases, performance requirements, regulatory requirements, codes, and standards of safety class SSCs are assigned "approval designators"in accordance with HNF-PRO-233, *Review and Approval of Documents*.

4. The QA program requirements are applied to safety SSCs.

5. Design criteria for safety SSCs are in accordance with criteria identified in Table 4-5.

6. For new projects or facilities, safety SSCs are identified as early in the design phase as practical. An SEL is included in the FSAR and is updated annually.

4.5.4 Safety Systems and Related Equipment List

Tables 4-7 and 4-8 show the safety classifications for SSCs at the PFP. Table 4-7 provides the safety classifications as determined for the PFP prior to installation of the Production Vertical Denitration Calciner (VDC) process for stabilization of plutonium-bearing solutions. The classifications in Table 4-7 are not affected by installation of the Production VDC process. Table 4-8 shows the safety classifications for equipment associated with the Production VDC process. Operation of the Production VDC is not authorized and the related safety classifications will be reevaluated prior to initiation of operations. Other than the safety class designation associated with Building 234-5Z Building HEPA filters and related ducting, which are already identified as safety class in Table 4-7, the only safety class item required by the Production VDC process is the glovebox criticality drain as shown in Table 4-8. Otherwise, the only classification of selected items related to Production VDC operations is safety significant which is due primarily to their function of providing worker protection or defense-in-depth. For reactive plutonium-bearing material stabilization operations, no additional items have been identified requiring safety classification other than those already classified in Table 4-7.

Tables 4-7 and 4-8 were prepared based on the definitions identified in Chapter 4.0, Section 4.5.1, the accident safety analysis provided in Chapter 9.0 and the system design description (SDD) documents (HNF-SD-CP-SDD-003; HNF-SD-CP-SDD-004; HNF-SD-CP-SDD-005; HNF-SD-CP-SDD-006; HNF-SD-CP-SDD-007; HNF-SD-CP-SDD-008; HNF-SD-CP-SDD-009; HNF-SD-CP-SDD-010; HNF-SD-CP-SDD-011; HNF-SD-CP-SDD-013; WHC-SD-CP-SDD-015; HNF-SD-CP-SDD-017; HNF-SD-CP-SDD-021; HNF-SD-CP-SDD-024; also see *Safety Systems and Related Equipment*, FH 2000).

The safety classifications for SSCs associated with the Laboratory Prototype Calciner are shown in the laboratory calciner addendum to this FSAR.

The basis for the classification of SSCs for the prototype calciner and the related PFP SDDs are identified in the addendum. The laboratory calciner is not currently authorized for operation.

The safety classifications for SSCs associated with the Magnesium Hydroxide Precipitation Process are shown in the related addendum (Carson 2000) to this FSAR. The basis for the classification of SSCs for the process and the related PFP SDDs are identified in the addendum.

The safety classfications for SSCs associated with the Bagless Transfer System (BTS) are shown in the calculation notes (FH 2000a) for the BTS. The basis for the classification of SSCs for the BTS and the related PFP SDDs are identified in the calculation notes.

4.6 DECOMMISSIONING

As technology advances and missions change, facilities and equipment become obsolete. Because special handling is required for the disposal of radioactive SSCs, the decontamination and decommissioning (D&D) program has been developed to ensure disposition in a manner that minimizes risk to employees, the general public, and the environment.

The specific objective of D&D operations is to remove contaminated PFP facility components and dispose of them appropriately as transuranic (TRU) waste, low-level waste (LLW), or mixed waste. Contaminated PFP components may include process gloveboxes and associated electrical and piping systems, ventilation systems, vacuum systems, and drain systems.

DOE Order 430.1, *Life-Cycle Asset Management*, requires the development of a decommissioning turnover plan, a decontamination plan if appropriate for the facility, and the completion of a deactivation readiness review.

4.6.1 Original Criteria

No formal criteria for D&D were used in the original plant design.

4.6.2 Current Criteria

Current D&D criteria are described in DOE Orders 6430.1A for incorporation into new facility design.

4.6.3 Decontamination and Decommissioning Activities. The D&D of plutonium handling facilities can be divided into six basic operational activities:

1. Removal of significant quantities of plutonium material to interim storage
2. Decontamination of glovebox internals and equipment removal
3. Packaging for disposal
4. NDA of material prior to disposal
5. Removal of service piping/wiring
6. Removal of all equipment from facility.

The first five activities are terminal cleanout operations (TCO). The last one is strictly D&D activity.

Overall D&D operations extend from completion of TCO activities to disposition of D&D items as waste. At the beginning of D&D operations, a process facility: (1) will not contain accessible quantities of plutonium, (2) will be isolated from process piping and electric services, and (3) will remain connected to fire protection and ventilation services. Equipment will then be decontaminated, size reduced, and packaged in approved waste containers.

Placement of all items in 20-yr retrievable storage or burial grounds completes D&D activities.

Detailed discussion of the procedures to be followed on the PFP D&D activities may be found in *Plan of Approach to Selected Decontamination and Decommissioning of Plutonium Finishing Plant Facilities* (Rockwell 1983a) and *Plan of Approach to Selected Decontamination and Decommissioning: Process Control Plan* (Rockwell 1983b).

Table 4-1. Isotopic Distribution of Plutonium at the Plutonium Finishing Plant Based on Inventory Records and Estimates.

Range (% ^{240}Pu)	Mass (g)	Number of items	^{238}Pu (%Pu)	^{239}Pu (%Pu)	^{240}Pu (%Pu)	^{241}Pu (%Pu)	^{242}Pu (%Pu)	^{241}Am (%Pu)
<3.99	8,166	23	0.00	96.89	3.04	0.05	0.00	0.02
4.00 to 6.99	1,470,646	3,202	0.01	93.43	6.04	0.25	0.04	0.16
7.00 to 9.99	63,808	419	0.01	91.10	8.35	0.43	0.10	0.61
10.00 to 12.99	477,026	2,195	0.07	86.68	11.88	0.93	0.19	0.73
13.00 to 15.99	109,272	235	0.52	81.05	14.92	2.39	1.15	2.50
16.00 to 18.99	1,295,254	1,440	0.16	81.17	17.01	1.11	0.57	1.68
>19.00	225,059	572	0.27	73.68	22.62	1.87	1.65	2.45
Total	3,649,231	8,086	--	--	--	--	--	--

Note: The percent plutonium (%Pu) is calculated on a per gram plutonium basis. The total for a row is greater than 100% because of the contribution of the ^{241}Am mass.

Table 4-2. Isotopic Distribution of Plutonium at the Plutonium Finishing Plant Based on Nondestructive Analysis (NDA) Verification Database.

Range ($\%^{240}Pu$)	Mass (g)	Number of items	^{238}Pu (%Pu)	^{239}Pu (%Pu)	^{240}Pu (%Pu)	^{241}Pu (%Pu)	^{242}Pu (%Pu)	^{241}Am (%Pu)	Age
<3.99	3,515	13	0.00	97.04	2.91	0.05	0.00	0.09	23
4.00 to 6.99	1,135,919	1,784	0.01	93.77	6.00	0.20	0.03	0.14	11
7.00 to 9.99	32,825	123	0.03	91.75	7.78	0.39	0.05	0.45	16
10.00 to 12.99	223,577	489	0.09	86.94	11.81	1.00	0.17	0.86	13
13.00 to 15.99	83,225	83	0.22	83.85	14.44	1.61	0.38	2.26	18
16.00 to 18.99	115,983	143	0.24	80.66	16.98	1.44	0.69	2.80	23
>19.00	56,568	87	0.30	72.87	23.14	1.90	1.79	4.05	24
Total	1,651,613	2,722	--	--	--	--	--	--	--

Note: The percent plutonium (%Pu) is calculated on a per gram plutonium basis. The total for a row is greater than 100% because of the contribution of the ^{241}Am mass.

Table 4-3. Plutonium Product Specifications.

1. Plutonium metal* (RMC Line)	
Chemical purity	
Plutonium assay	≥99.84 wt%
Atomic purity	
Atomic % plutonium	≥99.00
Isotopic purity	
^{238}Pu	<0.05 wt%
^{240}Pu	5.2 to 6.5 wt%
^{241}Pu	<1.0 wt%
Element impurity	
Gallium (Ga), aluminum (Al), and silicon (Si)	4(ppm Ga) + 10(ppm Al) + 10(ppm Si) ≤1,300
Americium	<200 ppm
Beryllium	<1 ppm
Boron	<5 ppm
Calcium	<500 ppm
Magnesium	<500 ppm
Carbon	<200 ppm
Cadmium	<10 ppm
Iron + Nickel	<400 ppm
Lithium	<10 ppm
Neptunium	<50 ppm
Thorium	<50 ppm
Uranium	<100 ppm
Tritium	<10 µCi/kg
Other	<100 ppm each
2. Plutonium nitrate (PRF)--	
Plutonium	= 250 to 375 g/L
Free acid	= 3.0M to 9.0M
Solids	= 0 to 1%
Organic	= 0 to 1%
Uranium	<1,700 µg/g Pu
Specific gravity	= 1.27 to 1.70

*Based on Rocky Flats specifications.

Table 4-4. Safety Structures, Systems, and Components Criteria. (2 sheets)

Structures, systems, and components (SSCs) that:		Safety SSC Designation	Previous Designation*
1.	Prevent or mitigate offsite dose in excess of 5 mSv (500 mrem) TEDE.	SC	SC-1
2.	Place or maintain an operating process in a safe condition that prevents or mitigates offsite dose in excess of 5 mSv (500 mrem) TEDE.	SC	SC-1
3.	Monitor the release of radioactive materials to the environment during and after accidents where the monitor's output initiates Emergency Response Plan or operator actions to place the operating process in a safe condition per criterion 2.	SC	SC-1
4.	Maintain double contingency protection against an accidental nuclear criticality.	SC	SC-1
5.	Support the safety function of a safety class SSC. This includes control and monitoring functions (operating air, electrical power, instrumentation, etc.).	SC	SC-1
6.	Prevent or mitigate a radiological dose or chemical exposure that challenges the risk evaluation guidelines of Appendix D.	SS	SC-1 or SC-2
7.	Place or maintain an operating process in a safe condition that prevents or mitigates consequences that exceed criterion 6.	SS	SC-1 or SC-2
8.	Prevent or mitigate exposure in excess of 50 mSv (5 rem) TEDE or an airborne chemical concentration in excess of ERPG-2 to facility operators who are relied on to achieve the safe condition of criterion 2 or 7.	SS	SC-1 or SC-2
9.	Monitor the release of radioactive and/or hazardous materials to the environment during and after accidents where the monitor's output initiates Emergency Response Plan or operator actions to place the operating process in a safe condition per criterion 7.	SS	SC-1 or SC-2
10.	Support the safety function of a safety significant SSC. This includes control and monitoring functions (operating air, electrical power, instrumentation, etc.).	SS	SC-1 or SC-2
11.	Prevent or mitigate an acute fatality to a facility worker or serious injury to a group of workers, except where the SSCs are controlled through an implemented institutional safety or radiation protection program.	SS	SC-3
12.	Provide defense-in-depth prevention or mitigation of an uncontrolled release of radioactive and/or hazardous material deemed significant in the safety analysis.	SS	N/A

* No longer applies to the designation of SSCs; used for existing SELs and reference documentation until they are revised.

NOTES

1. Consider initiating events with a frequency greater than 10^{-1} per year to be planned events and mitigate their consequences to within normal operational limits.

2. Where a postulated accident can cause multiple system failures, evaluate bounding consequences at a common receptor location. Select safety SSCs and determine residual consequences for the purpose of designating other structures or systems.

Table 4-4. Safety Structures, Systems, and Components Criteria. (2 sheets)

NOTES (continued)

3. For criteria 6-10, the previous designation was SC-2 except for cases where SC-1 designation was applicable to the prevention or mitigation of toxic chemical exposures in excess of the offsite risk guidelines.

4. Designate SSCs that may prevent the adequate function of safety SSCs through physical interaction (seismic, pipe whip, jet impingement, water damage, environmental changes, etc.) as the same level of importance as those potentially affected SSCs.

5. Water treatment systems that use chlorine are considered to pose a risk commonly accepted by the public, provided that their design is consistent with public water treatment plants. Do not designate such systems as SC or SS.

6. See Section 2.4 of HNF-PRO-704 for the procedural steps that this Table supports. In May 1995, this procedure descoped environmental and standard industrial SSCs from designation as safety SSCs. These and other balance-of-plant SSCs are considered to be "General Service" SSCs.

Table 4-5. Design Codes and Standards for Systems, Structures, and Components.

Category/application	General services	Safety significant	Safety class
Structural	UBC; ACI-318; AISC; UCRL-15910, AWS-D1.1	same as GS	ACI-349; ANSI-N690
	Guidance on applicable codes and standards is also provided by performance category per DOE-STD-1021		
Process equipment - vessels and tanks	ASME VIII; API; AWWA-D100; UL-58, -142	same as GS	ASME III[a]
Process equipment - piping and valves	UPC; ASME VIII; ASME-B-16.xx, B-31.1, B-31.3, B-31.9; AWWA, Hydraulic Institute Standards	same as GS	ASME III[a], ANSI-N278

Process equipment - heat exchangers	ASME VIII; TEMA; ASRAE	same as GS	ASME III[a]
Process equipment - ducts and fans	ASHRAE; SMACNA	same as GS	same as GS
Process equipment - pre- and HEPA filters	ASHRAE-52.68, ASME/ANSI-509, 510; Mil-F-51068C	same as GS	same as GS
Mechanical handling - cranes	CMAA; ANSI B30.xx; ASME NOG-1	same as GS	CMMA Nuclear Sections
Mechanical handling - other equipment	ANSI 16.xx; AISC	ANSI N14.6	same as safety significant
Electrical	NEC; NEXC; IES Lighting Handbook	IEEE-577	IEEE-308, -388, -379, -384, -603 (Section 5.8)
Instruments and controls	ISA; ANS-8.3, N42.18, N13.1	same as GS	ANSI-N320; ISA-S67.04; NQA-2; IEEE-627
Fire protection	NFPA	same as GS	same as GS
Chemical and toxicological hazards	OSHA; AICHE Safety Standards; ACGHI Requirements: NEPA	same as GS	same as GS
All applicable equipment	OSHA; UL; local and state standards; AWS; NEMA; ASTM; ANSI; NEPA	same as GS	same as GS

[a]ASME III or other comparable safety-related codes and standards that are appropriate for the system being designed.
[b]Standards in a lower safety category apply also to the higher safety categories unless otherwise listed.
[c]Codes and standards identified under "safety class" are invoked by DOE Order 6430.1A, and were developed specifically for commercial nuclear reactors. Their use for nonreactor applications requires judgement.
[d]Other criteria to be considered in design activities of the above will include such items as procurement levels, training, surveillance, in-service inspections, change control, maintenance, quality assurance, and NQA-1.
[e]The codes and standards identified in the table above apply to new facilities and modifications (except piping system modifications will be done to the code-of-record) and additions to existing facilities. The codes and standards originally applied (code-of-record) to a facility or an SSC will continue to apply for maintenance activities until the facility or SSC is modified.

Table 4-6. Criteria for Posting.

Radiation areas	
Area	Dose rate criteria
Radiation area	>0.005 rem/h and ≤0.1 rem/h at 30 cm
High radiation area	>0.1 rem/h at 30 cm and ≤500 rad/h at 100 cm
Very high radiation area	>500 rad/h at 100 cm
Hot Spot	5 times general area dose rate and >0.1 rem/h
Contamination areas	
Contamination	Contamination levels >1 time but ≤100 times 20 dpm/100 cm^2 (transuranic)
High contamination	Contamination levels >100 times 20 dpm/100 cm^2 (transuranic)
Fixed contamination	Removable contamination levels ≤ 20 dpm/100 cm^2 > 500 dpm/100 cm^2 (transuranic)
Soil contamination	Contaminated soil not releasable in accordance with DOE Order 5400.5
Airborne radioactivity	Concentrations ($\mu Ci/cm^3$) >10% of any DAC value

Table 4-7. Safety Systems and Related Equipment Safety Designation[1]
(4 sheets)

ITEM NO.	PARENT SYSTEM	SUPPORT SYSTEMS	FUNCTIONAL REQUIREMENTS	HNF-PRO-704 TABLE 5 CRITERIA
Safety Class (SC)				
1	Plutonium Building Structural Features: 232-Z, 234-5Z, 236-Z, 242-Z, 2736-Z, 2736-ZB. (HNF-SD-CP-SDD-007)	HVAC Supply Fan Seismic Shutdown System provides support for Item 1a. - See Item 7	1a: Seismic - Confine radiological releases, as defined in the accident analysis, during a seismic event. Building exterior surfaces and penetrations, and interior compartmentalization provide mitigation of Pu releases after a seismic event. However, the HVAC is assumed to fail during this event and the building structure is breached, but the building structure remains standing. The seismic accident analysis assumes this building breach and demonstrates that the system provides adequate mitigation to meet evaluation guidelines. The seismic shutdown system is considered a support system and provides necessary mitigation during this event. 1b: Non-Seismic - Confine radiological releases in all other accident scenarios in buildings. Building exterior surfaces and penetrations, and interior compartmentalization provide mitigation of release.	1
2		HVAC ductwork from HEPA filters to building exterior surfaces, including the HEPA filter frames.	Supports ability of building structure to provide radiological confinement for Item 1b. Confinement boundary from building structure walls to the HEPA filters includes this HVAC ductwork.	5
3		HEPA filters - See Item 5		
4	291-Z-1 Stack (HNF-SD-CP-SDD-006)		The stack must not fall on any of the buildings identified in Item 1, which could cause a loss of confinement. This is a 3/1 interference situation where possible failure of the stack may interfere with the confinement safety function provided by the buildings. Provides structural point to mount effluent monitoring system used to monitor accident conditions. Support system for Item 6. Provides elevated release point assumed during accident scenarios.	2,5
5	Final and Secondary HEPA filters: 234-5Z, 236-Z, 2736-Z, 2736-ZA, 2736-ZB, and 291-Z. (HNF-SD-CP-SDD-005).	Stack CAMs - See Item 6	Mitigate radioactive releases to protect onsite and offsite receptors. The filters provide part of the building confinement function, see Item 1b.	1

Table 4-7. Safety Systems and Related Equipment Safety Designation[1]
(4 sheets)

ITEM NO.	PARENT SYSTEM	SUPPORT SYSTEMS	FUNCTIONAL REQUIREMENTS	HNF-PRO-704 TABLE 5 CRITERIA
6	Effluent Stack Air Monitors and Alarms for: - 291-Z-1 for Buildings 234-5Z, 236-Z, 242-Z - 296-Z-5 for Building 2736-ZB - 296-Z-6 for Building 2736-Z (WHC-SD-CP-SDD-006)	291-Z-1 Stack - See Item 4	Monitor the release of radioactive materials to the environment during and after accidents (except for the seismic event) to initiate emergency response action or to initiate operator actions that will place or maintain the operating process in safe condition. Response to the seismic event is fully proscribed for evacuation and fail safe systems and does not require operation of the Effluent Stack Air Monitors and Alarms. Supports the final and secondary HEPA filter safety function by detecting a catastrophic filter failure.	3,5
7	HVAC Supply Fan Seismic Shutdown System (See Note 2 and *) (WHC-SD-CP-SDD-004)		Mitigate radiological release after a seismic event by shutting down the 234-5Z/236-Z ventilation supply fans, which prevents the facility from over-pressurizing. This system supports the confinement function of Item 1a. * Electrical supply to the seismic shutdown system is not SC because the system fails safe. In the event of a loss of power to the seismic shutdown system, the supply fans are deenergized.	2
8	Liquid Detector and Interlock in 26-in.-Hg Vacuum System (See Note 2 and *) (WHC-SD-CP-SDD-013)		Prevent criticality by detecting the aqueous solutions upstream of the geometrically non-favorable components of the 26-in.-Hg vacuum system and shutting down and isolating the system before solution reaches these components. * Electrical supply and compressed air supply to this system are not SC because the liquid detector and interlock fail safe. On loss of compressed air, the isolation valves close. On loss of electrical power to the detector and interlock circuits, the isolation valves close.	4
9	Glovebox Criticality Design Features (drains, sump discs, floor filler plates, sump raschig rings) (HNF-SD-CP-SDD-008)		Prevent criticality by maintaining a critically safe configuration.	4
10	Plutonium Vault Storage Arrays (racks, cubicles, pedestals)		Prevent criticality by maintaining a critically safe configuration.	4
11	Spill containment berm and spray shield for elevator hydraulic oil in Room 321		Prevent major oil fire and resultant facility damage by confining an oil spill.	1

Table 4-7. Safety Systems and Related Equipment Safety Designation[1]
(4 sheets)

ITEM NO.	PARENT SYSTEM	SUPPORT SYSTEMS	FUNCTIONAL REQUIREMENTS	HNF-PRO-704 TABLE 5 CRITERIA
	Safety Significant (SS)			
1	Criticality Alarm System (CAS) (See Note 2 and *) (HNF-SD-CP-SDD-003)		Prevent or mitigate radiation exposure to facility workers from criticality by warning personnel and causing their evacuation. *AC power is not SS due to DC power availability.	11
2	Plutonium Gloveboxes and Open Faced Hoods	Room CAMs - See Item 8	Prevent or mitigate radiation exposure to facility workers by minimizing contamination spread. Room CAMS used to monitor for safe working conditions around gloveboxes and hoods.	11
3	Public address function of the Private Automatic Exchange (PAX) System (HNF-SD-CP-SDD-009)		Mitigate the consequences of facility upset conditions by reliably notifying workers so that accidents can be controlled or workers can be evacuated. The PAX system backs up the Emergency Evacuation Alarms System, Item 9, as a defense in depth feature.	12
4	HVAC Exhaust System* (HNF-SD-CP-SDD-005)		Prevent and mitigate the release of radioactive materials that could expose facility workers by maintaining ventilation zone control (differential pressures). * This item provides a conservative, defensible position for the plant HVAC system that integrates the previously classified Emergency Exhaust System with the worker protection criteria of HNF-PRO-704.	11
5		Back-up Emergency Exhaust System	Supports the HVAC exhaust system function by providing a reliable source of exhaust HVAC flow in the event of a loss of electrical power.	12
6		HVAC Supply Fan Interlock with the Exhaust Fan System	Supports the HVAC exhaust system safety function by preventing the supply fans from running when the exhaust fans are deenergized.	10
7	Primary Pu Containers		Contain and isolate Pu from workers when stored outside gloveboxes.	8
8	Room CAMs - portable and fixed. Excludes CAMs associated with stacks, HEPA filters, and in-line duct or process monitors. (See Note 2) (HNF-SD-CP-SDD-011)	Standby Power System - See Item 10	Mitigate worker exposure to radioactive release by monitoring work areas and alerting facility workers to airborne radioactive concentrations exceeding limits. Facility workers initiate radioactive contamination control and protective actions upon alarm. Supports the safety function of gloveboxes and open faced hoods by monitoring parameters that indicate the gloveboxes and open faced hoods are, performing their radiological confinement function.	11, 10

Table 4-7. Safety Systems and Related Equipment Safety Designation[1]
(4 sheets)

ITEM NO.	PARENT SYSTEM	SUPPORT SYSTEMS	FUNCTIONAL REQUIREMENTS	HNF-PRO-704 TABLE 5 CRITERIA
9	Emergency Evacuation Alarms (See Note 2) (HNF-SD-CP-SDD-009)	PAX System - See Item 3 Standby Power System - See Item 10	Mitigate worker exposure to resulting from accident conditions by reliably warning facility workers of the upset condition and signaling appropriate facility worker response.	11
10	Standby Power System (See Note 3)		Provide backup electrical power to Room CAMs, Item 8, and the Emergency Evacuation Alarms System, Item 9 and power to public address system.	10
11	-241-Z Final and Secondary HEPA filters -232-Z exhaust HEPAs		Mitigate radioactive releases and provide part of the confinement boundary.	12
12	Effluent stack air monitors and alarms for: - 296-Z-3 for Building 241-Z - 296-Z-14 for Building 232-Z		Supports the final and secondary HEPA filter Safety function by detecting a catastrophic filter failure	5,9

Note 1: For safety systems and related equipment safety designations associated with the Laboratory Prototype Calciner, see the Laboratory Prototype Calciner addendum to this FSAR.

Note 2: The safety designation shown for each system only applies to those components of the system that: 1) perform the identified safety function, 2) monitor the critical operating parameters of the system (e.g., parameters such as flow or pressure), provide warning of malfunction of the system (alarms and indicator lights), or, 3) are necessary to place the system in a safe configuration (operational interlocks) are classified with the safety designation shown in the table. In addition, systems that ensure that the operational monitors, alarms, and interlocks function under adverse conditions (e.g., UPS or backup power systems for use during partial or complete loss of electrical systems) are assigned the same safety designation. The safety designation for these items is based on their function to alert personnel of off-normal conditions so appropriate actions can be implemented and to place systems in a safe mode to minimize the impacts of a malfunction.

Note 3: Standby Power System (SPS) includes diesel generators and select uninterruptable power supply systems (UPS). [See *Defining and Means of Maintaining the Standby Power System Portion of the PFP Safety Envelope*, HNF-SD-CP-SDD-024.

Table 4-8. Safety Classification for the Production Vertical Denitration Calciner Process (3 sheets)

ITEM	SAFETY CLASSIFICATION	SAFETY FUNCTION	RATIONALE	APPLICABLE HNF-PRO-704, TABLE 5 CRITERIA[1]
Safety Class (SC)				
Glovebox HC-230C-2 criticality drain and screen	Safety class	Prevent accumulation of critical solution volume and geometry in bottom of glovebox should tanks rupture and or water infiltrate glovebox.	Criticality drain prevents potential criticality which could cause serious worker exposure or fatality.	4
Safety Significant (SS)				
Calciner pressure relief device (PRV 230-6)	Safety significant	Prevent failure of the VDC from overpressurization.	Offgassing and flashing of water within calciner can result in pressurization of calciner due to a number of upset conditions. Pressure relief is set to relieve at 1.3 psi. Should the pressure relief device fail to relieve at lower pressures, catastrophic failure of calciner could result in hot Pu oxide, NOx, and steam being released to operating room due to failure of glovebox confinement boundary. Significant overpressurization of calciner poses serious health threat to multiple operators.	11
Calciner thermocouples and temperature control system for wall heaters; calciner high temperature alarm	Safety significant	Control temperature of calciner; protect structural integrity of calciner; annunciate on calciner high temperature to initiate shutdown of VDC heaters and calciner feed pump.	Loss of temperature control could result in significant structural degradation of calciner vessel and overtemperature condition in glovebox HC-230C-2. Glovebox loss of confinement accident poses significant health threat to multiple operators due to Pu inhalation hazard.	11
Glovebox high temperature alarm	Safety significant	Annunciate high glovebox temperature indicative of inadequate ventilation or loss of calciner temperature control; initiates shutdown of VDC heaters and calciner feed pump.	Same as above.	11
HC-230C-2 glovebox confinement structure and penetrations and ventilation exhaust ducting	Safety significant	Confine radiological and toxicological releases from glovebox vessels; prevent spread of Pu to room 230C.	Spread of Pu beyond glovebox boundary poses serious health threat to operators.	11
Vessels within Glovebox HC-230C-2	Safety significant	Provide criticality safe geometry.	Vessel geometry precludes criticalities for solutions containing less than 450 g-Pu/L. Criticalities can cause serious worker exposure or fatality. Vessel geometry provides defense-in-depth for criticality prevention.	12

Table 4-8. Safety Classification for the Production Vertical Denitration Calciner Process (3 sheets)

ITEM	SAFETY CLASSIFICATION	SAFETY FUNCTION	RATIONALE	APPLICABLE HNF-PRO-704, TABLE 5 CRITERIA[1]
Vacuum trap high level indication and vacuum system shutdown interlock in Glovebox HC-230C-2	Safety significant	Prevent liquid overflow into vacuum system	Portions of vacuum system are not criticality safe; shutdown interlock prevents potential criticalities in vacuum system which could result in serious worker exposure or fatality. Safety significant classification assigned because the glovebox vacuum trap high level interlock backs up a similar safety class feature in the plant vacuum system.	12
Transfer line encasement pipe (for transfer lines between Gloveboxes HC-227S and HC-230C-2)	Safety significant	Ensure leaks from primary transfer line drain to ventilated gloveboxes. Prevent spray or liquid leaks of Pu nitrate solutions into Zone 3 areas.	Encasement knocks down spray leaks and prevents liquid leaks to Zone 3 areas which are potentially occupied by workers. Airborne Pu poses serious health threat to facility workers.	11
Room 230C CAMs	Safety significant	Alert operators of presence of airborne radiological material in Room 230C.	Pu powder or aerosols spread beyond the Glovebox HC-230C-2 confinement boundary poses significant health threat to operators. CAMs are carefully located and calibrated to ensure adequate operator protection.	11
Dry Chemical Fire Suppression System	Safety significant	Prevent significant fire damage to glovebox confinement system.	Limited combustibles in Glovebox HC-230C-2 can be ignited. The dry chemical fire suppression system limits the magnitude of the fire and prevents spread of fire to the more combustible sections of the RMC line. Fires large enough to breach the confinement boundary of the glovebox pose significant health threat to operators.	11
Seismic shutdown interlock for VDC power, feed pump power, atomizing air feed, back pulsing air feed	Safety significant	Limit particulate and aerosol release from the VDC in a large seismic event that may fail the E-3 & E-4 exhaust system HEPA filters.	Without seismic shutdown, the VDC could pressurize and release significant quantities of PuO_2 powder or $Pu(NO_3)_4$ aerosols. As the seismic event could also cause the failure of the E-3 and E-4 ventilation system HEPA filters, the release from the pressurized VDC could result in a greater than 5 rem exposure to the maximum onsite receptor (see Section 9.1.10.1 and 9.2.9.4).	6

Table 4-8. Safety Classification for the Production Vertical Denitration Calciner Process (3 sheets)

ITEM	SAFETY CLASSIFICATION	SAFETY FUNCTION	RATIONALE	APPLICABLE HNF-PRO-704, TABLE 5 CRITERIA[1]
VDC low vacuum/feed pump shutdown interlock	Safety significant	Limit duration of pressurization events in the VDC; limit potential release of flammable organic vapors to the glovebox atmosphere should organic-containing material be injected into the VDC concurrent with a loss of vacuum event.	The low vacuum/feed pump shutdown interlock prevents multiple successive deflagrations in the VDC in the event organic containing material is injected into the calciner. The interlock also limits the quantity of organic gases/vapors that can be released into the glovebox atmosphere should organic-containing feed be injected into the calciner concurrent with a loss of process vacuum flow (See Section 9.2.9.1). The low vacuum/feed pump shutdown interlock limits the magnitude of potential organic deflagrations in the VDC and HC-230C-2 glovebox and thereby helps to ensure the integrity of the glovebox confinement boundary.	11

PLUTONIUM FINISHING PLANT
FINAL SAFETY ANALYSIS REPORT

CHAPTER 5.0

PLANT DESIGN

FEBRUARY 2001

This page intentionally left blank.

PREFACE

Revision 2 of Chapter 5.0 of the Plutonium Finishing Plant (PFP) Final Safety Analysis Report (FSAR) includes modifications for the following:

- Revisions to the description of the standby power and electrical systems
- Revisions to the description of glovebox HA-21I to include nuclear criticality safety features
- Clarification of the operation of the ventilation systems
- Clarification of the process/compressed air systems
- Incorporation of the Magnesium Hydroxide Precipitation Process
- Incorporation of the Bagless Transfer System

Other minor changes include editorial changes and additional clarifications.

The following summarizes the active and inactive processes performed at the PFP. Facility and systems descriptions are provided for both active and inactive processes. The active systems are currently or will be authorized for operation following approval of the FSAR, Revision 2, and controls implementation. The inactive descriptions are retained for historical purposes to support future material stabilization and D&D activities.

Active Processes.

- Plutonium material storage and support activities in the 2736-Z, 2736-ZA, and 2736-ZB Buildings, 2736-ZD vault, and the gloveboxes and vaults in the 234-5Z Building
- Reactive plutonium-bearing material stabilization in the 234-5Z Building using Gloveboxes HC-21C and HA-21I
- Waste packaging and reactive residue storage
- Transfer operations in gloveboxes HC-227S/T in the 234-5Z Building
- Low-level waste and waste water treatment in the 241-Z Complex and 243-Z Building, respectively
- The PFP Analytical Laboratory (PFP AL), Standards Laboratory, and Plutonium Process Support Laboratory (PPSL) in the 234-5Z Building
- Facility support systems [e.g., heating, ventilation, air conditioning (HVAC), radiation monitoring, steam, electricity, etc.].
- Bagless Transfer System operations in Glovebox HA-53BTS in the RMA Line in the 234-5Z Building

- Magnesium Hydroxide Precipitation Process operations in Gloveboxes HC-230C-3 and HC-230C-4 in the RMC Line in the 234-5Z Building.

Inactive Processes.

- Plutonium-bearing solution stabilization using the Production Vertical Denitration Calciner and Laboratory Prototype Calciner in the 234-5Z Building
- Plutonium recovery in the 236-Z Building
- Plutonium conversion in the 234-5Z Building
- Waste treatment in the 242-Z Building
- Laboratory waste concentrator.

It is noted that various sections of Chapter 5.0 present information concerning plutonium-bearing solution stabilization operations using the Production Vertical Denitration Calciner located in the RMC Line and the Laboratory Prototype Calciner located in the Plutonium Process Support Laboratories. Operation of either the production calciner or the laboratory calciner for solution stabilization is not authorized at this time and the related portions of Chapter 5.0 will be updated, if necessary, prior to initiation of operations.

The new packaged boilers operated by Johnson Controls, Inc. which provide steam to the PFP were previously incorporated in the FSAR. This included switching the emergency exhaust fans from those which are steam-driven to those which are connected to the standby power system. However, the conversion from using steam-driven fans to standby power driven fans has not been fully implemented. The emergency exhaust fans are currently run by the new steam supply system installed under the Hanford energy conservation program. Electrically-driven emergency exhaust fans are planned to be connected to the diesel-generator standby power supply at some future date. The emergency exhaust fan functions are unchanged from that described in the FSAR regardless of the type and source of power.

The significant areas of change in Revision 2 are indicated by vertical bars in the margin of each page.

5.0 PLANT DESIGN

5.1 SUMMARY DESCRIPTION

5.1.1 Location and Plant Layout

The Plutonium Finishing Plant (PFP) Complex (see Figure 5-1), while in transition to the decontamination and decommissioning (D&D) phase of its life cycle, conducts the following operations:

- Plutonium material receiving, storing, and shipping
- Reactive plutonium-bearing material stabilization
- Plutonium-bearing solution stabilization
- Laboratory support
- Waste handling
- Shutdown facilities surveillance
- Limited cleanout
- Maintenance.

The buildings and structures that comprise the PFP Complex are listed in Table 5-1. The principal PFP structure, the 234-5Z Building, was completed in 1949 to purify plutonium nitrate solutions, reduce the nitrate to plutonium metal, and fabricate plutonium metal parts. The 234-5Z Building houses PFP transition operations, process support facilities and services, the Analytical Laboratory (PFP AL), the Plutonium Processing Support Laboratory (PPSL), and the Standards Laboratory. The 241-Z Liquid Waste Treatment Facility and the 291-Z Building, which house ventilation exhaust fans and mechanical service equipment, were built at the same time as the 234-5Z Building. An incinerator, housed in the 232-Z Building, was completed in 1961 and was used to recover plutonium from combustible scrap. Plutonium reclamation and waste treatment equipment is housed in the 236-Z and 242-Z Buildings, respectively, which were completed in 1964 (see Table 5-2 for construction dates).

In the original design of the PFP Complex process facilities, all of the planned operations and laboratories, except waste collection and disposal, were provided in the 234-5Z Building; however, with increases in production, storage, and scrap recovery requirements, the following major additions were made:

- The 236-Z Building [Plutonium Reclamation Facility (PRF)]
- The 241-Z Complex (Liquid Waste Treatment Facility)
- The 232-Z Waste Incinerator Facility

- The 2736-Z Support/Storage Complex (2736-Z, 2736-ZA, 2736-ZB, and 2721-Z Buildings, 2736-ZC enclosed shipping/receiving area, and 2736-ZD vault)
- The 243-Z Low-Level Waste Treatment Facility (LLWTF)
- An upgraded men's changeroom, 234-5ZA, attached to the 234-5Z Building.

The 234-5Z Building is no longer used to purify plutonium nitrate solutions, reduce the nitrate to plutonium metal, nor fabricate plutonium metal parts. The building is currently used for stabilization operations for reactive plutonium-bearing materials and plutonium-bearing solutions. Plutonium recovery operations are no longer conducted in the PRF, but the building is still available for interim storage of in-process material. The Waste Treatment Facility (the 242-Z Building) is no longer capable of restarting its original operations without upgrading and/or reestablishing services to process and facility equipment. The 232-Z incinerator is being prepared for decontamination and decommissioning.

5.1.2 Principal Features

5.1.2.1 Site Boundary. The federally owned Hanford Site is located in the southeastern part of Washington State about 45 mi north of the Oregon border (Figure 5-2). The Hanford Site occupies about 560 mi^2 of arid land.

In the middle of the Hanford Site, on an arid terrace about 7 mi from the Columbia River, are the 200 East and 200 West Areas (Figure 5-3), where fuel reprocessing, plutonium processing and storage, laboratory facilities, and waste processing and storage facilities are located. The locations of the 200 Areas were chosen to provide the most isolation from the Hanford Site boundaries and are the most remote from both surface and subsurface water. A more detailed description of the Hanford Site is provided in Chapter 3.0.

Public transportation facilities nearest the 200 Areas are State Routes 24 and 240. State Route 240 passes within 2.5 mi of the PFP (Figure 5-3). A four-strand barbed-wire fence separates the highway right-of-way and the Hanford Site.

5.1.2.2 200 West Area. The 200 West Area is located on an upland plateau near the center of the Hanford Site (see Figure 5-3). The locations of the PFP Complex and other major facilities in the 200 West Area are shown in Figure 5-4. The PFP emergency response envelope (see Figure 5-4, which identifies the emergency response envelope as a circle with the 291-Z-1 stack as its center point) encompasses all structures within approximately 1,800 ft of the 291-Z-1 stack, which is the approximate point of discharge for most releases. This area includes the 231-Z Building, the 232-Z Building and 216-Z-9 crib, temporary office structures to the east, portions of the Central Waste Complex to the northwest, and environmental remediation activities.

5.1.2.3 Protected Area. The PFP is separated from the 200 West Area by a double-fenced security enclosure (see Figures 5-1 and 5-4) which contains an electronic surveillance system. Only personnel who have duties and

responsibilities associated with the operation of the plant and auxiliary facilities have access authorization to the complex.

5.1.2.4 Site Utility Supplies and Systems. The Hanford Site utilities servicing the PFP are electricity and water. A brief description of each follows. Details are covered in Section 5.4.

5.1.2.4.1 Electrical Power Supply and Distribution System. The electrical power supply and distribution system includes the following and is detailed in Section 5.4.2.

- Normal power supply--Electrical power is supplied to the Hanford Site by the Bonneville Power Administration (BPA) substation at Midway through a 230-kV loop serving all outer areas of the site. The H. J. Ashe switchyard provides a redundant supply of 230-kV electrical power. This source is switched automatically into the 230-kV loop in the event of power loss from the Midway substation.

- Standby power--Standby power for the PFP Complex is available from three 325-kW diesel-generators housed in the 2721-Z Building.

- Uninterruptible power supply--Uninterruptible power (batteries) is provided to operate standby power supply diesel generators in Building 2721-Z, seismic shutdown systems, alarm systems, emergency lighting, and the MICON™ control system in the event of loss of normal and standby power.

5.1.2.4.2 Water Supply and Distribution System. All of the water supply needs for the PFP are provided by three sanitary water system lines. Water from the 283-W filter plant and clear wells is supplied to the PFP sanitary water service loop by a 10 in. diameter line that feeds into the loop at the southeast corner, an 8 in. diameter line that feeds into the loop on the north side, and a 12 in. diameter line that feeds into the loop at the northeast corner (see Sections 5.4.7 and 5.4.8 for details).

5.1.2.5 Storage Facilities. Compressed gas storage facilities are discussed in Section 5.4.4. Liquid chemical storage is discussed in Section 5.4.13.

5.1.2.6 Ventilation Exhaust Stacks. The PFP ventilation exhaust stacks are described below and locations are shown in Figure 5-1 [see Section 5.4.1 for details of the heating, ventilation, and air conditioning (HVAC) system].

- 291-Z-1 stack--The 291-Z-1 stack is 200 ft high with a 16-ft 6-in. ID at the bottom, and a 13 ft 6 in. ID at the top. The stack is constructed of reinforced concrete and effluents are sampled and monitored.

- 296-Z-3 stack--The 296-Z-3 stack is 25 ft high with a 14 in. diameter. The stack is constructed of stainless steel and effluents are sampled and monitored.

- 296-Z-5 stack--The 296-Z-5 stack is 27 ft 7 in. high with a 34 in. diameter. The stack is constructed of stainless steel and effluents are sampled and monitored.

- 296-Z-6 stack--The 296-Z-6 stack is 14 ft 8 in. high in a 36-in. by 22-in. rectangular configuration. The stack is constructed of carbon steel and effluents are sampled and monitored.

- 296-Z-14 stack--The 296-Z-14 stack is 21 ft high with a 12 in. diameter. The stack is constructed of stainless steel and effluents are sampled and monitored.

- 296-Z-15 stack--The 296-Z-15 stack is 42 ft high with a 12-in. diameter and is constructed of stainless steel. This stack is not routinely sampled and monitored because of the small likelihood of any plutonium entering the 243-Z Building and then escaping the piping and train drums. The sampling and monitoring that is done is to confirm the low radioactive emissions.

5.2 PROCESS AND SUPPORT BUILDINGS

This section describes the structural specifications, building layout, major process areas in the PFP Complex, and the design bases for major PFP process and support buildings.

The PFP is a complex of facilities and support buildings performing various functions to support past and present missions; facilities and buildings are both active and inactive. This chapter will describe those facilities and buildings containing processing equipment and having plutonium material and/or hazardous material inventories warranting consideration or providing one of the confinement systems at the complex. These facilities are identified as major facilities/buildings in this chapter. A list of buildings and structures of the PFP Complex are provided in Table 5-1.

The facilities that have been identified as major facilities/buildings are as follows:

- 234-5Z Building
- Plutonium Reclamation Facility (236-Z Building)
- Waste Storage and Treatment Facility (241-Z Building)
- Exhaust Air Stack Building (291-Z Building)
- Plutonium Storage Facility (2736-Z Building)
- Product Shipping and Receiving Facility (2736-ZB Building).

Some support buildings/facilities also contain inventories of plutonium material and/or hazardous materials warranting consideration, or are necessary to maintain the confinement features of the PFP (i.e., the 291-Z-1 stack). These include the following:

- 242-Z Building (inactive)
- LLWTF (243-Z/243-ZA Buildings)
- HVAC building (2736-ZA Building)
- Enclosed Off-loading dock (2736-ZC)
- Experimental breeder reactor II cask storage (2736-ZD)
- Standby diesel generator building (2721-Z Building)
- 231-Z Building (Under the cognizance of another Fluor Hanford Organization)

- Incinerator Facility (232-Z) (inactive facility)
- Waste Crib (216-Z-9)
- 291-Z-1 stack
- 296-Z-3 stack
- 296-Z-5 stack
- 296-Z-6 stack
- 296-Z-14 stack
- 296-Z-15 stack.

The 216-Z-9 crib is a plutonium-containing waste crib located outside of the double fences that encompass the PFP facility. The 216-Z-9 crib is not a major process facility nor support building of the PFP Complex. The 231-Z Building served as the predecessor to the Z-Plant (234-5Z Building and support facilities) in the 1940's. This facility was originally used to fabricate plutonium metal and was equipped with processing equipment (gloveboxes, fabrication machinery, chemical storage, etc.). A change in mission for the facility resulted in its being used for office space, training, and a rigging shop. This building contains PFP plutonium inventory and is the responsibility of a separate Fluor Hanford organization. Entry into the facility is restricted because of contamination in some sections of the building interior.

Original design specifications and procedures for PFP facilities were based on Uniform Building Code (UBC) requirements applicable at the time of construction or modification, together with Atomic Energy Commission, U.S. Energy Research and Development Administration, or U.S. Department of Energy (DOE) criteria. A list of the major PFP facilities, when they were designed, when they were constructed, and applicable design requirements are shown in Table 5-2. Additional requirements including *Minimum Design Loads for Buildings and Other Structures* (ANSI A58.1), *Building Code Requirements for Reinforced Concrete* (ACI 318), and the *Manual of Steel Construction* (AISC), were also used in the design of these buildings.

Since June 1961, facility additions and alterations have been made in accordance with the Hanford Plant Standards applicable at the time of modification. Current design criteria and procedures for analysis of the effects of natural phenomena on the PFP buildings are defined in *Standard Architectural-Civil Design Criteria, Design Loads for Facilities*, SDC 4.1, Rev. 12 (DOE-RL 1993), and DOE Order 6430.1A, *General Design Criteria* (DOE 1989).

The 234-5Z, 236-Z, 232-Z, 241-Z, 291-Z, 2736-Z, and 2736-ZB Buildings and 291-Z-1 stack and their service and utility systems have been reviewed for compliance with DOE Order 6430.1A (DOE 1989). The results of these reviews are presented in WHC-SD-CP-ES-128, *Preliminary Evaluation of PFP Conformance to DOE Order 6430.1A, Principle Design Criteria* (WHC 1990).

Structural specifications establish the bases and engineering designs required to maintain the confinement integrity of major buildings in the PFP Complex. The type of structure, materials of construction, and construction classification are summarized in Table 5-3. Significant natural phenomena hazards analyses/design information and conclusions specific to the major PFP buildings are summarized in Table 5-2. The natural phenomena hazards are earthquakes, extreme winds, wind-driven missiles, snowfall, and volcanic

ashfall. Evaluation of structures, systems, and components (SSCs) against the natural phenomena hazard design requirements of volcanic ashfall loading is required only for new safety class 1 (now safety class) SSCs and equipment and modifications or additions to existing high hazard facilities (DOE RL 1993); therefore, the design criteria for volcanic ashfall loading and combined snow and volcanic ashfall loads are not applied to those facilities built before 1993. In the structural evaluations of the PFP Complex buildings, analysis of the roof was performed to verify design adequacy with regard to live, dead, and snow loads, which are the normal roof loads. The 234-5Z Building was analyzed and found to acceptably resist combined volcanic ashfall and snowfall (Giller 1990) and the 243-Z Building was designed to meet the volcanic ashfall loading criteria of 24 lb/ft^2 for Safety Class 1 SSCs (DOE 1989).

The structural evaluation of the existing PFP facilities design bases differs from new facilities in that the in situ load configurations and conditions of the structures and components were assessed. This assessment included reviewing drawings and conducting field walkdowns to determine deviations from the drawings and any observed deterioration. In-place strengths of materials were used in the analyses when available. If noted during the walkdowns, corrosion and other aging processes that may have had adverse effects on the strength of the components were also considered in the analyses.

The evaluation of existing structures is similar to evaluations performed on new designs, except that a known configuration is evaluated instead of several possible options in an iterative manner, as required during the design process. Because the process is defined, configurations of the buildings and components are known, and the actual live and dead loads are used. The structural evaluation acceptance criteria of the PFP structures and components can be less conservative than that of a new facility where live and dead loads are not known, but are based on anticipated processes and occupancy. It also was required that the confinement capability of the facilities be maintained after a natural phenomena event. The acceptability of the structural evaluations is subject to the interpretation used in preparing the accident and risk analyses of Chapter 9.0.

Most of the seismic qualification analyses for the PFP discussed in this chapter were performed in accordance with SDC 4.1, Rev. 10 (DOE-RL 1987), which used a zero period acceleration of 0.25 g. Since the completion of these analyses, Rev. 11 and Rev. 12 (DOE-RL 1989 and DOE-RL 1993, respectively) have been implemented. In these later revisions, the zero period acceleration is 0.20 g for Safety Class 1 items in nonreactor facilities. DOE-RL (1987) response spectra are based on 84% amplification factors, whereas DOE-RL (1989) response spectra are based on median amplification factors. DOE-RL (1987; 1989) response spectra at 5% critical damping are shown in Figure 5-5. The DOE-RL (1987) spectra are generally more conservative than those in DOE-RL (1989) except for a very narrow frequency range (18 to 21 Hz) where DOE-RL (1989) has an equally conservative or slightly more conservative spectra than DOE-RL (1987). None of the buildings evaluated by dynamic analysis have a frequency with a significant mass participation that fall within the 18 to 21 Hz range; therefore, buildings previously qualified under DOE-RL (1987), satisfy DOE-RL (1989) requirements.

The seismic analyses for the 234-5Z Building assumed a critical damping ratio of 7% (URS 1987). The 7% damping ratio was used in accordance with the recommendations of U.S. Nuclear Regulatory Commission (NRC) Regulatory Guide 1.61 (NRC 1973). The east-west and north-south seismic lateral loads will be resisted by the reinforced-concrete shear walls and the bolted steel members. The structure was assigned a 7% damping ratio specific to design basis earthquake (DBE) load levels. The resulting maximum combined stresses were above one-half the yield stress; therefore, use of 7% damping was justified. The analyses were performed before DOE-RL (1989; 1993) were issued. DOE-RL (1989) recommends that damping values for nonreactor structures be in accordance with *Design and Evaluation Guidelines for Department of Energy Facilities Subjected to Natural Phenomena Hazards*, UCRL 15910 (Kennedy et al. 1990). In Kennedy et al. (1990), the damping ratio for the above load-resisting structures is 10% for high hazard facilities; therefore, use of 7% damping is considered conservative.

The 291-Z Building is constructed with reinforced concrete for lateral load resistance; therefore, 7% damping was used again in the seismic analyses, which is in conformance with NRC (1973).

The 236-Z Building is also a reinforced concrete structure. In the preliminary seismic analysis, which used the 7% NRC (1973) damping ratio, resulting combined stresses were lower than one-half the yield stress; therefore, a lower damping ratio of 5%, specific to operating base stress levels, was used to avoid underestimating the amplitude of vibrations or dynamic stresses.

Table 5-4 provides a summary of the seismic analyses for the 234-5Z, 236-Z, 232-Z, 241-Z, 242-Z, 291-Z, 2736-Z, 2736-ZA, 2736-ZB, and 2721-Z Buildings and 291-Z-1 stack. This table shows the type of seismic analysis performed, the design response spectra of each building, the critical damping used, any consideration of soil structure, and the conclusions of each analysis.

The wind load analyses used the maximum velocity of 90 mi/h, based on the guidelines of DOE-RL (1989), and Kennedy et al. (1990). The wind load calculations are in accordance with the formulas and recommendations described in ANSI A58.1. The structures were all designed to withstand 20 lb/ft^2 of normal wind load. In addition to the normal wind load, the 2736-ZB and 2736-Z Buildings were designed to withstand tornado wind conditions with wind speeds of 175 mi/h and associated tornado-generated missiles identified in SDC 4.1, Rev. 7 (DOE-RL 1982).

The roof loading requirements of the major buildings were based on the UBC guidelines at the time of design. The roofs of all aboveground structures were designed for static vertical live and dead loads, including snow loads. Design requirements for combined snow and volcanic ashfall loading, and volcanic ashfall loading were not required until issuance of DOE-RL (1989). Analyses of roof designs to withstand natural phenomena hazards of combined snow and volcanic ashfall loads, if any, are discussed in individual building structural/design specifications in Sections 5.2.1 through 5.2.10. In many cases, specific analyses of roofs to resist combined snow and volcanic ashfall peculiar to the safety categorization of the building(s) were not performed,

though it may have been assumed that a roof would resist such natural phenomena due to dead, live, and snow design loadings.

Plan view drawings of the PFP buildings are shown in Figure 5-6. The principal structure is the 234-5Z Building, which contains plutonium processing facilities, laboratories, and an HVAC system. Offices, lunchroom, changerooms, maintenance shops, and Radiological Control provides for the tenants' requirements. Design of the 234-5Z Building provides a duct-level area to house service and utility distribution systems. The 234-5Z Building first-floor plan identifies the major processing areas in the building, for example, the Remote Mechanical A (RMA) and C (RMC) Lines, and locations of other process and support facilities. The duct level is a minimum-strength, metal deck between the first and second floors that contains most of the large ventilation plenums and ducts, and the piping loops for service throughout the building. The ventilation plenums and ducts and other services (e.g., telephone switchgear room, electrical room) are shown in the duct-level plan. Locations of support services (e.g., chemical preparation, ventilation supply fans, ventilation exhaust filter rooms) are shown in the second-floor plan.

Another major process building, the 236-Z Building (PRF), contains process equipment and services that were used for the recovery of plutonium from a variety of sources. The facility also has some maintenance shops and offices. Ventilation supply air and 26-in. mercury process vacuum services are provided from 234-5Z service systems. Process air, instrument air, and steam are supplied from the 291-Z Building. Services supplied by 236-Z installations include water from connections to the 8-in. PFP water supply loop, 17-in. mercury vacuum (air sample vacuum) system, and high efficiency particulate air (HEPA) filter banks for treating room exhaust air (E-3 system) and process exhaust air (E-4 system). Exhaust air is discharged to the atmosphere using the exhaust fans in the 291-Z Building and the 291-Z-1 stack.

A third major process facility is the 2736-Z Storage/Support Complex, which consists of the 2736-Z, 2736-ZA, 2736-ZB, 2736-ZC enclosed area, 2736-ZD vault, and 2721-Z Buildings. This is a stand-alone complex with its own HVAC systems, backup electrical power, changerooms, lunchroom, and offices.

Confinement Features. The exterior walls of 234-5Z, 236-Z, 242-Z, and 232-Z Buildings, and 241-Z Complex confinement features provide for physical barriers separating contaminated process hoods and vessels from the environment. The ventilation zone differential pressure (DP) is important to confinement by assuring that the airflow direction is from the clean zone 1 to the potentially contaminated zone 3 to the contaminated zone 4. Zone 1 is at a slightly positive pressure with respect to the outside building atmosphere, progressing negatively through zone 3 and then finally zone 4 to promote airflow toward the contaminated zone 4.

Zone 1 includes general office areas, lunchrooms, and some shop and service areas. It is not HEPA filtered and it is not discharged through the 291-Z Building. Zone 3 includes rooms that contain gloveboxes and hoods and/or rooms that have conditions that could result in contamination. Zone 4 includes the gloveboxes, hoods, and canyon cell, which are designated as contaminated areas.

Air from zones 3 and 4 exhausted through separate HEPA filters, and once cleaned the air joins to exhaust to the atmosphere through a stack. The stack is continuously sampled and monitored for radioactivity. The ventilation system for the majority of the PFP Complex is shown in Figure 5-7, which details the ventilation system for the 234-5Z, 236-Z, and 242-Z Buildings. For a more detailed description of the ventilation systems of the entire PFP Complex, see Section 5.4.1.

Processing rooms have strict controls for personnel and materials entry and exit for contamination control. Personnel access between zones 1 and 3 and between zones 3 and 4 is through airlocks. Additionally, gloveboxes use a seal-in/seal-out technique that does not cross tie the ventilation zones. Some equipment changes require a "greenhouse" access, which in effect, is a temporary airlock. Open-faced hood atmospheres are controlled by providing a specified air velocity from the room into the hood.

Radioactive materials are processed within enclosures such as gloveboxes, hoods, and cells that provide the primary confinement barrier to the release of radioactivity. Together with the ventilation system, these enclosures effectively reduce to acceptable levels the emissions of radioactive and other hazardous materials to the surrounding work spaces or to the environment. In addition, the enclosures are designed (e.g., rounded corners, smoothed welds, finished surfaces, and special surface coatings) to prevent material buildup and to enhance decontamination. Conveyor belts, enclosed in glovebox structures, move plutonium between gloveboxes. Encased piping (pipe-in-pipe) is used to transfer plutonium solutions between most gloveboxes and provides containment in case of a primary line leak; however, a few solution transfer lines are not encased and do not have leak detectors. These lines do not represent an unacceptable onsite/offsite risk because they are in the confinement structure in established radiation areas. Plutonium-containing solutions are transferred by vacuum wherever possible to reduce risks associated with transfers made under pressure.

To prevent the spread of contamination, radioactive materials within the enclosures are confined as close to the point of origin as practicable using nontestable HEPA filters installed on the supply and exhaust ducts of gloveboxes and on the exhaust ducts of hoods. Process gloveboxes typically are supplied with zone 3 room air through a HEPA filter. This filter protects the room from contaminated zone 4 glovebox air in case the airflow reverses. Both gloveboxes typically exhaust through a nontestable HEPA filter located in the top or upper portion of the enclosure, installed at the entrance to the exhaust duct. Exhaust air is then routed through two independently testable stages of HEPA filtration and discharged through an exhaust plenum (e.g., the 291-Z-1 stack). In the PRF (236-Z Building), the process cell and associated east access glovebox and west access glovebox are exhausted through four HEPA filter boxes (two boxes in corridor 10 and two in corridor 20), each containing two HEPA filters that are tested as one, and then through a single-stage testable HEPA filter bank before being discharged through the exhaust plenum and the 291-Z-1 stack (see Section 5.4.1.1.2 for additional details on the 236-Z HVAC system).

Some gloveboxes required a dry-air atmosphere to minimize metallic plutonium oxidation and/or plutonium powder moisture absorption during plutonium processing. On the RMA and RMC Lines, dry air from the dry air

generating system (see Section 5.4.3) was supplied to the conveyor gloveboxes (e.g., HC-1 and HC-2) (air is currently still supplied by the dry air system, however the desiccant equipment is not active). The conveyors serve as plenums that deliver air to the adjoining process gloveboxes. Air from the conveyors is drawn through each process glovebox to an exhaust duct opposite the conveyor junction. The air typically is exhausted through HEPA filters located at the exhaust duct entrance, routed to further HEPA filtration stages, and discharged through the exhaust plenum and the 291-Z-1 stack. Air from the dry air supply system (and, in some cases, exhaust) are regulated by a self-governing, diaphragm-operated supply valve. Exhausts are sized to accommodate the entire amount of air that the pressurized supply could deliver in case the supply valve fails in the fully open position. Separate diaphragm-operated valves regulate emergency exhaust on selected RMA and RMC Line gloveboxes to provide for added exhaust flow requirements in the event of a confinement breach (e.g., a glove or seal failure).

5.2.1 The 234-5Z Building

5.2.1.1 234-5Z Structural Specifications. The actual design of the 234-5Z Building was developed from the criteria that were in effect from 1943 to 1949. During this period, the Hanford Site above-ground structures, including the 234-5Z Building, were designed for static vertical live and dead loads. Seismic criteria were not added to the UBC until 1949 and were not included in the 234-5Z Building design criteria because the location of the Hanford Site was then regarded as a low-intensity, minimum-occurrence earthquake zone. Resistance to lateral wind forces, based on area wind data available at that time, was required.

The 234-5Z Building is approximately 500 ft long and 180 ft wide. The floor levels are the basement, first floor, duct level, and second floor. The frame is structural steel with an outer sheathing of aluminum panels over rock wool insulation and 16-gauge sheet metal. There are also 8 in. thick internal reinforced concrete walls, principally running in the east-west direction, and two box-type reinforced concrete stairwells. The stairwells extend to the roof; the reinforced concrete walls stop at the second floor.

The seismic evaluations of the 234-5Z Building have identified adequately those areas that are connected structurally and evaluated the effects of seismic interaction between adjacent structures. The conclusions are that the seismic interactions do not result in significant structural loads and do not affect the conclusions of the analyses of the individual structures.

5.2.1.1.1 Seismic Analysis. Historical seismic analyses indicated that 0.25-g DBE motions would produce nonlinear responses and possible structural collapse of the 234-5Z Building. Later, it was recognized that the building had considerably more capacity to resist DBE loads than previously believed. Therefore, comprehensive linear and nonlinear seismic analyses were performed. The objectives of these analyses were to consider all the building elements that realistically contribute to lateral (seismic) resistance and to determine whether the building could resist the DBE without collapse (URS 1987).

The expansion joint at column line 12 (identified in Figure 5-6, sheet 2) divides the 234-5Z Building into two sections similar in structural layout.

Both sections have concrete in-fill walls that, along with the second-floor slabs, represent the principal east-west lateral load-resisting system. Both sections depend on the frame action of the columns and steel beams as the principal north-south lateral load-resisting system. Because the two sections are similar, only the west section was analyzed in detail. The west section of the building is considered to be the more critical of the two because the east section contains lighter equipment, which decreases the mass of the structure, and the east section frames are wider than their counterparts in the west section. The wider frames in the east section will further reduce the north-south seismic stresses (URS 1987).

The seismic evaluation of the 234-5Z Building required a rigorous dynamic analysis using a detailed three-dimensional, nonlinear model. Element properties for the model were based on a detailed review and onsite measurements inside the building, as well as mockup cyclic testing of beam-column connections to determine moment rotation relationships. Equivalent static analyses were conducted to understand details of the structure's lateral-force-resisting system. Seismic demand on the structure was calculated using direct-integration time-history dynamic analyses for the three components of ground motion, including consideration of P-Delta (large displacement) effects (URS 1987).

The results show that the seismic response of the building is mainly linear elastic. Only four beam-to-column connections yield, and they remain comfortably below ultimate rotational capacities. The east-west displacements are small, 0.33 in. maximum at the roof. The maximum north-south displacement is over 7 in. at the roof. The north-south displacement at the second floor level is 3 in., maximum (URS 1987). The main conclusions of the 234-5Z Building seismic analyses were as follows.

- The building, as is, could resist DBE motions without collapse.
- Separation and some seismic pounding are expected between the second-floor slab and the stairwells. Shear cracks could develop in the stairwell walls. The integrity of the building and the use of the stairwells will not be threatened.
- North-south concrete walls along columns 4 and 8 would need to be isolated from the lateral load path so that the columns do not attract seismic shear forces that may exceed their capacity.

A further assumption is made that the building separates along column line 12 (the building joint) because of presumed differential motion between the east half and west half. In addition, the side panels are assumed to tear, buckle, or pull out of the girders at the attachments. This damage is slight on walls perpendicular to the earthquake direction and on walls nearer to the ground. The damage is more pronounced in walls parallel to the earthquake and at upper levels. A test was performed on panels in which a bounding condition of the seismic loads was applied (Giller 1989b). The panels suffered only minor damage around some of the fasteners; therefore, it is assumed in this analysis that the panels remain intact.

Seismic analyses and evaluations of all the gloveboxes (RMC and others), filterboxes, E-4 exhaust ducts, and seismic interactions were performed and

structural upgrades were identified (Ocoma 1988a, 1988b, 1990a, 1990b). The seismic qualification status and criticality prevention specifications of these gloveboxes and hoods are given in Table 5-5. During the analyses, the plutonium powder-containing gloveboxes and discrete segments of ventilation ducting that were not seismically qualified were assumed to fail and disperse plutonium within the facility. The building was also assumed to separate along column line 12 (the building joint), so it was expected that dispersible plutonium would exit the building through this separation and result in offsite (respirable) doses. Two cases were calculated for these seismic analyses.

- The ventilation systems are assumed to be either failed or shut down.
- Ventilation exhaust fan(s) continue to run as a result of continued supply of normal power following the earthquake or backup power from diesel generators.

In either case, it was found that the radiological consequences associated with these releases during the current transition phase of the PFP still met the risk acceptance guidelines for all except the "no ventilation" onsite dose case when the Laboratory Prototype Calciner releases are included (see Chapter 9.0, Section 9.2.4). However, it is noted that the laboratory calciner is not authorized for operation. The following list of seismic upgrades were implemented to prevent an increase in potential offsite doses.

- Seismic fan shutdown system was installed to shut down power to the supply fans.
- The FB-9A, 9B, 9A/B, and FB-8 filters have been removed to reduce plutonium inventory in the HVAC system.
- The FB-9A and FB-9B by-pass line has been removed to reduce plutonium inventory in the HVAC system.
- Filterboxes FB-14, -20, -21, and -22 were seismically upgraded.
- Glovebox HC-4 was seismically upgraded.
- Booster panel cabinet for gloveboxes HC-13 and HC-15 were seismically upgraded.

In addition to the above seismic upgrades to limit the consequences of a seismic event, see the Laboratory Prototype Calciner addendum to this FSAR for additional features to limit seismic event consequences. Note that the laboratory calciner is not authorized for operation.

5.2.1.1.2 Wind Analysis. The 234-5Z Building structure was evaluated for its response to wind-generated wall pressures and missiles. The design wind condition is specified in DOE-RL (1989), as an extreme wind of 90 mi/h and the wind-driven missile is defined as a 2 in. by 4 in. wood plank weighing 15 lb and traveling at 50 mi/h.

Loads from the wind analyses were compared to those from existing seismic analyses to qualify the structures for extreme wind loads. The extreme wind analyses and strength evaluations are included in *Extreme Wind Analysis PFP Structures 236-Z, 291-Z, and 234-5Z Buildings* (Giller 1989a).

Analyses of the 234-5Z Building show that the main load-bearing structure is not overstressed by the extreme wind or adversely impacted by the missile loads. The external skin panels were tested and found acceptable for missile resistance. Additionally, the roof deck was evaluated and found acceptable (Giller 1989a). The building was deemed to meet DOE-RL (1993) criteria.

5.2.1.1.3 Snowfall Analysis. The 234-5Z Building roof was analyzed for normal roof loading of a minimum 20 lb/ft^2 in accordance with ANSI A58.1 and DOE-RL (1989), guidelines. The effects of live and dead loads and snowfall were found acceptable (Giller 1990). The building was deemed to meet DOE-RL (1993) criteria.

5.2.1.1.4 Ashfall Analysis. The 234-5Z Building roof was analyzed for natural phenomena hazard combined snow and volcanic ashfall loading and was found to meet DOE-RL (1989), design criteria (Giller 1990) (24 lb/ft^2). The building was deemed to meet design criteria in DOE-RL (1993).

5.2.1.2 234-5Z Description.

5.2.1.2.1 Function. The radiological operations performed in the 234-5Z Building are as follows:

- Reactive plutonium-bearing material stabilization (by thermal stabilization) in RMA and RMC Line gloveboxes HC-21C and HA-21I, with gloveboxes HC-21A, HC-18BS, HA-23S, HC-13MD, HC-18M, HC-1, HC-2, HC-3, HC-4, HA-22B and HA-28 supporting this process (see Chapter 6.0, Section 6.4.1, for a description of RMA/RMC Line reactive material stabilization).

- Plutonium-bearing solution stabilization (by the Production Vertical Denitration Calciner [VDC] process) in RMC Line glovebox HC-230C-2 with gloveboxes HC-18BS, HC-18M, HC-1, HC-2 and HC-3 supporting this process (see Chapter 6.0, Section 6.4.1, for a description of solution stabilization).

- Non-organic-residue-containing-plutonium-bearing-solution treatment using the Magnesium Hydroxide Precipitation Process gloveboxes, HC-230C-3 and HC-230C-4, in the RMC Line area. Equipment and operations involved in the process are described in the Magnesium Hydroxide Precipitation Process addendum to this FSAR (Carson 2000). The addendum contains the required page changes. No further discussion is provided in this chapter.

- Packaging plutonium materials in the Bagless Transfer System (BTS) glovebox, HA-53BTS. Equipment used in the process is described in the calculation notes for the BTS (FH 2000). No further discussion is provided in this chapter.

- Load-in/load-out (LI/LO) operations using glovebox HC-227S and hood HC-227T and interim storage.

- Laboratory functions (see Section 5.4.14 for details of the three supporting laboratories). Operations involving the Laboratory Prototype Calciner in the Plutonium Process Support Laboratory (PPSL) are discussed in the Laboratory Prototype Calciner addendum to this FSAR.

- Other production gloveboxes are used for storage and handling operations.

A cutaway of the 234-5Z Building (with aerial view of other PFP buildings) showing locations of the RMA and RMC Lines and LI/LO operation is given in Figure 5-8.

5.2.1.2.2 Components.

Remote Mechanical A and Remote Mechanical C Lines. Operations in the RMA and RMC (or "Button") Lines of the 234-5Z Building consist of reactive plutonium-bearing material (thermal) stabilization, plutonium-bearing solution stabilization, LI/LO operations using glovebox HC-227S and hood HC-227T, and interim storage of plutonium materials in active gloveboxes. The reactive material stabilization process uses gloveboxes HC-21C and HA-21I, with gloveboxes HC-21A, HC-18BS, HA-23S, HC-18M, HC-13MD, HC-1, HC-2, HC-3, HC-4, HA-22B and HA-28 supporting the process. Plutonium-bearing solution stabilization (by the Production VDC process) uses RMC Line glovebox HC-230C-2 with gloveboxes HC-18BS, HC-18M, HC-1, HC-2 and HC-3 supporting this process. Chapter 6.0, Section 6.4.1, provides descriptions of RMA/RMC Line reactive material stabilization and RMC Line solution stabilization processes. In addition to solution stabilization operations in the RMC Line, solutions are also stabilized during operations performed using the Laboratory Prototype Calciner in the Plutonium Process Support Laboratory (PPSL). The equipment and process descriptions for the laboratory calciner are provided in the Laboratory Prototype Calciner addendum to this FSAR. See Figure 5-9 for the general location of the RMA and RMC Line gloveboxes and control areas in the 234-5Z Building although some of the details shown for the RMA/RMC Lines are not current. Locations of the gloveboxes and control station that are used in the reactive material stabilization (thermal stabilization) and solution stabilization (Production VDC) processes are shown in Figure 5-10.

The RMA and RMC Lines are used to reduce the inventory of unstable plutonium-bearing materials and solutions that do not meet criteria for secure, long-term storage. These materials and solutions are currently being stored in various gloveboxes and vaults at PFP. Following stabilization in gloveboxes in the RMA and RMC Lines, the stabilized materials in the form of PuO_2 are packaged for long-term storage in one of the vaults at the PFP.

The RMA Button Line portion of the RMA Line was used to produce plutonium oxide powders and buttons but is not currently authorized for production operations. The line is located to the north of the RMC Line and occupies rooms 235A-1, -2, and -3, and 232-A with the now inactive control room in room 233 (see Figure 5-9).

The RMC Line (or C Button Line) occupies rooms 227, 228A, 228B, 228C, 230A, 230B, 232, and 166 with the now inactive control room in room 229 (see Figure 5-9). Plutonium conversion operations, i.e., the conversion of plutonium oxide to plutonium metal buttons, were formerly conducted using the RMC Line but these operations are not currently authorized (see Chapter 6.0, Section 6.4.3).

Reactive Plutonium-bearing Material Stabilization Summary. There are five categories of reactive plutonium-bearing material containing less than 10 g of organic per charge that are thermally stabilized in the muffle furnaces in Glovebox HC-21C. The furnaces in Glovebox HC-21C are used to stabilize PRF sludges from the last PRF campaign, mixed uranium and plutonium oxides (MOX), floor sweepings, plutonium oxalates, and plutonium oxide to meet long term storage requirements. The furnaces in Glovebox HA-21I are used to thermally stabilize all of the categories of reactive plutonium-bearing material that are stabilized in Glovebox HC-21C except PRF sludges. Plutonium oxides consist of both "clean" and non-product quality plutonium oxides. "Clean" plutonium oxide is defined as materials containing no organic contaminants, plastic, debris or pyrophoric material whereas non-product quality plutonium oxides may contain some of these contaminants.

Processing operations are initiated with the selection of containers from storage. Only containers meeting the type A or B definitions shown in Figure 5-69 may be selected for processing to minimize the amount of hydrogen potentially available for reaction when opening the container. The containers of plutonium-bearing materials are sealed-in using either glovebox HC-21A, HC-13MD or conveyor glovebox HA-28, removed from the package, weighed, placed into a container called a boat which is then covered and transferred via the conveyer system to glovebox HC-21C or HA-21I. The boat cover is removed and the boat is placed into a muffle furnace and the appropriate temperature controller program is started. The controller (or control program) is pre-programmed to ramp and hold the furnace temperature at rates and temperature soaks specific to the material being processed. The material is cooled, ground, sampled, and analyzed to verify that the material meets vault storage criteria. A loss-on-ignition (LOI) analysis is used to verify volatiles have been removed. The processed material is then packaged for long term storage (see Chapter 6.0, Section 6.4.1, for a complete description of the reactive material stabilization process).

Plutonium-bearing Solution Stabilization Summary for the Production VDC Process. The PFP currently contains significant quantities of plutonium-bearing solutions that are in a form considered unsuitable for long-term storage. These solutions primarily consist of the following:

- Plutonium nitrate solutions
- Concentrated filtrate solutions
- Flush solutions.

As part of the PFP cleanout operations, these solutions are stabilized by conversion to plutonium oxide which is suitable for long term storage. The Production VDC process (not authorized for operation) is used to stabilize the solutions by heating the material to a temperature of 1000 °C. Only the plutonium nitrate solutions are suitable for direct stabilization using the Production VDC process. The other two solutions require pretreatment prior to

processing in the VDC. Only processing of the plutonium nitrate solutions in the VDC are covered in this revision of the PFP FSAR. The pretreatment and processing of the other two solutions will be added in a future revision of the FSAR.

Processing using the Production VDC begins by loading in the plutonium nitrate solutions using the LI/LO gloveboxes, HC-227S/HC-227T. The solutions are sampled and blended, as needed, and pumped to the VDC glovebox, HC-230C-2, where they are processed through the VDC. The finished product is transferred to glovebox HC-18M where a sample is removed. The sample is transferred to the PFP Analytical Laboratory where the LOI is determined. If the LOI results are acceptable, the finished product in glovebox HC-18M is appropriately packaged and transferred to the storage vaults. Items not passing the LOI are reprocessed through the muffle furnaces in Glovebox HC-21C or HA-21I as described for reactive material stabilization.

See Chapter 6.0, Section 6.4.1, for details of the solution stabilization operations using the Production VDC process and subsequent paragraphs of this section for descriptions of the components used in the solution stabilization operations.

In addition to solution stabilization using the Production VDC, solutions are also stabilized during operation of the Laboratory Prototype Calciner (not authorized for operation) in the PPSL. The laboratory calciner operations are discussed in the Laboratory Prototype Calciner addendum to this FSAR.

Reactive Material Stabilization Process Control Station (Room 230A). Room 230A (Figure 5-9) contains the HC-21C glovebox, a control console/annunciator panel for the HC-21C glovebox, a Computer Display Screen for the HA-21I gloveboxe (see Figure 5-10 for console locations), and a CO_2 cabinet. Control of the current RMA and RMC Line thermal stabilization process is maintained in this room. At least one operator is stationed here when the process line is in operation. Cameras provide remote viewing of the HA-21I glovebox. The 5-in. mercury vacuum system is operated from the control consoles and the 26-in. mercury process vacuum system is controlled from the MICON™ control station (see Section 5.4.5 for details of the vacuum systems).

- The HC-21C Control Panel. The furnace temperatures in glovebox HC-21C are controlled by digital temperature controllers with setpoint programming. Each furnace in HC-21C has a separate control system. The controllers are preprogrammed and the program is protected from unauthorized changes. The operator selects the program desired and activates startup of HC-21C from the control panel. The controller sends output to a silicon controlled rectifier (SCR), which regulates the power to the furnace. A temperature limit switch provides an independent control for furnace overheat. Lights on the control console indicate when power is supplied to the furnaces. The controllers are equipped with a temperature deviation alarm that removes power from the furnace when the furnace setpoint deviation reaches the alarm setpoint. A temperature monitor compares the input from three thermocouples set to measure glovebox temperature and removes power when the temperature exceeds the setpoint. The console also has a manual switch to remove power from the furnace elements.

- The HA-21I Control Computer. The furnace temperatures in glovebox HA-21I is controlled by a programmable logic controller (PLC). The setpoints and alarms are programmed on the PLC. Each furnace in HA-21I is controlled by the PLC. A personal computer (PC) interfaces with the PLC. The PLC is preprogrammed and the program is protected from unauthorized changes. The operator selects the desired program on the PC and activates start up. The PLC controller sends output to an SCR, which regulates the power to the furnace. A separate program on the PLC provides a temperature limit switch as an independent control for furnace overheat. Displays on the PC indicate when power is supplied to the furnaces. The PLC controllers are equipped with a temperature deviation alarm that removes power from the furnace when the furnace to setpoint deviation reaches the alarm setpoint. Glovebox temperatures are also monitored by the PLC. The PLC compares the input from three thermocouples and removes power from the furnaces when glovebox temperature exceeds the setpoint. The PC contains an icon for emergency shutdown of the furnaces in glovebox HA-21I. The 5-in. mercury vacuum system is operated by this control console.

Plutonium-bearing Solution Stabilization Process Control Station for the Production VDC Process. A Modular Automation System (MAS) located on the mezzanine in room 235B controls the Production VDC and instruments in the VDC glovebox, HC-230C-2. The controls and alarms for the MAS associated with glovebox HC-230C-2 are available on an operator display screen located near the local control panel at the control station in room 230C. The control station allows access to the MAS to control the operations in glovebox HC-230C-2. Due to the potential for high radiation exposure, the control station is separated from the glovebox by sufficient space or shielding to protect the operator from excessive exposures.

The Production VDC is automatically controlled from the programmable logic controller located in room 235B (refer to Figure 5-10). The local control panel in room 230C houses the furnace power supply computer console and emergency shutdown features. This panel is also used as a termination cabinet for control and power wiring between the program logic controller and the relay cabinet (MAS) located on the mezzanine in room 235B. The relay cabinet located in room 235B houses the bulk of the control components used to operate the calciner glovebox.

Details of the instrumentation and control for the production calciner process are provided in the following sections of the FSAR:

Chapter 5.0, Section 5.2.1.2.3, "Design Bases and Safety Assurance"
Chapter 6.0, Section 6.4.1.4, "Chemical Process Systems"
Chapter 6.0, Section 6.4.1.5, "Instrumentation and Control Systems"
Chapter 6.0, Section 6.4.1.9, "Identification of Items for Safety Analysis."

In addition to solution stabilization using the Production VDC in the RMC Line, the Laboratory Prototype Calciner in the PPSL also stabilizes solutions during operation. The laboratory calciner is discussed in the Laboratory Prototype Calciner addendum to this FSAR.

Remote Mechanical A Line Control Room (Room 233) Oxide Line Control Room. The control room (now unused) for the RMA Line is shielded by concrete, steel water walls, and water-filled viewing windows. The large, transparent panels provide good visibility from the control room of personnel working at the gloveboxes and of the level and color of solutions. It is a long, narrow room with control positions along a bench below the viewing windows. The original control room allowed operators to visually observe activities in the RMA Oxide Line. Spotlights and closed-circuit television were provided to aid in viewing. See Figure 5-9 for the location of the RMA Line control room.

Remote Mechanical C Line Control Room (Room 229) Button Line Control Room. This room (now unused) is a shielded facility from which the operation of most of the liquid handling and mechanical equipment is controlled. A series of control desks face the gloveboxes, and visibility of the various pieces of equipment is made possible by a line of water-filled windows along the south and west walls of room 229 and by the presence of windows on the north side of glovebox HC-1. Operators at control desks opposite the individual gloveboxes could operate the sweep arms, conveyor, hydraulic lifts, and much of the other equipment in the gloveboxes. See Figure 5-9 for the location of the RMC Line control room.

Remote Mechanical A and C Line Glovebox General Features. The RMA and RMC Line gloveboxes are constructed of stainless steel frames and floors and clear, self-extinguishing or nonself-extinguishing polycarbonate safety sheets, or glass and wire-mesh panels on the sides and top. The panels are penetrated by gloveports, bag-in/bag-out ports, sphincter ports, solution transfer lines, and instrument and electrical connectors. Thick polycarbonate panels, water walls, leaded safety glass, and lead-filled gloves provide neutron and gamma-ray shielding.

Remote Mechanical A and C Line Glovebox Equipment for Reactive Plutonium-bearing Material Stabilization (Thermal Stabilization). The following provides a detailed description of the support systems and equipment found in the RMA/RMC Line process gloveboxes used in the thermal stabilization process.

- The 4,000 W muffle furnaces have an operating temperature range of 150 °C to 1093 °C. A door safety switch removes power to the heating elements when the door is opened. Factory drilled holes have been located in the back plate of the furnace for the CO_2 supply line, the exhaust line, and two thermocouples. The holes for the CO_2 line in the furnaces located in gloveboxes HA-21I and HA-20MB are plugged.

- The boats (referred to as "cake pans") have a volume of 2.2 L. They are made of 1/8-in. Hastelloy X™.

- The exhaust line from each furnace in glovebox HC-21C ties into the plant 26-in. mercury vacuum system. The exhaust air first passes through a ceramic filter and then a needle valve that is used to adjust flow rates. An orifice and differential pressure gauge is used to maintain flow within limits. A rotameter is used to establish a differential pressure across an orifice to set-up flow. The rotameter is then bypassed and the offgas flow monitored using differential pressure across an orifice to detect variation in flow

during the processing cycle. Heat resistant tubing is used between the furnace and filter housing.

- The exhaust line from each furnace in glovebox HA-21I ties into a 5-in. mercury vacuum system. Similar to the HC-21C system, the exhaust first flows through a ceramic filter and then through an orifice and DP gauge to maintain flow within limits. The DP gauges are located on a rack located on the mezzanine in room 235. The flow is controlled by a needle valve to maintain an exhaust flow rate of at least 2 to 3 f^3/m.

- A baffle is installed in each of the furnaces to reduce the amount of material being sucked into the offgas line and depositing on the ceramic filter. From there the air passes through two stages of HEPA filtration before entering one of two 2.5 hp blowers located in the duct level (room 264). The blowers can be started remotely at the control station or directly at the pumps.

- A stainless steel housing with ceramic filter media is installed in the exhaust line to filter out suspended particles in the offgas. The filters remove particulates greater than 2 μm. The ceramic filters have a DP gauge to indicate if the filter becomes plugged. The DP is checked before starting the heating cycle. When the filter becomes plugged, it is cleaned and reused. The housing provides capability of cleaning.

- The CO_2 is supplied to glovebox HC-21C by a CO_2 station in room 230A. The station consists of a cabinet that houses two liquid CO_2 cylinders. A manifold automatically switches to another cylinder when one empties. The cylinders are equipped with a sight glass to determine liquid level. The station is equipped with a visual alarm mounted on the outside of the cabinet that alarms when the manifold switches. Each bottle is equipped with a vent that vents roughly 2 lb of CO_2 per day to reduce the bottle pressure.

- An electric Mettler balance in room 228C is used to weigh the product material once it has been canned (in addition to the scales located in gloveboxes HC-18M and HC-21A).

- Two canners are located in room 228C. One canner is used to seal a slip lid into a secondary can. The second canner is set up to seal the PUREX secondary can into a 7-in. can.

Remote Mechanical A Line Thermal Stabilization Process Gloveboxes. The RMA Line gloveboxes used for thermal stabilization processes are as follows: HA-22B, HA-23S, HA-28, and HA-21I. The criticality prevention specification and seismic qualifications of these gloveboxes are given in Table 5-5.

- Glovebox HA-22B. This glovebox is located in room 235-B. It is approximately 3 ft long, 2 ft 6 in. deep and 4 ft 6 in. high. It is used to seal-in containers of plutonium material for transfer by conveyor Glovebox HA-28 to Glovebox HA-23S for storage of the containers and for staging items into and from glovebox HA-21I.

- Glovebox HA-23S. This glovebox is located in room 235-B. It is 12 ft 3 in. long, 3 ft deep, and 8 ft 10 in. high (Figure 5-12). It is used for feed lag storage for the thermal stabilization process.

- Conveyor Glovebox HA-28. This glovebox is located in room 235-B/C, with the very end of the conveyor in room 235-A1. Conveyor Glovebox HA-28 houses a conveyor that is used to move items between gloveboxes HA-19, HA-20MB, HA-21I, HA-22B and HA-23S and for moving items to and from the RMC Line. HA-28 also serves as the ventilation supply plenum for Gloveboxes HA-23S, HA-21I, HA-19, HA-20MB and HA-22B in the RMA Line and Glovebox HC-230C-2 in the RMC Line.

- Glovebox HA-21I. This glovebox is used to thermally stabilize reactive plutonium-bearing material. It is about 13 ft long, with the inside of the glovebox floor being about 43 in. wide (Figure 5-13) with a criticality drain. The glovebox is supported by a stand so that the floor of the glovebox is 36 in. above the room floor. Barriers are installed between the legs of the support frame to prevent a fissile material transport wagon from being placed under the glovebox. Conveyor HA-28 runs along the south end of the glovebox and fits closely to the working floor. There are three muffle furnaces in HA-21I that are operated by a PLC. Offgas is removed via a dedicated 5-in. mercury vacuum system that empties into the E-4 exhaust system.

Remote Mechanical A Line Miscellaneous Gloveboxes. The remainder of the RMA Line gloveboxes (those not used in the thermal stabilization process) are inactive. Gloveboxes which are inactive comply with criteria given in Criticality Prevention Specification, CPS-Z-165-80010 (FH 2000) and PFP Operational Safety Requirements, WHC-SD-CP-OSR-010, which state that introduction of containers of plutonium material is prohibited. No new process equipment will be installed in these gloveboxes, and any changes made to these gloveboxes (following USQs) should be related to cleanup activities of the gloveboxes. Inactive gloveboxes of the RMA Line consist of the following: formerly wet process gloveboxes (HC-6, H-7A, HA-9A, H-14P) and dry process gloveboxes (H-8A, H-9B, H-9C, H-9D, H-9E, HC-10, H-11, H-12S, H-13MD, H-13G, H-13ABC, H-14CC, H-14DC, H-14S, H-15B, H-15, H-16CS, H-16BS, H-16L, and HA-19). See Figure 5-9 for RMA Line glovebox locations. A list of inactive RMA Line gloveboxes and their process functions is given in Table 5-6.

Remote Mechanical C Line Thermal Stabilization Process Gloveboxes. The RMC Line gloveboxes used for thermal stabilization processes are HC-1 (supply plenum only and to pass items between glovebox HC-18BS and glovebox HC-18M), HC-2, HC-3, HC-4, HC-21A, HC-21C, HC-18BS, HC-13MD, and HC-18M. The criticality prevention specifications and seismic qualifications of these gloveboxes are given in Table 5-5.

- Conveyor Gloveboxes HC-1 and HC-2. Gloveboxes HC-1 and HC-2 are conveyor gloveboxes. Glovebox HC-1 connects the middle section of HC-9B (through the cross conveyor) to all the other processing gloveboxes in room 228, except HC-7 and HC-17P. Glovebox HC-2 extends from glovebox HC-18BS to an airlock in room 230-B. Gloveboxes HC-21A and HC-21C are also connected to the HC-2

conveyor. The conveyors are in use to provide ventilation to the existing gloveboxes and to support the reactive material stabilization activity as described in Section 6.4.1.4.2. See Figures 5-9 and 5-10 for the locations of the glovebox conveyors.

The gloveboxes are equipped with 4 1/2 in. wide, electrically powered, slat conveyors that travel between 5/8 in. high guide rails separated by a distance of 7-5/8 in. Powder pans were used to transport PuF_4 powders, scrap materials, and other miscellaneous materials along the conveyors. The HC-1 conveyor glovebox also carried pressure vessels and the round pallets used to transport and store buttons. Electrically driven sweep arms at the various gloveboxes sweep the containers off and onto the conveyor.

The conveyor gloveboxes serve as plenums that deliver air to all the adjoining gloveboxes except the top and bottom sections of HC-9B and HC-17P (Figure 5-14). Air is normally exhausted through high-efficiency particulate air (HEPA) filters located in the gloveboxes and out the E-4 gas system. At least -0.5 in. w.g. pressure is maintained in the gloveboxes by the exhaust system.

HVAC supply air from the dry air system (also known as zone-4 supply air) enters at the top of glovebox HC-2 (conveyor) adjacent to glovebox HC-18BS, through a 4-in. self-governing regulating valve rated at 250 std ft^3/min. Flow is regulated between 25 to 250 std ft^3/min. The sensing pressure is applied directly to the diaphragm chamber to control pressure between -0.5 to -1.2 in. w.g. and is able to operate from full-open to full-closed within 3 s. As pressure increases to greater than -0.5 in. w.g. the valve closes, thus avoiding loss of negative pressure, overpressurization, or discharge of air through an open port (see Section 5.4.1 for more details of the HVAC system; see Section 5.4.3.1.3 for details of the dry air system).

A differential pressure switch connected to an annunciator in the power control room monitors the pressure in the dry-air gloveboxes and alarms if it exceeds -0.3 in. w.g. The operator can shut down the line if necessary.

Two similar valves regulate exhaust on an emergency basis. Each parallel 4-in., 200 std ft^3/min valve connects to a common, locally unfiltered 8 in. diameter duct to exhaust a total of 400 std ft^3/min. The valves are normally closed tight for any upstream pressures less than -0.5 in. w.g. They are set to start opening at -0.45 in. w.g. and to be opened fully before upstream pressure becomes positive. The resulting flow of unfiltered air goes to the 12 in. diameter E-4 header in room 263 above the RMC Line and to four primary filterboxes connected in parallel.

An electrically controlled valve located on the 8 in. diameter emergency exhaust duct is interlocked with the glovebox heat detectors. If a fire with sufficient heat to activate the heat detectors occurs, the emergency duct valve would close to prevent air flow removal of the Halon fire suppression gas. This would also

reduce the heat load on the first-stage filters and reduce the flow of air aiding the fire.

A 12 in. diameter unfiltered duct, equipped with a manual valve, is located on the west end of glovebox HC-2. This valve is used to regulate airflow during glovebox panel changes.

Large windows on the north side of conveyor glovebox HC-1 enable the control room operators to see from the control room into individual gloveboxes. Equipment controls are located on a console in line with each glovebox. In addition, this glovebox is equipped with a criticality drain serving the gloveboxes that it connects. It also has a fire detector.

- Conveyor Glovebox HC-3. Glovebox HC-3 is located in room 230C. The glovebox houses a conveyor that is used to move items between conveyor gloveboxes HC-2 and HC-4 and glovebox HC-230C-2.

- Conveyor Glovebox HC-4. Material is transferred from and to the HA-28 conveyor to and from HC-3. The criticality prevention specification limit and seismic qualification of this glovebox is given in Table 5-5.

- Glovebox HC-13MD. Glovebox HC-13MD is located in Room 228-B and is connected to the HC-1 conveyor glovebox. This glovebox has a radiological containment tent attached when needed to facilitate seal-in and bag-out of plutonium bearing materials.

- Gloveboxes HC-21A and HC-21C. These gloveboxes are stainless steel framed with the following dimensions: 10 ft 8 in. long (not including an airlock on the south end), 3 ft tall, and 3 ft 6 in. deep (Figure 5-15). Gloveboxes HC-21A and HC-21C are in rooms 230B and 230A, respectively. Glovebox HC-21A is used for product handling. Glovebox HC-21C is used for thermal stabilization of reactive plutonium-bearing materials. The inside of the working floor of each glovebox is 42 in. wide, with a sloping face along its entire length on the east side. Each glovebox has a lower section that is isolated from the upper section and will not be used for stabilization activities. Each glovebox is supported by a stand, and the glovebox floor is 54 in. above the room floor. The HC-2 conveyor runs along the north end of each glovebox and fits closely to the respective working floor. A filter assembly leads from the tops of the gloveboxes into the E-4 ventilation exhaust system of the 234-5Z Building.

  For Glovebox HC-21A operation, reactive Pu-bearing materials from Building 2736-Z and Building 234-5Z storage vaults are sealed into the gloveboxes. Batches for stabilization are made up by loading measured quantities into boats which are transferred to HA-21I or HC-21C. In-process materials from any other active glovebox can be transferred into HC-21A via the HC-2 conveyor glovebox. Emptied boats are returned to HC-21A. Glovebox HC-21A may contain electric scales, a storage rack, a mortar and pestle, and a Mettler balance to provide an alternate location for performing the operations

normally done in Glovebox HC-18M. In this case, approximately 10-g samples of powder are taken from product cans and placed into vials for LOI testing. PUREX slip-lid cans of thermally treated material that successfully meets the LOI testing requirements are sealed out of HC-21A in a polyethylene plastic bag, placed into a PUREX secondary can, and hand carried to the canners in room 228C.

Glovebox HC-21C contains a deactivated sweep assembly located next to the HC-2 conveyor system which was formerly used for transferring items from the conveyor across slide plates to the glovebox. Items are now hand transferred from the conveyor glovebox to Glovebox HC-21C. Glovebox HC-21C contains two muffle furnaces equipped with CO_2 purge systems and may contain two stainless steel desiccators. The CO_2 flow rate is indicated on rotameters and controlled by using built-in manual valves. Offgas is removed via the 26-in. mercury vacuum system. Carbon dioxide purge is used during the thermal stabilization of PRF sludge material. A rotameter is adjusted to provide the desired flow rate of CO_2 purge into each furnace. Purge by CO_2 gas is not required for stabilization of "clean" plutonium oxide. Two thermocouples are installed in the furnace to measure furnace temperature.

- Glovebox HC-18BS. This glovebox is 8 ft 1.8 in. long, 6 ft 10 in. deep, and 2 ft 6.1 in. high. It is used as product lag storage. A serpentine conveyor belt provides lag storage and carries product from HC-2 to the glovebox interior and also to the exit point for transfer from HC-18BS to HC-18M.

- Glovebox HC-18M. This glovebox is used for product sieving, grinding, sampling, weighing and load-out. It contains scales, mortar & pestle, sieve shaker, tools, and equipment for performing these operations.

Remote Mechanical C Line Glovebox for Solution Stabilization Using the Production VDC. RMC Line glovebox HC-230C-2 is used for solution stabilization operations using the Production VDC process. Figure 5-65 is an isometric view of glovebox HC-230C-2. The description of the Production VDC process in the glovebox is provided in Chapter 6.0, Section 6.4.1. In addition to solution stabilization using the Production VDC, solutions are also stabilized during operation of the Laboratory Prototype Calciner. The process and equipment for the laboratory calciner are discussed in the Laboratory Prototype Calciner addendum to this FSAR.

As shown in Table 5-5, the glovebox structure is seismically qualified for the design basis earthquake (DBE) of 0.2 g horizontal ground acceleration. However, the viewing windows have not been specifically designed to withstand the earthquake. The glovebox criticality prevention specification limits are also shown in Table 5-5 and are based on the Criticality Prevention Specification (CPS) (CPS 1997). The principal criticality limits are a plutonium nitrate feed concentration <450 g-Pu/l, and a maximum Pu product density of 5.5 g-Pu/ml.

Supporting the solution stabilization operations using the Production VDC are conveyor gloveboxes HC-3 and HC-2 and gloveboxes HC-21A, HC-18BS, HC-1 and

HC-18M which provide for material transfer, product sampling and packaging and product testing. These supporting gloveboxes are described in this section under the heading "Remote Mechanical C Line Thermal Stabilization Process Gloveboxes."

- Glovebox HC-230C-2. This glovebox is of lead-lined, stainless steel construction with either wire-reinforced glass or Lexan viewing windows and glove ports to permit access to internal components. The Lexan windows are used because the material does not warp under heat stress and requires an external heat source to initiate and sustain a fire (self extinguishing). The glovebox is provided with a criticality drain to prevent spilled solutions from reaching a depth that could result in a criticality.

  The glovebox provides confinement for the Production VDC process equipment which consists of various pumps, tanks, the calciner, an offgas scrubber and related piping, valves and instrumentation. Figure 5-66 shows the flow diagram for the Production VDC process system and Figure 5-67 presents the process flow sheet. The major components for the Production VDC process are described in this section of the FSAR under the heading "Remote Mechanical C Line Solution Stabilization Glovebox Equipment."

  Support services for the glovebox required for Production VDC process operations include ventilation supply and exhaust, 26-in. Hg process vacuum, bottled compressed dry air, plant process air, fire suppression, electrical power, Pu nitrate solution transfer line, caustic and acid supplies, and chilled water.

  Ventilation supply and exhaust systems are used to maintain negative pressure within the glovebox relative to room 230C. The ventilation systems also provide for removal of excess heat from the glovebox resulting from production calciner operation to prevent excessive internal glovebox temperatures.

  Ventilation supply for the glovebox is provided through the connection to the HC-3 conveyor glovebox. The transition section connecting the HC-230C-2 glovebox to the HC-3 glovebox is designed so that seismic forces will not be transmitted between the two gloveboxes. The transition section and glovebox HC-3 are not seismically qualified.

  Ventilation exhaust for the glovebox is through a testable HEPA filter at the E-4 exhaust system connection to the glovebox. The connection to the E-4 system contains a bellows, downstream of the filter, which is designed to fail in a seismic event such that seismic forces are not transmitted between the E-4 system and the glovebox. In addition, the HEPA filter media has not been specifically designed to withstand seismic forces.

  Offgases generated in the calciner during Production VDC process operations are removed by the 26-in. Hg process vacuum system. These gases are processed through a scrubber system prior to entering the vacuum system for discharge to the atmosphere.

Bottled compressed dry air is supplied from an external 4-bottle rack located in the hall outside room 230C. The dry air is required for atomizing the production calciner feed stream and to provide pulse-air to periodically backflush the calciner offgas filters to prevent plugging.

Plant process air is provided to run some of the process pumps in the glovebox and for operation of various process valves associated with Production VDC operations.

Because of the high temperature operations and potential for fire, the glovebox is provided with a fire detection system and a dry chemical fire suppression system. To minimize fire potential, combustible materials in the glovebox are kept to a minimum and gloves are pulled out of the glovebox when not in use.

Electrical power requirements are supplied from an electrical box on the end of the glovebox to components within the glovebox. Power is from a 480V panel in room 235B. The bulk of the power is required to operate the high temperature furnaces providing heat for the production calciner.

A solution transfer line connects glovebox HC-230C-2 in room 230C to glovebox HC-227S in room 227. The line enables transfers of Pu nitrate solutions to glovebox HC-230C-2 for processing. It also enables transfer of solutions from glovebox HC-230C-2 to glovebox HC-227S. The transfer line consists of an outer stainless steel encasement enclosing three stainless steel tubes. One tube is for transfer into glovebox HC-230C-2 and the other is for transfers out of the glovebox. The third tube is a spare. The outer encasement includes a leak detection system which is resistant to acids, bases, and solvents. The transfer line is not designed for the DBE but does meet *Uniform Building Code* (UBC) seismic requirements.

Nitric acid flush solution is provided by a connection between the glovebox and an external tank in room 230C. The acid is used to flush the feed pump and line and the production calciner.

A caustic solution (NaOH) is used in the scrubber in the offgas scrubber system. The NaOH is pumped from 55-gal drums from the solution drum station in room 230C.

Chilled water supply and return lines are provided for operation of the scrubber in the glovebox. The chiller unit is in room 263 external to glovebox HC-230C-2.

Remote Mechanical C Line Glovebox Equipment for Solution Stabilization using the Production VDC. The following provides a description of the equipment provided in glovebox HC-230C-2 which is used for solution stabilization operations using the Production VDC process. Equipment used in solution stabilization operations using the Laboratory Prototype Calciner is described in the Laboratory Prototype Calciner addendum to this FSAR.

- Calciner. The Production VDC is an annular-shaped chemical reactor with a 4-in. 310S stainless steel pipe on the inside and a 6-in. 310S stainless steel pipe on the outside. The 4-in. section is dome shaped and welded to the base plate and the outer 6-in. pipe is bolted to the base plate. The outer pipe is connected by a flange at the top to another 6-in. pipe above it. This second 6-in. pipe is flanged to plates that hold and cover the ceramic filter elements used to remove solid particles from the offgas. The vertical calciner is approximately 40 in. high. Figure 5-19 is a schematic of the Laboratory Prototype Calciner used in laboratory testing in the PPSL. The Production VDC for solution stabilization operations is similar in design and construction. The production calciner supports are seismically qualified for the UBC earthquake but the calciner has not been specifically designed to withstand seismic forces.

  The Production VDC operates by injecting liquid feed solution upward through the base into a bed of hot (1000 °C) oxide powder. The oxide powder is kept in motion through the action of an agitator driven from above. As the feed solution contacts the hot oxide, it flashes off the liquid as steam. The solid residue left behind quickly oxidizes as it works its way upward through the material bed. When the level builds up above a set amount, the top surface overflows into a collection vessel located below the calciner. The vapors and decomposition gases pass upward through a set of three one-micron ceramic offgas particle filters within the calciner vessel prior to treatment in the offgas scrubber.

  The production calciner is heated through a dual furnace system. A small cartridge heater operating at about 1400 °C heats the surface of the overflow dome to 1000 °C. A high power vertical tube furnace surrounds the lower section of the calciner. This "jacket heater" operates at up to 1650 °C providing radiant heat to the calciner vessel adjacent to the bed of oxide material.

- Process Tanks. The various process tanks consist of the feed receipt tank (FRT), feed pump tank (FPT), flush tank (FT), chemical addition tank, phase separator tank (PST), vacuum trap (VT), vent catch tank (VCT), and spent scrubber solution receiver tanks (SSSRT). The process tank functions, level monitoring instrumentation, materials of construction and sizes are described in the following subparagraphs. The supports for the various process tanks have been designed to meet UBC seismic requirements but the actual tanks have not been specifically designed to withstand seismic forces.

  - Feed Receipt Tank. The FRT basically provides surge capacity for Pu nitrate solutions transferred between the HC-227S LI/LO glovebox and the Production VDC feed pump tank in glovebox HC-230C-2. The tank is of glass construction with stainless steel end flanges. The tank is approximately 6 in. in diameter and 24 in. long with a nominal operating volume of 10 L. Tank level is monitored using a conductivity probe.

- Feed Pump Tank. The FPT provides storage capacity of Pu nitrate solutions for transfer by the feed pump to the production calciner. The tank is of glass construction with stainless steel end flanges. It measures approximately 6 in. in diameter by 24 in. long with a nominal operating volume of 10 L. Tank level is monitored by weight factor instrumentation.

- Flush Tank. The FT receives nitric acid from the external chemical addition tank in room 230C to provide flush solution for the feed pump, feed line and the production calciner. The tank is of glass construction with stainless steel end flanges. It measures approximately 6 in. in diameter by 12 in. long with a nominal operating volume of 4 L. Tank level is not monitored except by visual observation.

- Chemical Addition Tank. The chemical addition tank is located outside glovebox HC-230C-2 in room 230C. The tank contains the nitric acid solution for makeup to the flush tank. It is of stainless steel construction and measures approximately 8 in. in diameter by 16 in. long with a nominal operating volume of 10 L.

- Phase Separator Tank. The PST accumulates the overflow solution from the scrubber for periodic transfer to the SSSRTs. The PST also provides a second removal stage to separate the gases from the liquids. The gases flow to the VT and are discharged to the plant 26-in. Hg process vacuum system. The liquids are either returned to the scrubber or transferred to the SSSRTs.

  The phase separator tank is a 6 in. by 36 in. glass tank with stainless steel end flanges. The tank contains stainless steel demister material 6 to 7 in. from the top. Tank level is monitored by conductivity probes inserted through the top of the tank to give both high- and low-level indication.

- Vacuum Trap. The VT provides the vacuum interconnection between the Production VDC process equipment and the plant 26-in. Hg process vacuum system. Offgases from the calciner flow to the vacuum trap after passing through the scrubber and are released to the atmosphere via the plant vacuum system. The VT allows for vapor and liquid to be captured so as not to enter the vacuum system where they could present a criticality hazard. The liquids are then drained to the VCT.

  The VT is of glass construction with stainless steel end flanges. It measures approximately 6 in. in diameter and 18 in. long with a nominal operating volume of 7 L. Tank level is monitored by conductivity probes.

- Vent Catch Tank. The VCT provides for collection of vapors and liquids which may overflow from the FRT, FPT and FT. It also receives liquids drained from the VT.

The VCT is of glass construction with stainless steel end flanges. It measures approximately 6 in. in diameter and 12 in. long with a nominal operating volume of 4 L. Tank level is monitored by visual inspection.

- Spent Scrub Solution Receiver Tanks. The two SSSRTs receive spent scrubber solution from the PST. These solutions are then gravity drained to waste tank TK-D8 in Building 241-Z for eventual transfer to the tank farms. Each SSSRT consists of two parallel tanks. Each tank is of glass construction with stainless steel end flanges. They measure 6 in. in diameter and 48 in. long with a nominal operating volume of 20 L (40 L per bank). Tank level is monitored by weight factor instrumentation.

- Scrubber. The offgas scrubber processes the production calciner offgases by bubbling the heated gases through a chilled caustic solution. It cools and condenses out excess water vapor, while at the same time removing NO_x and corrosives from the offgases. A cooling loop is suspended down through the center of the scrubber. The cooling loop is positioned to allow circulation within the scrubber on the outside and inside of the cooling loop. A 1-in. pipe extends from the top of the scrubber to the base of the cylinder for offgas flow into the scrubber through a box constructed of stainless steel sintered plate.

  The scrubber is made of 6-in. tempered glass pipe with stainless steel end caps. It stands about 48 in. tall and contains about 15 L of NaOH solution. The gases pass downward under vacuum through a stainless steel inlet tube and dispersing filter. Small bubbles provide pumping action to circulate the scrub solution around the cooling coils and suspends precipitated solids. Condensate, caustic make-up solution and suspended solids overflow through an internal stand pipe and are transported under vacuum to the phase separator tank.

  - Chiller. The chiller pumps water through the scrubber cooling coils, providing cooling to maintain the scrub liquid at about 10 °C. The chiller operates from a 480 V power supply to provide 10,650 W of cooling capacity.

- Process Pumps. Two identical metering (positive displacement) pumps are provided, one (P-230-A) for the Pu nitrate feed solution, and one (P-230-B) for the scrubber caustic (NaOH) makeup. The pumps are electrically driven and are capable of accurately metering solutions from 0 L to at least 4 L, but no more than 10 L per hour. They are compatible with corrosive and caustic solutions and are capable of limiting output pressure to 50 psi or less.

  Three other pumps support Production VDC process operations, each of which are compressed air operated, double diaphragm pumps. Air is provided by the plant process air system. One of the pumps, P-230-C, provides recirculation of scrubber solution from the phase separator tank to the scrubber or transfers spent scrub solution

from the phase separator tank to the spent scrub solution receiver tanks. Pump P-230-D provides recirculation of spent scrub solution through the receiver tanks. The P-230-E pump is used for transfers of various solutions from the Production VDC process tanks to the HC-227S glovebox. Temporary connections may be made when there is a need for solution transfer.

All pumps are constructed of materials resistant to the corrosive affects of acids, bases, and solvents.

Remote Mechanical C Line Miscellaneous Gloveboxes. The following RMC Line gloveboxes are only used for interim storage and handling of plutonium material: HC-4, HC-7, HC-9B, HC-11, and HC-5. See Figure 5-9 for glovebox locations. Previous production process functions, equipment, and design bases of these RMC Line gloveboxes are given in Table 5-7. Schematics of various RMC Line gloveboxes are provided in Figure 5-16, sheets 1 through 11 (individual gloveboxes are called out in Table 5-7 where appropriate).

Room 227 Load-in/Load-out Operations. Room 227 in the 234-5Z Building houses hood HC-227T and glovebox HC-227S (see Figure 5-9 for layout and Table 5-5 for the criticality prevention specifications and seismic qualifications of the hood and glovebox). The hood and glovebox are used in the LI/LO operations for plutonium-bearing nitrate solutions and for blending processes in the glovebox. The glovebox is also used to transfer Pu nitrate solutions to glovebox HC-230C-2 in room 230C for stabilization operations using the Production VDC. Solutions are loaded into the glovebox using the hood which accommodates either product receiver (PR) cans or 10-L polyethylene bottles transported in their outer containers, though other containers also may be used. The glovebox may also be used to load-out solutions to suitable containers located in the hood or to smaller containers which are removed directly from the glovebox through bag-out ports. Chemical solutions required for LI/LO operations in glovebox HC-227S and hood HC-227T are supplied via piping from room 336.

Glovebox HC-227S is the source of solutions for transfer to the Laboratory Prototype Calciner for stabilization operations. The process description for operation of the laboratory calciner is provided in the Laboratory Prototype Calciner addendum to this FSAR.

Room 227. This room is located on the first floor of the 234-5Z Building. A chemical addition tank, used to receive solutions of concentrated or diluted HNO_3, is on the north wall of room 227 next to glovebox HC-227S. A vent line leads from the tank to the E-4 exhaust system. Solutions in the chemical addition tank can be vacuum transferred directly into batch tanks 1 and 2 in glovebox HC-227S, into all three receiver tanks in the glovebox, to the load-in head situated in hood HC-227T, or into polybottles placed in hood HC-227T.

Hood HC-227T. This hood is 8 ft 6 in. high, 11 ft 6 in. long, and 2 ft 10 in. deep. It is mounted on a frame 6 ft 6 in. tall (Figure 5-17). The hood contains PR can LI/LO heads (with necessary piping to glovebox HC-227S) for vacuum transferring solutions to and from liquid containers resting on a balance, container vent lines and a sampling point for an NO_x gas monitor. Two exhaust vents lead from the glovebox into the E-4 exhaust system of the

234-5Z Building. A row of four windows overlooks the hoist assembly. Another row of sliding panels overlooks the LI/LO heads and coverplates leading to the storage cabinets.

Glovebox HC-227S. This glovebox is 11 ft 8 in. high, 12 ft long, and 2 ft deep (see Figure 5-17). One electrical pump and one air-driven pump circulate solutions through the available piping that interconnects nine tanks. The air-driven pump also transfers Pu nitrate solutions to glovebox HC-230C-2 in room 230C for solution stabilization operations using the Production VDC process. Chapter 6.0, Section 6.4.1, describes the solution stabilization process using the Production VDC.

For solution stabilization operations using the Production VDC, the HC-227S glovebox receives Pu nitrate solutions from PR cans in the HC-227T hood and transfers the solutions to glovebox HC-230C-2 for stabilization operations. Figure 5-68 is a schematic diagram of hood HC-227T and glovebox HC-227S. Solutions are transferred from the PR cans to the glovebox using the load-in head in the hood. The solutions are blended and sampled and, if acceptable, pumped to glovebox HC-230C-2. The equipment used and processes are essentially the same as used for other solution LI/LO operations in glovebox HC-227S prior to installation of the Production VDC process in the facility. However, the VDC process required the installation of a new double encased transfer line to connect the HC-227S glovebox piping to the HC-230C-2 glovebox VDC equipment. A second line, in the same encasement, allows solution transfers from glovebox HC-230C-2 to glovebox HC-227S and a third line in the encasement serves as a spare.

A single pipe connects the glovebox to the 26-in. mercury vacuum system through a vacuum trap. The glovebox is connected to the E-4 exhaust ventilation system of the 234-5Z Building by a single ventilation duct. Process air is supplied by the process air supply system.

Glovebox HC-227S contains nine tanks that are used in the process of transferring solutions from glovebox HC-227S to polyjugs and for blending/sampling (see Chapter 6.0, Section 6.3.1, for details of the solution LI/LO process):

- Batch tanks 1, 2, and 3
- Receiver tanks 1, 2, and 3
- Load-out tank
- Vacuum trap
- Vacuum catch tank.

Each of the batch tanks is a glass cylinder assembly that is approximately 96 in. long, 6 in. in diameter, and 0.5 in. thick. The operating volume of a batch tank is 9.5 gal. Each tank has the following typical functions: solution-in (from the chemical addition tank in room 227), recirculation-in, vacuum-venting (for solution transfer to the vacuum trap tank), a spare, and solution-out. Polyjugs are filled with solutions transferred from batch tank 3 through the load-in head in HC-227T.

Retention tanks 1, 2, and 3 are glass cylinder assemblies approximately 30 in. long, 6 in. in diameter, and 0.5 in. thick. The operating volume of a retention tank is 3 gal. Each retention tank has the following typical

functions: solution-in (from the chemical addition tank in room 227), vacuum venting (for solution transfer to the vacuum-trap tank), air sparge, solution-out, and dip-leg transfer of solution out of the tank.

The load-out tank is a glass cylinder assembly approximately 24 in. long, 6 in. in diameter, and 0.5 in. thick, with an operating volume of 2.5 gal. It has following typical functions: vacuum venting (for solution transfer to the vent trap tank), solution-in (from the chemical addition tank in room 227), a spare, and drain. The load-out tank is used in conjunction with the load-out head in HC-227T.

The vacuum trap is a glass cylinder assembly that is approximately 18 in. long, 6 in. in diameter, and 0.5 in. thick with a 1-gal operating volume. It has the following typical functions: one for the 234-5Z Building 26-in. mercury vacuum supply system, a glovebox vacuum header, a drain, and a conductivity probe that annunciates an alarm upon detection of liquid.

The vacuum catch tank is a glass cylinder assembly that is approximately 12 in. long, 6 in. in diameter, and 0.5 in. thick, with an operating volume of 1 gal. It has five nozzles for the following typical functions: accepting drainage from the vacuum trap tank, venting (allowing the tank to vent exhaust into the glovebox, which is then exhausted by pipe into the E-4 exhaust system of the 234-5Z Building), a spare, a vent air sparge, and drain.

Laboratory Prototype Calciner Glovebox 188-1. A prototype vertical calciner and associated ancillary equipment (located in glovebox 188-1 in room 188 of the PPSL) is used to demonstrate direct denitration processing of various plutonium solutions to stable, storable solids. The equipment and processes associated with operation of the Laboratory Prototype Calciner are described in the Laboratory Prototype Calciner addendum to this FSAR. See Section 5.4.14 for a description of room 188. A detailed description of the development of the vertical direct denitration calciner process is provided in *Technical Assessment of the PFP Vertical Direct Denitration Calciner* (Merrick and Rickords 1996).

Recoverable Material Dissolution and Stabilization Gloveboxes. Additional capacity and capabilities for recovering plutonium were provided by four gloveboxes located in the 234-5Z Building (in addition to the PRF process capabilities). Glovebox HC-60, located in room 230, was used for hydrolysis of scrap containing greater than 20% organic. Glovebox HA-40F, located in room 169, is equipped with two furnaces that were used to calcine miscellaneous solids, primarily ash from the incinerator at the Rocky Flats Plant (RFP), Colorado. Glovebox HC-46F, located in room 170, contains dissolver pots and support equipment that were used for dissolving plutonium-bearing solids. See Table 5-8 for details of the equipment used by these gloveboxes in the miscellaneous treatment process.

Process Chemical Storage, Staging, and Preparation Rooms.

Room 165. Room 165 (shown in Figure 5-9) served as a storage location for calcium metal, iodine, and argon used during RMC Line plutonium metal production (the calcium and iodine have been removed). The room is 9 ft 6 in. by 12 ft 3 in. and serves as an entrance to vault room 166. The walls and ceiling are made of 0.75 in. thick plaster on metal lath with lighting

fixtures recessed in the ceiling. The room is equipped with wet-pipe sprinklers and rate-of-rise heat detectors. A ceiling diffuser delivers the S-3 room air, which can exit the room through a 0.38-in. space under the 40-in.-wide door. The room is used as a local supply room. The argon supply has not been capped and is available to provide 15 lb/in^2 (gauge) pressure of argon. The argon piping is equipped with a pressure regulator set at 15 lb/in^2 and a pressure relief valve (PRV) set at 18 lb/in^2. It is assumed that the pressure of flow from the S-3 ventilation air diffusers would push argon out of the room via under the door. See Section 5.4.13 for details of argon handling in this room.

Chemical Make-Up, Rooms 336 and 337. Facilities in rooms 336 and 337 (shown in Figure 5-20) were used to prepare and supply chemicals to the RMC Line. The rooms are currently used to provide acid to HC-227S (in room 227) for solution handling and associated blending operations and base for neutralizing acidic solutions. Tanks are arranged along the south wall of the rooms in a low-walled sump (see Figure 5-20). The tank area is hooded (except for tanks G-2, E-1, and HF1-1) and ventilates through roof exhausters. The room is equipped with safety showers, sump drains, and fire sprinklers. The walls and ceiling are constructed of 0.75 in. thick plaster on metal lath. Motor controls for outside chemical supply pumps are located in room 337. See Section 5.4.13 for details of the chemical contents of the chemical makeup rooms.

The 234-5Z Building and its services/utilities have been reviewed for compliance with current requirements of DOE Order 6430.1A (DOE 1989). The results of this review are presented in Tables 1 through 9 of WHC (1990).

5.2.1.2.3 Design Bases and Safety Assurance. The 234-5Z Building ventilation system is designed to maintain DPs between areas of differing contamination potential (see Section 5.4.1 for more details of the ventilation system).

Seismic evaluation studies have been made of the 234-5Z Building gloveboxes (presented in Table 5-5) and their exhaust ventilation ducts through the first testable stage of HEPA filtration, located on the duct level (Ocoma 1988a).

Each room, glovebox or hood has been analyzed by the methods outlined in Section 6.4.2.9.1 to ensure compliance with the criticality safety criteria presented in Chapter 4.0, Section 4.4.4, and Chapter 8.0, Section 8.3.4. Criticality safety features incorporated into the design of the RMC Line include the following.

- Process equipment is designed to be geometrically favorable even if filled with plutonium at the maximum credible concentration and optimum moderation.
- Process containers such as powder pans and pressure vessels are designed to be subcritical even if overbatched and moderated.
- Physical spacers are provided in storage gloveboxes to minimize interaction between plutonium batches.

- Criticality safety drains are provided to ensure that a critical depth cannot be achieved even if material is spilled and the glovebox is flooded.

- The stainless steel discs, filler blocks or plates have been placed in the sumps to prevent the accumulation of large amounts of solution.

- Raschig rings (neutron absorbers) have been placed in the sump in room 166 for criticality safety in the event of a large spill of solution.

- Vacuum traps are instrumented to detect liquid. Interlocks shut off the vacuum supply to prevent plutonium solutions from being syphoned to geometrically unfavorable equipment.

Shielding is provided at most of the gloveboxes. Lead glass, of appropriate thickness, is provided at those gloveboxes where operators or maintenance personnel are normally located. Additional lead glass is installed on some external gloveboxes as necessary to reduce dose rates to personnel working in those gloveboxes. A 3 in. thick Lexan™ and a 3 in. thick water wall are provided around the middle section of HC-9B to reduce the neutron exposure from the PuF_4 in the fluorinator section. An 8 in. thick water wall is provided around HC-11 where PuF_4 powder pans were stored. Water walls and concrete are provided around the control room to reduce neutron exposure.

All plutonium processing operations were confined within gloveboxes in the entire process until plutonium metal buttons were loaded out in triple-contained cans. Conveyer belts, enclosed in glovebox structures, moved the solid plutonium between gloveboxes. Encased piping (pipe-in-pipe) moved plutonium solutions between most gloveboxes. The lines between HC-4, HC-6, and HC-7 are not encased but have plastic sleeving. The line that transferred pickling solution between HC-17B and HC-7 also is not encased. Processes that used the unencased lines are now inactive.

All gloveboxes are maintained at negative pressure (-0.3 to -1.5 in. w.g. relative to the room) to confine plutonium to the gloveboxes should a small break in the confinement barrier occur. Differential pressure gauges, located in all gloveboxes, measure the negative pressure in the gloveboxes relative to the room. Two stages of filtration are provided before E-4 ventilation exhaust is discharged to the atmosphere via the 200 ft high stack.

Installations throughout the facility provide continuous air monitors (CAM) with alarms, criticality detectors with alarms, smoke and heat detectors, fire alarms, evacuation alarms, and intercommunication systems.

Fire protection is provided by several means. An automatic wet-pipe sprinkler system with standard spray upright and pendent sprinkler heads provides fire suppression equipment throughout most the building. These sprinklers provide coverage in conformance with applicable National Fire Protection Association (NFPA) codes and standards (NFPA 1979a). Details on design standards are found in Chapter 4.0. Compartmentalization and fire barriers are used to restrict the spread of fires. Minimal use of combustible

construction materials is required to limit fuel sources. Detection systems (e.g., heat, smoke), alarm systems, fire-fighting equipment (fire extinguishers), and facility worker fire-safety awareness and fire-prevention training are in place. Noncombustible materials were used whenever possible in the construction of this building. Where combustible materials were essential, every effort was made to minimize the quantity and provide backup protection. The roof is a Factory Mutual Approval Guide (FM) fire class I roof installed over a previously existing metal deck in a 1983 facility upgrade. The exterior walls are constructed of corrugated 16-gauge aluminum, over 1.5 in. of rock wool insulation that is supported by structural steel. The interior walls are metal partitions, plaster on metal lath, gypsum board on metal studding, and, in the case of vaults and process areas, 8 in. thick reinforced, poured concrete. The floors generally are poured concrete finished with tile in some areas. The exception is the floor in the duct level, which is metal deck. All interior finish is of noncombustible material. Stairwells 1 and 2 are isolated with fire barriers. See Section 5.4.11 for more details of fire protection equipment in the 234-5Z Building.

Nuclear criticality safety is ensured by using geometrically favorable equipment design; engineered barriers; and/or administrative controls that limit quantities of plutonium in the gloveboxes, vessels, filter boxes and rooms, and 26-in. mercury vacuum system.

Criticality, fire, NO_x, and evacuation alarms; the CAM alarms; intercommunication systems; and the commercial telephone system alert personnel to emergencies. Safety communications systems are discussed in Section 5.4.10. Fire alarms are discussed in Section 5.4.11.

Design Bases and Safety Assurance for Remote Mechanical A/Remote Mechanical C Line Gloveboxes/Hoods. The original RMA Line installation was completed in the early 1950's, and the RMC Line installation was completed in 1960. The original design specifications for the lines have been destroyed but specifications for other facilities (e.g., PRF and 242-Z) built about the same time are available and assumed to be applicable to the RMA and RMC Lines.

The process equipment for the most part complies with DOE Order 6430.1A (WHC 1990). Specific nonconformance items not identified earlier in this section include the following:

- Lack of redundancy in equipment and instrumentation
- A few solution transfer lines between gloveboxes are not doubly encased and do not have leak detection capability
- Ventilation exhaust from the middle of HC-9B, which potentially contained hydrogen fluoride gas, was not scrubbed to remove the hydrogen fluoride gas content
- Water walls are not equipped with leak detectors and alarms
- Area radiation monitors are not installed.

These factors are also considered in the Chapter 9.0 accident analysis and do not represent undue safety risks.

Most of the process equipment for the RMA and RMC Lines was fabricated onsite in the 200 Area shops. The exceptions were commercially available 300 Series stainless steel and carbon steel pipes, valves, pumps, and glass tanks. Process piping was generally 304-L stainless steel although some 316-L was used. Carbon steel piping was used for dry air supply, cooling water supply, and caustic supply. Valves, pumps, and other similar equipment were specified as equivalent to a specific commercial product but specifying the materials of construction such as 300 Series stainless steel, and carbon steel.

The process equipment, such as tanks, calciners, pressure vessels, etc., was designed and fabricated according to the Hanford Site standards applicable at that time. The 1960 standards applicable to piping used in the installation of the RMC Line are shown in Table 5-9.

These standards called for fabrication and installation in accordance with American Standard Code for Pressure Piping ASA B31.1, Section 6, Chapter 4.0 (1955) with welding according to Division VII. Piping hangers and supports were according to ASA B31.1, Section 6, Chapter 1.0. The ASTM codes used for stainless steel pipe are shown in Table 5-10.

In addition, American Standard Code ASA B 16.5 (1957) was used for flanges and fittings. In 1988 for RMC Line equipment upgrades, the corresponding specification used for seamless and welded austenitic stainless steel was ASTM Code A 312-86b. Also, the equipment in 1988 complied with DOE Order 6430.1, which included all other codes and standards applicable to the design, with DOE Order 5480.1B, and with DOE-RL Order 5700.1A. It is noted that the design and installation specifications applied the best available standards and codes at the time of construction.

The major pieces of equipment in the RMC Line gloveboxes and the material of construction, design pressure, and design temperature are listed in Table 5-7. Glass vessels (5-in.-ID) were tested at 20 lb/in^2 (gauge) and 4 in. diameter glass vessels were tested at 40 lb/in^2 (gauge).

The gloveboxes are fabricated of stainless steel frames with top and side panels of clear polycarbonate. The large windows provide reasonable visibility from the control room to the glovebox internals as well as improved visibility for the floor worker. The window panels are penetrated by glove ports, glovebox load-in/seal-out ports and sphincter seals. Most of the gloveboxes are provided with an equivalent of 1 in. thick lead glass shielding and lead filled gloves for gamma ray shielding. Glovebox HC-9B also has 3 in. thick Lexan™ panel or water wall for neutron shielding of the center section due to the presence of PuF_4 powder pan storage.

Steel, 12 in. thick water walls with viewing windows are provided around the control room to reduce neutron exposure to control room occupants. Control room windows are constructed of double plastic sheeting with water between them. A water wall and 3 in. thick Lexan™ panel are located around the outside of glovebox HC-11C which stored PuF_4 powder cans (a high neutron source).

Air supply to gloveboxes are regulated by self-governing, diaphragm-operated supply valves. Glovebox exhausts are sized to accommodate the entire amount of air supplied in case the supply valve fails in the fully open position. Separate diaphragm-operated valves regulate emergency exhaust on selected RMA and RMC Line gloveboxes to provide for added exhaust flow requirements in the event of a confinement breach (e.g., a glove or seal failure). The conveyors serve as plenums that deliver air to all adjoining gloveboxes except the top and bottom sections of HC-9B and HC-17P.

Air is normally exhausted through nontestable HEPA filters located at the gloveboxes and through the E-4 exhaust system. Glovebox design calls for a general operating differential pressure range of -0.5 in. w.g. to -0.7 in. w.g. This negative pressure is maintained in the gloveboxes by the exhaust system in accordance with the DP zoning of the building. A DP switch connected to an annunciator in the power control room monitors the pressure in the dry-air gloveboxes and alarms if the pressure exceeds -0.3 in. w.g. Two valves regulate exhaust on an emergency basis to a common, locally unfiltered duct. The valves are normally closed for any upstream pressures less than -0.5 in. w.g. Any flow of air under positive pressure opens the valve to redirect the airflow to a 12 in. diameter E-4 header in room 263 above the RMC Line area (and then airflow passes into the E-4 ventilation exhaust system of the 234-5Z Building). A valve located on the 8 in. diameter emergency exhaust duct is interlocked with the glovebox heat detectors. If a fire with sufficient heat to activate the heat detectors occurs, the emergency duct will close to reduce the heat load on the first-stage filters and reduce the flow of air aiding the fire. A 12 in. dia, unfiltered duct equipped with a manual valve is located on the west end of glovebox HC-2. This valve is used to regulate airflow during glovebox panel changes. Each glovebox has a DP gauge to monitor its interior pressure relative to the room. A condensation dew point hygrometer system, with a sample tube in glovebox HC-21C, is located in room 235B (it is currently inactive).

Wet process gloveboxes (those gloveboxes that were designed to handle solutions such as plutonium nitrate) or those containing significant quantities of fissile material that may be flooded in an accident condition, are equipped with criticality drains. A criticality drain is a 3 in. diameter bag port attached to the side of the glovebox at a height such that the port opening is below the maximum allowed glovebox floor liquid accumulation depth. An open ended plastic bag is attached to the port. The open end is closed for radiological confinement purposes by a precision-finished steel roller balanced on a polished steel plate inside a protective cage, or by a weighted knife-edged clamp. The weight of the liquid entering the port bag moves the steel roller off the bag or pulls the bag out from under the knife-edge clamp, thus freeing a path for drainage to the room floor. Accompanying contamination is a less severe hazard than a criticality incident. Gloveboxes HC-1 and HC-5 each have a criticality safety drain provided to ensure that a critical depth cannot be achieved in the event that material is spilled and the gloveboxes are flooded. The sumps and criticality drains for criticality prevention are geometrically favorable. The sumps have liquid level alarms. "Dry" gloveboxes have no active sumps since liquids are not present. "Dry" gloveboxes are connected to glovebox HC-1 with matching floor levels. In the unlikely event that liquid should enter a dry glovebox, it would drain to glovebox HC-1 which has a criticality drain. Accumulation of solids on the

floor of "dry" hoods is administratively limited to less than 240 g/ft^2 of plutonium.

Design Bases and Safety Assurance for Thermal Stabilization Gloveboxes, HA-21I and HC-21C. Each furnace in the thermal stabilization gloveboxes is equipped with a temperature indicating controller (the furnaces in glovebox HA-21I have a temperature controller on the PLC with indication on the PC) with an associated thermocouple to monitor for furnace temperature deviation. Programmed into the controller is a deviation band alarm that is set at ±20 °C. When the furnace temperature deviates from the program setpoint by ≥20 °C, power is removed from the furnace. If the thermocouple or controller fails, or is removed from the system, the furnace power control circuit fails open and power is removed from the furnace.

Each furnace in gloveboxes HC-21C and HA-21I is equipped with a high temperature alarm switch and associated thermocouple to monitor furnace temperature. The alarm switch is part of the PLC programming for glovebox HA-21I. The alarm switch will remove power from the furnace upon exceeding the established setpoint of 1050 °C. The purpose of removing power is to prevent damage to the heating coils in the furnaces. If thermocouple or alarm switch fails, or is removed from the system, the furnace power control circuit fails open and power is removed from the furnace.

A heat detector in glovebox HC-21C is set to activate the Halon Fire Suppression System when the glovebox temperature reaches the setpoint of 93 °C. The glovebox temperature monitor alarms at a temperature of 70 °C. This provides enough cushion to avert a Halon release into the glovebox. The glovebox temperature setpoint in glovebox HC-21C could be exceeded, and the Halon system activated by either a fire of combustible material in the glovebox, or possibly total failure of both furnace temperature control systems and interlocks. A strobe light will actuate and the fire alarm gongs sound once the Halon system setpoint is exceeded. The release of the Halon is delayed for 30 s. A Halon release hold button is available to delay the release of Halon for 30 s, and the button can be repeatedly pushed or held down, as needed, to further delay Halon release. A heat detector in glovebox HA-21I is set to activate the dry chemical fire system when glovebox temperatures reach the setpoint of 93 °C. The glovebox "High Select" temperature monitor alarms at a temperature of 70 °C. This provides enough cushion to avert a dry chemical release into the glovebox. When glovebox temperature reaches 70 °C, an interlock in the glovebox temperature monitor removes the power to the muffle furnaces. The glovebox temperature setpoint in glovebox HA-21I could be exceeded, and the dry chemical system activated by either a fire of combustible material in the glovebox, or possibly total failure of both furnace temperature control systems and interlocks.

Each furnace in glovebox HC-21C has a separate control system. The controllers are preprogrammed and the program is protected from unauthorized changes. Lights on the control consoles indicate when power is supplied to the furnaces. Each furnace in glovebox HA-21I is controlled by the PLC. The PLC is preprogrammed and the program is protected from unauthorized changes. A PC interfaces with the PLC, and serves as the focal point for control of the gloveboxes. Displays on the PC indicate when power is supplied to the furnaces.

The windows of the HA-21I, HC-21C, and HC-21A gloveboxes are made of Lexan or some other equivalent, equally heat-resistant material.

The HA-21I glovebox is provided with a criticality drain to prevent liquid accumulation from reaching a depth that could result in a criticality. The HA-21I glovebox is provided with a 5-in mercury vacuum system.

The 26-in. mercury vacuum system for furnaces in glovebox HC-21C must be operable to remove butene or other gases which can potentially be generated during processing of organic containing material.

A manual switch for the HC-21C glovebox is located on the control console and is used to remove power from the furnace elements. The manual button must be pulled out to power furnace heating elements. Power to the control system is not affected by the emergency shutdown switch, only furnace power. A manual switch is located on the exterior of glovebox HA-21I, which removes power from all furnace elements in this glovebox when the button is depressed. Also an emergency stop button is located in Room 230A to shutdown the HA-21I furnaces. The PC computer station contains an icon for emergency shutdown of the furnaces in glovebox HA-21I.

Material foam over into a furnace can occur but has not been identified as a problem. A scraper and paint brush can be used to sweep up material from the bottom of the furnace once it has cooled. This material would then be mixed with the charge material.

For space and criticality safety considerations, a maximum of one boat may be in each furnace in gloveboxes HC-21C and HA-21I during use. Total quantity of material is restricted by the inventory limits of the glovebox.

Design Bases and Safety Assurance for Solution Stabilization Glovebox HC-230C-2 for the Production VDC. The design bases and safety assurance items for this glovebox and the enclosed Production VDC process equipment primarily involve features to provide radiological, chemical, criticality, and fire safety. In addition, process safety is generally provided by instrumentation, controls, interlocks and alarms which indicate and/or mitigate undesirable process situations.

Some design bases and safety assurance features for solution stabilization components are provided in Section 5.2.1.2.2 of this chapter. More in depth information is provided in Chapter 6.0, Section 6.4.1, Reactive Pu-Bearing Material Stabilization and Pu-Bearing Solution Stabilization.

Design Bases and Safety Assurance for the HC-227S Glovebox and HC-227T Hood. A NO_x gas monitor is provided in room 227. The sampling point for the monitor is located below hood HC-227T.

The liquid level in the chemical addition tank located in room 227 is monitored visually and alarmed by a level detection element that sounds at a panel below the feed valve wall in room 227.

A conductivity element in the top of the vacuum trap of glovebox HC-227S monitors for liquid in the trap. Detection of liquid closes an electric valve to isolate the 26-in. mercury vacuum system from the vacuum trap.

The HC-227S glovebox floor contains a criticality drain with a sump probe alarm set to activate if liquid exceeds a depth of 0.5 in.

Nonsparking bronze tools, ground straps, and the use of noncombustible tools and materials are used during this process to minimize the chances of combustion of any radiolytically produced hydrogen released from the polyethylene containers or LI/LO processes.

Vacuum supplied by the 26-in. mercury vacuum system (see Section 5.4.5) is used to transfer solutions during the LI/LO process. Vacuum is used to avoid the pressurization of transfer lines during piping of solutions.

Design Bases and Safety Assurance for Laboratory Prototype Calciner Glovebox 188-1. The design bases and safety assurance provisions for the Laboratory Prototype Calciner and related equipment and operations are provided in the Laboratory Prototype Calciner addendum to this FSAR.

Design Bases and Safety Assurance for Process Chemical Storage Rooms. The design bases and safety assurances of the process chemical storage rooms is discussed in Section 5.4.13.

5.2.2 The 236-Z Building

5.2.2.1 236-Z Structural Specifications. The 236-Z Building is located south of the southeastern corner of the 234-5Z Building and is connected to it by the 242-Z Building. The building is essentially a four-story structure, 79 ft by 71 ft by about 47.5 ft high, surmounted at the southwest corner by a two-story penthouse, which is 22.5 ft high.

The 236-Z Building was designed in accordance with the 1961 UBC (UBC 1961), which included a seismic criterion (0.10 g) that is significantly lower than the present-day criterion (0.20 g) used for design of high hazard nonreactor facilities at the Hanford Site (DOE-RL 1993). Seismic analysis showed that the 236-Z Building could withstand a 0.25 g ground acceleration, which exceeds the 0.20 g DBE for high-hazard nonreactor nuclear facilities (see Tables 5-2 and 5-4).

With the exception of the roof, the south end of the process cell, and the fourth-floor ceiling, the building is constructed of reinforced concrete. The roof is constructed of an open-web steel joist frame, a steel deck with rigid insulation that consists of light-weight concrete fill, and gravel-covered built-up roofing. A portion of the south wall is also the 1 ft thick wall of the process cell and includes an opening in the reinforced concrete wall. This opening is filled by a pair of large steel double doors that are surrounded by a concrete block wall. A HEPA filter is installed in the west door. The south wall has a bridge-shaped cross section of concrete blocks with welded steel plates added to preclude leakage during a seismic event. An equipment transfer facility, added after initial construction of the 236-Z Building, is located against the large door. This facility consists of a 35 ft by 13 ft airlock (room 72) and two anterooms (rooms 70 and 71) (see Figure 5-6, sheet 1 for location of rooms and doors). The room 72 airlock outer double doors each have an inlet HEPA filter (see Section 5.4.1 for additional details of the 236-Z Building ventilation system). The tanks and

columns used in the solvent extraction process are located in the process cell, a three-story room in the center of the 236-Z Building. The process cell is 52 ft long by 32 ft wide by 26 ft high and has 2 ft thick concrete walls (except on the south side, which is an exterior wall). The equipment in the process cell includes many long, narrow, upright metal tanks or columns that vary in length from 2.5 ft to about 50 ft and are 4 to 6 in. in diameter. Because of their height, the extraction column (CA) and stripping column (CC) extend into the column penthouse.

5.2.2.1.1 Seismic Analysis. Seismic analyses and evaluations were performed for the 236-Z Building to determine whether it can resist the 0.25-g DBE (URS 1988a). Three-dimensional, lumped-mass beam models of the building were developed. Seismic forces and moments for these models were computed using the modal superposition response spectrum method of dynamic seismic analysis. The overall seismic forces and moments were distributed to the individual walls and diaphragms and evaluated against their calculated code-allowable capacities. The evaluation indicated that the 236-Z Building will meet the code requirement to resist the DBE motions postulated for the Hanford Site. Specific conclusions for the key structural members are as follows.

- Roof--The metal roof deck has a maximum demand/capacity ratio of 0.94, indicating that it meets the code requirement.

- Concrete floor slabs--All slabs meet code acceptance criteria.

- North-south walls--All reinforced concrete walls oriented in the north-south direction have demand/capacity ratios of less than 0.62 for shear and overturning moments. All north-south walls meet the code requirement.

- East-west walls--All east-west walls, except one, have acceptable demand/capacity ratios of less than 1.0 for shear and overturning moment. East-west wall 4 has a ratio of 1.23 for overturning; however, this is a minor wall, and the loads from this wall can be carried by the adjacent east-west wall 3, which has more than adequate capacity to carry the additional overturning force.

- Concrete block wall--The concrete block wall (4 in. and 8 in. thick) at the south cell wall does not meet the acceptance criteria because it has a demand/capacity ratio greater than 1.0. This ratio is not based on inspection since inspection results were not available. It is to be emphasized that this is not a load-carrying wall and its performance will not affect the structural behavior of the building. The entire area of the concrete block wall has been covered with welded steel plates that overlap into the poured concrete wall. The plates were installed on the exterior side with anchor bolts and sealed all around to preclude a leak path.

In addition to the conclusions enumerated above for the building, seismic analyses and evaluations of all the PFP gloveboxes (presented in Table 5-5) and filter boxes were performed (Ocoma 1990a), and recommended structural upgrades were identified.

5.2.2.1.2 Wind Analysis. The wind analysis for the 236-Z Building consisted of calculating wind-generated moments, shears, and torsions at specific elevations of the building. The results of the 236-Z Building extreme wind analysis are shown in Giller (1989a). A comparison of the wind and seismic values shows that the wind moments, shears, and torsions are less than the seismic values, which were shown to be within acceptable limits. By association, the wind condition is acceptable for the main structure of the building. The evaluation of the roof deck showed an acceptable safety margin of 1.24. Evaluation of wall axial loads and bending moments shows values within the acceptable limits; therefore, the 236-Z Building meets the code requirements to withstand extreme wind loading. The analysis also evaluated the effects of wind-generated missiles and determined that the building can withstand the impact loads.

5.2.2.1.3 Snowfall Analysis. The 236-Z Building roof was analyzed for normal roof loading of a minimum 20 lb/ft^2 in accordance with ANSI A58.1 and DOE-RL 1989 guidelines. The analysis indicates that the roof can withstand the effects of live and dead loads and of snowfall (Giller 1990).

5.2.2.1.4 Ashfall Analysis. The 236-Z Building roof has not been analyzed for natural phenomena volcanic ashfall loadings.

5.2.2.2 236-Z Description.

5.2.2.2.1 Function. The 236-Z Building (PRF) houses the majority of the plutonium recovery process equipment used to convert various plutonium-bearing materials and aqueous feeds to a purified plutonium nitrate product suitable for conversion to plutonium metal or PuO_2. The process included the following:

- Recoverable material dissolution and scrap stabilization [miscellaneous treatment (MT)]; hydrolysis, clarification, and calcination
- Plutonium purification; feed preparation, solvent extraction (SX) and stripping, and organic cleanup
- Concentration and clarification of the aqueous product and waste streams.

Most of these process steps were located in the PRF in the 236-Z Building. Some of the miscellaneous processing took place within the 234-5Z Building of the Plutonium Finishing Plant (PFP). A cutaway view of the 236-Z Building is given in Figure 5-21.

The Plutonium Reclamation Facility (PRF) process systems are inactive and are not authorized to operate. Active electrical power to the PRF is limited to the 17 in. mercury vacuum system, criticality alarm system, normal lighting/receptacle panels, elevator, security systems, building support systems (e.g., HVAC), and emergency lighting/receptacle panels. A total restoration of PRF electrical power is not planned. Power to PRF process systems and equipment will remain deactivated except when required for PRF facility clean-out and deactivation.

This section identifies the associated major components that remain in place. Note that reactivation of these process systems, either in part or in total, would require the performance, documentation, review, and approval of new hazard and accident analyses with associated modifications (as required) to this final safety analysis report (FSAR).

5.2.2.2.2 Components. The process cell contains the major processing equipment formerly used for plutonium recovery operations. Building floor plans that indicate the location of the process cell for the 236-Z Building are shown in Figure 5-6 (sheets 1 through 4).

Recoverable Material Dissolution and Stabilization (Miscellaneous Treatment) Process Equipment. A variety of components were used to stabilize (hydrolyze, decarbonize) and dissolve recoverable plutonium from various solid and liquid materials. A cluster of five gloveboxes in room 41 (see Figure 5-6, sheet 4 for the location of the room) contains MT processes. The MT was a multipurpose facility capable of small-scale processes for plutonium recovery from scrap. Primary equipment in room 41 included dissolver pots, hot plates, centrifuges, condensers, and furnaces. Capabilities of MT processes included receiving, inspecting, screening, sorting, and weighing plutonium-bearing materials (glovebox MT-1; see Figure 5-22), dissolving of bulk metallic plutonium in nitric acid using electrolytic dissolvers (glovebox MT-3), residue stabilization and recovery of plutonium oxide powder by distillation of polystyrene cubes and burning of residual carbon (glovebox MT-4), acid dissolution and leaching of plutonium from solids (glovebox MT-5; see Figure 5-23), clarification of plutonium-bearing nitrate solutions from MT-5 for transfer to the PRF canyon and cementing of solid residuals for waste disposal (glovebox MT-6; see Figure 5-24).

Two receiver tanks (TK-25 and TK-26) are located in positions EM and EN (see Figure 5-25). These tanks receive clarified dissolver solution from the MT gloveboxes.

Additional capacity and capabilities were provided by four gloveboxes located in the 234-5Z Building. Glovebox HC-60, located in room 230C, was used for hydrolysis of scrap containing greater than 20% organic. Glovebox HA-40F, located in room 169, is equipped with two furnaces that were used to calcine miscellaneous solids, primarily ash from the incinerator at the Rocky Flats Plant (RFP), Colorado. Glovebox HC-46F, located in room 170, contains dissolver pots and support equipment that were used for dissolving plutonium-bearing solids. Two continuous refluxing dissolver/condensers installed in the 236-Z Building process canyon were used for dissolving crushed sand and S&C from the Remote Mechanical C (RMC) Line in the 234-5Z Building.

Two nearly identical dissolvers, located in the 236-Z process cell, were used to dissolve crushed sand and S&C from the RMC Line. The dissolvers were supported by three systems: acid feed, product treatment, and offgas treatment. Three interconnected gloveboxes in room 43 of the 236-Z building also supported dissolver operations.

Cans of feed material were dropped into the dissolvers from the charging glovebox. The dissolvers contained hot nitric acid provided by the acid feed system. Gases evolved during dissolution passed through a reflux condenser and scrubber before being vented into the 236-Z process cell. The product

solution flowed to a settling tank where large entrained solids were removed. The product then flowed to a centrifuge where remaining solids were removed. The product solution was used as feed to the SX system.

The major components of the S&C dissolver system include the following:

- Two reflux dissolvers, TK-08 and TK-124
- Two condensers, TK-09 and TK-125
- Acid feed system tankage
  - TK-A-101
  - TK-A-112
  - TK-A-102
  - TK-EC-01
  - TK-ED-02
- Product treatment system
  - solids settling tank, TK-53
  - centrifuge "A"
- Offgas treatment system
  - two deentrainers, TK-10A and TK-12A
  - two offgas scrubbers, TK-10 and TK-12
- Sorting glovebox
  - canning machine
- Loading glovebox
  - gauge ring
  - loader
- Dissolver charging glovebox.

Purification. Plutonium purification was accomplished by feed preparation, solvent extraction, and organic cleanup. The positions of the associated major components within the canyon are shown in Figure 5-25. The tank locations, function, working volume, and overflow capacity are described in Table 5-11. The tanks are interconnected with vents and drain lines to maintain mass, volume, and geometric criticality limits, and to provide primary containment. All process tanks associated with plutonium purification have been drained. The process cell and the gloveboxes that provide access for manual operation are the primary confinement barrier. The following sections identify and describe the major components associated with feed preparation, solvent extraction and organic cleanup, chemical makeup, and associated support equipment (i.e., pumps, filters, and centrifuges).

Feed Preparation. In the feed preparation system, chemicals (e.g., an anti-emulsifying agent, ANN, and HNO_3) were added to an aqueous solution to produce a feed solution suitable for plutonium separation by solvent extraction. The feed preparation tanks (15, 16, 17, and 18) are located in the process cell (canyon) and are made of banks of welded stainless steel cylindrical vessels connected together at the top and bottom. This arrangement provides fixed volume, mass, and geometry for criticality safety.

Typical tank configurations are shown in Figure 5-27. The bank is mounted on a supporting dunnage with tapered plugs. The plugs fit into the 2-ft-thick concrete wall of the canyon. The concrete wall serves as support for the vessels and radiation protection for personnel. All piping goes through the plugs to the access glovebox. The gloveboxes contain the piping, valves, pumps, instrumentation, filters, and small vessels that service the equipment in the process cell.

Solvent Extraction and Organic Cleanup. Solvent extraction was used to generate a purified plutonium nitrate solution suitable for feed to the RMC Line. Organic cleanup was used to clean organic solvent for reuse in the solvent extraction process. A schematic diagram of the solvent extraction and organic treatment systems is shown in Figure 5-26. As shown in this figure, a number of abbreviations are used to designate process streams. The first two letters identify the column (e.g., CA, CC, OA) and the last one or two letters identify the type of stream. For example, CAIS designates the CA column intermediate scrub. These codes are as follows:

F	Feed	CA	Plutonium extraction
I	Intermediate	CC	Plutonium stripping
P	Product	CO	Organic recovery
R	Recycle	CU	Uranium scrub
S	Scrub	CX	Degraded organic removal
W	Waste	OA	Acid scrub
X	Extractant		

There are six solvent extraction and organic treatment columns (tanks 32, 33, 34, 48, 69, and 123). These tanks are 4, 5, or 6 in. diameter columns 4 to 51 ft high as shown in Figure 5-28. The columns are made from stainless steel, Pyrex™ glass, and/or Kynar™ pipe. The CA column contains stainless steel perforated plates spaced at 4-in. intervals. The CC column contains stainless steel perforated plates spaced at 2-in. intervals. The remaining columns contain plastic Raschig ring or Intalox™ saddle packing. The SX, CC, and CU columns have air pulsers for improving mixing and movement of the aqueous and organic phases through the column. The pulsing action is imparted by means of a pulse generator that connects to the bottom of the column via a hydraulic pulse leg. The pulse height is dependent on the frequency of the pulse and the air pressure of the supply air. The pulse frequency is varied between 30 and 100 cycles/min at air pressures of 20 to 50 lb/in^2 (gauge) to produce the desired pulse height and maintain efficient aqueous-organic emulsion type operation.

Chemical Makeup and Metering Equipment. The chemical makeup vessels are located in room 40 of the 236-Z Building. The vessels are fabricated from stainless steel, except for tanks A-107 and A-110.

Tank A-103--The vessel has a 280-L capacity, 1,200-lb scale, and agitator. It is used as a pump tank for 1 M NaOH.

Tank A-105--The vessel has a 1,700-L capacity and is used as a head tank for 12.4 M HNO_3. The tank is equipped with a digital readout and is refilled from a 32,000-L storage tank located outside the building.

Tanks TK-A-101 and TK-A-102 (Dissolver Acid Preparation)--These 1,570-L cylindrical tanks, located in chemical preparation room 40, are constructed of 304-L stainless steel. Each is equipped with an agitator and gauge for volume determination.

Tank A-106--The vessel is similar to tank A-105 and is used as a head tank for 1.8 M $Al(NO_3)_3 \cdot 9\ H_2O$.

Tank A-112--The vessel has a 280-L capacity, 1,200-lb scale and agitator. It is used for the makeup of 5,000-ppm Mistron™ - 0.5 M HNO_3. A timed metering pump is used to add about 3 L of solution to each SX feed batch.

Tank A-107--The PVC plastic vessel has a 300-L capacity, volume calibration scale, and an agitator. It is used for the makeup of 0.4 M Na_2CO_3 (CXX) solution.

Tank A-108--The vessel is similar to tank A-103. It is used for the makeup of 1.5 M HNO_3 (CAS).

Tank A-109A--This tank has been removed from the facility.

Tank A-110--The vessel is similar to A-107 and has weight factor instrumentation. It is used for the makeup of 2.0 M HNO_3 - 0.2 M HF (COX) or 3 M HNO_3 - 1 M ANN (flush) solution.

Tank A-114--The vessel is similar to tank A-103. It is used for the makeup of 20% TBP in CCl_4 (CAX).

Tank A-115--The vessel is similar to tank A-114 and is used as a head tank for CCl_4.

Support Equipment.

Pumps--Some of the columns and most of the tanks used pumps. The majority of these pumps are located in either the east or west gloveboxes, depending on the location of their respective columns or tanks. The pumps were required to pump fluid of approximately 1.5 specific gravity at flow rates of ~15 gal/min at a discharge head of 85 ft.

Three types of pumps were used in the solvent extraction system (given below):

- Centrifugal--Corcoran, Deanline, Eastern
- Nutating--Saturn
- Air Operated--Magnum 600.

Motor-operated centrifugal pumps used the solution flow for cooling. The electric motors used on these pumps are Underwriter's Laboratories listed and equipped with thermal overload shutoff devices.

The Saturn pump is a motor-operated, nutating, diaphragm-type pump. This pump can be operated with no solution flow without damaging the pump. There are two of these pumps in the system. Saturn pumps were used only in the organic cleanup function.

The Magnum 600 is an air-operated, diaphragm pump. Normally, the air pressure used was less than 50 lb/in^2 (gauge).

Filters--Two filter systems (the 16.1 and 16.2 filters and the 51 filters) were used in the solvent extraction system. These filters removed large solids (greater than 100 mm) from various solution streams in the system.

Centrifuges--Centrifuges were used for clarifying four different process streams in the PRF. They were as follows:

- S&C product (A)
- Solvent CAW (B-1 and B-2)
- Batch dissolver product
- Product clarification (D).

The B-1, B-2, and C centrifuges are installed in glovebox MT-6. The A centrifuge is installed at location EF on the east wall glovebox of the second floor. The D centrifuge is installed at the WV location of the west wall glovebox on the second floor.

The centrifuge contains an internal bowl, which is rotated at a high speed. The spinning action of the bowl forces solids to the side of the bowl. The solution, now free of solids, overflows from the bowl. Periodically the cover is removed, and the bowl is scraped and cleaned of solids.

Aqueous Solution Concentration.

Product Concentration. The product concentrator was used to concentrate the plutonium product from solvent extraction before use as feed to the RMC Line (Figure 5-29). Before being fed to the product concentrator, the CCP stream was routed to TK-58, a 4-in. pipe partially filled with clean CCl_4, to remove organic material that may have been present in the aqueous product from the CC column.

The product concentrator is a jacketed, falling film type, steam-heated evaporator. It is made of welded titanium and contains titanium Raschig ring packing. The 30-lb/in^2 (gauge) steam, introduced to the 6 in. diameter by 7-1/2 ft outer pipe, was used to heat the inner 4 in. diameter pipe and 1 in. by 1/16 in. packing. Plutonium nitrate flowed down through the heated pipe and over the packing. The concentrate then flowed by gravity into a stainless steel receiver tank. Live steam was introduced at the bottom to strip soluble organic from the solution. The vapor exited the concentrator via a deentrainment section and entered the condenser (TK-44). Two 6 in. long tantalum mist eliminators deentrained mist from the vapor that was condensed by a shell and tube condenser (tank 44). The vapor entered the shell side of the stainless steel horizontal condenser and was cooled and condensed by water flowing through the coiled tubes.

The concentrated product was clarified using a centrifuge and stored in tanks 45, 46, and 128. The product was pumped to tanks BT-1, -2, or -3 in glovebox HC-227S, 234-5Z Building, then loaded out into product receiver cans or sent to the RMC Line for conversion to metal.

Filtrate Evaporation. The filtrate evaporator was used to concentrate dilute aqueous solutions for use as feed to the solvent extraction process. The filtrate evaporator (tank 21) is a 304-L stainless steel thermosyphon evaporator with tube and shell heat exchanger. An overhead vapor deentrainment section, containing tantalum mist eliminators, connects the evaporator to a shell and tube condenser (tank 22). The condenser was sized for a 20,000 Btu/h design duty. It has one tube bundle 6 in. in diameter by 6 ft high. Vapor entered the shell side of the stainless steel horizontal condenser and was cooled and condensed by water flowing through the coiled tubes. The condensate was normally routed to the D-8 tank.

Aqueous Waste Treatment. When the PRF was in operation, aqueous wastes containing plutonium were received from a number of sources (Figure 5-30). The bulk of the solvent extraction liquid waste was collected in receiver tanks, sampled and then analyzed. If below about 0.05 g/L plutonium, the solutions were transferred to tank TK-D8 of the 241-Z Complex. Liquid waste containing high plutonium concentrations were sent to aqueous waste treatment prior to discharge to the 241-Z Complex.

General. Maintenance shop facilities are located on the service (east) side of the building (room 16) on the ground floor. The PR can unloading facility in room 19 (see Figure 5-6, sheet 1), has been removed from service and partially dismantled. Nondestructive analysis (NDA) equipment has been installed in this room and is used to measure the plutonium content of miscellaneous packaged solid wastes. The second floor of the service side has a maintenance glovebox and ventilation exhaust filters. Building service equipment and electrical switchgear are on the third floor of the facility. On the fourth floor are chemical preparation, MT, the operating control room, slag and crucible dissolver charging equipment, and offices for building personnel. Sections of two extraction columns (CA and CC) penetrate the cell ceiling and are housed in gloveboxes on the fourth, fifth, and sixth floors. Most of the major control activities carried out by operating personnel are located on the fourth floor.

A remotely operated overhead crane in the process cell can be used to remove or replace process equipment. Equipment can be moved by the crane to a special maintenance station at the north end of the process cell. The CA and CC columns, located in the penthouse, do require partial disassembly before being moved into this maintenance cell by the overhead crane. The cell crane is remotely operated from the third floor. The work area is viewed through water-filled-shielding viewing windows. This maintenance area is shielded partially from the rest of the cell by a 10-in. concrete wall. The maintenance station is equipped with a lead-covered stainless steel hood panel and leaded safety glass windows.

5.2.2.2.3 Design Bases and Safety Assurance. Plutonium is a highly radioactive fissile pyroforic material that requires criticality prevention standards and radiation safety practices be carefully followed throughout the processes. Both engineered and administrative controls are employed to prevent accidents and to minimize consequences. Engineered controls include the use of long, narrow columns and tanks that provide criticality safe geometry; remotely controlled operations; the confinement of pumps, valves, and piping connections inside of gloveboxes; the use of equipment that is engineered for reliability; and the use of radiation detection instrumentation

to alert personnel if an accident occurs. Though the PRF is currently not authorized for operation, plutonium-bearing solutions may still exist in the piping of the process cell and plutonium residues may remain in columns. Therefore, the design bases for process cell equipment (i.e., piping, columns, and tanks) will be retained until the PRF is cleanout.

The PRF was designed to confine plutonium and meet commercial and industrial safety criteria. The design of operating area compartments and critical safety (nuclear and chemical) structures has been reanalyzed and upgraded a number of times since the facility was built. This section describes the designs of the individual process vessels and their enclosures.

The 236-Z process cell is constructed of noncombustible materials (concrete walls, floors and ceiling, with a stainless steel floor liner capable of holding spills from leaking piping or vessels). The process cell uses limited or controlled air in-leakage to prevent loss of containment. The cell walls and the ceiling are 2 ft thick, providing limited radiation protection in the event of a criticality. The process equipment was designed to be geometrically favorable for criticality safety. Personnel exposures were limited by minimizing "hands on" operation through extensive use of mechanical equipment. Valving and pumps are located outside of the process cell but inside gloveboxes. Major components can be replaced and repaired in the hot maintenance shop, which is located just outside of the process cell. Stainless steel-paneled gloveboxes containing safety glass viewing windows and hood gloves provide access to the process cell. The gloveboxes are located on both sides of the cell on the first two floors. Process piping is carried in process tank dunnage that is secured in the port that penetrates the shielding wall to equipment in the cell, and to pumps, valves, flowmeters, and other equipment in the gloveboxes that most frequently require maintenance.

The south wall of the process cell contains double doors, serviced by a large airlock structure outside the south wall. This arrangement permits controlled movement of equipment into the cell.

Cell entry by personnel is infrequent but is done when the cell crane cannot accomplish what is needed (e.g., cell floor cleaning, installation of new tanks, failed equipment removal). Entries into the cell is key locked, and special work authorizations are required for maintenance of equipment, including the crane.

The process vessels and piping were designed to contain contaminated (plutonium-bearing) solutions. Generally, these streams were operated at atmospheric pressure and relatively low temperatures. Specific equipment items, listed on Table 5-11, were designed to meet the American Society of Mechanical Engineers (ASME) *Boiler and Pressure Vessel Code* and the ASTM Code for pressure piping (*Standard Specification for Austenitic Stainless Steel Tubing*, *Standard Specification for Austenitic Stainless Steel Pipe*, *Standard Specification for Chrome-Nickel High Temperature Steel*, *Boiling Nitric Acid Test*, *Welded and Seamless Steel Pipe*, *Alloy Steel Bolting*, and *Alloy Steel Nuts*, *External and Internal Threaded Fasteners*). Standard practice is to provide welded tube sheets for primary loop (i.e., those that contain plutonium-bearing solutions on either the tube or shell side) process heat exchangers. Secondary loop heat exchangers usually rely on rolled, rather than welded, tube sheet. The tanks are connected to ventilation systems,

overflow drain lines, and overflow collection tanks. Contaminated effluent lines are of all welded construction with bolted, flanged joints where required.

The process vessel design drawings specify standard Schedule-40 piping and flanges, which is in accordance with the provisions of *ASME Boiler and Pressure Vessel Code*, Section VIII. The specifications for fabrication, testing, and inspection were as follows:

- Fabrication Standard--American Welding Society (AWS) D1.1/D1.3/B3.0 or HS-BS-0013 (Hanford Standard) Kynar™ per Fluoroflex-K, Cat SK-7
- Performance Specification--ASME Section IX and AWS D1.1/B3.0
- Filler Material--ASME Sect. II/AWS A5
- Inspection--Visual (VT) (Non Rated Service), Welding Std. IN (1), SSP 2.5.0 (Hanford Standard), Penetrant (PT) Welds with Liquid Service, Welding Std. IN (1), SSP 2.1.0 (Hanford Standard), Radiograph accessible welds, and Severity Level 3.

Most of the vessels and piping were operated at ambient temperatures and pressures. The S&C dissolver was the only vessel operated at pressure and was subject to erosion by recirculating solids. Consequently, it was designed for severe operating conditions. Laboratory corrosion data do not provide a satisfactory basis for predicting vessel design life because local corrosion/erosion conditions cannot be duplicated. Consequently, the facility design included a fully installed and instrumented unit and a spare vessel that could be installed remotely. All equipment and service lines were pressure tested with water at 20 lb/in^2 (gauge) after installation to verify that the connections, piping, and vessels were leak tight. The vessel design did not include an estimated design life or corrosion rate; the materials of construction (glass, 304-L stainless steel, polyester plastic, and Kynar™) were chosen to give maximum expected life of the equipment based on analysis of laboratory and plant operating experience. The pressure vessel design conditions are summarized in Table 5-12.

All pressurized process piping was designed and fabricated in accordance with the American Standard Code for Pressure Piping (Table 5-13). Piping was either welded in accordance with American Standards Association (ASA) B31.1 or, if it fell out of this scope, was fabricated using 304-L stainless steel in accordance with Hanford Specification HW-4924-S for stainless steels, and HW-4926-S for carbon steels. Valves, strainers, and gaskets were made of 300-L series stainless steel in accordance with the manufacturer's design specifications for the intended application. The backflow preventors are rated for 100 lb/in^2 (gauge). Safety relief valves and pressure reduction valves (PRVs) were ASME rated and sized by the manufacturer. The diaphragm control valves are rated for 600 lb/in^2 (gauge) at 800 °F.

Most of the columns and tanks for the solvent extraction process are located in the process cell. If any of these columns or tanks should leak, the solution would be safely contained on the floor of the process cell until it can be cleaned up. For the volumes of material available in the tanks, the cell floor is considered an infinite slab for criticality purposes. Equipment

that handles radioactive solutions is located in gloveboxes on the first, second, fourth, fifth, and sixth floors. Each glovebox is maintained at a lower negative air pressure than the room air surrounding the glovebox. This difference in pressure enhances the barrier between the operator and radioactive materials by directing air flow into the contaminated glovebox. HEPA filters at the air supply inlet of gloveboxes are a barrier to contamination spread into the room if air flow becomes reversed. Seismic qualifications of these gloveboxes are presented in Table 5-5.

All of the solvent extraction columns are single-barrel vessels. The diameter of these vessels is designed to be geometrically favorable for criticality safety. With the exception of the small, single-barrel tanks in the gloveboxes, the tanks in the process cell are four-barrel tanks (Figure 5-27). The small diameter of each vessel in a tank coupled with the spacing between vessels is designed to make each four-barrel tank geometrically favorable. The four-barrel tanks also have sloping bottom lines which facilitate drainage.

Process piping throughout the PRF typically is stainless steel. Fluorocarbon pipe is used for solutions that contain free fluoride ions that are corrosive to stainless steel. The slag and crucible dissolvers are made of stainless steel pipe lined with fluorocarbon.

The Magnehelic™ pressure gauges and instruments are designed to withstand 4 lb/in^2 over or under pressurization without loss of function or accuracy. The piping materials specifications were:

- American Society for Testing Materials (ASTM) 262-55T--Boiling HNO_3 test for dissolver castings
- ASTM A53-59T--Welded and seamless steel pipe
- ASTM A193-59T--Alloy-steel bolting for high temperature service
- ASTM A194-59T--Alloy-steel nuts for bolts for high-pressure and high-temperature service
- ASTM A307-58T--External and internal threaded fasteners
- ASA B16.5-1957--Steel pipe flanges and flanged fittings
- HWS-8067-S--Stainless steel welding electrodes and filler.

The MT gloveboxes were designed to confine plutonium and provide for inlet and outlet air ventilation through HEPA filter systems. The process equipment was designed to provide confinement during normal feed preparation and stabilization. The spacing and size of the equipment is used in conjunction with administrative mass and concentration limits to provide criticality control. The glovebox, ventilation system, and process equipment were designed to minimize the amount of contamination, should a fire or explosion occur, by maintaining airflows and pressure drops.

The roof is tar and gravel over a concrete slab on a metal deck. An Underwriters Laboratory (UL) listed class A polyurethane foam has been applied over this assembly. The exterior walls and floors are poured concrete and concrete block. The interior walls consist of plaster on metal lath, poured concrete, and concrete block. Fire detection and suppression systems are detailed in Section 5.4.11.

Criticality safety features incorporated into the design of the plutonium recovery operations include the following.

- The process equipment is designed to be geometrically favorable even if operated with plutonium at the maximum credible concentration (if the plutonium precipitates during a process upset) and optimum moderation.

- Spacing between major pieces of process equipment is fixed to reduce neutron interaction.

- Process cell tanks are spaced from the walls, floor, and ceiling to reduce neutron reflection from the concrete.

- Process containers such as cans or polybottles are designed to be subcritical even if overbatched and moderated.

- Liquid level in the east and west glovebox floors is physically controlled by weirs, with each floor weir discharging to a lower level and the lowest discharging to the process cell floor bays.

- The depth of liquid in the process cell floor bays is physically controlled by weirs that direct flow of solutions from bay sections near the east and west walls to the center of the cell. The process floor bays can hold all the tankage of the cell without exceeding the maximum safe depth.

- Process waste is collected in geometrically favorable tanks that are physically isolated from sources of concentrated plutonium. These tanks are connected to waste storage systems through lines operated by supervisor-controlled valves. Transfers are made only after sampling verifies acceptable plutonium content in the waste.

- Cooling water systems are designed to ensure that any leakage would flow into the process system and not discharge into the waste storage system.

Operating procedures incorporate administrative criticality safety requirements. These requirements include plutonium mass limits, limits on the number and size of containers, spacing limits between containers, concentration limits, and the depth of solution spills.

The PFP is equipped with an integrated criticality detector system. Detector coverage includes all areas where the occurrence of a criticality is considered possible. Periodic operability checks of both detectors and alarms are made and personnel response to criticality alarms is checked by drill exercises.

Although plutonium conversion is no longer being performed, the associated gloveboxes and process cells contain residual radioactive material and may be used for the storage of in-process material. The gloveboxes and cells provide the primary confinement barrier to release of radioactivity. Gloveboxes are maintained at negative pressure (-0.3 to -1.5 in. w.g.) to ensure plutonium is confined should a small break in the confinement barrier should occur. Airflow is through a nontestable high-efficiency particulate air (HEPA) filter at the glovebox exit and at least two testable HEPA filter stages in series in the E-4 offgas treatment system. Pressure drop across filters is indicated by Magnahelic gauges and is periodically monitored to detect filter plugging.

The process cell tanks are shielded by a 24-in. concrete wall. Individual gloveboxes, such as at the maintenance cell, have provisions to add lead glass shielding as needed. Leaded gloves are used in most positions to reduce gamma ray exposure to the hands and arms. Surveys are taken frequently to assess radiation levels at workstations.

The CAMs are provided to monitor workplace breathing air in rooms where there is a probability of airborne radioactivity. Portable CAMs are used when performing nonroutine maintenance activities. Filtered and fresh-air-supplied respirators are available, if needed.

Criticality, fire, and evacuation alarms, CAM alarms, intercommunication systems, and the commercial telephone system provide for alerting personnel to emergencies. Each system is detailed in Section 5.4.10, and additional detail of the fire protection system is given in Section 5.4.11.

The 236-Z Building and its service and utility systems have been reviewed for compliance with the requirements of DOE Order 6430.1A (DOE 1989). The results of these reviews are presented in Tables 1 through 9 of WHC (1990).

5.2.3 The 232-Z Building

5.2.3.1 232-Z Structural Specifications. The 232-Z Building is approximately 37 ft wide by 57 ft long. The building is a single story over the process and storage areas and two stories over the service areas at the north end. The respective roofs are about 15 ft and 19 ft above grade and consist of concrete over metal decking, with an insulation and built-up asphalt gravel covering. The facility structure is constructed of concrete blocks. It has its own ventilation air supply and exhaust air filtration system, with exhaust air being routed to the atmosphere through the 296-Z-14 stack. The incineration equipment in this building is no longer used and has been cleaned out of plutonium material.

5.2.3.1.1 Seismic Analysis. Seismic analysis for the 232-Z Building has not been formally documented. By inspection, the 232-Z Building was deemed incapable of resisting DBE motions (Ballinger 1993). In the event this facility fails as a result of seismic and/or other natural forces, a portion of the residual plutonium inventory could be released to the environment from the E-4 ventilation exhaust system duct upstream of the HEPA filters. The

acceptability of the failure and consequences is discussed in Chapter 9.0, Section 9.2.4A.

5.2.3.1.2 Wind Analysis. The wind analysis for this building is not documented.

5.2.3.1.3 Snowfall Analysis. The snowfall analyses for the 232-Z Building is not documented.

5.2.3.1.4 Ashfall Analysis. The 232-Z Building roof has not been analyzed for natural phenomena volcanic ashfall loadings.

5.2.3.2 232-Z Building Description.

5.2.3.2.1 Function. The 232-Z Building housed an enclosed system of gloveboxes and hoods used for sorting solid plutonium contaminated wastes, leaching noncombustibles, chopping wastes for size reduction, and incinerating the combustible wastes. Solutions and ash from this process facility were processed for plutonium recovery in the 236-Z Building. A cutaway view of the 232-Z Building is given in Figure 5-31.

This building has its own air supply ventilation system; exhaust ventilation is provided by two fans that discharge to the atmosphere through the 296-Z-14 stack.

5.2.3.2.2 Components. The plutonium recovery processes in this building were shut down years ago and the facility is not in use. The process equipment, which includes the incinerator hood and the glovebox housing the offgas scrubber, is inactive and has been isolated. The building ventilation supply and exhaust systems, including the HEPA filtration systems, are in operation, though sections of the exhaust ventilation system piping connecting hoods and gloveboxes to the E-4 system have been isolated and removed (see Section 5.4.1 for more details). Installed safety systems, such as the fire detection and alarm system, the automatic wet-pipe sprinkler system (temporarily deactivated), CAMs on HEPA filtered exhaust (with local audible and visible alarms), and instruments for DP measurements between ventilation zones are operable. Building surveillance is provided on a shiftly (at least once every 12 hours) frequency for detection of abnormalities. The building is heated with ceiling heaters.

The 232-Z Building has undergone bulk plutonium removal from the gloveboxes and hoods and associated ventilation exhaust piping and decontamination and decommissioning activities have been completed. All ventilation ducting, whether still in place or removed, and the main pieces of process equipment (e.g., the incinerator glovebox and scrubber cell) have undergone NDA.

5.2.4 The 241-Z Complex

5.2.4.1 241-Z Structural Specifications. The 241-Z Complex (or Liquid Waste Treatment Facility) consists of five structures: the 241-Z Building, the 241-ZA sampling building, the 241-ZB caustic tank (inactive and scheduled for removal), the 241-Z-RB retention basin (scheduled for removal) and the 241-ZG changeroom. The 241-Z Building consists of two parts: a corrugated metal

enclosure located above a belowgrade structure consisting of five separate cells with sumps, each containing a tank that is used to accumulate the potentially radioactive liquid wastes generated in the PFP for chemical adjustment before transfer to 244-TX. (Tank TK-D6 has been emptied, isolated and is unavailable for liquid storage.) The belowgrade structure is constructed of reinforced concrete, and the approximate dimensions are 20 ft wide, 92 ft long, and 22 ft deep, with cell walls of the sumps being 1 ft thick (each cell is 17 ft wide, 17 ft long, and 22 ft deep-see Figure 5-32). The roof (consisting of 6 in. thick, reinforced concrete coverblocks allowing access to the waste tanks) is at approximately grade level. Atop the coverblocks is the pre-engineered corrugated metal enclosure that serves as a weather cover to house the ventilation filter enclosures, 1,500-lb capacity monorail crane for lifting coverblocks and tools, steam jet piping for sampling equipment, tanks TK-D10 (inactive) and TK-D11 (chemical addition tank), and instrument racks.

The 241-ZA sampling building is a corrugated metal square structure 12 ft on a side. The 241-ZB caustic tank and 241-Z-RB retention basin are scheduled for removal. The 241-ZG Changeroom is a corrugated metal structure.

5.2.4.1.1 Seismic Analysis. Seismic analysis of the 241-Z Building belowgrade reinforced concrete vault is not documented; however, seismic analysis of the reinforced concrete vault cover blocks shows that the blocks will withstand DBE motions (Ocoma 1988a). Although the in-cell tanks can fail during a seismic event, cover blocks will not fall into the cells and cause further tank damage (see Chapter 9.0, Section 9.2.4A). It is assumed that the corrugated metal enclosure above the waste tanks of the 241-Z Building will not withstand the DBE. The 241-ZA sampling building, 241-ZB caustic tank, 241-Z-RB retention basin, and 241-ZG changeroom have not been analyzed for the DBE.

5.2.4.1.2 Wind Analysis. Wind and missile design analyses for the corrugated metal structure of the 241-Z Building are formally documented in Giller (1990). The analysis was performed by comparing the 241-Z Building specification for wind forces with the Hanford Site criteria, which determined the specification forces were less than the DOE-RL (1989), criteria for extreme wind forces. It is assumed that the corrugated metal enclosure of the 241-Z Building will not withstand extreme wind forces and associated missiles. The 241-ZA sampling building, 241-ZB caustic tank, 241-Z-RB retention basin, and 241-ZG changeroom have not been analyzed for extreme wind forces and associated missiles.

5.2.4.1.3 Snowfall Analysis. The 241-Z Building corrugated metal roof was evaluated (Giller 1990) by comparing the normal load roof design capacity with the DOE-RL (1989) normal roof load criteria. The corrugated metal structure of the 241-Z Building was found to be adequately designed for live and dead loads (Giller 1990). The 241-Z corrugated metal structure has not been analyzed for snowfall. The 241-ZA sampling building, 241-ZB caustic tank, 241-Z-RB retention basin, and 241-ZG changeroom have not been analyzed for snowfall.

5.2.4.1.4 Ashfall Analysis. The 241-Z, 241-ZA, 241-ZB, 241-Z-RB, and 241-ZG facilities have not been analyzed for natural phenomena volcanic ashfall loadings.

5.2.4.2 241-Z Complex Description.

5.2.4.2.1 Function. The 241-Z Complex (or Liquid Waste Treatment Facility) consists of five structures: the 241-Z Building, 241-ZA sampling building, 241-ZB caustic tank (now inactive and scheduled for removal), 241-Z-RB retention building (scheduled for removal) and 241-ZG changeroom. This complex serves to adjust and temporarily store PFP radioactive liquid waste (RLW) before transfer to the 244-TX receiving facility.

5.2.4.2.2 Components.

241-Z Building. The five below-grade storage tanks (tanks TK-D4, TK-D5, TK-D6, TK-D7, and TK-D8) are made of stainless steel, and each has a capacity of 4,300 gal. Nuclear criticality safety for these tanks is provided administratively by limiting plutonium concentrations and quantities. A list of the tanks and their associated equipment in the 241-Z Building is shown in Table 5-14. See Figure 5-33 for the layout of a typical Building 241-Z storage tank.

Tank TK-D8 receives PFP aqueous wastes. The wastes originate from the PPSL, PFP AL, and periodic flushes from the 26-in. mercury vacuum seal water. During plutonium solution stabilization operations with the Production VDC or Laboratory Prototype Calciner, wastes transferred to TK-D8 include caustic scrubber liquor from the spent scrub solution tanks. The waste collected in TK-D8 is batch transferred via steam jet to TK-D5 after sampling. Chapter 7.0 details the waste management processes of the PFP.

The pH of the stored waste is adjusted using NaOH or KOH before transfer to the 244-TX receiving facility. Chemicals, such as $Fe[NO_3]_3$ from TK-D11 in the 241-Z Building, are needed as required to meet Waste Acceptance Criteria (see OSD-184-Z-00010).

Tank TK-D5 is equipped with a pump and a steam jet. The pump is a 3-hp, 4-stage with 51 to 58 ft of head at the discharge nozzle. It has a high temperature interlock set for 200 °F. Pump operation is interlocked with controls located at the 244-TX vault so that waste transfers cannot be made without personnel in attendance at the 244-TX receiving facility. The steam jet receives 50 psig inlet steam, has 100 gal/min discharge, an operating temperature of 100 °F, and has a maximum operating temperature interlock set for 200 °F, 14.5 ft suction lift, and a discharge head of 22 ft of water. The maximum operating temperature for TK-D5 tank transfers is 200 °F. The steam jet is used when TK-D5 requires an NDA. The steam jet is configured to remove all solution in TK-D5.

Leak detection is provided for the transfer line (2 in.-LSW/HSW-M9) to tank TK-D8 by a leak detection element (to relay panel LDE-D84A). A second leak detection element (to panel LDE-D84B) is provided for a 2-in.-spare-M9 transfer line (currently capped with a plug). Both leak detector relay panels send to panelboard L located in the corrugated metal aboveground structure. Signals from the leak detection elements are sent to the leak detector junction box number 1, which in turn is directed to LDI-84A and LDI-84B in the 234-5ZA Building. The leak detectors are powered by a 15 A circuit breaker in panelboard L.

There are approximately 25 drains from the multiple-branched pipe system that are open to the zone 3 air space. Each of these drains has a water P-trap as a design feature to mitigate possible suck back because of air pressure differences; however, these P-traps dry out over time. These drain lines are routed to the pipe drain header to which the Building 241-Z transfer pipe is connected.

Tank TK-D6, which is a confirmed leaker, has been isolated and abandoned in place. Tanks TK-D4, TK-D7, and TK-D7 overflow tank are used to catch overflow from the TK-D8 and TK-D5 tanks.

Waste tank data are periodically recorded on instrument readout charts in 241-ZA Sampling Building. The Building 236-Z control room for the 241-Z Complex is not continuously manned.

Various penetrations (pipes, electrical) allow in-leakage of building air through the floor (cell ceiling) to the cells and into the tanks. Exhaust air is drawn from the cells and tanks by two separate headers connected to a common header and is then heated, filtered through a two-stage testable HEPA filter, sampled and monitored continuously for radioactivity, and discharged to the atmosphere through a 25-ft stainless steel stack (296-Z-3).

241-ZA Sampling Building. The 241-ZA sampling building houses the sampler glovebox (GB-2-241-ZA) used to take samples from the below-grade waste tanks via dip leg, dip legs to each tank using only one steam jet that ejects the liquid into TK-D5. It also houses the annunciator panel and an inactive and disconnected sampling glovebox (GB-1-241-ZA).

241-ZB Caustic Tank. The 241-ZB caustic tank once housed caustic tank TK-D9, which was used in buffering transuranic (TRU) waste in the 241-Z below-grade storage tanks. The tank is scheduled for removal. The 55-gal drums of caustic will be brought in by truck as required for buffering of the 241-Z tank waste.

241-Z-RB Retention Basin. The 241-Z-RB retention basin is a concrete retention basin previously used to hold waste from 241-Z Complex prior to discharge into the PFP crib system (which is now isolated from PFP discharges). The basin is scheduled for removal.

241-ZG Changeroom. The 241-ZG Building houses the changeroom for workers who are to enter the 241-Z sump metal shack and the 241-ZA Sampling Building. It is a corrugated metal structure.

Transfer Line to 244-TX receiving facility. The transfer line has no documented operating pressure, though it is believed that the lowest maximum operating pressure is 230 psig. There is no rupture disk/PRV in the line to limit pressures. The control panel at 244-TX has a TK-D5 pump enable switch that must be turned on in order for any pumping from TK-D5 to 244-TX to take place.

Transfer Lines to 241-Z Building. There are four pipe lines that direct liquid waste to the 241-Z below-grade tanks: two 2 in. diameter spare pipes, a 2 in. diameter spare LSW/HSW pipe, and a 2 in. diameter LSW/HSW pipe. Each pipe line is enclosed in a 4 in. enclosure pipe, which is in turn enclosed by

a 10 in. diameter sheet metal duct. The pipe lines are secured at various locations by 16 gauge galvanized steel ducting attached to concrete anchor blocks. The underground conduit

Cathodic Protection System. The transfer piping is protected from corrosion by a cathodic protection system which consists of anodes, anode junction boxes, vertical prepackaged anodes, test stations, and a rectifier. Anode headers and loop cables are routed in the same trench, directly over the pipe lines. Anode junction boxes are enclosed in a concrete junction box enclosure with a steel cover, buried at grade level. The anode headers and anode loop cables test stations consist of a test station conductor with two pipe test conductors exothermically welded to the 2 in. LSW pipe line, and a reference electrode connected to a reference electrode lead wire. The test conductors are enclosed in a concrete test station enclosure with a steel cover, buried at grade level.

Detailed discussions of the 241-Z Complex processes and the wastes handled by it are found in Chapter 7.0, Section 7.2.2.

5.2.4.2.3 Design Bases and Safety Assurance. Exhaust air from the 241-Z Complex (which has a potential for radioactive contamination) is continuously monitored and sampled any time forced ventilation is occurring through the stack.

The 241-Z Complex is constructed of noncombustible materials. It houses belowgrade tanks that contain liquid waste and has essentially no combustible contents. The roof, exterior walls, and interior walls are corrugated metal. The floor is poured concrete. All finish materials are noncombustible.

The 241-Z Building belowgrade tanks and sumps are not a geometrically favorable design. Therefore, the fissile content is controlled by the engineered barriers, evaluation of analytical results, and/or administrative controls.

5.2.5 The 242-Z Building

5.2.5.1 242-Z Structural Specifications. The 242-Z Building (previously the Waste Treatment Facility) is not in use. The approximate dimensions of the building are 40 ft wide, 26 ft long, and 23 ft high. The tank room occupies about 10 ft by 40 ft of the south portion of the building. The tank room extends the full inside height of the building. The north portion of the building, which was the control room, has a mezzanine over its west half that was used for chemical addition tanks. The south wall of the 242-Z Building is reinforced concrete. The remainder of the building has a structural steel frame covered with metal lath and plaster internally and insulating material wall panels externally. The roof is constructed of metal decking covered by insulation and built-up asphalt and gravel. The 242-Z structure is between the southeastern corner of the 234-5Z Building and the 236-Z Building (see Figures 5-6, sheets 1 and 2). A corridor runs along its east side, connecting the 234-5Z, 242-Z, and 236-Z Buildings (though the entrance connecting the 242-Z Building and the corridor has been sealed shut by welded steel plates). An entrance enclosure at the west end of the control room was used for outside entry into the 242-Z Building and the analytical laboratories in the 234-5Z

Building, however this entry has been sealed shut by welded steel plates. Both the east side corridor and the west side entrance enclosure are considered to be part of the 234-5Z Building, not the 242-Z Building. A cutaway view of the 242-Z Building is given in Figure 5-34.

5.2.5.1.1 Seismic Analysis. The 242-Z Waste Treatment Facility was analyzed (Giller 1991a) using the ANSYS PC/linear computer program to determine whether the facility could withstand DBE loads. The structural geometry, member section properties, and building masses were modeled, and a dynamic modal analysis was performed to determine the building frequencies. The analysis showed stresses of some members are not within the code allowables. The structure can be qualified with minor modifications to two column baseplates and by replacing two rod braces with larger diameter rods. During the DBE, structural failure is assumed for these members, though the facility would survive. The acceptability of the failure and the consequences are discussed in Chapter 9.0, Section 9.2.4A.

5.2.5.1.2 Wind Analysis. The results of the extreme wind and missile design/analyses for the 242-Z Building are stated in Giller (1990). The results show that the main load-bearing structure can withstand extreme wind forces, and wind-generated missiles will not penetrate the wall panels.

5.2.5.1.3 Snowfall Analysis. The 242-Z Building roof was analyzed for normal roof loading of a minimum 20 lb/ft^2 in accordance with ANSI A58.1 and DOE-RL (1989) guidelines. The analysis indicates that the roof can withstand the effects of live and dead loads and of snowfall (Giller 1990).

5.2.5.1.4 Ashfall Analysis. The 242-Z Building roof has not been analyzed for natural phenomena volcanic ashfall loadings.

5.2.5.2 242-Z Description.

5.2.5.2.1 Function. The 242-Z Building houses equipment that was used to treat PRF wastes and extract americium from the wastes. Following the exothermic reaction rupture of an ion exchange column used for extracting americium, high levels of contamination where deposited in the rooms, necessitating the isolation of the facility. Entry to this building is nonroutine and strictly controlled. The main effort is to confine the contamination to the building rooms. In 1977, a testable HEPA filter was added to the building E-3 exhaust system. In 1981, glovebox ports were sealed, nonessential services were disconnected, and contaminated surfaces were treated with Butvar™, a strippable coating.

5.2.5.2.2 Components. The tank room in the 242-Z Building houses large process vessels, which are piped to the process gloveboxes of the control room.

5.2.6 The 291-Z Building

5.2.6.1 291-Z Structural Specifications. The 291-Z Building, known as the exhaust fan house, exhaust air stack building, and compressor and fan house, is a reinforced concrete structure located south of the central part of the 234-5Z Building. Of irregular shape, its approximate dimensions are 74 ft

wide by 143 ft long. Its overall height is approximately 23 ft, with only 4 ft above grade. This building houses the exhaust fans, the mechanical service equipment, and the substation.

5.2.6.1.1 Seismic Analysis. The 291-Z Building was evaluated for DBE loads (URS 1980). Preliminary analysis and evaluation indicated that the building is structurally adequate to resist lateral forces from a DBE. Subsequently, confirmatory detailed seismic analyses were carried out (URS 1980). The analyses verified that the 291-Z Building can survive a DBE.

5.2.6.1.2 Wind Analysis. The integrity of the 291-Z Building walls was checked for resistance to missile penetration from a 15 lb wood plank and to forces from a 90 mi/h extreme wind. The analysis shows that the 291-Z Building can withstand the wind forces and missile (Giller 1990).

5.2.6.1.3 Snowfall Analysis. The 291-Z Building roof was analyzed for normal roof loading of a minimum of 20 lb/ft^2 in accordance with the guidelines of ANSI A58.1 and DOE-RL (1989). The analysis indicates that the roof can withstand the effect of live and dead loads and snowfall.

5.2.6.1.4 Ashfall Analysis. The 291-Z Building roof has not been analyzed for natural phenomena volcanic ashfall loadings.

5.2.6.2 The 291-Z Building Description.

5.2.6.2.1 Function/Components. Ventilation exhaust for the 234-5Z, 242-Z, 236-Z, and 291-Z Buildings is provided by seven electric motor-driven fans in the 291-Z Building (see Figure 5-6, sheet 1 for the floor plan of the 291-Z Building). These fans and the inlet and exhaust plenums are the primary contents of the 291-Z Building. Two steam-driven fans that provide emergency exhaust in the event of loss of electrical power are also located in Building 291-Z. The 291-Z Building ventilation supply and exhaust systems are used only to remove the heat generated by the motors and other equipment. Evaporative coolers supply air cooling in the summer. Exhaust is provided by exhaust outlets. A cutaway view of the 291-Z Building is given in Figure 5-35.

The 291-Z Building consists of an electrical room (room 500, also designated as the 252-Z-2 substation), a compressor and pumps room (room 501), two fan rooms (rooms 502 and 509), two exhaust plenums (rooms 503 and 510), two cross passageways (rooms 504 and 506), an inlet plenum (room 505), an air supply room (room 507), and a discharge plenum extending to the stack (room 508).

The inlet plenum (room 505), which divides the facility, enters at an angle and then makes a horizontal run. On each side of the inlet plenum is a fan room with a discharge plenum below. The inlet plenum is 136 ft long, 15 ft wide, and varies in depth but is about 20 ft deep.

Each fan room (140 ft long, 13 ft wide, and 13 ft 6 in. deep) has positions for four electric exhaust fans and one steam-turbine exhaust fan. There are four electric-powered fans and one steam-turbine-driven fan (deactivated) in the west fan room (room 509), but only three electric fans and one steam-turbine-driven fan (scheduled for deactivation) in the east fan

room (room 502). The east exhaust plenum (room 503) and west exhaust plenum (room 510) are combined in a common plenum (room 508) that discharges to the 291-Z-1 stack. Below the inlet plenum (room 505), where it enters at an angle, is a cross-passageway (room 504) connecting the two fan rooms. There is also a cross-passageway (room 506) on the south side of the inlet plenum. Room 507, formerly the stack sample room, is now equipped with air supply units that, along with others that are individually installed throughout the 291-Z Building, provide conditioned air. See Figure 5-6, sheet 1, for the room locations.

On the east side of the 291-Z facility is a switchgear room (room 500), also designated as the 252-Z-2 facility, which contains the 13.8 kV/440 V transformers for the 291-Z, 236-Z, and 232-Z facilities. This room is 35 ft long and 18 ft wide. South of the switchgear room is a mechanical room (room 501) in which two 90-lb air compressors, emergency compressed nitrogen gas supply, two instrument air compressors (not in use), and two 17-in. mercury air sample vacuum (ASV) pumps are located. A hygrometer located in room 501 is used to measure the moisture content of the air that services the room. This hygrometer is connected to an indicator in room 321A of the 234-5Z Building. There is a sump (4 ft wide, 13 ft 6 in. long, and 7 ft 2 in. deep) located in the northeast corner of the mechanical equipment room. There are three electrical pumps, and one backup steam jet installed in the sump, which discharge to a header going to the 234-Z Building. See Figure 5-6, sheet 1 for room locations.

5.2.6.2.2 Design Bases and Safety Assurance. The 291-Z Building is capable of functioning during design basis accidents, as discussed in Section 5.2.6.1.

5.2.7 The 291-Z-1 Stack

5.2.7.1 291-Z-1 Stack Structural Specifications. The 291-Z-1 reinforced concrete stack is located adjacent to the 291-Z Building. The stack and the 291-Z Building are separated by an expansion joint. Because the stack is separated structurally from the 291-Z Building, it is possible to evaluate the stack independently of the building (URS 1988b). The stack is constructed of reinforced concrete and is 200 ft tall. The stack has an interior diameter varying from 13 ft 6 in. at the top to 16 ft 6 in. at the base. The thickness of its walls also varies, though not uniformly, from 6 in. at the top to 9 in. at the base. The stack foundation is a massive concrete footing block that is approximately octagonal in shape and has a dimension of 32 ft across its flat sides. The foundation block is 27 ft, 2 in. thick, and its top is about 3 ft 5 in. above the finished grade. A 16 ft dia, 90° elbow opening in the footing connects the bottom of the stack to the duct of the 291-Z Building.

5.2.7.1.1 Seismic Analysis. A preliminary and conservative seismic evaluation of the 291-Z Building and stack indicated that the building was structurally adequate to resist lateral forces resulting from postulated DBE loading, but the stack showed overstress (URS 1980). The seismic demand of the stack was calculated by the linear elastic response spectrum procedure, assuming a fixed base.

In a more recent study, the demand on the stack was calculated using an equivalent stick model (URS 1988b). The soil half space surrounding the structure was modeled by frequency-independent springs to account for soil-structure interaction effects. The stack responses were calculated using the time history model superposition procedure with the free-field time histories conservatively applied at the embedded base level. The calculated demand was then compared with the capacity of the stack. The capacity of the stack to resist horizontal and vertical DBE loading was rigorously calculated on the basis of nonlinear behavior of concrete and reinforcement bars. The nonlinearities considered were concrete cracking, parabolic compression behavior of concrete with crushing and ultimate strain specification, and elastic-plastic behavior of reinforcing bars. The capacity for reinforcement bar yielding initiation and the ultimate capacity were calculated for each section of the stack. The results of this study show that the stack has enough ultimate capacity to resist the postulated DBE loading with ductile behavior.

The URS (1988b) study rigorously and conservatively evaluated the capacity of the 291-Z-1 stack to resist a postulated DBE with a zero period acceleration of 0.25 g. Alternative calculations were also performed to show the conservatism of the present evaluation. The conclusions of this study may be summarized as follows.

- The dynamic analysis and evaluation of the 291-Z-1 stack demonstrates that the stack reinforcing has enough ductile capacity to resist the DBE loading without collapse.
- The maximum horizontal and vertical displacements at the top of the stack have been shown to be less than 8 in. and 0.2 in., respectively.
- The maximum horizontal acceleration at the top of the stack has been calculated to be less than 0.8 g.

5.2.7.1.2 Wind Analysis. The wind loading analysis for the 291-Z-1 stack consisted of calculating moments and shears at specific elevations along the stack (Giller 1989a). These moments and shears are compared to demand/capacity curves developed in the 291-Z-1 stack seismic analysis.

The results from the extreme wind analysis of the 291-Z-1 stack demonstrate that the extreme wind demand is significantly less than the stack capacity and the seismic demand at all elevations (Giller 1989a). Therefore, the stack is qualified for the extreme wind condition.

5.2.7.1.3 Snowfall Analysis. The normal roof loading analysis is not applicable to the 291-Z-1 stack because there is very little horizontal surface area compared to the vertical stiffness. The stack can withstand snow loads (Giller 1990).

5.2.7.1.4 Ashfall Analysis. The 291-Z-1 stack has not been analyzed for natural phenomena volcanic ashfall loadings, though it is assumed that ash fall would have little effect on the structure due to the low horizontal surface area of the stack.

5.2.7.2 291-Z-1 Stack Description.

5.2.7.2.1 Function. The purpose of the 291-Z-1 stack is to provide an outlet for the E-3 and E-4 exhaust gases of the 234-5Z, 242-Z, 236-Z, and 291-Z Buildings.

5.2.7.2.2 Components. See Section 5.4.1.1.6 for details of the equipment in the 291-Z-1 stack.

5.2.7.2.3 Design Bases and Safety Assurance. The 291-Z-1 stack is constructed of reinforced concrete. This stack is capable of functioning during design basis accidents, as discussed in Sections 5.2.7.1.

5.2.8 2736-Z Support/Storage Complex

The 2736-Z Support/Storage Complex consists of the 2736-Z, 2736-ZA, 2736-ZB, 2736-ZC enclosed area, 2736-ZD vault, and 2721-Z Buildings. The 2736-Z Building is designated the primary plutonium storage facility. The 2736-ZA Building contains the equipment that provides exhaust ventilation for 2736-Z. The 2736-ZB Building is used for shipping, receiving, repackaging, and NDA of nonliquid plutonium material. The 2736-ZC is an enclosed off-loading dock and a building corridor. The 2736-ZD is an aboveground vault used for storage of experimental breeder reactor II (EBR-II) casks. The 2721-Z Building provides backup electrical power. The layout of the complex is shown in Figure 5-6, sheet 1. (See Chapter 6.0, Sections 6.2.1, 6.3.1, and 6.5.4) for a more detailed description of 2736-Z Support/Storage Complex operations).

This complex houses all operations required to make the facility capable of performing all of its functions and procedures during normal conditions. The MICON™ automation system provides monitoring and control of the 2736-Z support/storage complex following an upset in the complex HVAC and/or power systems.

5.2.8.1 The 2736-Z Building.

5.2.8.1.1 2736-Z Structural Specifications. The 2736-Z Building is a one story (65 ft long by 56 ft wide) structure constructed of reinforced, 14 in. thick concrete walls supported by cast-in-place concrete columns. The roof is a cast-in-place reinforced concrete slab that is 6.5 in. thick. The 2736-Z Building was designed to meet the design criteria specified in DOE-RL (1982), and has been found to meet design criteria from latter revisions of the Hanford Plant Standard (e.g., DOE-RL 1989). The 2736-Z, -ZA, and -ZB Buildings were designed to the criteria in DOE Order 6430.1A (DOE 1989).

Seismic Analysis. This building was seismically qualified at the time of its construction in the 1970-71 timeframe in Anderson (1971) and Lein (1972). The method used in Lein (1972) was reaffirmed in 1991 by a study that independently verified the building as a rigid structure and validated the appropriateness of the modeling method used at the time of construction (Giller 1991b). The structure was reanalyzed in 1994 for normal-operating and natural-phenomenon loads (Giller 1994a). Equivalent static methods, as

opposed to dynamic methods, were used as recommended by Kennedy et al. (1990) for simple regular structures that have uniform mass and stiffness distributions. All structural members of the 2736-Z Building were found to have positive margins of safety with respect to the material design strengths.

Additional seismic considerations in the mid-1970's provided container integrity assurance through shaker table testing of the pedestal storage configuration, and the establishment of operating specifications for storage that provide controls on container contents and packaging materials. The seismic qualification of storage cubicles, pedestals, and racks were reanalyzed in 1994 (Ocoma 1994). It was found that the precast concrete cubicles and the pedestals in vaults 1, 3, and 4 were adequate to withstand DBE loads as were the two different types of metal storage racks in vault 2 used for storage of 7-in. cans and lard cans; however, it was found that the anchor bolt loads of the storage racks in vault 2 used for storage of lard cans exceeded allowable load capacities. It was also determined that nonrated chains were used to secure the lard cans in their storage cubicles. Originally, nonrated chains were placed across the opening of the racks to prevent lard cans from being shaken out of the storage cubicles during a DBE. These nonrated chains have been replaced with aircraft chains. Overhead bracing has been added to the top of the storage racks. Currently, the storage racks are bolted to the wall they are adjacent to, the concrete floor, and each other. With the bolts and overhead bracing in place, the storage racks can withstand DBE loads; however, it was found that the addition of the overhead bracing has caused some of the base floor anchor bolts to be raised slightly from their respective drill holes. Further strengthening of the floor bolts was carried out in July of 1995 to compensate for the loosening of the base floor anchor bolts.

Wind Analysis. According to Lein (1972), the 2736-Z Building was designed to withstand a tornado wind of 175 mi/h resultant wind speed and various tornado-generated missiles described in DOE-RL (1982), which exceed the DOE-RL (1989) criteria of 90 mi/h extreme wind and a 2 in. by 4 in. wood plank missile for nonreactor facilities.

Snowfall Analysis. The 2736-Z Building roof was analyzed for normal roof loading of a minimum 20 lb/ft^2 in accordance with ANSI A58.1 and DOE-RL (1989) guidelines. The analysis indicates that the roof can withstand the effects of live and dead loads and snowfall (Giller 1990).

Ashfall Analysis. The 2736-Z Building roof has not been analyzed for natural phenomena volcanic ashfall loadings.

5.2.8.1.2 2736-Z Description.

Function. The 2736-Z Building is designated the primary plutonium storage facility. A cutaway view of the 2736-Z Building is given in Figure 5-36.

Components. The building consists of four vaults (vaults 1, 2, 3, and 4) for plutonium material storage (holding a total of approximately 500 kg), divided by a corridor that runs the width of the building. Each vault is about 28 ft x 28 ft. Vaults 1, 3, and 4 contain precast concrete storage cubicles; vault 2 has steel shelves and open floor storage.

Vault 1 contains 68 storage cubicles constructed of precast concrete panels 8 in. thick (see Figure 5-37). Each cubicle has a cross-sectional area 1 ft by 2 ft and is approximately 8 ft tall. Sixty-six cubicles have pedestal storage rings for fixed array storage and two have shelves so that storage container locations are not fixed. The cubicles are described as follows:

- The fixed array cubicles have a maximum of 45 storage rings per cubicle: 9 storage rings for each of 5 pedestals. Each storage ring is 10 in. from the storage ring above or below and is 6 in. from the nearest storage ring to the side.

- Each shelved-storage cubicle has 15 shelves. All cubicles in this room have two interlocking doors made of 8-in.-thick precast concrete.

The doors of each cubicle are 8 in. thick, made of concrete, flush with the top of the cubicles and have a 0.5 in. gap from the bottom of the doors to the floor. A ventilation duct attached to the top provides continuous airflow through each cubicle and thermocouples located in the top of each cubicle permit air temperature monitoring.

Vault 2 contains shelved-storage space for 700 items of plutonium material. Each cubicle measures 9 in. by 9 in. and is approximately 12 in. deep. Containers are kept on the shelf by a spacing-loaded wire on the front (to load and unload) and a 2 in. lip at the bottom of each shelf. In addition, there are approximately 588 ft^2 of open floor space in this room for fissile-material storage in shipping and storage container arrays up to the limit allowed by the specifications. Ventilation for this room is provided by supply and exhaust ducts mounted near the ceiling on the east and west walls, respectively. The walls of this vault are 14 in. thick.

Vaults 3 and 4 cubicles are constructed of precast concrete panels 8 in. thick. Each cubicle has a cross-sectional area 1 ft by 2 ft and is approximately 8 ft tall. There are 68 of these cubicles per vault, all of which have pedestal storage rings for fixed array storage. The maximum number of storage rings per cubicle is 28 (14 rings for each of 2 pedestals). Each storage ring is 12 in. from the storage ring above or below, and 7.38 in. from the nearest storage ring to the side. Each cubicle has two doors constructed of precast concrete approximately 8 in. thick. The doors, when closed, leave an 8 in. gap between them to allow air circulation by natural convection. There is also a 6 in. gap between the bottom of each door and the floor as a further aid to ventilation. Ventilation for these rooms is provided by supply and exhaust ducts mounted near the ceiling on the west and east walls, respectively. Vault 3 contains selected material that is under International Atomic Energy Agency (IAEA) oversight. Eight cameras in the vault are assigned to monitor selected material and provide videotapes for IAEA oversight review. The materials selected for IAEA oversight also have security seals.

A vault safety and inventory system is installed in vaults 1, 3, and 4 of the 2736-Z Building. This system monitors container temperature, ambient air temperature, dimensional changes of the container, container presence, and container identification number. Data processing equipment located in the 2736-Z Building provide the data logging and processing of information

received from the container monitors. Vault inventory system anomalies are annunciated in rooms 104 and 306A of the 234-5Z Building.

Design Basis and Safety Assurance. See Section 5.2.8.7.

5.2.8.2 The 2736-ZA Building.

5.2.8.2.1 2736-ZA Structural Specifications. The 2736-ZA Building is one story, approximately 40 ft long by 22 ft wide, and is situated approximately 5 ft to the west of the 2736-Z Building. The building is constructed of poured reinforced concrete. The 296-Z-6 stack is 14 ft 8 in. high in a 36 in. by 22 in. rectangular configuration. The stack is constructed of carbon steel.

Seismic Analysis. The 2736-ZA Building was designed and constructed to withstand seismic category I loading in accordance with criteria in Hanford Plant Standards for that time (circa 1971). The 2736-ZA Building was designed to provide a stand alone, two-stage, testable, HEPA filter exhaust system for the plutonium storage vaults in the 2736-Z Building. The exhaust fans and filters are mounted on seismic snubbers and were analyzed by the supplier using dynamic-response techniques and determined to be resistant to a DBE.

The building was reanalyzed in 1994 using an equivalent static analysis method (Giller 1994b) and compared against DOE-RL (1993) seismic loading requirements for safety class 1 or 2 nonreactor nuclear structures. All structural members of the building were found to have positive margins of safety with respect to the material design requirements.

Analyses of the storage vault exhaust system were also performed in 1994 (Ocoma 1994). The specific elements analyzed were the exhaust stack, the exhaust fan and HEPA filter assembly, the diesel generator, and the exhaust interface duct assembly connecting 2736-Z to 2736-ZA. The diesel generator has since been removed and replaced with an intertie to the 2721-Z diesel generators. Though this equipment was assigned a safety class of 3 at that time (now designated as safety significant), it was deemed that the equipment should remain operable following a safety class 1 DBE (0.20 g ground acceleration). It was concluded in Ocoma (1994) that the function and operability of the exhaust system was reasonably provided for following a ground acceleration of 0.20 g for the diesel engine and a ground acceleration of a 0.20 g for the filter housing and exhaust fan/motor assembly. Because of differential motions of up to 0.216 in. in-line displacement and 0.17 in. lateral displacement between the 2736-Z and 2736-ZA Buildings, a light gauge sheet metal portion of the interface duct assembly could undergo shear-tearing failure, leading to very small cracks. The duct, however, will remain in place and provide an acceptable flowpath after the DBE.

An evaluation of the potential for a release of plutonium through the cracks in the duct is shown in Chapter 9.0, Section 9.2.4A.

Wind Analysis. The analysis performed to verify the adequacy of the building to the requirements of DOE-RL (1989) for extreme wind and wind missile indicate that the building can withstand these events (Giller 1990).

Snowfall Analysis. The analysis performed to verify the adequacy of the building to the requirements of DOE-RL (1989) for snow loading on the roof indicate that the building can withstand these events (Giller 1990).

Ashfall Analysis. The 2736-ZA Building roof has not been analyzed for natural phenomena volcanic ashfall loadings.

5.2.8.2.2 2736-ZA Description.

Function. The 2736-ZA Building houses the ventilation equipment for the 2736-Z Support/Storage Complex.

Components. The 2736-ZA Building consists of two rooms. Room 649 is approximately 11 ft by 11 ft and formerly housed a diesel generator. Room 650 is approximately 26 ft long by 22 ft wide and houses the exhaust fans and filters for the 2736-Z Building. Temperature readout devices for the 2736-Z Building also are located here. The ventilation system exhausts through testable HEPA filters, is sampled and monitored for radioactivity, and exits the 296-Z-6 stack, which projects 30 in. above the roof and 14 ft 8 in. above grade.

Design Basis and Safety Assurance. See Section 5.2.8.7.

5.2.8.3 The 2736-ZB Building.

5.2.8.3.1 2736-ZB Structural Specifications. The 2736-ZB Building is one story (132 ft long by 90 ft wide). The walls and roof are constructed of reinforced concrete. The 2736-ZB Building was designed to provide support facilities for the 2736-Z plutonium storage vaults. These support functions include shipping and receiving areas, a nondestructive plutonium assay laboratory, and a glovebox for repackaging cans of plutonium to support the long-term storage mission of the vault. The floor plan is shown in Figure 5-6, sheet 1.

Seismic Analysis. The project design criteria required conformance to SDC 4.1 safety class 1 seismic design criteria for the 2736-ZB structure and the ventilation system because it was acknowledged that plutonium might be dispersed within the facility during a seismic event from failure of confinement provided by the repackaging glovebox. The structure was analyzed using a rigid response method at 0.25 g. The stresses under static loadings were found to be low and within acceptable code limitations with adequate margins to be qualified (Goakey 1980). The approach used to qualify the mechanical equipment, such as the ventilation supply and exhaust systems, was to procure a frame mounted assembly with snubbers attached to structures embedded in a floor and seismically isolated from ducts using flexible connections. The equipment assemblies were modeled and dynamically analyzed by the vendor and shown to have acceptably low loads, though the supply fans are not seismically rated. The filter housing assemblies used in the ventilation equipment package are commercially available shaker-test qualified equipment.

The 2736-ZB Building was reanalyzed in 1994 using an equivalent static analysis method (Weiner 1994). All structural members of the building were found to have positive safety margins with respect to the material-design

strengths. The repackaging glovebox was also analyzed in 1994 (Ocoma 1994). It was found that the glovebox support frame and anchorage was adequate to withstand DBE loadings (i.e., the anchor loads and stresses in the support frame members, connections between the support frame and the glovebox, and the filter housing support were less than the allowable values). The seismic qualification of the room 636 repackaging glovebox is presented Table 5-5.

Wind Analysis. The 2736-ZB Building was analyzed for extreme wind and wind missiles in accordance with SDC 4.1, Rev 11 (DOE-RL 1989). The building was found to be able to resist such winds and missiles (Giller 1990 and WHC 1990).

Snowfall Analysis. The 2736-ZB Building roof was analyzed for normal roof loading of a minimum 20 lb/ft^2 in accordance with ANSI A58.1 and DOE-RL (1989) guidelines. The roof analysis indicates that the roof can withstand the effects of live and dead loads and snowfall (Giller 1990).

Ashfall Analysis. The 2736-ZB Building roof has not been analyzed for natural phenomena volcanic ashfall loadings. It is assumed that the ashfall loading does not exceed the snow loading and, therefore, the roof does not fail.

5.2.8.3.2 2736-ZB Description.

Function. The 2736-ZB Building is used for plutonium material shipping, receiving, sorting, and packaging and is located immediately to the south of the 2736-Z Building. A cutaway view of the 2736-ZB Building is given in Figure 5-38.

Components. Three shipping and receiving/storage areas (rooms 638, 641, and 642) each provide approximately 1,000 ft^2 of floor space. Each floor space can accommodate a maximum of 100 shipping containers the size of 55-gal drums while maintaining the necessary criticality prevention spacing requirements between the containers, as well as corridor access to staging areas. The three staging and receiving areas are physically separated by walls. Room 638A, 639 and 640 are seviced areas associated with room 638, and room 640A is a sub-room area located in Room 641.

Room 638 is monitored by smoke detectors and protected by a wet-pipe fire protection sprinkler system.

Empty container storage is provided by the 2731-ZA and 2731-Z Buildings.

The staging area provides approximately 1,500 ft^2 of floor space to accommodate the shipping container loading and unloading operations. A gantry and electric half-ton hoist with a manual trolley are used to move drums. This area includes two enclosures: a container-handling equipment storage enclosure and a shipping container decontamination enclosure that is approximately 100 ft^2.

A repackaging area (room 636) that is approximately 680 ft^2 is provided for repackaging plutonium material. The Building 2736-ZB repackaging glovebox is located in this room.

Repackaging Glovebox. This is a standard, seismically qualified glovebox (see Figure 5-39). It is constructed of stainless steel frames and floors and clear, self-extinguishing polycarbonate safety sheets, or glass and wire-mesh panels on the sides and top. The panels are penetrated by gloveports, bag-in/seal-out ports, sphincter seals, solution transfer lines, and instrument and electrical connectors. Thick polycarbonate panels, leaded safety glass, and lead-filled gloves provide neutron and gamma-ray shielding. The glovebox has a dedicated dry air system located in room 602 (see Section 5.4.3.1.3), a hygrometer, quick disconnect fire extinguisher, and an open-face hood for over-sized containers. Heat detectors are situated in the glovebox and smoke detectors are placed in the room.

The glovebox air of the repackaging glovebox is continuously sampled and analyzed for moisture content by the condensation dew point hygrometer, which is set to alarm when the dew point rises above -10 °F. This ensures that the air moisture in plutonium material containers is below 1% to prevent possible moisture adsorption on plutonium powders and subsequent pressurization of the container during storage due to gases generated by the radiolysis of water.

A decontamination room (room 630), equipped with a shower, sink, and other necessary supplies, is provided for personnel decontamination.

Capability for repackaging is provided to handle plutonium oxide powder and plutonium metal. Shielding materials are to be used to keep personnel exposure as low as reasonably achievable (ALARA) and within the limits as discussed in Chapter 8.0.

An NDA laboratory (room 637) is provided to house all of the NDA laboratory and computer equipment. Space is provided for a laboratory standards storage facility and two offices for laboratory personnel. Approximately 1,800 ft^2 of floor space is provided to accommodate the calorimeters (pre-equilibration baths, etc.), segmented gamma scan assay system, gamma energy analysis system (isotopic analysis system), neutron well coincidence counters, associated minicomputers, and NDA equipment. A monorail and manual hoist are provided for handling waste drums. See Chapter 6.0, Section 6.5.4, for additional detail concerning the 2736-ZB NDA laboratory.

The mechanical room (room 602) houses the MICON™ local control unit (LCU), computer terminal, as well as the communication lines to and from the computer system, dry air and instrument air compressors (see 5.4.3 for details on the compressed air systems), HVAC supply fans, fire riser, NDA supply fans and refrigeration cooling coils, and NDA electrical heating coils.

There are no protective clothing requirements associated with the work areas of the 2736-ZB Building except for the repackaging glovebox room.

The 2736-ZB Building has its own HVAC supply and exhaust systems. The building air supply is provided by two systems: one supplies the major portion of the building and recycles a part of the exhaust air from the lunchroom and front offices, and the other provides constant temperature air (with a refrigerated system in summer) for the NDA laboratory. All NDA laboratory exhaust air is HEPA filtered and sampled and monitored. After filtration, approximately 80% of the exhaust air is recycled to the NDA laboratory supply air system. The remaining 20% is exhausted to

atmosphere after filtration through the 296-Z-5 exhaust stack. If the recycled air is found to be contaminated above the allowable limit for breathing air, it is diverted for HEPA filtration and discharge to the atmosphere through the 296-Z-5 exhaust stack. The exhaust and recirculation fans, vacuum pumps, and two 17-in. mercury vacuum pumps (see Section 5.4.5.1.2 for details of the air sample vacuum system) are located in room 600. Discharge to the atmosphere, which is sampled and monitored, exits through the 34 in. diameter stainless steel 296-Z-5 stack. Air supplied to the administrative areas is exhausted to the atmosphere unfiltered and unmonitored. See Section 5.4.1.1.7 for more details on the HVAC system.

Design Basis and Safety Assurance. See Section 5.2.8.7.

5.2.8.4 The 2736-ZC Area.

Details of the enclosed loading dock and corridor are provided here to complete the description of the 2736-Z Support/Storage Complex.

The 2736-ZC is an enclosed off-loading dock and a corridor that allows all-weather access to the shipping and receiving areas. The off-loading dock is external to the 2736-ZB Building and provides an area of approximately 1,700 ft^2 to stage and store cargo-restraint transporters. The cargo-restraint transporters are used for offsite receiving and shipping (Figure 5-40). The dock is enclosed in a metal building with a 15-ft eave height, electric roll-up doors with seal pads, electrical outlets, and lighting. Within this enclosure is a 4,000-lb capacity 360° jib crane with a chain hoist and drum handler for removal and placement of the drums from the cargo-restraint transporter. The cargo-restraint transporters are removed from the Safe Secure Transport by a winch with a 1,000-lb capacity. Airlocks provide access from the enclosed corridor rooms 643 and 644 of the 2736-ZB Building. Separate airlocks are provided for personnel and material access. In addition, administrative controls are developed to maintain safeguards and security control during shipping and receiving operations.

The majority of the shipping containers are waste containers. Other shipping containers contain plutonium oxide powder, plutonium metal, or miscellaneous scrap materials from various onsite and offsite sources.

The plutonium material packages received at the 2736-ZC loading dock are moved into the 2736-ZB Building before opening. In an emergency, temporary CAMs and a greenhouse could be erected to open a package in 2736-ZC.

5.2.8.5 The 2736-ZD Storage Facility.

The 2736-ZD storage facility, located south of 2736-ZC, is a reinforced concrete cylindrical vault 8 ft tall and 9 ft in diameter, with 1-ft-thick interlocking cover and base plate. The vault wall is about 10 in. thick. The cover and base are gasketed and bolted into place by stainless steel bolts. This facility is used to store EBR-II casks (maximum number of casks permitted in the vault is 7). The vault currently contains three EBR-II casks. According to Criticality Prevention Specification (CPS-Z-165-83070), the EBR-II cask is a 60 in. tall, 17 in. diameter steel casing with a 38 in. high, 6 in. diameter central payload cavity. Irradiated metallic fuel is contained inside a primary containment consisting of a 4 in. diameter (Schedule 40)

stainless steel pipe. This vessel is then enclosed inside another 6 in. diameter stainless steel container. Both vessels are weld-sealed and placed inside the cavity of the cask. This facility has no support equipment nor does it receive any Hanford Site utilities. Though this facility has not been analyzed for natural phenomena hazards, the probability of vault storage failure to such phenomena (seismic, wind, wind-generated missile, etc.) would be very low considering the design of the vault. As the lid and base interlock into the cylinder section, these pieces will move as one in a DBE. Overturning of the vault during a DBE is not likely because the ratio of the height to the diameter is less than 1. Failure of the EBR-II casks would also be required before any release of fuel material.

5.2.8.6 The 2721-Z Building.

5.2.8.6.1 2721-Z Structural Specifications. The generator building is 46 ft long by 19 ft wide and is constructed of poured reinforced concrete walls 1 ft thick. It is located approximately 26 ft to the west of 2736-ZB. A floor plan of the 2721-Z Building is shown in Figure 5-6, sheet 1. The 2721-Z Building has been analyzed to determine whether the building meets or exceeds current natural phenomena hazards design (see Tables 5-2 and 5-4).

Seismic Analysis. The 2721-Z Building was built using the same design characteristics as the 2736-ZB Building. As such, the building and its equipment were designed to withstand a 0.25 g DBE (WHC 1990).

Wind Analysis. The 2721-Z Building was built using the same design characteristics as the 2736-ZB Building. As such, the building was designed to withstand a 175 mi/h wind. The building was also designed to meet wind-driven missile criteria for high hazard facilities (WHC 1990).

Snowfall Analysis. The 2721-Z Building was built using the same design characteristics as the 2736-ZB Building. As such, the building can withstand current snowfall loading criteria (WHC 1990).

Ashfall Analysis. The 2721-Z Building roof has not been analyzed for natural phenomena volcanic ashfall loadings.

5.2.8.6.2 2721-Z Description.

Function. The 2721-Z Building provides backup electrical power to the PFP. See Sections 5.4.2.1.9 and 5.4.2.1.10 for a description of the function of this facility.

Components. The 2721-Z Building houses three diesel-driven generators to provide backup power to the PFP facilities. The switchgear room is situated on the north end of the building.

5.2.8.7 Design Bases and Safety Assurance. Shielding, container array, and safeguards were primary design concerns and ensure that personnel exposures are ALARA, in addition to ensuring criticality safety and secured storage and systems for the plutonium material. The vault safety and inventory system provides reduced radiation exposure to personnel conducting inventory of plutonium material stored in the 2736-Z Building, capability for automatically

conducting an inventory of plutonium material, and early detection of container distortion caused by internal pressurization.

The 2736-Z Building is self-contained and does not depend on Building 234-5Z services, except that: (1) the ventilation systems may be controlled from room 714 (MICON™ power control room) of the 234-5ZA Building via local control units (LCU) 5A and 5B located in room 321A of the 234-5Z Building as well as LCU 6 in the 2736-ZB Building, (2) the MICON™ system will support the 2736-Z Support/Storage Complex following an upset in the complex HVAC and/or power system, and Building 234-5Z and Building 291-Z provide normal electric power.

Vaults 1 and 2 and Vaults 3 and 4 of the 2736-Z Building are separated by fire walls. The building has a construction classification of fire resistive. The facility has a tar and gravel built-up roof on a concrete deck. The ceiling, floors, interior, and exterior walls are poured concrete. The 2736-ZA Building is an all-concrete construction building with concrete interior finish. All walls, floors, and finishes are noncombustible. The 2736-ZB Building has a construction classification of fire resistive. The roof consists of built-up tar on a reinforced concrete deck, supported by concrete columns. The exterior walls are reinforced poured concrete, and the interior walls are poured concrete and gypsum wallboard. The gypsum wallboard is sealed, taped, painted, and supported by metal studs. The ceiling varies throughout the building. The office area has a suspended lay-in acoustical tile assembly. The locker rooms, laboratories, staging, shipping, and receiving areas have a suspended gypsum board assembly. The remaining areas are open to the underside of the roof. The floor is poured concrete and finished with tile and paint. The 2721-Z Building is an all-concrete construction building with concrete interior finish. All walls, floors, and finishes are noncombustible. Fire detection, criticality alarms, air monitoring, communications, and other support systems are discussed in Section 5.4.

The NDA laboratory in the 2736-ZB Building is designed to limit the workstation dose rate to 0.5 mrem/h. The 2736-Z, 2736-ZA, 2736-ZB, and 2721-Z Buildings and their services/utilities have been reviewed for compliance with the requirements of DOE Order 6430.1A (DOE 1989). The results of these reviews are presented in Tables 1 through 9 of WHC (1990).

5.2.9 The 243-Z Complex

5.2.9.1 243-Z Structural Specifications. The 243-Z Building, or LLWTF, is a one-story (70 ft long by 35 ft wide) metal structure. The building has concrete flooring and below-grade structures (sump and tank pit).

5.2.9.1.1 Seismic Analysis. The 243-Z Building was designed and constructed in accordance with the 1988 UBC, Kennedy et al. (1990), and criteria in DOE-RL (1989) for safety class 3 SSCs. Therefore, the building was designed for a 0.12 g zero period acceleration.

5.2.9.1.2 Wind Analysis. The 243-Z Building was designed and constructed in accordance with ANSI A58.1, Kennedy et al. (1990),

DOE-RL (1989), for safety class 3 SSCs. This states that the building was designed to withstand a 70-mi/h wind without missiles.

5.2.9.1.3 Snowfall Analysis. The 243-Z Building roof was designed for a dead load of 25 lb/ft^2 and a live load of 20 lb/ft^2. The roof was designed to meet DOE-RL (1993) 20 lb/ft^2 snow loading requirements.

5.2.9.1.4 Ashfall Analysis. The 243-Z Building roof was not required to be designed for natural phenomena volcanic ashfall loadings in accordance with DOE-RL (1993).

5.2.9.2 243-Z Description.

5.2.9.2.1 Function. The 243-Z LLWTF is a low-hazard process facility. It provides the best available treatment of low-level contamination, both chemical and radiological, for PFP effluent that was once disposed to the 216-Z-20 crib. The facility is comprised of two buildings: (1) the 243-ZA Building sump, which holds the influent sump tank, and (2) the 243-Z Building, which holds the remainder of the equipment of the facility. The functions of the 243-Z Complex are controlled by the MICON™ operator station.

5.2.9.2.2 Components.

The 243-ZA Building Sump. Located to the east of the 243-Z Building, the sump contains the influent sump tank (1,000 gal), influent surge tank (5,000 gal), and two 5-hp turbine pumps. The influent sump tank is 7 ft tall with no overflow and is located in the lower sump. The influent surge tank is 18 ft tall with overflow and is located in the upper sump area.

The 243-Z Building. The building consists of five rooms: vestibule (room 101), changeroom (room 102), drum washing room (room 103), drum turning room (room 104), and process room (room 105), as shown in Figure 5-6, sheet 1.

The vestibule (airlock) provides direct access to the changeroom for personnel outside the building. From the changeroom, another door provides access to the process plant section of the 243-Z Building.

The process room contains particulate prefilters, pumps, adsorption media treatment trains one and two, sampler, associated valving and piping (primarily Schedule 80 PVC), and instrumentation needed to operate and monitor the plant.

Adsorption media trains one and two both have 15 replaceable 55-gal drum process canisters with associated piping. Liquid flowing through a media train passes through three stages of adsorption in the following order:

1. Granulated activated carbon (six canisters in each train in parallel)

2. Bone char (six canisters in each train, two stages with three drums in parallel)

3. Cation exchange resin (three canisters in each train).

Each media train can clean influent at a maximum rate of 30 gal/min. Train 1 or train 2 can be removed from service for maintenance without stopping the influent flow to the 243-Z Building. Redundant pumps and filters are included in the process for the same reason. Saturated canisters are uncoupled from the process piping by quick disconnect couplings and transported by hand cart to the drum turning room.

After passing through the media trains, the treated effluent pH is monitored as it is transferred to manhole Z7 to ensure that the effluent from the 243-Z Building does not exceed the environmental release limit stated in *Water Quality*, HNF-PRO-456, and in "Dangerous Waste Regulations," *Washington Administrative Code* (WAC 173-303-090). Exceeding the pH limit will result in an alarm that will notify the MICON™ operator. Total alpha is determined by a composite effluent sample taken from the treated waste stream before it leaves the 243-Z Building. Additional sampling points after each bone char, granulated activated carbon, and cation exchange resin are also available for grab samples to ensure media integrity. If the effluent is tested and found not to meet the requirements for release, it is recycled for retreatment. See Chapter 7, Section 7.2.3, for a description of the waste water treatment process.

The drum washing room is used for washing new 55-gal adsorption canisters (activated carbon and bone char only) to remove small particulates before they are placed into the treatment trains. A floor sump in the south-west corner of the room provides for disposal of wash water to tank 101. New 55-gal canisters are brought into the room using a ramp from outside and held there until ready for placement in a train. A single door provides access into room 103. Sanitary water and process air are provided to this room. Process air takes the form of compressed air, which is used to blow a canister dry after drainage.

The drum turning room is used for draining liquids from saturated 55-gal adsorption canisters before transportation and disposal of the drums. The liquid that is drained is considered radioactively and/or chemically hazardous and is drained back into the influent sump tank.

5.2.9.2.3 Design Bases and Safety Assurance. The 243-Z LLWTF was designed according to *Functional Design Criteria Plutonium Finishing Plant Liquid Low Level Waste System Modification* (Lueck 1992). The building and its service/utility systems have been reviewed for compliance with the requirements of DOE Order 6430.1A (DOE 1989).

The 243-Z Building requires electrical power, process air, and sanitary water services supplied from other buildings. Fire alarms are indicated at the local fire alarm control panel and transmitted to the Hanford Fire Department (HFD) via radio fire alarm reporter.

The LLWTF stream is provided with leak detection and double containment from near the 243-ZA sump tie-in with existing 15-in. PVC coming from manhole Z4 until it leaves the 243-Z Building as treated water. Double containment is accomplished by two methods: (1) a pipe within a pipe with leak detection when routed underground, and (2) the concrete floors of the 243-Z Building are coated with a special protective coating. Nine floor drains all lead to a building sump. If a major leak or rupture occurred, or water from the fire

protection system was released inside the 243-Z Building, the liquids would flow, by gravity, through double-contained floor drain piping to the building sump. Spilled effluent from the concrete sump is cycled through the 243-Z Building for retreatment. Once the liquid is treated, tested, and released, it is no longer considered as very low activity liquid waste and is routed to the sewer system for disposal at the Treated Effluent Disposal Facility (TEDF).

Solution is continuously routed to TK-102 by the feed pumps to 243-Z. A flow control valve can be adjusted to allow more flow or less flow by the MICON™ operator depending on the flow rate into TK-101. MICON™ bypass switches for the TK-101 pumps are located at the 243-Z panelboard for those times when the MICON™ has no control power.

Ventilation exhaust enters into an open-faced enclosure of lower air pressure and then passes through a single-stage HEPA filter before being exhausted out the 296-Z-15 stack (see Section 5.4.1 for greater detail on the HVAC system for the 243-Z Building). Criticality alarm and communications systems are discussed in Section 5.4.10. Fire detection and fire protection are discussed in Section 5.4.11.

5.2.10 Auxiliary Facilities

These structures consist of administrative and support buildings and trailers, various storage sheds, and housing for equipment such as generators and fans. They also include the 2701-ZA/ZB, which houses central security for the PFP. The other structures are described in Table 5-15.

5.3 SUPPORT SYSTEM

5.3.1 Development of Support Requirements

Basic support systems (utilities) for the PFP are required regardless of its processing status. The support services required include ventilation, environmental surveillance and alarms, fire protection alarms, and lighting. This basic support requirement is equated to the reduced load configuration requested in Regulatory Guide 3.39 (NRC 1976).

The minimum utility services required following the maximum Chapter 9.0 hypothetical occurrence have been identified. In case of an emergency event, the plant can be placed in a safe condition in which there is no impact to the onsite or offsite receptor in excess of that discussed in Chapter 9.0. In this safe operational condition the emergency load is used to maintain the integrity of the Chapter 9.0 safety envelope to prevent an unacceptable release. The elements of this emergency load are the safety class and safety significant items determined according to HNF-PRO-704 listed in the *Safety System/Equipment List*, HNF-SD-CP-TI-108. Ventilation and containment and environmental surveillance equipment are the primary elements of concern. The safe shutdown load is a minor one, lasting for the first few minutes of any event, and is supported by the uninterruptible power supply (UPS).

In the 2736-Z Building, continuous ventilation is required to maintain the ventilation confinement designation of zone 2 for the vaults. In this case the normal process load is equivalent to the emergency load.

The support systems were designed and are operated based on the operating configuration of the plant and the process lines. These configurations do not conform strictly to those in Regulatory Guide 3.39 (NRC 1976). The correlation of the support system configuration to Regulatory Guide 3.39 is shown in Table 5-16. System loads for the PFP, as determined from its previous mission, are provided in Table 5-17. Current, reduced process loads fall within those given in Table 5-17, indicating that the PFP support systems can meet current mission requirements. Section 5.4 describes the systems available to provide these load requirements under various operational conditions.

5.3.2 Arrangement of Support Systems

This section summarizes the location of the various support facilities in relation to their functional objectives. Support system arrangements and their safety considerations are described in Section 5.4.

The ventilation support systems are located in the same buildings as the primary services. Compressed air support systems are in the same rooms as the primary services. Other compressed gas support systems involve valving-in or changing cylinders connected to the primary manifold, so the support systems are in the same locations as the primary services. Sanitary water is provided from the 283-W water treatment facility by the 200 West Area water distribution system.

5.4 SERVICE AND UTILITY SYSTEMS

5.4.1 Ventilation Systems

The original documented design bases for the PFP ventilation systems are not available. Normal operating parameters for the ventilation systems and components are presented in this section. Flow quantities for the ventilation systems, if available, are presented in Section 5.4.1. Operating experience has demonstrated that the PFP ventilation systems are functionally adequate.

All buildings served by the PFP ventilation systems are zoned to control confinement of radioactive materials, except for the 243-Z/ZA Complex which does not have zone designations; however, zone designations are not consistent for all of the PFP facilities. Within the 234-5Z, 232-Z, 236-Z, 242-Z, and 291-Z Buildings and 241-Z Complex, by historical convention, zone 1 is designated as those areas where plutonium contamination would not normally be present (e.g., office areas, lunchroom, certain maintenance shops, hallways). No contaminated materials or personnel wearing protective clothing are allowed in zone 1 areas. Zones 3, 3A, and 3B (collectively referred to as zone 3, and which now include areas that were previously identified as zone 2) consist of areas where radioactive materials (e.g., plutonium) are stored or handled in contained form, and where there is potential for contamination (e.g., rooms

where hoods and gloveboxes are located). Zone 4 consists of the inside of hoods, gloveboxes, and process cells, directly exposed to plutonium, that may be grossly contaminated. The DPs are maintained between the zones to assure that airflow is from the lowest potential contamination areas, to intermediate potential contamination areas, to highest potential contamination areas, as shown in Figure 5-41. The DPs for the various zones are shown in Table 5-18. Airflows are correlated with the differential pressure set points as shown in Table 5-18 and are set at the start-up of the HVAC system; however, the airflows change as the filters become loaded.

Zone designations in the 2736-Z Support/Storage Complex were established to meet design philosophy and requirements outlined in DOE Order 6430.1A (DOE 1989) designations. For these buildings, zone 1 is designated as having the highest potential for contamination (e.g., repackaging hood) and zone 4 as the clean zone. In these buildings, DPs also are maintained to assure that airflow is from the lowest potential contamination areas to the highest potential contamination areas.

Radioactive contamination within process areas is confined as close to the point of origin as practical through the use of HEPA filters installed on the exhaust ducts of hoods and on both the supply and exhaust ducts of gloveboxes. Exhaust ventilation air from zone 3 (zone 2 in the 2736-Z facility) areas is filtered through one stage (two stages in the 2736-ZB Building) of testable HEPA filtration before discharge to the atmosphere through a stack. Exhaust ventilation air from zone 4 (zone 1 in the 2736-Z facility) areas is filtered through two stages (three stages in the 2736-ZB Building) of testable HEPA filtration before discharge to the atmosphere through a stack. The HEPA filters (except exhaust filters on gloveboxes) are tested in accordance with criteria established in ASME N510 to demonstrate acceptable performance.

Backup capacity is provided for key features of the ventilation systems (e.g., supply and exhaust fans [see Section 5.4.2.1.2]). Two independent 13.8 kV lines (C8-L1 and C8-L2) supply normal electric power to the PFP facilities. Four supply fans (234-5Z) and four exhaust fans (291-Z) are supplied (through appropriate transformers) from circuit C8-L1. Four supply fans (234-5Z) and three exhaust fans (291-Z) are supplied from circuit C8-L2. Should one circuit fail, manual switching can be done to power all supply and exhaust fans from the remaining circuit. Backup ventilation is provided by the emergency steam turbine dirven exhaust fans.

Detailed accident analyses for the PFP have not identified any scenario where continued operation of the 234-5Z ventilation system is essential to prevent a release of plutonium having unacceptable consequences. Sections 9.1.7, 9.1.8, and 9.2.4 provide a comprehensive overview of the ventilation system as it relates to safety issues. Although a temporary loss of ventilation is acceptable (i.e., onsite and offsite releases), the consequences of a long-term loss has not been evaluated, and the acceptable period of time for ventilation loss is unknown. This finding permits most ventilation equipment to be assigned as Safety Significant. The exception is that when the ventilation system is operating, the final filters and stack CAMs are Safety Class. The PFP seismic accident analysis, found in Chapter 9.0, concludes that operation of the electric exhaust fans following a DBE

does not contribute to an airborne release of plutonium or hazardous materials having consequences above the risk acceptance guidelines.

In the 234-5Z Building, a fire damper is installed in the duct that connected the 9B filter and the 9AB filter (both filters have been removed); the fire damper is located close to where the 9B filter was located. There are only seven other fire dampers installed in the PFP ventilation systems, and three of these are out of service.

5.4.1.1 Major Components and Operating Characteristics. Ventilation for major PFP facilities is provided by six separate systems (each system having a dedicated ventilation exhaust stack):

- 242-Z, 234-5Z, 236-Z, and 291-Z Buildings (exhausted by the 291-Z-1 stack)
- 241-Z and 241-ZA Buildings (exhaust by the 296-Z-3 stack)
- 2736-ZB Building (exhausted by the 296-Z-5 stack).
- 2736-Z and 2736-ZA Buildings (exhausted by the 296-Z-6 stack)
- 232-Z Building (exhausted by the 296-Z-14 stack)
- 243-Z Building (exhausted by the 296-Z-15 stack).

The major components and operating characteristics of these systems are discussed in the following sections. Ventilation is on a once-through basis except for small-volume recycle of room air to supply laboratory refrigeration air-conditioning systems and for the 2736-ZB Building, which recycles air from the administration area and from the NDA laboratory.

5.4.1.1.1 The 234-5Z Building.

Ventilation Supply. Ventilation supply air is controlled as required to limit release of radioactive contaminants to the environment and minimize the spread of contamination.

Zone 1 and 3 Ventilation Supply. Four to five supply fans are normally in use and have sufficient capacity to allow proper balancing of the individual air zones. The remaining three to four fans provide backup for normal fan maintenance activities. The supply fans draw air from outside the building through roughing filters to remove airborne dust and dirt, through pre-heaters, air washers, and re-heaters and then deliver the air to the supply plenum at a year-round temperature of approximately 70 °F, with outside design temperatures of -10 °F to 110 °F. Each supply unit consists of the following:

- Filters
  - Size: 72 filters (24 in. by 24 in. by 8.75 in.) = 288 ft^2
  - Type: commercial dry-type fiberglass
- Preheaters
  - Pressure drop: 0.3 in. w.g.
  - Steam rate: 7,100 lb/h at 30 lb/in^2 (gauge) steam
- Air washers
  - Pressure drop: 0.66 in. w.g.

  - Pump capacity: 165 gal/min at 35 ft head (wet sump type)

- Reheat coils
  - Pressure drop: 0.20 in. w.g.
  - Steam rate: 2,650 lb/h at 30 lb/in^2 (gauge) steam

- Fan
  - Capacity: 76,100 ft^3/min at 5 in. w.g. water static pressure
  - Motor: 125 hp; 1,200 r/min.

Air pressure in the supply plenum is controlled to +2 in. w.g. by pneumatically operated control dampers on two of three operating supply units so equipped. The plenum is protected with relief dampers that relieve to the outside of the building.

A schematic of the Building 234-5Z ventilation system is shown in Figure 5-7. Five ducts lead from the supply plenum chamber to the various building zones ventilated by the system. A sixth, 60-in.-diameter steel duct mounted on the roof of the 234-5Z Building supplies air to the 236-Z Building (a schematic of the typical supply duct flow pattern through the 234-5Z Building is shown in Figure 5-42). Flows for the supply ducts are controlled at the outlet of the plenum by dampers that are modulated by pneumatic controllers based on signals from DP sensors located in the respective zone being controlled. The supply is divided into distribution mains and submains to supply air throughout the building. The duct contains a control damper, at the outlet of the plenum, that is modulated by a pneumatic controller based on signals from a pressure sensor in corridor 47, in the 236-Z Building. Flows from the supply ducts are controlled at the outlet of the plenum by dampers identified as A through F, modulation of which is controlled by pneumatic controllers located within the respective zone being controlled. A simplified view of air flow through the ventilation system of the 234-5Z Building is given in Figure 5-43. Typical flowrates of the supply systems, their controlling dampers, and the areas supplied are found in Table 5-19.

Ventilation air flow in Zones 2, 3, and 4 of Building 234-5Z is based on 30 air changes per hour, whereas the "ASHRAE Design Guide for Department of Energy Nuclear Facilities" (ASHRAE 1993) and the Hanford Site Radiological Design Guide (WHC-SD-GN-DGS-300H) recommends 4 to 8 air changes per hour. The normal design air flow for Building 234-5Z is 239,000 cubic feet per minute. Based on this value, the ventilation air flow is more than adequate to maintain plutonium airborne concentrations within the limits as specified in Appendix A of 10 CFR 835.

Supply fan S-10 takes a small quantity of air from zone 1 (approximately 1,600 ft^3/min) on the second floor and forces it under a slight positive pressure to an annulus space around each zone 3 and zone 4 filter in the large final filter rooms (309 to 316, and 318). The S-10 fan need not operate to perform this function and is currently out of service. The associated damper must be open to prevent unfiltered air from bypassing the filters if the filter gaskets are lost. The S-10 fan is located in room 321.

Recirculating, refrigerant-cooled air-conditioning systems are installed in the following areas: rooms 229, 221-A, 132, 136, 150-151, 306-A, and in PRF rooms 44-45.

Supply fans, supply plenums, and dampers associated with the ventilation supply system for zone 1 and zone 3 areas are constructed of steel. The floor of the main supply plenum is made of metal roof decking covered with a waterproof seal. Ducts are constructed of galvanized steel sheet metal. Ventilation supply air is routed to the various offices, hallways, restrooms, maintenance shops, laboratories, operating rooms, etc., of zones 1 and 3 through supply ducts. Supply air is introduced through ceiling diffusers to provide downflow ventilation to the various areas. Ventilation exhaust grills are located near the floor.

Zone 4 Ventilation Supply. Zone 4 ventilation supply for any specific glovebox is from one of two sources: (1) supply air via associated zone 3 areas through inlet HEPA filters, or (2) air supplied by the dry air system. Those gloveboxes which required dry (i.e., low moisture) air during their processing functions received such air from the dry air system (with the attached conveyor gloveboxes serving as zone 4 dry air supply plenums). The desiccant equipment of the dry air system is currently inactive, so that only normal air is being supplied to dry air gloveboxes from the process fans of the dry air system (about 850 ft^3/min). See Section 5.4.3.1.3 for additional information concerning the dry air system.

Air locks are provided between zones 1 and 3 and at building entrances whenever there is routine personnel traffic. All exterior doors other than those provided with airlocks are equipped with tamper indication devices (e.g., paper seal to detect use), but the doors may be used for emergency purposes. Emergency doors are equipped with signs on both sides indicating that the door is to be used for emergency purposes. Airlocks are equipped with audible alarms that will sound if both doors are open. The airlock doors are not interlocked. Airlock doors are fitted with gaskets to reduce in-leakage to a minimum.

All zone pressures in the 234-5Z Building are controlled automatically by pneumatically operated transmitters and controllers. Pressure sensors in each zone generate signals to control the supply air to each zone by operation of the supply dampers. One sensing signal controls the two dampers supplying zone 3. All supply fan dampers are designed to fail in an open position on loss of powered ventilation. All exhaust fan dampers are designed to fail in a closed position except the dampers to exhaust fans EM-1 and EM-2, which are designed to fail open, to allow natural stack draft to maintain normal ventilation flow direction and a minimal differential pressure across the ventilation zone boundaries. Any zone can be switched to manual control. Each zone is equipped with pressure recorders with readout in the control room (room 321) of the 234-5Z Building. The control room is manned 24 h/day. Typical zone pressures are shown in Table 5-18.

Ventilation Exhaust. Ventilation exhaust from the 234-5Z Building is provided by three systems identified as E-1, E-3, and E-4, which exhaust zone-1, zone-3, and zone-4 areas, respectively (Figure 5-7 shows exhaust flows from zones 1, 3, and 4).

An atmospheric reference system provides a standard reference for use in the measurement of the static pressure of an area. The system consists of a tank and associated piping. The tank, located in room 321 (Figure 5-44), is equipped with a 1 in. diameter line that extends through the roof level to the atmosphere. Just above the roof level, the line bends downward 180° to minimize impacts from the weather because it is an open line. Piping is provided between the atmosphere reference tank and the areas to be monitored for static pressure.

Zone 1 Ventilation Exhaust (E-1). Air is exhausted from the zone 1 areas of the first floor and duct level and some on the second floor by fans EM-11 and EM-12 (the nominal capacity of each is 30,750 ft^3/min; one is a standby) and discharged directly to the atmosphere through the roof without HEPA filtration; however, most of the zone 1 second-floor areas are exhausted through natural-flow gravity counter-weighted dampers in ducts directly to cowls on the roof. Fans EM-11 and EM-12 are located on the second floor of the 234-5Z Building in room 321 (Figure 5-44).

Some equipment in zone 1 is provided with hoods equipped for removal of small amounts of fumes or dust, and exhausted by fans that discharge through the roof to the atmosphere. Air is also exhausted from zone 1 by (1) the S-10 fan, which provides about 1,600 ft^3/min air to the filter frames in the filter rooms and (2) process fans of the dry air system that exhausts a small amount of air directly to the atmosphere. The fans and the supply-air system are located on the second floor of the 234-5Z Building in room 321 (Figures 5-6, sheet 3 and 5-44).

The office annex, associated with the PPSL, on the southwest corner, first floor of the 234-5Z Building, is classified as a zone 1 area. The offices are exhausted to the atmosphere by two small restroom-type exhaust fans and a gravity-type exhaust ventilator. Supply air is provided through wall-mounted heat pumps.

The northern section of the second floor of the 234-5Z Building (which contains offices, a lunchroom, restrooms, and engineering spaces) is also classified as a zone 1 area. Ventilation exhaust from this area is discharged to the atmosphere by exhaust fans (e.g., two lunchroom fans, an 800 ft^3/min exhaust fan, and exhaust fan EM-11).

Zone 3 Ventilation Exhaust (E-3). Air from zone 3 is exhausted through grills near floor-level in the various rooms. The air flows to the E-3 filter manifold. Dampers in the exhaust duct branches facilitate control of airflow through the grills to properly balance the system. The system is maintained at a pressure of -0.15 to -0.05 in. w.g. for contamination control. The air from zone 3 space is filtered through a single stage of testable HEPA filters that are located in seven filter rooms (rooms 311 through 316 and 318), any three of which may be in normal service and the remainder in standby. Each filter room contains 112 HEPA filters (24 in. by 24 in. by 11.5 in.), sealed individually in a steel frame filter wall that divides the room into an inlet side and an outlet side (Figure 5-45). Two manifolds with dampers on the inlet and discharge ducts of the rooms allow selection of any room combination. The exhaust air from the filter rooms (approximately 161,000 ft^3/min) flows into a common plenum (see Figures 5-7) for discharge to atmosphere through the 291-Z-1 stack.

Zone 4 Ventilation Exhaust (E-4). All exhaust air from zone 4 areas (e.g., open-faced hoods, gloveboxes), which are potentially contaminated or known to be contaminated, is routed through at least two testable stages of HEPA filters. Exhaust gasses from the zone 4 areas pass through the first stage of HEPA filtration at the duct-level (second floor) of the 234-5Z Building via dedicated filterboxes. Exhausts from these filterboxes are manifolded and routed to E-4 filter rooms 309 and 310 in the 234-5Z Building (Figure 5-6, sheet 3), which provide a second stage of testable HEPA filtration. Each filter bank room contains 128 filters identical to those used for the E-3 exhaust system previously discussed. During normal operation, one filter room is in operation with the other on standby. The E-4 ventilation exhaust is combined with the E-3 exhaust downstream of the filters in the stack manifold. The combined air flow is directed to the filter plenum, then directed to the 291-Z exhaust plenum (see Figure 5-7 for the airflow diagram of E-3 and E-4 exhaust to the exhaust plenum), passed through the 291-Z exhaust tunnel (see Figure 5-6, sheets 1 and 3 for location of exhaust tunnel) and is finally discharged to the atmosphere through the 291-Z-1 stack (see Figures 5-42 and 5-43 for flow patterns to the various plenums in the 234-5Z and 291-Z Buildings). The E-4 system exhaust flow is approximately 37,000 ft^3/min and the system is maintained at -0.5 to -2.0 in. w.g. to minimize the potential for backflow into zone 3 areas.

Ventilation exhaust from zone 4 gloveboxes and cells are exhausted through non-tested HEPA filters located in the top of the cells and gloveboxes.

The high hazard gloveboxes and powder boxes in the RMC and RMA Lines have remote alarms for high glovebox pressure (see Section 5.4.10). The RMC Line high-pressure alarms for the interconnected HC-2, HC-3, HC-4, and HA-28 conveyor gloveboxes are created by two DP switches that are calibrated annually and are currently in calibration. The RMA E-4 controller/recorder (which controls the RMA glovebox pressure for the RMA interconnecting conveyor) serves as the pressure sensor. This controller/recorder is calibrated annually and is currently in calibration. High pressure in the gloveboxes should be reduced by readjustment of the dampers.

Exhaust ventilation from Zone 4 process gloveboxes, cells, etc. where hydrogen fluoride gas was used, was segregated from the normal E-4 exhaust ventilation system, filtered through two stages of testable HEPA filters and discharged to the exhaust plenum, which handles the filtered E-3 and E-4 ventilation system exhaust air. Capability for diversion to the E-4 filter system (rooms 309 and 310) was provided as a manual backup. The E-4 exhaust streams from gloveboxes typically go through a nontestable HEPA filter before the first stage testable HEPA filter. (Currently, exhaust ventilation from Zone 4 process gloveboxes, cells, etc. where hydrogen fluoride gas was used has been rerouted to pass through Filter Box FB-21, while the original filter boxes have been removed from service. Glovebox HC-9B is disconnected from Filter Box FB-9B, Filter Box FB-9B is disconnected from Filter Box FB-9AB, and Filter Box FB-9AB's supply duct is disconnected from the ventilation system while Filter Box FB-9AB's outlet duct is directed to Filter Box FB-8.)

Inlet air to the 26 in. mercury process vacuum pumps, located on the second floor of the 234-5Z Building, is treated by a demister and two stages of testable HEPA filters (see Section 5.4.5). Exhaust air from the vacuum

pumps is routed to the E-4 filter banks (rooms 309 and 310), which provide a third stage of testable HEPA filtration for this effluent gas stream.

Electrical Driven Exhaust Fans. Seven exhaust fans (EF-1 through EF-7), each rated at 72,500 ft^3/min at 11 in. w.g. and powered by 200-hp electric motors, are installed in the 291-Z Building. Four of the seven fans are operated in parallel to exhaust the desired volume of filtered waste air from the PFP to atmosphere through the 291-Z-1 stack. Two of the installed fans (EF-3 and EF-4) are equipped with modulating dampers, which control the required flow of air through these fans to maintain the pressure in the manifold ducts to the E-3 and E-4 filter rooms at the desired level. Manual valves allows either EF-3 or EF-4 to be a modulating fan while the other fan operates at 100%. Two of the fans (EF-5 and EF-6) have manually set dampers that are air-adjustable for added control of the ventilation exhaust flow.

Steam Driven Emergency Exhaust Fans. Two emergency steam-turbine-driven fans (ET-8 and ET-9), each rated at 108,700 ft^3/min at 4.75 in. w.g., are set to start up automatically if the DP in the plenum chamber, upstream of the exhaust fans, becomes greater than or equal to 3.5 in. w.g. Ventilation supply fans (room 321) automatically shut down on startup of the steampdriven exhaust fans. Operation of the ventilation supply and exhaust fans is controlled from room 321 in the 324-5Z Building.

5.4.1.1.2 The 236-Z Building. The 236-Z supply and exhaust systems were designed and built to use some of the extra capacity of the original 234-5Z Building supply and exhaust systems. Ventilation of the 236-Z Building is provided by a once-through supply and exhaust system. Normally occupied areas of 236-Z (e.g., offices, corridors) are classified as zone 3 and process areas (e.g., gloveboxes, cells, hoods) are classified as zone 4 for confinement of radioactive materials, with ventilation exhaust systems designated as E-3 and E-4, respectively.

Zone 1 and 3 Ventilation Supply. Conditioned ventilation supply air for the 236-Z Building is provided by supply fans located in room 321 of the 234-5Z Building at approximately 42,600 ft^3/min. The air is routed to the 236-Z Building through a 60 in. diameter steel duct mounted on the roof of the 234-5Z Building. This duct is approximately 520 ft long and extends to the 236-Z Building where it is divided into distribution mains and submains for supplying air throughout the building. The duct contains a pneumatic control damper near the outlet of the room 265 supply plenum which is modulated based on signals from a differential pressure sensor located in corridor 47. This sensor, together with a DP transmitter in room 44, senses building ambient pressure changes and controls the supply air to maintain the desired building negative pressure with respect to atmosphere. A number of volume dampers also are installed in duct work on each floor of the building for flow control. Supply air is introduced through ceiling diffusers (rated at 15,670 ft^3/m, 12,370 ft^3m, and 14,560 ft^3m) to provide downflow ventilation to the various building areas. Exhaust ventilation grills are located near the floor.

Zone 4 Ventilation Supply. Zone 4 supply ventilation is from associated zone 3 areas through floor-level HEPA filters installed on the gloveboxes. Supply air to the process cell is provided through HEPA filters located near the ceiling of the second and third levels. Supply and exhaust ventilation of

236-Z is controlled from a panel in room 321 of the 234-5Z Building. The control panel is attended 24 hours a day.

Zone 1 and 3 Ventilation Exhaust. E-3 exhaust air in the 236-Z Building is routed to a west and east vent shaft, which are combined (the west vent shaft is directed to an underground crossover exhaust duct, 48 in. by 48 in., from stairway 2 to room 18) with air sample vacuum system exhaust air (see Section 5.4.5 for additional details of the air sample vacuum system). The combined flow goes to the exhaust plenum for distribution to filter banks A and D in room 26 on the second floor of the 236-Z Building. The filter banks are operated in parallel and provide a single stage of testable HEPA filtration. The E-3 ventilation exhaust air is discharged to an exhaust plenum on the first and second floors, which directs flow to an underground, 52 in. by 84 in. exhaust duct that leads to the 291-Z Building for discharge to the atmosphere by the 291-Z exhaust fans and the 291-Z-1 stack.

Zone 4 Ventilation Exhaust. The ventilation exhaust air from the E-4 system is passed through two independently testable stages of HEPA filtration. The first stage of filtration is by filterboxes near the zone 4 sources and the second stage of filtration is by filter banks B and C in room 26. The E-4 ventilation system exhausts to the plenum, together with the E-3 exhaust, for discharge via underground, 52 in. by 84 in. exhaust duct to the atmosphere by the 291-Z exhaust fans and the 291-Z-1 stack.

Zone 3 and 4 Filter Banks. Four banks of filters (filter banks A, B, C, and D) are located in room 26. Valving capabilities permit use of all four banks for E-3 exhaust filtration with either of the two middle banks (banks B and C) used for E-4 exhaust filtration. The 291-Z exhaust fans, together with dampers and control instrumentation, maintain the 236-Z Building E-3 and E-4 systems at the required negative operating pressures.

The 236-Z Building supply and exhaust ventilation schematic is shown in Figure 5-46.

5.4.1.1.3 The 232-Z Building.

Ventilation Supply. Approximately 2,000 ft^3/min of air is provided by infiltration throughout the deactivated supply system on the second floor of the 232-Z building.

Zone 1 and 3 Ventilation Supply. Zone 1 supply, which is blanked off, consisted of the second-floor room housing the air supply system and ventilation controls, and the first-floor restroom, changeroom, chemical mix room, and electrical switchgear room. Zone 3 consists of the process and storage areas.

Zone 4 Ventilation Supply. Supply air to the zone 4 glovebox and incinerator is from zone 3 through HEPA filters on the glove box and incinerator. The 232-Z Building ventilation supply system is shown on Figure 5-47.

Ventilation Exhaust.

Zone 1 and 3 Ventilation Exhaust. Exhaust air from zone 1, which is blanked off, was to the atmosphere through the use of locally controlled manual off/on switches in the restroom and chemical mix room. Exhaust air from the first-floor electrical switchgear room and from the second-floor ventilation supply and control room, which are also currently out of service, was discharged to the atmosphere by roof exhausters.

Air from zone 3 areas (E-3 exhaust system) was originally exhausted through nine in-floor HEPA filters located throughout the process area. Five of the filters are currently in use and four are now blanked off and out of service. These HEPA filters, operated in parallel, discharge to two exhaust ducts below the building floor.

Zone 4 Ventilation Exhaust. Air from zone 4 (E-4 exhaust system) was exhausted through an installed nontestable HEPA filter and routed through two independently testable stages of HEPA filtration before discharged to one of two exhaust ducts below the building floor to the 291-Z Building. The exhaust system runs from one of the exhaust ducts below the floor through three parallel sets of two HEPA filters in series. Any two sets are in service to filter the required air with the third serving as a standby. Two installed fans, with a nominal rated capacity of 2,000 ft^3/min each, provide exhaust for the 232-Z Building and discharge to the atmosphere through the 296-Z-14 stack. This stack is 21 ft high with a 12 in. dia, and is constructed of stainless steel. Exhaust effluents are sampled and monitored. Either exhaust fan can provide the required ventilation with the second fan on standby.

Confinement of radioactive contaminants was controlled by maintaining controlled DPs between zones 1, 3, and 4. Zone 1 is inactive and unoccupied. The exhaust system is capable of maintaining -0.25 in. w.g. relative to the ambient atmosphere and provides for at least six air changes per hour in zone 3 (process area). In addition the system is capable of maintaining zone 4 (glovebox and scrubber cell) at least -0.5 in. w.g. relative to zone 3. Zone 3 pressure is maintained by a DP controller and zone-4 pressure is maintained by a manual volume damper. Exhaust ventilation is shown on Figure 5-47.

The exhaust system has two-stage testable HEPA filtration (not counting the existing floor filters) and allows filter changeout of either filter without interrupting ventilation service. Redundancy is provided by having three separate banks. Any two sets must be in service to filter the required air with the third as a standby.

A stack monitor on the exhaust system samples the exhaust stream exiting through the stack. The monitoring system alarms locally and in room 714 (MICON™ power control room) of the 234-5ZA Building.

5.4.1.1.4 The 241-Z Complex.

Ventilation Supply. Supply air to the service building is provided by gravity-flow of atmospheric pressure outside air. Supply air to the vault area cells is provided from the service building by leakage around the cell cover blocks and other openings. Supply air to the enclosure that houses the

tank sampler glovebox also is provided by atmospheric pressure outside air. The building is heated with steam.

Ventilation Exhaust. One exhaust ventilation system with two branches serves both the 241-Z tanks and cells. Exhaust ventilation from the tanks is through the vessel vent system, which consists of a 4 in. diameter header with tie-ins to each tank and a demister. A valve in the header, upstream of the demister, controls the vessel vent exhaust flow to 100 ft^3/min. The vessel vent system exhaust joins the cell ventilation exhaust downstream of the demister. The 241-ZA tank sampler glovebox and tank TK-D9 caustic supply tank are also exhausted through the vessel vent system. Exhaust ventilation from the 241-Z cells is through a 15 in. diameter vitreous clay duct. A schematic flow diagram for the 241-Z Complex ventilation exhaust system is shown in Figure 5-48.

Exhaust air from the two systems is heated to protect the HEPA filters from moisture buildup, and routed through two stages of HEPA filtration, in series, before discharge to the atmosphere through the 25 ft tall, 14 in. dia, stainless steel stack. Two sets of HEPA filters provide redundancy and/or capacity as required by facility configuration. Two installed exhaust fans, one with a nominal capacity of 1,000 ft^3/min for normal use and one with a nominal capacity of 2,000 ft^3/min for use when additional flow is required (e.g., in-cell maintenance), provide the desired negative pressure on the tanks and cells. No backup electric power is provided for operation of the exhaust fans. Exhaust air from the 241-Z Complex is continuously monitored and sampled any time forced ventilation is occurring through the stack. The monitoring system alarms locally and in Room 714 (MICON™ power control room) of Building 234-5ZA.

5.4.1.1.5 The 242-Z Building.

Ventilation Supply. Ventilation supply air is provided to the 242-Z Building through the Building 234-5Z supply plenum and the S-3A distribution duct (Figure 5-7).

Zone 3 Ventilation Supply. Supply air is introduced through ceiling diffusers that provide downflow ventilation to the various building areas, and is classified as zone 3 for contamination control.

Zone 4 Ventilation Supply. Air supply to the zone-4 gloveboxes and process cells is provided through HEPA filters installed near the floor. Supply air is manually regulated by dampers to provide a zone 3 pressure of 0.2 in. w.g., with respect to outside atmosphere.

Ventilation Exhaust.

Zone 3 Ventilation Exhaust. Air from zone 3 (exhausted through grills near the floor in the various rooms) was originally filtered through the Building 234-5Z single-stage HEPA filtration system on the E-3 exhaust. Following the 1976 ion exchange column rupture and resultant contamination spread in the 242-Z Building, four in-parallel HEPA filters were installed on the zone 3 exhaust in the Building 234-5Z duct level, upstream of the Building 234-5Z E-3 HEPA filters, to provide treatment through two stages of testable HEPA filters before exhaust to the Building 234-5Z plenum (Figure 5-7).

Zone 4 Ventilation Exhaust. Air from zone 4 is filtered through a HEPA filter installed on the glovebox exhausts and by a single-stage testable HEPA filter in room 308, then routed to the Building 234-5Z E-4 exhaust system where it is filtered through an additional testable stage of HEPA filtration (room 309 or 310) before being exhausted to the Building 234-5Z plenum (Figure 5-7).

As with all zone 3 and 4 filters throughout the building, each filterbox is equipped with local or remote DP measurement devices to monitor filter performance. Pressure readings are recorded as a part of routine building surveillance activities.

5.4.1.1.6 The 291-Z Building and the 291-Z-1 Stack.

Ventilation supply air for the various rooms (except for the plenums in rooms 503, 507, 508, and 510) is provided at the rate of approximately 22,000 ft^3/min by five fans (EC-11, -12, -13, -14, and -15). The five fans are operated as evaporative coolers during the summer. Two fans supply the south end of the building through room 507, two supply the north end, and one supplies rooms 500 and 501. During the summer months, the supply is conditioned by evaporative cooling; otherwise, unheated outside air is supplied.

Supply air is not distributed by duct work and diffusers to this normally unoccupied building. Ventilation exhaust air is discharged to the atmosphere by natural flow, counter-weighted dampers directly to cowls on the roof. The dampers control the exhaust flow to maintain a small positive pressure in the building. The 291-Z-1 exhaust stack has a design flow of 395,700 ft^3/min. Room and equipment locations for the 291-Z Building are shown in Figure 5-6, sheet 1.

One near-isokinetic CAM unit monitors the ventilation exhaust air released through the 291-Z-1 stack at the 50-ft level of the stack. Two sampler pumps, one for the CAM and one for the record sampler, provide continuous air sampling at 2 ft^3/min each. Sample filters are changed periodically, samples are analyzed, and radioactive emissions are calculated. The monitoring system will alarm locally and in room 714 (MICON™ power control room) in the 234-5ZA Building. Backup power is provided for operation of the sampler/monitor and alarm systems.

5.4.1.1.7 The 2736-Z Support/Storage Complex. The 2736-Z Support/Storage Complex consists of the 2736-Z Building (primary plutonium storage facility), the 2736-ZA Building (exhaust ventilation building), the 2736-ZB Building (materials receiving and handling building), 2736-ZC enclosed area, 2736-ZD vault, and the 2721-Z Building, which houses three diesel-powered generators used for supplying standby electric power. The ventilation system for the 2736-Z Support/Storage Complex is shown in Figure 5-49.

The 2736-Z Support/Storage Complex HVAC system is monitored remotely from the 234-5ZA Building, room 714 (MICON™ power control room). A local control unit (LCU), cabinet number 6, located in room 602 in the 2736-ZB Building receives information from the monitoring and measurement instruments (e.g., pressure transmitters and flowmeters) and transmits this information to the PFP distributed control system's (DCS) operator consoles located in rooms 714

and 712. Operator commands initiated at the consoles are routed to LCU-6, which maintains desired zone pressures. Switching equipment on and off (e.g., supply and exhaust fans) is done manually or automatically from the control room. The DCS has internal and external diagnostic capabilities that can alert the operator of equipment malfunction or loss of data communications between the LCU and the operator consoles. If the LCU fails or all power is lost, the HVAC will fail in a predetermined, safe configuration to maintain confinement by shutting down the supply and exhaust fans and positioning dampers to a non-energized state. The PFP DCS is on backup power and UPS.

Ventilation zones for the 2736-Z Support/Storage Complex and their associated controls assure confinement of radioactive materials, although zone designations are reversed from those for other PFP buildings, follow the same confinement philosophy. Air is controlled to flow from areas where radioactive contamination would not normally be present (zone 4) to zones with increasing potential for air contamination by maintaining DPs between zones.

2736-Z Building. HVAC supply air is provided by fans in the 2736-ZB Building, and exhaust ventilation is supplied by fans in the 2736-ZA Building.

Ventilation Supply. Fans SF-5 and SF-6, located in room 602 of the 2736-ZB Building (Figure 5-49), each with a capacity of 6,000 ft^3/min, provide 12,000 ft^3/min of conditioned air during simultaneous operation. The required supply airflow can normally be provided by one fan with the other on standby; however, dissipation of the radioactive decay heat from plutonium material may require simultaneous fan operation to maintain the desired 2736-Z air temperature. Steam coils and temperature control instrumentation provide a controlled supply air temperature during the winter months. During the warmer seasons, refrigerated cooling provides supply air at the desired temperature. Standby electric power for operation of the supply fans, control instrumentation, LCU-6, the criticality alarm system (CAS), fire detectors and alarms, and CAM units is provided by diesel-generators located in the 2721-Z Building.

If normal electrical power fails, storage batteries provide power for the continued operation of the LCU-6/DCS, CAS, fire detectors and alarms. Design capacities of the battery backup systems were based on the load serviced. The battery systems are not seismically qualified and do not provide Institute of Electrical and Electronic Engineers (IEEE) Class 1E power.

The 2736-Z Building contains four vaults for storage of packaged plutonium material and a hallway, with air locks, running the length of the building. Vault 1 contains 68 storage cubicles, each with continuous airflow provided through a ventilation supply duct attached to the top of each cubicle. Thermocouples in the top of each cubicle provide air temperature monitoring. Supply air to vaults 2, 3, and 4 is through ceiling diffusers located near the wall of each vault, adjacent to the hallway. Automatically adjusted dampers control the supply air to each vault in the 2736-Z Building. The CAMS are located in each vault to monitor the status of work-place airspace.

Ventilation Exhaust. Exhaust air from the 2736-Z vaults is collected through ceiling exhaust grills and ducts located near the outside walls (east or west) in each room. Approximately 12,000 ft^3/min of exhaust air from the

2736-Z Building is filtered through two stages of HEPA filters located in the 2736-ZA Building (Figure 5-49). The filtered exhaust air is discharged to the atmosphere through the 296-Z-6 stack, a stack 14 ft 8 in. high in a 36-in. by 22-in. rectangular configuration, which extends 30 in. above the roof of the 2736-ZA Building. The stack is constructed of carbon steel. Two exhaust fans (EF-1-1 and EF-1-2), each with a capacity of 6,000 ft^3/min, and four HEPA filters (two banks of two in-series), which provide two stages of HEPA filtration for the ventilation exhaust, are located in room 650 of the 2736-ZA Building. Either exhaust fan can provide the required ventilation exhaust flow with the second fan and one bank of filters on standby, except that if both supply fans are operating, both exhaust fans also operate.

Filtered exhaust air is near-isokinetically sampled and continuously monitored for airborne radioactive particulate contamination. CAM high radiation, failure, and loss of sample/monitor vacuum alarms annunciate in the room 714 (MICON™ power control room) in the 234-5ZA Building. Air sample filters are periodically changed, analyzed, and radionuclide emissions are calculated (see Chapter 8.0, Section 8.5.2.9 for more details on the ambient air sampling and monitoring systems).

The 2736-Z Building ventilation system control instrumentation normally maintains the building pressure at -0.30 in. w.g. If the pressure increases to -0.05 in. w.g., visual and audible alarms in the 234-5ZA Building MICON™ power control room (room 714) alert the power operator to take action to restore the desired building air pressure. Loss of the EF-1-1 or EF-1-2 exhaust fans is also alarmed in room 714 of the 234-5ZA Building. The 2736-Z Building is classified as a ventilation zone 2 facility. The supply and exhaust systems are shown in Figure 5-49.

The 2736-ZA Building. The 2736-ZA Building, approximately 5 ft west of the 2736-Z Building, consists of two rooms. Room 649 houses controls for operation of the EF-1-1 and EF-1-2 exhaust fans and associated instrumentation and controls, CAMs, a stack sampler, and an instrument air compressor, which are housed in room 650. Backup power for Building 2736-ZA equipment comes from the three diesel-generators in Building 2721-Z via MCC-EP-1 in Building 2736-ZB.

Ventilation Supply and Exhaust. Ventilation supply air for room 650 is normally provided by in-leakage (Figure 5-49); however, in the event that room 650 air temperature is greater than or equal to 95 °F, a temperature controller activates a motor controlled damper that allows filtered room air to be exhausted to the atmosphere through two stages of HEPA filtration by exhaust fans EF-1-1/EF-1-2. Should the room temperature increase to greater than or equal to 105 °F, the temperature controller will activate another motor controlled damper that allows additional filtered room air to be exhausted to the atmosphere through two stages of HEPA filtration by the exhaust fans EF-1-1/EF-1-2. Room air intake for the exhaust system, through either F-3-1 or F-3-2, allows filtered outside air to be drawn into the room. Electric heaters with temperature controls provide winter heating. Figure 5-49 shows the ventilation supply and exhaust systems of the 2736-ZA Building. Supply and exhaust ventilation for room 649 is provided by wall louvers.

The 2736-ZB Building.

Ventilation Supply. Ventilation air for the 2736-ZB Building is supplied by two systems (Figure 5-49).

One system provides conditioned air (steam heated or refrigeration cooled and filtered) by using two supply fans, SF-1 and SF-2, located in room 602 of the 2736-ZB Building. Each fan has the capacity to provide 8,800 ft^3/min of supply air for distribution to all areas of the building except that portion housing the NDA laboratory. Normal supply air ventilation requirements are provided by one operating fan with the other on standby. The fan distributes 2,600 ft^3/min to ventilation zone 4 areas (e.g., lunchroom, offices, restrooms), with the remainder to ventilation zone 2 areas. Air supplied to zone 4 restrooms is exhausted to the atmosphere by exhaust fan EF-3. Air is supplied to the zone 1 repackaging glovebox from the dry-air system discussed in Section 5.4.3.1.3.

The second system provides filtered, conditioned air to the NDA laboratory section of the building with supply fans SF-3 and SF-4 (one operating, one on standby) at a flow rate of 6,300 ft^3/min. The supply air is maintained at the required temperature by electric heating in winter and refrigeration cooling during the warmer seasons. Supply air is distributed to the NDA areas through supply ducts and ceiling diffusers.

Ventilation Exhaust. Zone 1 exhaust air from the repackaging room and glovebox access hoods is filtered through a single-stage HEPA filter (two discharge ports, each filtered). Glovebox exhaust is through a HEPA filter installed on the outlet. These filtered exhausts, together with zone 2 exhaust air; unfiltered vacuum-pump exhaust from room air sampling; and exhaust air from the 2736-ZB Building, room 600 (zone 3), which houses the ventilation exhaust fans EF-1 and EF-2, HEPA filters, etc., are combined, filtered through two additional stages of HEPA filtration, and discharged to the atmosphere through the 296-Z-5 stack. The 296-Z-5 stack is 27 ft 7 in. high with a 34 in. diameter The stack is constructed of stainless steel. One exhaust fan (EF-1 or EF-2) provides the necessary exhaust ventilation flow (approximately 7,200 ft^3/min) with the other on standby. Redundant HEPA filtration is provided by four filter banks, two in parallel operation and two on standby. Stack discharge air is continuously sampled and monitored (Giller 1994a). Stack CAM high-radiation, failure, and loss-of-sample/monitor vacuum alarms are annunciated in room 714 (MICON™ power control room) in the 234-5ZA Building. Room CAM alarms (high rad/failure) alarm in the RCT office (room 631 of the 2736-ZB Building). Sample filters are periodically changed, analyzed, and radionuclide emissions are calculated. Backup power is provided for operation of the monitor, alarm systems, and the 2736-ZB ASV pump.

A heat exchanger system, consisting of two heat transfer coils, a pump, and interconnecting pipes filled with ethylene glycol, is used for recovery of heat/cold from the 2736-ZB ventilation exhaust. A heat transfer coil upstream of the EF-1/EF-2 exhaust fans is heated/cooled by the exhaust flow. When the outside air temperature is below 68 °F or above 80 °F, the ethylene glycol is recirculated to the preheater/precooler coil, located in the air supply duct upstream of the steam heater and the refrigeration unit, to provide preheating/precooling to conserve energy.

Exhaust air is collected from the NDA laboratory by three, HEPA-filtered exhaust ducts. These filtered exhaust flows are combined, filtered through two additional stages of HEPA filtration, and recycled to the NDA supply system by fans RF-1 and RF-2. Recycled air (approximately 400 ft^3/min) is diverted to provide supply air for the mechanical equipment room (room 600). Redundant HEPA filtration is provided by four filter banks, two in parallel operation and two on standby. The recycled air is continuously sampled and monitored for radioactive content by a CAM. If radioactive content of the air exceeds the allowable limit for breathing air (airborne concentrations exceeding 10% of the applicable DAC), an alarm annunciates at the MICON™ power control room (room 714) of the 234-5ZA Building and the RCT office in room 631 of the 2736-ZB Building, and activates EV-19 to allow dampers D-17 to open, D-6 to open, and D-18 to close. This diverts the ventilation recycle exhaust air for discharge to the atmosphere through the 296-Z-5 stack. After radiation levels recede back to acceptable concentration levels, EV-19 is manually reset to place the ventilation air recycling system back into a recirculating mode. The NDA ventilation supply and exhaust now becomes a once-through system until the air monitor indicates that recycling of exhaust air can be resumed. The 2736-ZB Building supply and exhaust ventilation systems are shown on Figure 5-49.

The NDA laboratory is classified as a ventilation zone 2 with the pressure maintained at -0.20 in. w.g. An LCU, located in room 602, controls the dampers, supply/exhaust fans, and the heating/cooling of the laboratory. Loss of pressure control, temperature control, loss of a supply or exhaust fan, and other trouble situations are alarmed in the 234-5ZA Building MICON™ power control room (room 714), which is attended at all times. The operator can assume manual operation of the system to provide the necessary corrective action.

The 2721-Z Building. The 2721-Z Building, located approximately 26 ft west of the 2736-ZB Building, houses three diesel-driven generators and associated switchgear that provide backup electric power for the PFP. Normal supply ventilation is discharged to the atmosphere through wall louvers with exhaust ventilation powered by two electric, through-the-wall exhaust fans, one on the north wall and one on the south wall. A temperature controller turns on the exhaust fans when cooling is required and electric heaters when heating is required. Room air conditioning is provided for the switchgear in Building 2721-Z to provide temperature control for the generator synchronizing and control components.

Additional supply and exhaust airflow is required during operation of the diesel generators. On startup of a diesel generator, a motorized exhaust damper and the inlet damper open simultaneously, which provides air for combustion and for cooling the generator. Each generator cubicle has associated inlet/outlet dampers. The inlet/outlet dampers automatically close when the diesel generator is shut down. Diesel exhaust is discharged to the atmosphere via through-the-wall piping.

5.4.1.1.8 243-Z Building.

Ventilation Supply. Ventilation supply air (approximately 1,400 ft^3/min) is provided to the 243-Z Building by a single manual on/off supply fan. The supply fan draws outside air into the building from an outside air louver and

filter section. The air is heated, when required, by a duct-mounted electric heater with a thermostat. A flow switch shuts down the HVAC system if no air flow is detected after 1 min. A freezestat turns off the exhaust fan and the supply fan when air temperature downstream of the duct heater is 35 °F or less and activates an alarm light in the HVAC control panel.

Three single-package air conditioning units (manually starting only) can be operated during the summer months. These units are interlocked with the exhaust fan and can only be operated when the exhaust fan is operating. Unit heaters are energized by individual remote wall thermostats when the space temperature drops to 45 °F or lower.

Ventilation Exhaust. The exhaust fan will maintain the building under 0.1 in. w.g. by exhausting slightly more air (approximately 1,600 ft^3/min) than is being introduced through the outside air intake. Shutoff dampers will fail closed and seal the building from the outside in the event of power failure, fire, or scheduled fan maintenance. A backdraft damper will close on a reverse of air flow through the intake plenum. Air is transferred through the open-faced drum turning hood enclosure and passed through a prefilter and HEPA filter bank before being exhausted out the 45 ft tall 296-Z-15 stack.

5.4.1.2 Safety Considerations and Controls.

5.4.1.2.1 Ventilation Supply and Exhaust Systems. Supply air for normally occupied areas is filtered, washed, heated as required, and distributed by supply fans, a supply plenum, control dampers, and control instrumentation. Redundant supply fans in room 321 of the 234-5Z Building (Figure 5-44) and in room 602 of the 2736-ZB Building (Figure 5-49) assure that supply ventilation air is provided to the facilities for personnel comfort, process ventilation, contamination control, and for equipment and/or other cooling needs during supply system component failure or scheduled maintenance.

Supply plenum pressure (234-5Z Building) is maintained automatically at +2 in. w.g. by control dampers on supply units 2, 3, and 4, two of which normally operate. The plenum is protected from overpressure by relief dampers that exhaust outside the building.

Pressures in zones 1, 3, 3A, and 3B are controlled automatically by regulation of the supply dampers. Differential zone pressures assure that airflows should be from lowest to highest contamination potential. Zone pressures are provided by instrumentation with indicators located on the panel board in the control room (room 321). The power operator has the ability to override the automatic damper controls to increase/decrease zone pressures to the desired procedural values. Abnormal zone pressures are alarmed visually and audibly in the control room.

The numerical identification of ventilation zones in the 2736-Z Support/Storage Complex is reversed from that used for the major portion of the PFP facilities (e.g., zone 1 is contaminated and zone 4 is clean in this complex). The Zone DPs are controlled by the MICON distributed control system. The software control is contained in the configuration management plan, (HNF 1998). The software program is provided in the computer software document (WHC 1999). The power operator in room 714 (MICON™ power control

room) in the 234-5ZA Building has the capability to override the computer control to increase/decrease zone pressures to the desired values. Abnormal zone pressures also are alarmed visually and audibly in the MICON™ power control room.

Air locks, provided between a clean zone and a potentially contaminated zone, minimize the potential for contamination of the clean zone in the event of a flow reversal. Similarly, HEPA filters installed on ventilation air supplied to a contaminated zone (e.g., glovebox, process cell) minimize the potential for contamination release from the contaminated zone.

Redundant installed exhaust fans (in the 291-Z Building) and redundant operating exhaust fans (in the 2736-ZA and 2736-ZB Building) are provided to maintain desired zone pressures and exhaust flows during component failure and/or maintenance. Two of the seven electric-motor-driven exhaust fans in the 291-Z Building are connected to diesel-generators in the 2721-Z Building to ensure the 234-5Z Building remains under slightly negative pressure in the event normal power is lost (one of the two emergency exhaust fans operates with the other as a standby). Inlet dampers to the emergency exhaust fans are electrically operated (with backup power, if necessary). High pressure indication in the exhaust plenum results in the automatic shutdown of the supply fans in room 321 of the 234-5Z Building to minimize the potential for pressurizing ventilation system zones.

Backup electric power is also provided for operation of the 2736-ZA and 2736-ZB Building exhaust fans and HVAC control and monitoring circuits. Uninterruptible power (storage batteries) will power LCU-6/DCS for ventilation control for a limited time on loss of normal and backup electric power.

Fire dampers and fire screens are only briefly described in Section 5.4.1. A study of fire potential and consequence concludes that fire dampers are not required (Goodwin 1987).

5.4.1.2.2 Air Cleaning Systems. Exhaust gases from potentially contaminated and contaminated ventilation zones flow through HEPA filters before discharge to the atmosphere. Prefilters and filter media are used for air exhausted from zone 3 areas into the E-3 exhaust system duct work. The use of these prefilters helps control buildup of lint and dust within the system duct work. Since there is no way of testing the prefilters, credit for their filtration of radionuclides cannot be taken.

The HEPA filters consist of a continuous sheet of molded glass medium pleated back and forth over itself so that it is self-supporting. The medium is permanently bonded to an outer casing of plywood or metal that extends the full depth of the medium (Figure 5-50). The HEPA filters are tested in place and have a minimum particle removal efficiency of no less than 99.95% and a maximum resistance, when clean, of 1.0 in. w.g. when operated at rated airflow capacity.

Installed HEPA filters are tested in accordance with and meet the requirements of ASME N510. Periodic retesting meets or exceeds ASME N510 requirements and demonstrates that the filters are performing satisfactorily. Those filters that fail to meet ASME N510 requirements are replaced.

The DP readings are taken periodically across the E-3 and E-4 filter rooms and E-4 filterboxes. Those filters that can be visually inspected are inspected periodically for sagging, discoloration because of moisture, or collection of crystals on the filter. If the damage appears to be severe, the filter may be changed out.

If a problem is discovered during examination of a HEPA filter, an NDA of the HEPA filterbox is performed to check for buildup of contamination (e.g., plutonium) on the filter or its containment. This NDA is performed in accordance with approved analytical procedures using gamma ray spectroscopy. Locations on the filterbox, or filter, are marked, and NDA measurements are performed at specified distances in accordance with solid-angle calculations. Attenuation calculations are also performed to account for container material density with calibration based on the self-attenuation of the material matrix being assayed. The procedures used have been reviewed and concurred with by Los Alamos National Laboratory technical staff, Pacific Northwest National Laboratory (PNNL) technical staff, and numerous other outside technical organizations (e.g., Westinghouse Idaho Nuclear Company, U.S. Department of Energy-Headquarters, and Safeguards overviews).

Air from potentially contaminated ventilation exhaust zones (zone 3) is filtered by at least one stage of testable HEPA filtration before discharge to atmosphere (E-3 ventilation exhaust system). Redundant filters or filter banks are provided so that failed filters may be isolated for replacement with continued filtration service provided by the installed spares.

Air from known contaminated ventilation exhaust zones (zone 4) is filtered by at least two stages of testable HEPA filtration before discharge to the atmosphere through a stack (E-4 ventilation exhaust system). The E-4 exhaust systems normally contain a HEPA filter on the glovebox or cell exhausts with the first testable HEPA filter located in a filterbox on the duct level or the second floor of the 234-5Z Building. Exhaust flows from these filters are manifolded to one of two rooms (309 and 310), each containing a bank of testable HEPA filters (second stage), before discharge to the atmosphere through a stack. The HEPA filter inlet air is treated as necessary to prevent moisture accumulation within the filters. The 241-Z below grade storage tanks vent exhaust is heated to preclude HEPA filter wetting.

The ventilation exhaust system which had potential for hydrogen fluoride (HF) gas contamination contained HEPA filters that were segregated from the E-4 exhaust system to preclude HF damage to the E-4 HEPA filters in rooms 309 and 310. Following the cessation of the HF operation, ventilation exhaust from these areas was rerouted through the E-4 filter manifold. Filterboxes FB-9A, FB-9B, and FB-9AB, which were used to filter the potentially HF-contaminated exhaust air, were removed from service and isolated from the RMC Line in 1996 to reduce plutonium holdup in the ventilation system. The FB-9A and FB-9B by-pass line was also removed to reduce plutonium holdup.

5.4.1.2.3 Air Monitoring Systems. Monitoring for airborne radioactive material is performed by CAMs in occupied areas where the possibility of airborne contamination exists. The location and function of these CAMs in the PFP is discussed in detail in Chapter 8, and the associated alarm

communication is discussed in Section 5.4.10. Airflow is provided for the fixed head sampling units and CAMs by the ASV system. Small, portable, self-contained CAM units are also employed to ensure uniform coverage. Airborne radioactivity is alarmed locally, and for some installations, remotely, at the appropriate radiological control office; room 221A radiological control office in the 234-5Z Building, and room 631 radiological control office in the 2736-ZB Building.

CAMs are also provided to monitor selected filter inlet and outlet streams and for gases discharged to atmosphere through the PFP stacks; 291-Z-1, 296-Z-3, 296-Z-5, 296-Z-6, and 296-Z-14. Stack CAM high radiation, failure, and loss-of-sample/monitor vacuum alarms annunciate in room 714 (MICON™ power control room) in the 234-5ZA Building. Backup power, with the exception of the 296-Z-3 stack discussed earlier and the 291-Z air sample vacuum pump which supplies vacuum for the 296-Z-6 sampler and monitors, is provided for operation of the monitor, alarm systems. Stack flows are isokinetically sampled to provide representative samples of stack discharges. Samples are periodically changed and analyzed for radioactive content.

The PFP ventilation supply and exhaust system, the air cleaning system, and the air monitoring system have been reviewed for compliance with the requirements in DOE Order 6430.1A (DOE 1989). The results of this conformance evaluation are presented in Table 3 of WHC (1990).

5.4.1.2.4 Seismic Fan Shutdown System. The seismic shutdown system monitors for seismic activity and shuts down key ventilation supply fans to prevent pressurization of the 234-5Z and 236-Z Buildings if an earthquake of magnitude 0.07 g or greater is detected. The system also shuts off power to the 234-5Z Building exhaust fans, with the exception of the emergency exhaust fans (EM-1 and EM-2). Several other systems are connected to the seismic shutdown switch including the Laboratory Prototype Calciner (See the Laboratory Prototype Calciner addendum to this FSAR, Section 2.3.3.2.12). The seismic fan shutdown system consists of three major components; redundant accelerometers, manual shutdown button, and a dedicated UPS. The seismic accident analysis in Chapter 9.0, Section 9.2.4A assumes that the redundant accelerometer portions of the seismic fan shutdown system are in place and operating. When the 234-5Z Building ventilation system is shut down, the supply fan dampers fail in the open position and the exhaust dampers, except those leading to the emergency exhaust fans EM-1 and EM-2, fail in the closed position. The emergency exhaust fans and their inlet dampers are not connected to the seismic fan shutdown system and may continue to operate following the seismic event should normal or backup power be available and the equipment not significantly damaged in the event. On loss of both normal and backup power, the inlet dampers to the emergency exhaust fans are designed to fail open. This allows natural drafting through the 291-Z-1 exhaust stack.

The primary components in each redundant accelerometer-activated system located on the first floor of the 234-5Z Building in corridor 14 (Figure 5-6, sheet 1) are as follows:

- An accelerometer system with two horizontal force-balance accelerometers oriented in the north-south and east-west directions with a latching output relay

- Two seismically qualified relays
- An online/bypass switch to allow maintenance of the accelerometer without interfering with ventilation system operation.

The redundant accelerometer-activated systems deactivate seismically qualified circuit breakers for the ventilation supply fans in room 266 and seismically qualified contactors for the stage 2 process fans in room 321. No power is required for the redundant accelerometer activated systems to perform these actions.

The manual shutdown system provides a means for an orderly shutdown of the normal ventilation system and a back-up method for a seismic event if both accelerometer-activated systems fail. Activation of the manual shutdown system immediately shuts down all the supply fans and miscellaneous exhaust fans. After a delay of about 20 s, the main exhaust fans (except fans EM-1 and EM-2) in the 291-Z Building are shut down. Manual shutdown of the ventilation system is enacted from the Room 321A power control room in Building 234-5Z. Power for the seismic fan shutdown system is provided by a UPS located adjacent to the accelerometers in corridor 14.

The ventilation seismic shutdown system is also interconnected with Laboratory Prototype Calciner equipment to terminate operations during a seismic event. This minimizes the potential radiological releases from the calciner process equipment resulting from the seismic event. The interconnection with the shutdown system and the resulting effect on the calciner equipment due to the seismic event is described in the Laboratory Prototype Calciner addendum to this FSAR.

5.4.2 Electrical Systems

5.4.2.1 Major Component and Operating Characteristics. Major components in the supply of electric power to the Hanford Site, individual processing plants, processing systems, monitoring systems, and alarm systems are high voltage transmission lines, transformers, large switchgear units, diesel generators, and dc battery stations. These components are designated either as safety significant or general service.

The high-voltage transmission lines are at two voltage levels, 230 kV and 13.8 kV. The building distribution is three-phase 480 V and 208Y/120 V. Three diesel-generators in Building 2721-Z provide Standby electrical power to monitoring equipment, alarm and evacuation systems, and other essential equipment when normal electrical power is not available (see Section 5.4.2.1.9). The PFP also has several UPS systems to provide continuous power to programmable controllers, facility computers, plant monitoring, and plant communication systems (see 5.4.2.1.16).

5.4.2.1.1 Electrical Supply (230 kV) System. Electrical power to the Hanford Site is supplied from the BPA substation at Midway through a 230-kV transmission loop and a 230-kV single transmission line from the H. J. Ashe switchyard. Transmission is at 230 kV, three-phase, 60 Hz, and electrical power for the 200 Areas is received at the 251-W substation (see Figure 5-51).

At the 200 Area substation, 230 kV is stepped down by two transformers to 13.8 kV/three-phase/60 Hz. From the 251-W substation, electrical power is supplied to the 200 East Area and the 200 West Area at 13.8-kV. The transformers, incoming lines, and switches at the 251-W substation are physically separated to prevent failure of one component from involving others. Although the 230 kV system is not seismic category I, the system was designed to BPA standards for public power stations, which included IEEE standards and guidelines current to the time of design.

5.4.2.1.2 Electrical Supply (13.8 kV) System. Circuits C8-L1, C8-L2, C8-L3, and C8-L4 supply the electrical power to the 200 West Area. Circuits C8-L1 and C8-L4 are carried on a common pole at the west side of the 200 West Area and circuits C8-L2 and C8-L3 are carried on a common pole on the east side of the 200 West Area. The 13.8 kV pole transmission lines from the 251-W substation to the PFP are not Seismic Category I. The transmission line system is designed to BPA standards for public power stations, which included IEEE standards and guidelines current to the time of design (though they are not seismically qualified).

13.8 kV, Lines C8-L1 and C8-L2. These lines provide the largest electrical power load to the PFP, 13.8-kV substations, and the principal buildings (Figure 5-52):

- Substation C8-S6 (also known as 252-Z-1) for the 234-5Z Building with transformers C2505F and C2506F, each 1,000 kVA, 13.8 kV/480 V, three-phase, Wye/Delta
- Substation C8-S19 (also known as 252-Z-2) for the 291-Z Building with transformers C0380F and C0385F, each 1,000 kVA, 13.8 kV/480 V, three-phase, Wye/Delta
- Substation C8-S46 for the 2736-ZB Building, with transformer C5874P, 500 kVA, 13.8 kV-480/277 V, three-phase, four-wire, Delta/Wye
- Building 2702-Z, 3-10 kVA, 13.8 kV-208Y/120 V transformer.

Either line, C8-L1 or C8-L2, is capable of supplying power to meet the 13.8-kV connected load requirements of the PFP; however, during normal plant operating condition, the PFP load is divided between the two lines.

- Transformers C2505F, C0380F, and C5874P are connected to line C8-L1
- Transformers C0385F and C2506F and the remaining above listed loads are connected to line C8-L2.

13.8 kV, Line C8-L4. This line provides normal electrical power for the remaining PFP loads and pole-mounted transformers for smaller buildings (Figure 5-52):

- The 2701-ZA and 2701-ZD Buildings, 1-50 kVA, 13.8 kV-240/120 V, pole-mounted transformer via ATS-3.

- The PFP security and operations control facility, the 2701-ZA, 2701-ZD, and 2705-Z Buildings, and the 3-15 kVA, 13.8 kV-208/120 V transformers.

5.4.2.1.3 Not Used.

5.4.2.1.4 Substation C8-S6 (251-Z-1), the 234-5Z Building, Room 266. In substation C8-S6, the transformers are separated physically from the switchgear. The transformers are located outside the building, and the switchgear is located in room 266 on the duct level of the 234-5Z Building. The switchgear is connected to the transformers by bus duct. At the present time normal plant operation is supplied by the >1,000 kVA temporary transformer located in position 2, which is connected to the 13.8-kV line C8-L2. The 1000 kVA transformer located in position 1, which is connected to the 13.8-kVA line C8-L1, is currently out of service. (Note; Once permanent replacement transformers are secured the temporary transformers will be replaced and the system will be returned to its original configuration.) Substation C8-S6 supplies electrical power to the 234-5Z Building and to some small loads in other buildings (see Figure 5-52). The switchgear in room 266 also supplies power to the emergency bus during normal electrical supply to the plant.

5.4.2.1.5 Substation C8-S19 (252-Z-2), the 291-Z Building, Room 500. In substation C8-S19, the transformers are an integral part of the switchgear and the transformers and switchgear are located in room 500 of the 291-Z Building (see Figure 5-52). At the present time normal plant operation is supplied by the >1,000 kVA temporary transformer located in position 6, which is connected to the 13.8-kV line C8-L2. The 1,000 kVA transformer located in position 5 is connected to the 13.8-kV line C8-L1, is currently out of service. (Note: Once permanent replacement transformers are secured the temporary transformers will be replaced and the system will be returned to its original configuration.) The substation provides electrical power to the 241-Z, 241-ZA, 241-ZG, 232-Z, 236-Z, 243-Z, 243-ZA, 243-ZB, and 2736-Z Buildings. The switchgear also supplies power to the automatic transfer switch ATS-2 during normal electrical supply to the plant. ATS-2 loads include emergency exhaust fans EM-1 and EM-2 located in Building 291-Z, the motor control center (MCC) MCC-FC for 243-ZA and 243-ZB, the 291-Z sump pumps in room 501, and panel CP.

5.4.2.1.6 Substation C8-S46, the 2736-ZB Building, Room 602. Substation C8-S46 consists of a 500 kVA pad-mounted transformer outside the 2736-ZB Building, a panelboard (NP-VF-1) north of Building 2721-Z, and load centers in room 602 (see Figure 5-52). During normal plant operation, the transformer is connected to the 13.8-kV line C8-L1. The substation provides electrical power to the 2736-ZA, 2736-ZB and 2736-ZC Buildings.

5.4.2.1.7 Summary of PFP Building Electrical Power Sources. This section provides an overview of the electrical power sources for the listed buildings. Smaller buildings are served by pole-mounted transformers.

- 234-5Z--Electrical power is supplied from substation C8-S6, room 266, the 234-5Z Building.

- 232-Z--Electrical power for building lighting is supplied from substation C8-S19, the 291-Z Building, room 500, bus 500, but the electrical control panel (MCC-1) and neutron panel have been removed. The building is supplied with electrical power from the MCC electrical panel number 1 (MCC-EP-1) in the 2736-ZB Building. A local panel in 232-Z distributes the power for fan control, instrumentation, and stack monitoring.

- 236-Z--Electrical power is supplied from substation C8-S19, room 500, the 291-Z Building.

- 241-Z, 241-ZA, and 241-ZG--Electrical power is supplied from substation C8-S19, the 291-Z Building, room 500.

- 242-Z--Electrical services to the building have been disconnected.

- 243-Z LLWTF--Electrical power comes from substation C8-S19, the 291-Z Building, room 500.

- 270-Z--Electrical power comes from substation C8-S6, the 234-5Z Building, room 266.

- 291-Z--Electrical power is supplied from substation C8-S19, the 291-Z Building, room 500.

- 2736-Z--Normal electrical power comes from the 480-V MCC-1 in the 291-Z Building, room 500. A 25-kVA transformer reduces the voltage from 480 V to 240/120 V for building electrical requirements. Standby electrical power is supplied from panel PCV-3 in the 234-5Z Building.

- 2736-ZA--Normal electric power is supplied from 13.8 kV line (C8-L1) to a 500-kVA, 13.8 kV to 480/277-V, pad-mounted transformer via panel NP-VF-1 located at the north end of Building 2721-Z. Standby power is supplied from the three diesel-generators in Building 2721-Z via MCC-EP-1 in Building 2736-ZB.

- 2736-ZB--Electric power is supplied to the building from the 13.8-kV line (C8-L1) to a 500-kVA, 13.8-kV to 480/277-V, pad-mounted transformer. The main power distribution centers are located in mechanical room 602. Electric power is provided to the 2736-ZC Building.

- 2904-ZA and 2904-ZB--Electric power is provided to these buildings from the 234-5Z 480-V distribution system as 480-V single phase.

- 2704-Z--Electric power is provided from substation C8-S6, the 234-5Z Building, room 266.

- General Area Lighting--Electric power to the general area lighting is provided from various electrical panels. The source of the power is the closest source to the area requiring general lighting.

5.4.2.1.8 240-V, 208-V, and 120-V Service. Power required for equipment less than 480 V (i.e., lighting, cranes, etc.) is provided by 480-208Y/120 V, 13.8 kV-240/120 V, or 480-240/120 V transformers. Power to the stepdown transformer is provided from the 480-V distribution circuit breaker panels.

5.4.2.1.9 Standby Electrical Power Available to the PFP. Standby electrical power is available to the PFP for DOE-, ANSI-, NFPA-, or IEEE-defined emergency systems. These emergency systems include monitoring systems, audible (siren) systems, fire alarm systems, some criticality alarm systems, security systems, emergency lighting, and some building ventilation systems.

Under normal operating conditions, emergency bus loads and the central 125-Vdc stationary battery chargers are supplied with power from normal 480-V buses and panels. The self-contained battery operated emergency lights are being charged by the ac branch circuit powering the normal lighting in the same area. The following standby electrical power sources are available to the PFP.

- Three, 325-kW, diesel generators in the 2721-Z Building, west of Building 2736-ZB, comprise the largest portion of standby power for the PFP.
- A central, 125-Vdc, stationary battery station to provide continuous dc power.
- Self-contained, fully automatic, battery operated emergency light packs.
- UPSs.

In the event that normal power to the 200, 300, and 400 buses are interrupted, the electrical switchgear in room 266 automatically disconnects the 400 bus by opening F8X340, starting the diesel generators, and closing F8X309 to connect the 400 bus to the generators.

5.4.2.1.10 Three, 325-kW, Diesel Generators in the 2721-Z Building. The diesel generators provide standby power to the emergency bus in room 266 of the 234-5Z Building, motor control center MCC-EP-1 in the 2736-ZB Building, automatic transfer switch ATS-2 in room 500 of the 291-Z Building, and automatic transfer switches ATS-3 and ATS-4 in the 2701-ZA Building (see Figure 5-52). The following is a list of emergency loads connected to the diesel generators in the 2721-Z Building on loss of normal electrical power (controlled by the transfer control panel).

- The emergency switchgear in room 266 has four feeder breakers and provides power to the constant voltage panels throughout the PFP, the 125 Vdc battery chargers in room 266, closed-circuit television system, the UPS, evacuation siren, some criticality alarms, communications equipment, and CAM units (see Figure 5-52).
- MICON™ controlled circuit breaker in power distribution panel provides power to the 2736-ZA and 2736-ZB Building emergency loads,

exhaust fans, HVAC control circuits, monitoring circuits, UPS system, perimeter lighting, etc. (see Figure 5-52).

- Automatic transfer switch ATS-2 in emergency position provides backup power to exhaust fans EM-1 and EM-2 and to panel EP-291A in the 291-Z Building (see Figure 5-52). Panel EP-291A feeds Contactor C which is controlled by the MICON™ and is capable of load shedding as necessary to keep the on-line emergency exhaust fan (either EM-1 or EM-2) provided with adequate power.

- Automatic transfer switch ATS-3 in emergency position provides power to the 2701-ZA Building emergency loads, the UPS system, and the EA series panels. The normal power to the automatic transfer switch comes from a 13.8 kV-240/120 V pole-mounted transformer C6323L connected to line C8-LA (see Figure 5-52).

- Automatic transfer switch ATS-4 in emergency position provides power panel A in the 2701-ZA Building. The normal power to the automatic transfer switch comes from a 13.8 kV-208Y/120 V pole-mounted transformer connected to line C8-L4 (see Figure 5-52).

If normal power to the transfer control panel (NP-VF-1) feeding Building 2736-ZB or to any of the transfer switches (ATS-2, ATS-3, or ATS-4) fails or assumes unacceptable limits, automatic circuity in the transfer switches will disconnect the emergency load from the normal power, start the diesel generators in the 2721-Z Building, and then transfer the emergency load to the diesel generators.

The standby power subsystems are tested to assure proper performance upon loss of electrical power. The diesel generators are tested once a month, under load, to verify proper operation of the generators. Testing of the transfer mechanism located in Building 234-5Z is performed semi-annually according to procedure. Room 308 UPS and switchgear batteries are load tested annually to verify capability to meet load demands.

A MICON™ local control unit (LCU-7), located in the 2721-Z Building, monitors and controls proper voltage levels for most of the operations in the PFP. When the computer receives a loss-of-power signal from any of the loads, it starts the diesel generators within the 2721-Z Building. The sequences of events, monitored and controlled by the MICON sytem during loss of normal power or off-normal conditions are shown in Table 5-33. Further discussion is contained in Sections 5.4.2.2.2, 5.4.2.2.3, and 5.4.2.2.8.

Upon the return and detection of normal power, the MICON system offloads the diesel generators and opens breakers 701, 702, and 703 (see Figure 5-70).

5.4.2.1.11 Not Used

5.4.2.1.12 125 Vdc Stationary Battery Station. These batteries provide direct current electrical power to the main switchgear direct current breaker control circuits in switchgear room 269 in the 234-5Z Building; room 500 in the 291-Z Building; evacuation sirens; and siren controls (see Figure 5-52).

5.4.2.1.13 Self-Contained Fully Automatic Battery Lights. These emergency light packs are installed throughout the PFP to meet NFPA 101 requirements and to provide additional lighting in areas not required by NFPA 101 to reduce safety hazard to plant personnel. They are powered by lighting circuits of the area.

5.4.2.1.14 Summary of Backup Electrical Power Source. This section provides an overview of the backup electrical power sources for the listed buildings.

- 234-5Z--Backup electrical power is supplied from the emergency switchgear in room 266, the 234-5Z Building. This is switchgear section four of the main switchgear. In emergency mode, the emergency bus is powered from the three, 325-kW, diesel generators in the 2721-Z Building.

- 232-Z--Backup electrical power for ventilation and stack sampling/monitoring is supplied from motor control center MCC-EP-1 in the 2736-ZB Building.

- 236-Z--Backup electrical power is supplied from the emergency switchgear in room 266 in the 234-5Z Building.

- 241-Z and 241-ZA--CP panel backup electrical power is supplied via the automatic transfer switch ATS-2 circuit supplying power to panel EP-291A.

- 242-Z--Backup electrical power has been disconnected.

- 243-ZA--Backup electrical power is provided to EP-291A panel board by ATS-2 from the diesel generators in the 2721-Z Building.

- 291-Z--Backup electrical power is supplied via the automatic transfer switch ATS-2 circuit supplying power to panel EP-291A, CP panel, and emergency exhaust fans EM-1 and EM-2. The backup power source is the three, 325-kW, diesel generators in the 2721-Z Building.

- 2736-Z--Backup electrical power comes from the constant voltage distribution in the 234-5Z Building to panel E in the 2736-Z Building.

- 2736-ZA--Backup electrical power is supplied from the diesel generators in the 2721-Z Building through a MICON™ controlled circuit breaker.

- 2736-ZB--Backup electrical power is supplied from the diesel generators in the 2721-Z Building through a MICON™ controlled circuit breaker.

- 2701-ZD--Backup electrical power is provided to EA-D panel board by ATS-3 from the diesel generators in the 2721-Z Building.

- 2701-ZA--Backup electrical power is provided to the UPS for the 2701-ZA Building from the diesel generators in the 2721-Z Building through ATS-3. Panel A in the building is supplied with back-up electrical power from the diesel generators through ATS-4.

- General Area Lighting--The general area lighting is not supplied with backup electrical power.

5.4.2.1.15 240-V, 208-V, and 120-V Emergency Power. Emergency power requirements (less than 480 V for the above listed buildings) are obtained by 480-208Y/120-V or 480-240/120 V stepdown transformers. The power source for the stepdown transformers is the electrical emergency system in the immediate area or building.

5.4.2.1.16 Uninterruptible Power Supply System. The PFP has several UPS systems to provide continuous power to programmable controllers, facility computers, plant monitoring, and plant communication systems (Figure 5-53).

All UPS systems are connected to the plant backup electrical system. If power is lost to the plant facility, the batteries associated with the UPS system will continue to provide uninterrupted electrical power to the UPS connected loads. When the emergency electrical system is re-powered by the diesel generators, the UPS load is shifted from the UPS batteries to the emergency electrical system. Although there is no defined service life for the batteries of the numerous UPS systems, they have each been designed and sized to properly function during the transition from loss of normal power to backup power. Each system of batteries is functionally tested and maintained, in accordance with approved preventative maintenance procedures at specified intervals based on the system's safety categorization. The UPS systems installed in the PFP are as follows:

- The 234-5Z Building, corridor 14--Seismic shutdown system

- The 234-5ZA Building, room 308--MICON™ control system and material accountability systems

- The 2701-ZA Building--Security systems

- The 2721-Z Building, room 647--MICON™ local control unit and controller for diesel generators

- The 2736-ZB Building, room 623--Ventilation system, safeguards, computers, security cameras

- The 234-5Z Building, room 267--Private automatic exchange (PAX) switcher

5.4.2.2 Safety Considerations and Controls. The electrical high-voltage distribution system on the Hanford Site was designed and installed as a dual system. The PFP 480-V electrical distribution system was divided between normal electrical loads and emergency loads; emergency loads are those loads that will receive electrical power from diesel generators or batteries when the normal utility power is not available. Switching of emergency loads from

the normal electrical power system to diesel generators or batteries is automatic.

5.4.2.2.1 Historical Background. The electrical distribution system on the Hanford Site was installed in the early 1940's in accordance with codes and requirements in force at the time. The high-voltage distribution system (230 kV and 13.8 kV) was designed as a dual transmission system. With the dual transmission system, all plant loads can be switched to one transmission line, and the plant can continue to operate at full capacity. This system permits maintenance or repair to be performed on one or the other transmission line without affecting plant operation.

The same design practice was instituted in the plant electrical distribution system by dividing heavy plant loads between switchgear sections/transformer banks and by the addition of a plant emergency electrical distribution system. Loads requiring emergency electrical power are connected to this system.

5.4.2.2.2 Loss of Normal Power. When power from the BPA is not available, automatic voltage sensing circuits senses an under-voltage condition and initiate a signal to start the diesel generators. After the diesel generators have reached operating voltage and frequency, the backup power system loads are transferred to the diesel generators. The diesel-generator electrical system is designed to respond to a partial or total loss of normal power to the three automatic transfer switches, MCC-EP-1 in Building 2736-ZB or to the emergency switchgear bus (see Figure 5-52).

5.4.2.2.3 Emergency Load Transfer Method. The three automatic transfer switches respond independently to loss of normal power for the systems they service and transfer the loads to the diesel generators in the 2721-Z Building. The emergency switchgear in the 234-5Z Building, room 266 provides switching by opening the normal supply circuit breaker and closing the emergency supply circuit breaker. These breakers have a three-level electrical interlock, preventing both breakers from closing at the same time. Switching the emergency loads to the diesel generators will take place when the diesel-generator frequencies are synchronized and the diesel-generator voltage is within specified limits. Backup power is supplied to Building 2736-ZB by opening the normal power circuit breaker and closing the backup power circuit breaker in Building 2721-Z.

When normal power is reestablished, the transfer switches are automatically reset to their normal positions. The emergency switchgear has to be manually reset to normal position. Equipment that trips offline during a power interruption normally has to be manually reset.

5.4.2.2.4 230 kV Transmission System Reliability. The Hanford Site 230 kV transmission line loop is supplied with power from two different high-voltage circuit breakers in the Midway substation and a 230 kV transmission line tap connecting the Hanford Loop to the H. J. Ashe substation. The Midway substation is supplied with power from the Grand Coulee Dam powerhouse, Priest Rapids Dam, Wanapum Dam, and John Day Dam. The H. J. Ashe switchyard receives power from Ice Harbor Dam and McNary Dam. The 230 kV system is also backed up by the 500 kV BPA system.

Routine maintenance is performed on the transmission line by the Hanford Utility Group. The entire 230-kV transmission line system is on steel towers. A loss of power at both the Midway and H. J. Ashe substations would have to occur before the plant diesels would start (see Figure 5-51).

5.4.2.2.5 13.8 kV Transmission System Reliability. The PFP is supplied with electrical power by three 13.8-kV transmission lines from two 30,000-kVA transformers in the 251-W substation. The entire PFP electrical load including the electrical load of smaller buildings and trailers can be switched to two of the 13.8-kV transmission lines. Two of the transmission lines enter the 200 West Area on wooden poles on the west side; and the other transmission line enters the area on wooden poles on the east side.

Routine maintenance is performed on the transmission line by the Hanford Utility Group. A loss of both transformers in substation A-8 (251-West Area) would have to occur before the diesel generators would start.

5.4.2.2.6 480-V Plant Distribution System Reliability. The major portion of the 480-V load is divided between two substations. In addition, the PFP has a backup electrical system powered by diesel generators when the BPA transmission system is not available.

5.4.2.2.7 Plant Emergency System Reliability. The PFP is supplied with backup power from three diesel generators, each 325 kW, in the 2721-Z Building. Design practice does not permit the total connected load to the three diesel generators in the 2721-Z Building to exceed the capacity of two diesel units. This permits one diesel unit to be out of service for maintenance or repair.

With the diesel generator start signal, the appropriate number of diesel generators in the 2721-Z Building will start and synchronize on a common emergency bus. After a predetermined time, when the emergency load demand is stabilized and is less than the full-load capacity of two 325-kW diesels, the third diesel will sequence offline and shut down. The same sequence will repeat for the second diesel depending on load, but one diesel will remain online as long as normal power is not available.

The diesel generator fuel system has a storage capacity of 2,000 gal and no less than 1,500 gal should be on hand. Each 325-kW diesel generator (fully loaded) will consume 30 gal of diesel fuel per hour. The fuel supply system will operate the diesel generators for a period of 24 h without refueling. The diesel generator fuel system level and the general conditions of the generators are checked once every 8-h shift.

The diesel generators are run synchronized with the utility system once a month for approximately an hour. The adequacy of these systems to support the potential emergency loads shown in Tables 5-16 and 5-17 has been deemed acceptable. Redundancy exists in the form of three diesel generators; however, the distribution system has many potential single-point failure locations. Historically this backup system has operated whenever required, although the reliability of the entire system has not been analyzed. The MICON™ system provides the capability to test the generators under load. The MICON™ can apply load by sending power back through the Hanford Site power grid.

In either an emergency or long-term shutdown of a process, an important step is to shutoff electrical power. The discussion of process shutdown in Chapter 6.0, Section 6.1.3, demonstrates that the removal of electrical power shuts down the process and places the plant in a safe configuration. An analysis of the loads and shutdown process indicates that backup power, defined as IEEE Class 1E, is not a prerequisite to safe shutdown.

5.4.2.2.8 125 Vdc Battery Station Availability. An additional reliability feature of the electrical system is the 125-Vdc battery system. It is used for monitoring and switching control for both the C8-S6 (252-Z-1) and C8-S19 (252-Z-2) substations. The battery station is located in room 269 of the 234-5Z Building and is continuously charged by either one or both of two battery chargers operating in parallel (see Figure 5-52).

5.4.2.2.9 Not Used.

5.4.2.2.10 Rechargeable Emergency Light Wall Units. Emergency lighting during a power failure is supplemented by individual rechargeable wall units strategically located for personnel safety.

5.4.2.2.11 CAS. The CAS is made up of nine criticality alarm panels. Each panel has an IEEE-rated industrial battery system with sufficient capacity to support the alarm system in normal operation for at least 4 h. A charging system is integral to the panel to maintain the battery's charge. The charger in each panel is wired into a 120-Vac power source, which is a part of the backup system. Readouts on the panel indicate the state of charge and whether the system is on 120 Vac or battery.

5.4.2.2.12 System Reliability Conclusion. The PFP electrical system has been reviewed for compliance with the requirements of DOE Order 6430.1A (DOE 1989). The results of this review are presented in WHC (1990).

5.4.2.2.13 System Design Compliance Conclusion. See WHC (1990) for the PFP system design compliance in accordance with DOE Order 6430.1A (DOE 1989).

5.4.3 Compressed Air Systems

The compressed air systems at PFP are process air, instrument air, dry air, and breathing air. These systems are described in that sequence in Section 5.4.3.1. These systems are Safety Significant or Non-Safety Class. Breathing air systems are discussed in Chapter 8, Section 8.5.1.

5.4.3.1 Major Components and Operating Characteristics.

5.4.3.1.1 Process Air (90 lb/in^2 [gauge]). The design bases for the process air system are not available because of the age of the facility, except that UBC and accepted standards in effect at the time of construction were applied. Compressed air at a nominal pressure of 90 lb/in^2 (gauge) is provided as a general purpose air supply throughout the PFP for air cylinders, aspirators, air tools, etc. The compressed air system equipment is located in room 501 of the 291-Z Building. The equipment consists of a receiver tank and two water-cooled, two-stage, reciprocating compressors, each equipped with built-in inter- and aftercoolers, and a coalescing oil and water separator.

Each compressor is powered by a 100-hp motor and is rated at 530 $stdft^3/min$. An emergency compressed nitrogen gas supply (one cylinder, 228 ft^3, 2,200 lb/in^2, 2-stage regulator with 70 to 90 lb/in^2 outlet pressure) is available to start the compressors.

A backup air compressor for the 291-Z Building (similar to the air compressors located inside room 501), located outside of the building, is available in instances when the air compressors fail or are shut down for maintenance purposes.

The Laboratory Prototype Calciner air requirements are provided by a dedicated compressed air system. A fractional horsepower high air quality portable air compressor is installed in the 234-5Z Building, Room 262, duct level above the PPSL. This compressor supplies high quality compressed air at approximately 65 psig to Room 188 for use by the Laboratory Prototype Calciner (see the Laboratory Prototype Calciner addendum to this FSAR, Section 2.3.3.2.6).

Air is distributed from the receiver tank through a 2 in. diameter line to the 234-5Z Building duct level where the service line becomes an air header for general distribution of air throughout the building. The compressors also provide air to the 234-5Z Building instrument air system through an additional coalescing oil and water filter, a receiver tank, and a series of prefilters, dryers, and afterfilters located in the 291-Z Building.

A 1 in. diameter line to the 236-Z Building provided air for general purpose and this line has been blanked off in 291-Z. The line to the 236-Z Building was routed from near the air receiver in the 291-Z Building, underground to the 236-Z Building, where it is tied into the compressed air system located in the equipment room on the third floor. An air line to the 232-Z Building, also underground, is plugged inside of the building because air service is no longer required there. Other buildings serviced by the process air system in the 291-Z Building are the 241-Z and 243-Z complexes.

Cooling water for the Ingersoll Rand compressors is recirculated through two primary loops, one for each compressor, of the closed loop cooling system (CLCS). The CLCS is discussed in Section 5.4.8.

5.4.3.1.2 Instrument Air. Instrument air is distributed throughout the 234-5Z Building at 90 lb/in^2 (gauge) and is reduced to less than 30 lb/in^2 for general use in instrument controls for the ventilation system, for the process systems, and where non-oily, clean, dry-air is needed. Instrument air is supplied from the same equipment as the process air described in Section 5.4.3.1.1, which is located in room 501 of the 291-Z Building. Instrument air is distributed to the 234-5Z, 291-Z, 242-Z, 2736-ZA, 241-Z, 241-ZA, and 236-Z Buildings.

The 2736-ZA and 2736-ZB Buildings have additional instrument air capabilities. A small compressor in room 650 of the 2736-ZA Building, powered by a fractional horsepower electric motor, serves as backup to the normal instrument air for the 2736-ZA Building (which is supplied from the 291-Z Building system). The 2736-ZB Building, which is not serviced by the instrument air system in the 291-Z Building, uses instrument air from room 602 of the 2736-ZB Building. This system is similar to the small compressor

in the 2736-ZA Building, and serves as a backup to the dry air system described below in Section 5.4.3.1.3.

5.4.3.1.3 Dry Air. An electric dry-air generating system is located in room 321 of the 234-5Z Building. (Note: A backup steam-driven dry-air generating system in room 321 has been deactivated.) The electric dry-air generating system has the capability of providing 1,500 ft^3/min of air. The desiccant equipment of the dry air system is currently inactive, so the dry air system is currently only used to provide normal supply air to those gloveboxes attached to the dry air supply plenum. There is no need for dry air for the building and process operations. See Section 5.4.1 for details of the HVAC system. Flow can be regulated by control valves at each glovebox serviced by the header. In this condition, the process fans on the dry-air generating system still provide air to the process gloveboxes to maintain proper glovebox pressure. The dry-air fans were installed in accordance with standard practices for industrial dry air at that time.

Repackaging Glovebox Air System. Dry air to the repackaging glovebox in the 2736-ZB Building, room 636, is supplied by two air compressors, AC-1 and AC-2, each rated at 55 std ft^3/min at 100 lb/in^2 (gauge). Each compressor is driven by a 15-hp electric motor. Each of two air dryers is capable of supplying dry air with a dew point of -40 °F at 47 std ft^3/min and 100 lb/in^2 (gauge). A 140-gal receiver tank is capable of supplying a 5-min. reserve of dry air to the glovebox in the event of a power failure. This dry air reserve provides sufficient time for personnel to place any hygroscopic material located in the glovebox into a configuration that prevents absorption of moisture. The dry-air generating system serves as a backup to the instrument air system in the 2736-ZB Building and is located in room 602 of the 2736-ZB Building. The dry-air system was installed in accordance with standard practices for industrial dry air at that time.

5.4.3.2 Safety Considerations and Controls. The instrument air supply system was installed in accordance with standard practices for industrial instrument air. The instrument air system requires high reliability and safety assurance because of its function with pneumatic controls for process and ventilation systems. To meet this need, the process and instrument air system in the 291-Z Building is designed so that only one of the air compressors is required to satisfy the compressed air requirements, with the second compressor automatically starting if system pressure drops below 65 lb/in^2 (gauge). A backup diesel-powered compressor, located outside of the 291-Z Building, is also tied into the instrument and process air systems and can provide air if needed. The emergency compressed nitrogen gas supply (one cylinder, 228 ft^3, 2,200 lb/in^2) with a 70 to 90 lb/in^2 outlet pressure is available to aid in starting the air compressors in room 501 of the 291-Z Building.

The instrument air compressor in the 2736-ZB Building, which is not part of the compressed air system based in the 291-Z Building, is tied into the emergency power electrical system serving the 2736-ZB Building. Backup instrument air for the 2736-ZB Building is supplied by the dry air compressors in room 602 of the 2736-ZB Building.

The instrument air in the 2736-ZA Building, which is normally supplied by the system in the 291-Z Building, has a small compressor in room 650 as a

backup. Backup electrical power to this compressor comes from the same backup power system that serves the 2736-ZB Building.

The compressed air systems have been reviewed for compliance with the requirements in DOE Order 6430.1A (DOE 1989). Results of this review are provided in Tables 3, 6, 8, and 9 of WHC (1990).

The MICON™ control system will duplicate monitoring and control functions of the dry air system.

5.4.4 Compressed Gas Systems

Compressed gases are used in the PFP for maintenance, process, and laboratory needs. The gases are procured from industrial sources in standard-size, high-pressure cylindrical tanks referred to as bottles. The bottles are handled and stored in accordance with accepted industrial practices. The locations of the compressed gas storage facilities are shown in Figure 5-54. These gas systems are Safety Significant or Non-Safety Class.

5.4.4.1 Major Components and Operating Characteristics. The compressed gas storage buildings at the PFP are listed in Table 5-20. Each building is designed to accommodate the specific gas(es) in a safe and acceptable manner. As technologies and processes have changed, some of these facilities have either been modified or taken out of service. Current site standards (design, construction, and operations) set forth necessary criteria for the renovation and/or installation of services.

5.4.4.1.1 The 2734-Z Building, Gas Bottle Storage Building. The gas bottle storage building, 2734-Z Building, is located in the southeastern part of the PFP Complex (see Figure 5-54). It consists of a 73 ft by 16 ft concrete pad that is 2 ft 8 in. above ground level, on which is a wood frame building 72 ft by 11 ft by 7 ft high. The 2734-Z Building is currently used for temporary storage of empty drums.

5.4.4.1.2 The 2734-ZA Building, Cylinder Storage. The 2734-ZA Building is located about 3 ft from the south wall of the 234-5Z Building. It provides storage for empty flammable gas cylinders. The structure rests on a concrete slab that is 5 ft 4 in. by 16 ft and consists of concrete blocks on three sides with corrugated transit doors in front. It is 7 ft high at the front; the doors are 4 ft high with open gaps above and below the doors, 1 ft at the bottom and 2 ft at the top. The roof is sloped to the rear and is corrugated transit. The ceiling is 1-h fire-rated wallboard on a steel roof frame.

Two heat detectors are located within the building; they are tied into the zone 45 annunciator, RAFR 2780. Explosion-proof electrical fixtures are installed.

5.4.4.1.3 The 2734-ZB Building, Gas Bottle Storage. The 2734-ZB Building is located against the south wall of the 234-5Z Building. It provides storage for breathing air (compressed air) cylinders. The building is 5 ft by 15 ft 4 in. by 7 ft 6 in. high and consists of a structural steel frame with aluminum roof and siding. The siding is 6 ft high. The building is open above and below the siding on the front and the west side. The

bottles are mounted in vertical racks and held in with link chains. The lighting is designed in accordance with class 1, division 1, group A hazardous installation.

5.4.4.1.4 The 2734-ZC Building, P-10 Storage. The 2734-ZC Building is structurally identical to the 2734-ZA Building (see Section 5.4.4.1.2). This building is used to store oxygen cylinders and cylinders of P-10 (90% argon, 10% methane) gas and supplies P-10 gas to the Analytical Laboratory.

5.4.4.1.5 The 2734-ZD Building, Argon and Oxygen Gas Storage (out of service). The 2734-ZD Building provides storage for empty, non-flammable gas cylinders. It is located within 3 ft of the south wall of the 2734-5Z Building. The building is 9 ft by 13 ft by 7 ft 6 in. high and is built similarly to the 2734-ZB Building (see Section 5.4.4.1.3). Electrical installation conforms to the 1971 edition of the "National Electrical Code," *Fire Protection Handbook*, NFPA (1971).

5.4.4.1.6 The 2734-ZF Building, Gas Bottle Storage. This building, with dimensions of 13 ft by 6 ft by 7 ft 5 in., is constructed of corrugated aluminum and steel and is open to the south wall of the 234-5Z Building. A single 30-in.-wide door leads into the building. The building is used to store argon cylinders.

5.4.4.1.7 The 2734-ZG Building, Nitrogen Storage. This building, with dimensions of 21 ft by 6 ft by 7 ft 6 in., is constructed of corrugated aluminum and steel and is open to the south wall of the 234-5Z Building. Two doors lead into the building; one 42 in. and the other 32 in.

5.4.4.1.8 The 2734-ZH Building, Argon and Nitrogen Storage (out of service). The building is located in a corner formed by the south wall of the 234-5Z Building and the west wall of the 234-5Z Building South Annex. It is about 3 ft from each wall. It consists of a 9 ft by 14 ft 10 in. by 7 ft 6 in. high steel frame structure with aluminum roofing and siding on a concrete pad. Areas above and below the siding are open. The side adjacent to the south annex wall was for acid storage, and is 5 ft by 5 ft 6 in. wide. Two doors are provided, one was for acid storage and one was for gas cylinder storage. Electrical installation conforms to the NFPA (1971).

5.4.4.1.9 The 2734-ZJ Building, Liquid Nitrogen Storage. The 2734-ZJ Building is located in back of the 234-5Z Building on the west side. Vendor-owned equipment is supplied for liquid nitrogen storage. Liquid N_2 is stored in the vendor's tank. An evaporator and a heat exchanger are installed to provide N_2 at 70 °F in the fixed piping headers serving operations and the laboratories in the 234-5Z Building.

5.4.4.1.10 The 2734-ZK Building, Argon, P-10, Nitrogen, Propane, Acetylene, Helium and Miscellaneous Flammable Gas. The 2734-ZK storage structure is located outside the 234-5Z Building on the north wall. This structure is an unheated shelter for storing gas cylinders. Constructed of steel, transit, and isolated from the 234-5Z Building by a rated fire barrier, service lines from 2734-ZK are routed through the wall to the Maintenance Shop for the use of argon gas. 2734-ZK is also used for storage of flammable gas. Ventilation occurs by natural air movement through the expanded metal grating doors, through spaces above (7 in.) and below (3 in.) the access doors.

Airflow from this structure is not monitored. The access doors are not full length.

5.4.4.1.11 Other Compressed Gas Facilities. An argon supply is also kept in an outdoor shed on the north side of the 2736-ZB Building toward the west. Argon service is provided to a capped-off fitting inside the repackaging glovebox in the 2736-ZB Building. The argon is used to inert the repackaging cans while packaging plutonium metal. Oxygen, nitrogen, argon, acetylene and propane are stored in a concrete, transite and steel enclosure at the 234-ZB Building for use by construction personnel.

5.4.4.2 Safety Considerations and Controls. Compressed gases are used for process operations, laboratory operations, and maintenance operations. These gases provide a potential for explosion. The compressed gas systems were installed and are operated in accordance with standard practices for handling industrial compressed gases. There are several engineered barriers included in these standard practices to minimize this hazard.

- Safety relief valves are installed on pressurized tanks.
- Melting pins are installed as a backup pressure relief feature in case of fire.

The administrative barriers that are practiced to minimize the hazard of explosion are as follows.

- Gas bottles are chained to prevent inadvertent tipping or falling over.
- When in use, bottles are checked daily for proper operation.

The compressed gas systems have been reviewed for compliance with the requirements of DOE Order 6430.1A (DOE 1989). Results of this review are provided in Tables 3, 6, and 9 of WHC (1990).

5.4.5 Vacuum Systems

5.4.5.1 Major Components and Operating Characteristics.

5.4.5.1.1 Process Vacuum System (26-in. mercury vacuum). The 26-in. mercury process vacuum system provides high-capacity vacuum service to PFP facilities for vacuum transfers of liquids and other high vacuum requirements. The process vacuum system is Non-Safety Class except for the header liquid detection interlock system, which is Safety Class. A 4 in. diameter stainless steel piping header is routed throughout the duct level of the 234-5Z Building with branches serving process areas and the 236-Z Building.

The air pulled into this system, in many cases, comes from inside contaminated enclosures and is usually moist from use as the source of a vacuum transfer of contaminated liquid, thus, each major branch is equipped with demisters. Liquid effluents in the demisters, which may contain trace amounts of contamination, are routed to the 241-Z Building waste tanks for disposal.

The equipment for the process vacuum system is located in room 308, of the 234-5Z Building. Vacuum is provided by two vacuum pumps, each rated at 950 ft^3/min at approximately 26-in. mercury, and powered by 50-hp electric motors. During normal operations, one pump is operating and one is on standby. The inlet stream to the pump contains two sets of two-stage testable HEPA filters. During normal operations, one set is operational and one set is on standby. The vacuum pumps discharge to a 140-gal water trap-silencer tank to separate the seal water from the discharged gas. The gas is routed out of the trap-silencer tank up through a demister and into the E-4 ventilation system ahead of the final E-4 filter bank. Hence, the vacuum system effluent air is treated by three stages of testable HEPA filtration before atmospheric discharge. A seal-water pump rated at approximately 30 gal/min recirculates the seal water from the bottom of the trap-silencer tank through a glycol-cooled heat exchanger back to the vacuum pumps. A simplified schematic of the 26-in. mercury process vacuum system is provided in Figure 5-55.

The seal water cooling system consists of two water-to-glycol heat exchangers, each rated at 100,000 Btu/h, and a glycol secondary cooling subsystem. The glycol secondary cooling system is located outside and south of the 234-5Z Building. It consists of two evaporative coolers, each rated at 100,000 Btu/h and two pumps, each rated at 40 gal/min and powered by a 5-hp electric motor. During normal operation, one pump is running and one is on standby. Water from the process water supply system is evaporated in the evaporative coolers to remove heat from the glycol cooling loop, which cools the primary process water sent to the vacuum pumps.

The inlet to the vacuum pumps from the vacuum header is a 6 in. diameter stainless steel line. The discharge line from the vacuum pumps is a 6 in. diameter stainless steel line to the trap-silencer tank, and a 4 in. diameter stainless steel line from the trap-silencer tank to the E-4 header. All four HEPA filters on the inlet line to the vacuum pumps are equipped with DP alarms and taps for filter efficiency testing.

To preclude contamination of the glycol secondary cooling system, low DP across the system and the primary-process water-cooling system will shut down the glycol secondary system and seal-water pumps, isolate the glycol secondary system by remote valve actuation, and sound an alarm. Loss of negative pressure from the E-4 header will shut down the vacuum pumps and sound an alarm. High water level and low water level in the trap-silencer tank will shut down the vacuum pumps, the seal-water pump, and sound an alarm; however, fresh water is continuously added to the trap-silencer tank by a rotameter (while the pumps are operating) for bleed-off and make up for seal water lost by normal evaporation. Fresh water can also be added to the trap-silencer tank by the OCS from the MICON™ control station (rooms 712 and 714 of the 234-5ZA Building). Bleed off from the trap-silencer tank goes into the tank drain which routes the waste liquid to the 241-Z or 243-Z facilities (depending on sampling results). Liquid detectors are installed in a liquid detection loop on the inlet line for the vacuum pumps ahead of the HEPA filters. When activated, these detectors will shut down the operating vacuum pump, close both HEPA filter isolation valves, and sound an alarm. The vacuum pumps cannot run or be started unless the seal water pump is running or the manual bypass switch is on. The liquid detection interlock system is independent of the MICON™ control system.

5.4.5.1.2 Air Sample Vacuum System. The Air Sample Vacuum System (ASV) is also referred to as the 17-in. Hg Vacuum System. The ASV system provides the motive force for room fixed-head samplers, CAM units (excluding portable CAMs) and the 296-Z-6 effluent stack sampler and monitors. One system serves the 234-5Z, 291-Z, 2736-Z, 2736-ZA, and 232-Z Buildings. Vacuum pumps for this system are located in Room 501, Building 291-Z. Inlet air to the vacuum pumps is collected and filtered by one stage of testable HEPA filters before discharging directly to the 291-Z Building exhaust fan inlet plenum. These filters are located in Room 308, Building 234-5Z. The seal water for the vacuum pumps is cooled by the CLCS. The ASV failure alarm systems associated with stack CAMs are designated as "Safety Class" (formerly Safety Class 1). The remainder of the ASV system is "Safety Significant" (formerly Safety Class 3).

The 236-Z building has its own complete air monitoring system. Two vacuum pumps are installed in Room 35 of the 236-Z Building, each rated at 400 cu. ft/min at 17-in. Hg and powered by a 25-hp electric motor. The outlet air from the vacuum pumps is discharged into the E-3 exhaust system. The seal water to the vacuum pumps is cooled by the CLCS.

Two vacuum pumps (one operational and one standby) are installed in the 2736-ZB Building to service CAM units, fixed-head samplers and the 296-Z-5 effluent stack sampler and monitor. The capacity of each pump is rated at 180 cu. ft/min at a 17-in. Hg vacuum. Discharge is through two testable HEPA filters then through the exhaust plenum to the 296-Z-5 stack.

5.4.5.1.3 Dedicated Glovebox Exhaust Vacuum System (5-in. mercury vacuum). The 5-in. mercury process vacuum system is a dedicated system that serves to remove offgas generated from the furnaces used for thermal stabilization in glovebox HA-21I. The exhaust flows through a ceramic filter followed by a needle valve, which is used to adjust flow rates with an orifice and DP gauge to maintain flow within limits. The DP gauges are located on a rack located on the mezzanine in room 235 B/C. From there the air passes through two stages of HEPA filtration before entering one of two 2.5-hp blowers28. The blower offgas exhaust is to the 234-5Z Building E-4 exhaust system. The blowers, located in the duct level (room 264) can be started remotely from the control station or directly from the pumps.

5.4.5.2 Safety Considerations and Controls. Except for the header liquid-detection interlock subsystem, the 26-in. mercury vacuum system causes no serious safety concerns if it fails to operate. The header liquid-detection subsystem is designated as Safety Class because it provides one of the double contingency requirements for the prevention of a nuclear criticality. The subsystem is designed to detect and halt the flow of liquids, which might be a solution containing plutonium, to the testable HEPA filters upstream of the vacuum pumps. The testable HEPA filters do not have inherently criticality-safe geometry. The remainder of the 26-in. mercury vacuum system is designated Non-Safety Class since it has no safety function and is designed to be geometrically safe from a criticality point of view. All inlet gases are doubly filtered by testable HEPA filters. Each filter is equipped with a high DP alarm across the filter to warn of potential filter plugging.

Other controls that are installed to enhance confinement include shutting down the vacuum pumps on loss of negative pressure from the E-4 header, and

high and low water-level alarms in the trap-silencer tank that shut down the vacuum pumps and the seal water pump. The seal-water system has a continuous bleedoff. Fresh water is added continuously by a rotameter to make up for normal evaporation. The OCS in the MICON™ control station (234-5ZA Building, rooms 712 and 714) can add fresh water to the seal-water system, as desired. Also, low DP across the water and glycol loops will shut down the secondary glycol cooling system, the seal water pump (SWP-1), and secondary closed loop solenoid valve.

Those parts of the process vacuum system that are most likely to be contacted by product nitrate materials are designed to be safe from criticality by geometry (demisters, drop legs, headers, liquid-detection loops). The HEPA filter housings that are located between the liquid-detection loop and the vacuum pumps are not geometrically favorable. There are no criticality implications of water getting into the filters, but there could be if the liquid is product nitrate.

The ASV system is important to air sampling and monitoring of potentially contaminated areas within the confines of the buildings and to the monitoring of stack effluents. Its failure could result in failure to detect and measure airborne particulate contamination either within the areas monitored or contamination release in stack effluents. In the event of a loss of ASV service, backup systems, such as portable CAMs, respirators, and manual detection devices, would be employed, and operating activities would be curtailed as necessary to minimize the possibility of contamination spread or release. Because the stack CAMs are Safety Class, the ASV failure alarm system servicing those CAMs is also Safety Class.

The vacuum systems have been reviewed for compliance with the requirements in DOE Order 6430.1A (DOE 1989). Results of this review are provided in Table 5 of WHC (1990).

5.4.6 Steam Supply and Distribution Systems

5.4.6.1 Major Components and Operating Characteristics. Steam is supplied to the PFP from an oil-fired package boiler located in Building 234-5Z-BA (outside the PFP security fence) to the north of the PFP, near the 231-Z Building. The steam supply from the 200 East area powerhouse has been terminated. The steam distribution system from the 200 East Area powerhouse has been isolated from the PFP and its dedicated package boiler.

Steam is transmitted from the package boiler to the PFP Complex through an 8 in. diameter, Schedule 40 carbon steel insulated line. The steam line to the PFP from the package boiler has not been qualified to withstand a DBE event. No credit is taken for this line in the Chapter 9.0 accident analysis of the DBE event. Steam is supplied from the packaged boiler at 85-100 lb/in^2 (gauge).

The 8 in. diameter steam supply line enters the north side of the 234-5Z Building in the duct level, at column 16, 200 ft from the west end of the west annex building, 26 ft above grade. The line then extends vertically through the second floor into the second-floor machinery room (room 321), where the steam is supplied to the facilities through three branch

headers identified as the upper, middle, and lower headers. Figure 5-56 is a PFP steam supply flow schematic diagram.

The upper header, a 6 in. diameter line, extends directly south throughout the second floor, then east for approximately 60 ft at which point it enters the duct level and exits the 234-5Z Building south wall and extends to the 291-Z fan house.

Steam at 50-100 lb/in^2 (gauge) is also provided to the 2736-ZB Building from a tie-in to this 6-in. header between the south wall of the 234-5Z Building and the 291-Z fan house. Steam pressure for the 2736-ZB Building (with double valve isolation capabilities) is reduced to 15 lb/in^2 (gauge) for heating of ventilation supply air.

In the 291-Z fan house, the 6-in. line provides 85-100 lb/in^2 (gauge) steam to 5 subheaders: one to the 232-Z Building (which has been isolated inside 291-Z building); one to the 236-Z Building (which has been isolated inside 291-Z building); one header which leaves 291-Z building at 50-60 lb/in^2 gauge and separates into two headers, the 2715-Z paint shed (reduced, as necessary, to 15 lb/in^2 gauge), and the 241-Z Building to provide jet transfer of loquid wastes and for space heat; and one header to each of the steam-driven emergency ventilation exhaust fans in the 291-Z fan house. Steam used to be supplied by underground line from the 291-Z fan house to the 236-Z Building, where the steam is routed through headers to the third floor (corridors 10, 20, 30, and 33) as shown in Figure 5-57. Steam pressure is reduced to 15 lb/in^2 (gauge) for reheating ventilation supply air.

Steam supplied to the middle header in 234-5Z is currently blanked off.

Steam supplied to the lower header in 234-5Z at 50-100 lb/in^2 (gauge) is reduced, as required, to 50 lb/in^2 (gauge) by PRVs. Steam from this header supplies space heating for the 234-5ZA Building. Steam from this header is also reduced to 30 lb/in^2 (gauge) by a PRV and piped to each of the eight ventilation air supply units, located in room 321 of the 234-5Z Building, through a 10 in. diameter line. Steam coils with associated steam traps, condensate drains, and control instrumentation provide heating of the ventilation air supply. Formerly, the 50 lb/in^2 (gauge) steam was reduced by a PRV to 15 lb/in^2 (gauge) to supply a secondary general service loop that was routed to supply additional steam requirements (e.g., supplemental room heating, process service) in the 234-5Z Building. That PRV station has been removed and the piping has been abandoned in place.

5.4.6.2 Safety Considerations and Controls. Steam required for space and process heating and other services, distributed throughout the facilities, has industrial and personnel safety concerns. Design and installation of the steam distribution system provides insulated lines, isolation valves, pressure regulating valves, PRVs, steam traps, and control instrumentation to assure that the steam supply and distribution system can be operated and maintained in a safe manner.

It should be recognized that loss of steam for an extended period of time during very cold weather could result in extensive damage because of the freezing of building water lines that provide fire suppression and other PFP water services.

The steam supply and distribution system have been reviewed for compliance with the requirements in DOE Order 6430.1A (DOE 1989). Results of this review are provided in Table 5 of WHC (1990).

5.4.7 Water Supply and Distribution Systems

5.4.7.1 Major Components and Operating Characteristics. Water for the 200 Area is drawn from the Columbia River at the 100-B Area and pumped to a 25,000,000-gal reservoir. A second pumphouse at the 100-D Area and a separate line provide a backup supply to the reservoir. Diesel-powered pumps provide emergency water on loss of power to the electricity-driven supply pumps. Water from the 25,000,000-gal reservoir is pumped to the 200 East and 200 West Area reservoirs as shown in Figure 5-58. Two lines supply the 200 East Area 3,000,000-gal reservoir. One line supplies the 200 West Area 3,000,000-gal reservoir.

Water from the 200 West Area reservoir is pumped to the 283-W Water Treatment Facility for sedimentation, filtration, chlorination, and testing. Sanitary water produced by the treatment facility is routed to two covered storage vessels (clearwells) with a total capacity of 400,000 gal.

Sanitary water is supplied to the 200 West Area supply headers by four electrically driven pumps, two rated for 2,000 gal/min at 215 ft of head and two rated for 600 gal/min at 250 ft of head. Two steam-driven pumps rated for 600 gal/min at 250 ft of head are provided for backup service on loss of electricity or failure of an electricity-driven pump. The two 600-gal/min electric pumps are normally operated and supply water to the system at 90 lb/in^2 (gauge). Two elevated tanks, a 50,000-gal tank at the Reduction Oxidation (REDOX) Plant (S-Plant) and a 100,000-gal tank located near the 200 West shops, are tied in to the supply system to augment the supply during peak demand periods.

Sanitary water is provided to the PFP Complex from three lines, all originating from the 283-W facility as shown in Figure 5-59 (see Table 5-21 for location descriptions). One 12-in. line enters the complex at the northeast corner where it joins the PFP 10-in. general supply loop. The second 12-in. line is reduced to 10-in. and enters the PFP 10-in. general supply loop in the southeast corner of the complex. An 8-in. line enters the north side of the complex where it connects to the PFP 10-in. general supply loop. The supply lines are equipped with check valves upstream of their loop tie-in to prevent drainage of the loop should a supply line break. A 50,000-gal elevated water tank (drained and not currently in use) formerly served as a backup water supply to the PFP facilities.

All water requirements of the PFP facilities are provided from connections to the sanitary water service loop. Water supplied to the PFP facilities is not metered. A list of connections to the sanitary water loop with locations, line sizes, and services is shown in Table 5-21.

Sanitary water is used for personal needs (e.g., drinking fountains, hot water tanks, restrooms, showers, lunchroom), ventilation supply air washing and evaporative cooling, process services (e.g., chemical makeup, process cooling makeup), CLCS makeup, flushing drums at the 243-Z Building, safety

showers, and fire protection. The majority of the loop connections (see Table 5-21) provide dedicated fire protection water; however, the largest normal use of water is for air washing and evaporative cooling of the ventilation supply air for the PFP Complex. Both sanitary and process water are provided by several service connections to the sanitary water supply header. Wherever this occurs, a reduced pressure, backflow preventive device is installed to prevent cross-contamination of the sanitary water service from the process water loop. The water downstream of the backflow preventive device is termed process water.

Demineralized water is supplied at a minimum flow of 1 gal/h to a calorimeter in the NDA laboratory by a wall-mounted, laboratory-type, cartridge demineralizer. A similar demineralizer is used for supplying demineralized water to the 234-5Z Building standards laboratory, room 221E.

5.4.7.2 Safety Considerations and Controls. The major safety consideration associated with the PFP water supply and distribution system is that water always be available for the fire protection system. These concerns are minimized by the installed system that provides three independent supply lines and a supply loop that encircles the facilities. The supply lines and loop are equipped with isolation valves to isolate line breaks. The fire protection systems are discussed in detail in Section 5.4.11.

A second safety concern is that the sanitary water system, which also provides PFP process water, does not become contaminated. Reduced pressure backflow preventers are installed, wherever the sanitary water supplies the process to prevent cross-contamination. Water that is used for the process and separated from the sanitary water system by a backflow prevention valve is identified as process water. A preventive maintenance program is in place to ensure operability of the reduced pressure backflow devices.

Should the water supply to PFP be lost, plant operations that require water would be shut down. The ventilation system and the air sampling system could be maintained through continued operation of the instrument air system and the ASV system from cooling supplied by the CLCS.

The water supply system has been reviewed for compliance with the requirements in DOE Order 6430.1A (DOE 1989). Results of this review are provided in Table 6 of WHC (1990).

5.4.8 Cooling Water Systems

5.4.8.1 Major Components and Operating Characteristics. The current cooling needs of the PFP are being met by a CLCS and the cooling water spray for the ventilation supply air. The water for these systems, makeup water in the case of the CLCSs, are supplied from the sanitary water system as described in Section 5.4.7.

The first CLCS is associated with the process vacuum system, located in room 308 of the 234-5Z Building. That system uses a primary cooling water (PCW) loop to the vacuum pumps and a glycol secondary cooling loop. Heat is removed from the secondary loop by cooling towers outside of the building.

The process vacuum system, and associated CLCS, is discussed in more detail in Section 5.4.5.1.1.

The second CLCS, which is much larger than the one associated with the process vacuum system, consists of seven PCW loops and one secondary cooling water (SCW) loop. The system operates by circulating PCW through the area/equipment to be cooled and then to a heat exchanger where heat is transferred to the SCW.

The PCW loops each consist of one circulating pump, an expansion tank, and a heat exchanger (with the SCW loop) located in the same rooms as the equipment serviced by the PCW loop. The PCW loops service the following areas and pieces of equipment.

- PCW loop 1--Various process equipment in the east and west gallery, gloveboxes in the 236-Z Building (PCW loop equipment is in room 35 of the 236-Z Building).
- PCW loop 2--ASV 1 in room 35 of the 236-Z Building (cooling and seal water).
- PCW loop 3--ASV 2 in room 35 of the 236-Z Building (cooling and seal water).
- PCW loop 4--ASV 1 in room 501 of the 291-Z Building (cooling and seal water).
- PCW loop 5--ASV 2 in room 501 of the 291-Z Building (cooling and seal water).
- PCW loop 6--Air compressor 1 in room 501 of the 291-Z Building.
- PCW Loop 7--Air compressor 2 in room 501 of the 291-Z Building.

The SCW is circulated through two fluid coolers located outside of the 236-Z Building. The building designation for the fluid coolers and co-located equipment is the 243-ZB Building. In addition to the two fluid coolers, the 243-ZB Building contains the two circulation pumps used for the SCW loop.

The ventilation supply air for the PFP buildings is conditioned by a water spray directed at inlet filters. Water is applied to the filters only during the summer, providing for cleaning and evaporative cooling to the supply air. The system is supplied by the sanitary water system, which is described in Section 5.4.7.

5.4.8.2 Safety Considerations and Controls. If the CLCS that is associated with the process vacuum system were to fail, then the process vacuum for the PFP would be lost. This failure would impact operations but is not significant to safety.

The other CLCS provides PCW services to select process gloveboxes, the instrument air compressors in the 291-Z Building, and the ASV pumps in the 236-Z and 291-Z Buildings. It is designed so that the loss of one PCW loop

has no impact on the other PCW loops, allowing operation of alternate equipment. For example, if the PCW loop to ASV 1 in room 35 of the 236-Z Building were to fail, ASV 2 would be brought online and would be cooled by a different, unaffected, PCW loop.

If the SCW loop of this CLCS were to fail, then all PCW loops would be shut down because of an inability to transfer heat. In this event all process glovebox, instrument and process air, and ASV cooling services would be lost. Chapter 6.0 contains the discussions of glovebox operations and processes, if any, that may be used in these gloveboxes, including the use of cooling water. Loss of process and instrument air would result in the loss of air-controlled equipment and eventual shut down of the ventilation system to a safe configuration. Loss of process vacuum or ASV service would result in the loss of operations using process vacuum, operability of room CAMs, fixed head air samplers, and the 296-Z-5 and 296-Z-6 stack samplers and monitors. Normal operations would be interrupted upon loss of the ASV, though portable CAMs would be used where necessary in surface contamination areas and temporary vacuum pumps would be installed to serve as the motive force for the stack samplers and monitors.

To help reduce the chance of contamination entering the PCW loops from process areas/equipment, the SCW loop is maintained at a greater pressure than the PCW loops. Thus, a leak between the SCW and PCW loops would result in a flow of water from the SCW loop to the PCW loops.

5.4.9 Liquid Effluent Systems

There are four types of liquid effluent streams from the PFP Complex: (1) a sanitary sewage stream, (2) a waste water stream, (3) a RLW stream from the 241-Z Building, and (4) a French drain effluent stream. See Chapter 7.0 for more details on the PFP waste water effluent systems processes.

5.4.9.1 Sanitary Sewage. Two sanitary sewage systems, shown in Figure 5-60, collect wastes from the PFP restroom sinks, showers, toilets, and from lunchroom sinks for disposal in septic tanks and tile fields. The systems collect wastes from the 234-5Z Building, mobile office trailers, the 2704-Z office building and the 2701-Z, 2701-ZA, 2701-ZD, and 2705-Z Buildings, and route it to septic tanks and pump stations and to the 2607-W1 regional drain field located to the east approximately one-half mile away. The sanitary sewer system effluents, by their nature, are neither chemically nor radioactively hazardous.

Sanitary sewage wastes from the mobile office trailers next to the 2705-Z operations control facility are routed to the 2607-WB septic system, pump stations and to the 2607-W1 regional drain field. Sanitary sewage wastes from the 270-Z office building, 2701-ZD Security Building, and operations control facility are also routed to this system through a tie-in to the line that parallels the north wall of the 234-5Z Building. Sanitary sewage wastes from the 2736-ZB restrooms and from the 234-5Z south annex are routed to a second septic tank, and then to the pump station and 2607-W1 regional drain field.

5.4.9.2 Facility Waste Water. Waste water discharged from the 234-5Z, 236-Z, 291-Z, and 2736-ZB Buildings is routed through a system of drain headers (drain headers D1, D2, and D3) and manholes to pump station 1 where the effluent combines with waste water from T Plant and the 222-S Laboratories before being pumped to the TEDF in the 200 East Area (see Figure 5-61 for waste water streams and manholes). Tables 5-22 through 5-25 identify the particular waste water streams, their building of origination, their collection header, and the discharge point.

The drainage system for the north side of the 234-5Z Building handles the effluents from the ventilation supply fans, steam condensates, and north side storm drains. The original designation for this drainage system was the 234-5Z ventilation steam condensate/dry air compressor cooling water. Because the majority of the waste water now comes from the supply fans following the inactivity of the dry air compressors, the drainage system has been renamed the supply fan waste water stream. Thus, the manholes and storm drains along this waste water stream are labeled S-1 through S-7. The stream then flows through manholes C-2, C-3, C-4, and finally to Pump Station 1.

The drainage system consists of 15 or 18 in. diameter vitreous clay pipe. The vitrified clay pipe originally installed in 1948 was comprised of 3-ft lengths of pipe. Past process misroutings contaminated the pipe from the 236-Z Building through manholes Z-3 to Z-9 and the 216-Z-20 crib. The LLWTF removes contamination from the effluent stream after contacting the pipe. New PVC pipe was installed downstream of manhole C-1 where the effluent was rerouted from the 216-Z-20 crib to the TEDF. The piping between the LLWTF outlet and manhole C-1 was remediated using an in situ-form liner to fix the contamination in place and provide a new, clean pipe formed inside the old pipe. This liner and clean pipe surrounding the old pipe provides double containment of the waste water effluents as the effluents are sent from the PFP Complex to the TEDF. The in situ-form liner and new pipe also were installed on the pipe from manhole Z-2 to manhole Z-7 to stop leaks in the line. These leaks were caused by earth settling on the pipe during the operational lifetime of the pipe. The PVC drain pipe installed by the TEDF project, was arbitrarily labeled pipe C and the manholes C-1, C-2, etc.

The 216-Z-20 crib is located southeast of the PFP facilities, as shown in Figure 5-61. The crib, which was designed and constructed in 1981, was activated in January 1982 and deactivated in June 1995. The crib consists of two parallel runs of 6 in. diameter perforated PVC pipe and one additional 10 in. diameter PVC pipe running between the parallel pipes. These pipes are 7.5 ft below grade. The pipes lay on a bed of small rock 12 in. in depth. An additional 12 in. of rock was placed atop the pipes. A biological barrier in the form of a 20 mm thick sheet of PVC was placed on top of the gravel. The edges of the PVC sheet were overlapped and sealed for 3 in., then the area was filled with gravel. A manhole (identified as Manhole 9) was located at the head end of the crib. The manhole served as the connection point for two former existing drain lines. One drain was a 15 in. clay pipe that carried liquid waste from PFP and the second drain was an 18 in. clay pipe that carried liquid waste from the 231-Z Building.

The 216-Z-21 seepage basin (also referred to as the 207-Z retention basin) is located approximately 300 ft northeast of the 216-Z-20 crib and covers an area of approximately 10,000 ft^2 (Figure 5-61). The basin was taken

out of service in May 1995 when its effluent stream was rerouted from manhole S-7 to the TEDF. The old pipe to the basin was capped off with grout.

To the east of manhole Z-7 is the inactive 2904-ZA sample building (Figure 5-61). This 12-ft by 12-ft pre-engineered, corrugated-metal building housed the online alpha monitor as well as a composite sampler and a flow meter. A single riser penetrates the effluent line for purposes of sampling the stream. The building and its equipment was deactivated in February 1994.

The inactive 2904-ZB sample building is located next to the deactivated manhole Z-9 (Figure 5-61). This building provided a sample point at the entrance of the 216-Z-20 Crib. This building was deactivated in May 1995 when the waste water stream was rerouted from the 216-Z-20 Crib to the TEDF. The old drain pipe downstream of manhole C-1 to manhole Z-9 was plugged with grout and manhole Z-9 was filled with concrete.

The 225-WC waste water sampling facility is located above the effluent stream, 20 ft east of manhole C-4 (Figure 5-61). The 225-WC facility is a pre-engineered building made of corrugated metal. Normal electrical power is supplied via pump station 1. Backup power is currently not supplied to this facility. The 225-WC facility contains six risers that penetrate into the effluent pipe to allow access to the stream for sampling and monitoring purposes. This facility monitors pH, flow, and conductivity in the liquid effluent. The pH monitor has a recorder. The conductivity probe is used to detect electrolyte-type (salt or acid) liquids that might come into the effluent stream. The sampling equipment and effluent source descriptions are discussed in Chapter 7.0.

5.4.9.3 The 241-Z Complex Stream Wastes. The TRU waste streams from various sources within 234-5Z and 236-Z (i.e., labs, 26-in. mercury vacuum, PRF solvent extraction, and RMC scrubber) are contaminated or have a high potential of being contaminated. These waste streams are transported by an extensive drain system (headers D4, D5, and D6) through a double-encased steel line with leak detection to the TK-D8 waste accumulation tank in the 241-Z Building. Wastes are transferred from the TK-D8 tank to the TK-D5 tank for storage and treatment before being discharged to the 244-TX receiver facility. Tanks TK-D4, TK-D7, and the TK-D7 overflow tank serve to retain overflow from the TK-D8 and/or TK-D5 tanks (see Chapter 7.0 for a detailed description of the 241-Z Complex waste treatment processes). (See Figure 5-62 for a diagram of the 241-Z radioactive waste treatment system.)

5.4.9.4 French Drains. Liquid wastes with insignificant potential for radioactive contamination (e.g., steam condensates from traps on outside steam supply lines) are locally disposed to the ground through French drains. A French drain consists of a buried vertical section of perforated cement or vitreous clay pipe, filled with rock and gravel, which provides local disposal of liquid waste waters. French drain waste disposal is discussed in Chapter 7.0, Section 7.2.2.

5.4.10 Safety Communication and Alarm Systems

The role of safety communication and alarm systems in the PFP Complex is to provide audible and/or visual information concerning abnormal conditions.

The communication systems provide standard and emergency communication exchanges. Standard alarm signals (e.g., horns, sirens, gongs) are used at the PFP Complex to provide notifications of specific abnormal conditions. All PFP safety SSCs interface with specific communication and alarm systems.

Safety Class stack alarms are associated with stack CAM systems. They provide notification of excessive release from the plant that could result in offsite and onsite releases above site guidelines. Safety Significant alarms are associated with other environmental monitoring, CAS, and liquid effluent monitoring systems or provide notification to personnel for fire, evacuation, warning, or radiation protection. The PFP Complex communications and alarms systems consist of the following:

- Plant (commercial) telephone system, including crash system phones
- Internal PAX telephone and public address system
- Siren system (evacuation and take cover warning)
- Emergency lighting
- Fire alarm/notification system
- CAM system
- CAS.

The 270-Z Building houses the PFP emergency control center and functions as a staging area in case of evacuation. For most emergencies reentry efforts would be planned in and conducted from this center.

Backup power is available for the various alarm systems from three diesel generators in the 2721-Z Building. In addition, the fire alarm system, emergency lighting, and the CAS have battery backup power systems. The following sections provide details of system components and the function of components in response to normal, abnormal, and accident conditions.

5.4.10.1 Major Components and Operating Characteristics.

5.4.10.1.1 Plant and Crash Telephone Systems. Voice communications within the PFP facility and with other Hanford Site locations are accomplished using the plant telephone system. This equipment consists of standard commercial telephone equipment with telephone sets placed in offices and other locations throughout the facility.

The crash alarm telephone system is a feature of the plant telephone system. This system, primarily used for area or site emergencies, allows a message to be given over selected phones throughout the facility. The messages given provide information to the building emergency director and the facility workers, and may serve to initiate other alarms, such as the evacuation or take-cover alarms. The crash alarm phones are marked and are strategically located in the facility.

5.4.10.1.2 Private Automatic Exchange System. A PAX telephone system provides communications within the plant. The PAX also has public address capability. The PAX switcher and public address systems are powered by a UPS located in Room 308 of Building 234-5Z. In turn, the UPS is powered off the Building 234-5Z emergency bus by the Building 2721-Z diesel-generators. In the event of an emergency, the PAX can be used to provide emergency

instructions to plant personnel. Additionally, intercom services are provided for the RMC Line and the PRF.

5.4.10.1.3 Emergency Audible Alarm (Siren) System. The emergency siren system at the PFP consists of 32 sirens and one siren controller. Two sirens are 120 Vac, located in the 270-Z Building; two are 480 Vac, located in the ventilation plenum and on the roof of the 234-5Z Building; and the remaining 28 are 125 Vdc, located throughout the rest of the PFP Complex. The siren controller regulates the tone of the sirens, indicating the proper action to take; a steady tone indicates an evacuation response, while a wavering tone indicates a take-cover response. There are siren control switches in several strategic locations in the PFP Complex: the Power Control Room (Room 321) in the 234-5Z Building; Patrol's AMS building (2701-ZA); and the Operations office in the 2736-ZB Building. Both the Power Control Room and the AMS are manned 24 hours a day, while 2736-ZB is manned whenever any type of vault operations are performed. All sirens, and the siren controller, are powered from emergency power panels in the 234-5Z Building. The all clear signal for the evacuation/take-cover alarms can be communicated by voice using the PAX system or crash alarm phones.

5.4.10.1.4 Emergency Lighting. Emergency lighting in the PFP complex is provided by stand-alone units located along evacuation routes as required by NFPA 101 and additional units located to reduce safety hazard to plant personnel. The stand-alone units consist of incandescent lamps with a battery and battery charger. The units are connected to the normal lighting circuits and activate when power is lost to the normal lighting circuit.

5.4.10.1.5 Fire Alarms. The fire alarm system for the PFP consists of a high-reliability, supervised system to notify the HFD of an alarm at any one of the fire alarm control panels. The system consists of low-voltage circuits. Fire alarms can be triggered by activation of any automatic suppression system, signals from smoke or heat detectors, and by manual activation of auxiliary alarm pull boxes in the building or at master alarm boxes. Any fire alarm activates all fire alarm gongs and alerts the 200 Area fire station. Section 5.4.11 contains more detailed information on the fire alarm system of the PFP.

5.4.10.1.6 CAM Systems. For the purposes of this discussion, there are two types of CAM systems at the PFP: room/portable CAMs and stack CAMs. The room CAMs are designed to detect elevated levels of airborne alpha contamination in a work environment and sound an alarm to warn affected personnel. Operational requirements for room CAMs are described in HSRCM-1, *Hanford Site Radiological Control Manual* (DOE 1994). Room CAMs are located in areas indicated by the guidelines of HNF-PRO-331, *Work Place Air Sampling*, and where recommended in PNNL air sampling evaluations for the PFP. Representative CAM locations at the PFP Complex are shown in Chapter 8.0.

CAMs and their associated alarm function mitigate some potential facility worker hazards at PFP. In general, during stabilization activities, the primary boundary to release of radionuclides to occupied rooms are gloveboxes, process systems, or sealed plutonium storage containers. The primary boundaries to plutonium release inside PFP can fail through several potential mechanisms, such as improper maintenance, equipment degradation, or abnormal glovebox pressurizing events. In many cases, there is no obvious indication

that a plutonium release has occurred. The CAMs serve to validate the satisfactory performance of the barriers to plutonium release. If one of these primary barriers fail and plutonium is released into PFP, then alarms will be actuated when the alarm setpoint is reached. Upon actuation of the alarm, facility workers are trained to promptly evacuate the affected air space. This action serves to reduce the potential plutonium inhalation dose received by the affected facility workers. The public and onsite workers are not significantly affected by these potential plutonium releases inside PFP because the exhaust air flow is filtered by the applicable exhaust ventilation system prior to release outside of PFP.

In the event of a loss of normal power, some room CAMs are provided with backup power from the diesel-generators for the CAM alarms, detectors, individual vacuum pumps (where applicable), flow rate measurement equipment, and counting and failure lamps, from the backup power system (diesel generators). All CAMs alarm locally and some CAMs alarm remotely. All room CAMs use the ASVs described in Section 5.4.5.1.2.

If for some reason a room CAM is not able to perform its function, or is not available, portable CAMs with their own vacuum source can be used. These CAMs can also be used in areas without room CAMs but where maintenance or other activities might cause a release of airborne contamination. Portable CAMs are designed to detect elevated levels of airborne alpha contamination.

Stack CAMs are provided to monitor the release of gaseous effluents to the environment. This helps to ensure the integrity of the HEPA filtration system and provides prompt indication of elevated plutonium concentrations in effluent streams. All stack CAMs are powered by the normal electrical distribution system of the PFP with backup power received through diesel generators. The stack CAMs, remote alarms, and the failure alarm portion of their associated vacuum system, are Safety Class; however, the CAMs are only required to be operable when forced ventilation is occurring through the stack being monitored. Only the failure alarm portion of the vacuum system is Safety Class because if the vacuum fails, then appropriate action can be taken to monitor the associated stack effluent or filters by other means. All stack CAM failure and alarms are indicated on a panel in room 714 (MICON™ power control room) of the 234-5ZA Building.

The 291-Z-1 stack CAM (234-5Z, 236-Z, and 242-Z Buildings), the 296-Z-3 stack CAM (241-Z Building sumps and tanks), and the 296-Z-14 stack CAM (232-Z Building) are self-contained, providing their own vacuum source from portable vacuum pumps. The 296-Z-5 (2736-ZB Building) and 296-Z-6 (2736-ZA Building) stacks use the ASV system as described in Section 5.4.5.1.2.

5.4.10.1.7 CAS. The CAS is intended to supply continuous monitoring for high-radiation (criticality) events within the PFP Complex. It initiates a criticality alarm to affected personnel and establishes the approximate time of the event. Two methods of detection are used by the CAS at the PFP: gamma detectors and neutron detectors. The gamma detectors are used throughout the PFP Complex while the neutron detectors are used only in the 2736-Z Building.

The requirements for CAS equipment location, testing, and calibration are given in HNF-PRO-546, *Nuclear Criticality Safety Manual*; HNF-IP-1115, *Nuclear Criticality Alarm Manual for the Plutonium Finishing Plant*; and HNF-SD-CP-SDD-

003, *Definition and Means of Maintaining the Criticality Alarm System Portion of the PFP Safety Envelope*. Under these requirements, criticality detector stations, horns, and blue-flasher lights are located strategically throughout the PFP Complex associated with the following buildings: 2736-ZB, 236-Z, 234-5Z, 2736-Z, and 241-Z Building. Nine criticality alarm panels, each coordinating the detectors in a single zone, are located in the following buildings: one in 241-ZG, one in 2736-ZA, four in 234-5Z, two in 236-Z, and one in 2736-ZB. Upon detection of a criticality by no less than two detectors in a single zone, the criticality alarm panel initiates an audible (horn) and visual (blue flashing light) alarm. Eight of the nine criticality alarm panels are interconnected to enable a single alarm to activate all eight. The ninth panel (CAP 8), in the 241-ZG Building, is not interconnected to the other zones.

A typical individual CAS zone consists of the following equipment: criticality detector stations with three criticality alarm detectors each, a criticality alarm panel and associated components, criticality alarm horns and blue flasher lights (zone 7 in the 241-Z Building and zone 9 in the 2736-ZB Building only), and backup battery power supply (zone 7 has an additional UPS). Other equipment related to the CAS, such as the remote monitoring equipment, multiplexer unit, criticality alarm annunciators, and alternating current loss relays, may be available but are not essential for the detection or alarming of a criticality event.

Upon initiation of a CAS alarm, the time delay on the Access Delay Doors within the plant is overridden. This allows immediate egress of all areas of the plant to minimize potential personnel exposure.

5.4.10.1.8 Miscellaneous Radiation Protection Systems. The PFP can provide portable radiation detection devices to areas of concern within the PFP Complex.

5.4.10.1.9 Safety Annunciator. An annunciator (ANN-714) for the stack effluent monitor alarms, process vacuum leak detector alarms, and the seismic fan shutdown system disabled alarm is located in room 714 (MICON™ power control room) of the 234-5ZA Building. The stack effluent and seismic fan shutdown alarms are either safety class or safety significant. Currently, the process vacuum leak detector alarms are not the primary alarms and thus are not safety alarms. These alarms will be reclassified when the controls for the process vacuum system are connected to the MICON™. The normal power for the annunciator is the 308 UPS. This power is monitored by a special annunciator window that is powered by the room 269 switchgear control batteries.

5.4.10.2 Safety Considerations and Controls. The functioning of alarm systems and appropriate actions are detailed in the building emergency plan for the PFP HNF-IP-0263-PFP. The communication and alarm systems have been reviewed for compliance with the requirements of DOE Order 6430.1A (DOE 1989). Results of this review are provided in Tables 4, 5, and 7 of WHC (1990).

5.4.10.2.1 Emergency Signals and Responses. The following sections describe the emergency signals.

Evacuation Signals. Two distinct evacuation signals can be relayed by the alarm systems. One is activated by a criticality, and the other is a general evacuation alarm. A steady siren is sounded for general evacuation. In addition, the PAX may be used to announce evacuation.

Failure of the CAS or loss of normal power supply initiates an annunciator. The CAS operates from a 24 volt storage battery system with a float charger to maintain the batteries. The battery system is designed to operate the CAS system in normal operation for at least 4 h without an operable battery charger. Each individual criticality alarm panel can then be switched back to ac power provided that the backup diesel generators are operating or normal power has been restored.

In the event of a criticality, the local sensors (except criticality alarm panel 8 in the 241-ZG Building) signal the system and howlers (ah-oo-gah horns) are sounded throughout the complex. In addition, there may be visual signals to nearby personnel from flashing blue lights. Panel Z-8 only actuates howlers in the immediate area of Building 241-Z. Personnel are instructed to run a minimum of 100 ft from the facility and assemble at prearranged staging areas.

Fire Alarms. Fire alarm gongs are sounded in response to smoke, heat detectors, pull boxes, and upon the activation of any suppression system. All personnel are required to evacuate in an orderly manner from the affected building to the primary staging area in response to an activated fire gong alarm.

Take Cover Signals. A wavering take cover siren is available to signal personnel of an event where evacuation may be a hazardous action. Take cover instructions may also be relayed by means of the crash alarm phones or the PAX.

Continuous Air Monitors. The CAM systems provide both local and annunciator panel responses at various locations. The local signal varies with the specific type of CAM, but usually includes a bell and a flashing red light. Remote annunciation is provided by the CAM system (including stack monitors) at various selected locations. In addition, failures of selected equipment associated with selected CAMs, such as air sample vacuum pumps, are annunciated on panels. All CAMs alarm locally. Selected CAMs also alarm on annunciator panels located in radiation monitoring offices.

Access Denial System. This system is classified and, therefore, not discussed.

5.4.10.2.2 Off-Normal Conditions. This section describes the functioning of the alarm and communications systems during off-normal conditions such as power failure, loss of ventilation, loss of water, loss of steam, or loss of air.

Loss of Normal Power. Criticality alarms are battery-powered and can function independently of the normal power supply. Three diesel generators supply backup power to the 234-5Z, 291-Z, 2736-ZB, 2736-ZA, 2701-ZA, and 2701-ZD Buildings. Evacuation fire alarm bells and lights are connected to their own individual battery packs for backup power. There are also separate

emergency-generator and battery-powered lights in all occupied areas. The PAX phones are equipped with UPS to allow phone communication during power loss. The public address amplifiers are connected to emergency power to allow paging capability. The fire alarm control panels have battery backup and can function independently of the normal power supply.

Loss of Ventilation. The PFP ventilation is described in Section 5.4.1. Loss of negative pressure is annunciated on OCSs in the MICON™ control station (rooms 712 and 714 of the 234-5ZA Building). Actions to be taken can be announced over the PAX system. At minimum, personnel will evacuate zone 3, except those wearing respiratory equipment. The 241-Z Complex ventilation will shut down on loss of power. As noted in Section 5.4.1, following detection of high pressure by the DP switches in the RMC Line interconnected conveyors (HC-2, HC-3, HA-4, and HA-28), an alarm (both audible and flashing light) is activated in the MICON™ control station. High pressure in the RMA Line interconnecting conveyor also will activate an alarm (both audible and flashing light) in the MICON™ control station (room 714). The alarms will cease after pressure has been reduced to acceptable levels.

Loss of Water. Impending loss or reduction of water supply to the PFP Complex may be verbally communicated to appropriate management and effective water conservation measures undertaken in accordance with the building emergency plan.

Loss of Steam. There are no effects of loss of steam upon the alarm and communication systems. However loss steam will alarm indicating a loss of steam turbine emergency exhaust system.

Loss of Compressed Air. There are no effects of loss of compressed air including instrument air upon the alarm and communication systems. A loss of compressed air will result in a loss of normal ventilation.

5.4.11 Fire Protection Systems

The fire protection systems cover many of the buildings that make up the PFP Complex. Descriptions of the plant and the individual buildings are given in Sections 5.1 and 5.2. This section discusses the fire protection systems and relevant fire protection design features of the PFP Complex and individual buildings. The fire protection sprinkler coverage for the PFP Complex is shown in Figure 5-63.

5.4.11.1 Design Bases.

5.4.11.1.1 Maximum Fires and Fire Hazards. The criteria for fires are given in the FHA (McKinnis 1998). Details of the design basis fire analyses are given in Chapter 9.0. The following sections provide summary descriptions of design basis fires, special hazards and exposure hazards, and fire protection design features of individual buildings. Design basis fires evaluated in the FHA include the Maximum Possible Fire Loss (MPFL) and the Maximum Credible Fire Loss (MCFL). Based on DOE Order 5480.7A, estimates of the MPFL assume that one automatic suppression system will fail, and manual fire fighting efforts are also ignored. Estimates of the MCFL are based on the assumption that the fire protection features, including automatic

sprinkler systems, function as designed. For these cases where the MPFL is equal to the MCFL, there are either no automatic suppression systems present or the automatic suppression systems are not expected to significantly reduce the damage potential.

The 234-5Z Building. A detailed description of this building can be found in Section 5.2.1. Fire hazards are described as follows:

The fire hazard in building 234-5Z is limited since the building is largely constructed of non combustible materials and the combustible content is limited. The fuel loading in 234-5Z consists primarily of ordinary combustibles located in the office and lab spaces on the first and second floors. Typical combustibles consist of office furniture and supplies. The total quantity of combustibles and flammable liquids in use in the laboratory is less than 5 gallons. Several active and inactive gloveboxes contain plutonium bearing and combustible materials. A fire which breaches a glovebox could spread contamination.

Liquid propane is used infrequently for a variety of types of maintenance. The quantity of LPG is administratively restricted to 465 g (16.4 oz) per cylinder, with no more than 2 cylinders allowed in any single room and no more than 6 cylinders allowed in a building containing an inventory of transuranic material. An analysis given in Rogers 1996 indicated that a fire involving a release of propane is not credible (frequency of occurrence is less than 10^{-6}/yr). The propane fires are therefore not considered. Fire scenarios involving propane could be required if administrative controls on the propane were revised.

A maximum possible fire scenario was developed in the FHA for the 234-5Z office and laboratory areas. The worst case fuel load is 430 kg (946 lb) cellulose content and about 30 kg (66 lb.) of plastic or approximately 511 kg (1,124 lb.) wood equivalent. The results indicate that a fire involving this combustible loading is not expected to cause structural failures. Fire involvement is expected to be contained within the analytical lab areas. See Section 6.3.2 of the FHA (McKinnis 1998) for more details of this scenario.

A fire in the glovebox area is also possible. The FHA indicates that fuel load in this area is equivalent to 2790 kg of wood. A fire in the glovebox area is expected to be the worst case for fires within the contaminated areas (Zone 3). Structural failure is not expected. The area of an unmitigated fire is expected to be confined to the C line and A line glovebox area and to adjoining offices and laboratory spaces. The concrete walls are expected to limit fire spread as discussed in Section 6.3.2.5.3 of the FHA.

A leak or accidental discharge from the hydraulic elevator pump located in Room 321 could result in 568 liters of hydraulic oil being spilled on the floor. If ignited, the oil could present a significant fire hazard. The most severe fire results from a breach of the hydraulic elevator pump, piping or reservoir located in Room 321. The FHA analysis (Section 6.3.4) indicates this fire can lead to significant building structural damage. Structural failure of columns and roof assemblies can potentially collapse the wall separating the front side from the back side. Worst case assumptions can result in the collapse of the E-4 filter bank walls, exposing the contaminated

filter to the fire. However, activation of the sprinklers, while not extinguishing the liquid fire, will prevent the fire from spreading throughout the second floor. The cooling effect of the water is expected to prevent significant structural damage to the facility. The automatic sprinklers will therefore prevent contamination releases.

Pu bearing materials such as plutonium nitrate and Pu filtrate solutions are stored in Rooms 172 and 236. These materials are normally confined in vented containers. The solutions can generate hydrogen which can result in a potential fire/explosion hazard. If the ventilation system is operational, the steady state hydrogen concentration will be much less than the lower flammability limit. If the ventilation system is not operational, flammable concentrations could build up over long periods of time. However, even using very conservative assumptions, analyses in Section 6.3.5 of the FHA indicate that while a hydrogen detonation could result in metal shrapnel fragments that could cause local damage in the room, the resulting shock wave is not expected to cause failure of the room walls or ceilings.

The building is protected from exposure hazards as follows.

- The 242-Z, 243-Z, 234-5ZA, 236-Z, 2736-Z (vault corridor), and 2736-ZA Buildings are protected with automatic sprinklers and the transformers on the north side of the building are protected with an automatic deluge system.

- The separation distance, noncombustible construction, and limited number of openings in the 2727-Z and 2731-Z Buildings.

- The 291-Z Building is located belowgrade and has fire resistive construction.

Fire Protection Design Features. Noncombustible materials were used whenever possible in the construction of the 234-5Z Building. Where combustible materials were essential, every effort was made to minimize the quantity. The roof is a FM Fire Class I approved roof over a pre-existing metal deck. Corrugated 16-gauge aluminum over 1.5 in. rock wool insulation supported by structural steel comprise the exterior walls. The interior walls are metal partitions, plaster on metal lath, gypsum board on metal studding and, in the case of vaults and process areas, 8 in. thick, reinforced, poured concrete. The floors are generally poured concrete, which is finished with tile in some areas. Exceptions are the main supply plenum floor in the ventilation supply plenum and the duct-level deck, which are made of metal roof decking covered with waterproof seal. Gloveboxes are constructed of stainless steel and have panels made of polycarbonate (over half of the gloveboxes have these) or safety glass. Stairwells 1, 2, 6, 12, and 13 are currently isolated with fire barriers. Fire-associated risks and accident analyses are discussed in Chapter 9.0.

Feed items for the RMC Line process that originated in PRF potentially contain tributyl phosphate (TBP). One of the thermal decomposition products of TBP is butene. Butene, in the proper concentrations, is flammable. Combustion of large amounts of butene gas could cause a rupture in the glovebox. It is unlikely that sufficient gas could be generated to rupture

the glovebox. Four independent barriers are in place to prevent hazardous flammable levels.

- All sludge items originating from PRF (or if origin is uncertain) are sampled for organic content. Material with greater than 10 g organic per charge will not be fed into the furnaces.

- Any flammable gases are removed and diluted by continuous circulation through the furnace of about 2 to 3 ft^3/min of air.

- A cover gas of CO_2 is introduced into the furnace in the temperature regime where flammable gas could be generated. The CO_2 is fed into the furnace at a flow rate of 30 to 35 ft^3/h. Before each cycle, the operator will verify that one of the CO_2 cylinders is at least one-eighth full.

- The material is slowly heated at a ramp rate of 5 °C/min at 175 °C and held at this temperature for 1.5 h. This will assure that all of the TBP has decomposed before reaching the auto ignition temperature of butene, which is 324 °C.

The automatic sprinkler systems and deluge systems will limit damage from fires outside gloveboxes in the building. The laboratory or office areas will suffer limited damage.

In accordance with FHA recommendations, a berm has been placed around hydraulic elevator components. The elevator components are mounted on or near a wall, such that the berm comprises three sides of the containment, with the wall serving as the fourth. The berm, sized to contain two times the maximum volume potentially spilled, limits the spread of a hydraulic oil fire thereby limiting the number of structural members exposed to the fire. Because the hydraulic system is pressurized, spray shields have been installed around pressurized components to prevent oil from spraying outside the berm should a small leak develop in the system.

The hydraulic oil fire presents a special problem since the sprinklers can carry floating burning liquids from the source to other areas. The automatic sprinklers will however contain the fire to within the fan room, and there is no contamination spread from the liquid pool fire scenario.

Controlling a fire in a glovebox before significant damage occurs can be achieved by an automatic fire suppression system. Currently there are three different types of existing automatic fire suppression system used in the PFP gloveboxes:

1. Total flooding Halon systems
2. Dry chemical systems
3. Limited water bottle stations.

The type of fire suppression required depends on the process conducted in the glovebox, and whether the glovebox is active or not. The suppression systems are shown in Table 5-32. The suppression systems are discussed in section 7 of the FHA and glovebox fires are discussed in detail in Chapter 9 and the FHA. Based on the analyses performed at the time the Halon systems

were installed in the RMC line, it was determined that Halon concentrations at or near 75% could result in adverse conditions or reactions with burning metals. Thus there is no potential for an adverse reaction between Halon and burning metals because Halon concentration is less than 10%.

The 236-Z Building. The 236-Z Building houses the inactive PRF process equipment and services for MT, slag-and-crucible dissolution, filtrate concentration, feed preparation, plutonium solvent extraction, product concentration, and waste treatment processes. The PRF is currently used for storing in-process residues and solids that are awaiting processing to vault-storable form. A detailed description of this building can be found in Section 5.2.2.

Fire Exposure Hazards. The 236-Z Building is subject to exposure from fires in adjacent structures or objects (see Figure 5-1). The building is protected from exposure hazards as follows.

- The 234-5Z and 242-Z Buildings are provided with automatic sprinkler protection, so they do not present an exposure hazard.
- The 2727-Z Building is a noncombustible building and the west wall of the 236-Z Building is concrete. This arrangement mitigates any exposure hazards that could be presented by the 2727-Z Building.

The fuel loading in 236-Z is generally limited. The canyon area is currently inactive and contains almost no combustibles. The building is constructed of fire resistant construction. The major fire hazard is a fire in the gloveboxes. Because of the limited fuel load, fires in the gloveboxes are not expected to spread beyond the rooms containing the gloveboxes. The fires could however result in contamination being released from the glovebox. Glovebox fire consequences are addressed in the accident analysis section of this FSAR.

Fire Protection Design Features. This building has a construction classification of fire resistive. The roof is tar and gravel over a concrete slab on a metal deck. A product directories of UL-listed class A polyurethane foam has been applied over this assembly. The exterior walls and floors are poured concrete and concrete block. The interior walls consist of plaster on metal lath, poured concrete, and concrete block. Fire barriers isolate stairwells 1 and 2.

The 232-Z Building. This building was formerly used to house an incinerator and dry radioactive waste recovery process. The building is now in layaway status. There are no special hazards associated with this building. See Section 5.2.3 for a detailed description of this building. Analyses in the FHA indicate a fire will not result in structural damage to the building.

Fire Exposure Hazards. The 232-Z Building is subject to exposure from fires in adjacent structures or objects (see Figure 5-1). The building is protected from exposure hazards by the separation distance, noncombustible construction and limited number of openings in the 2736-ZC, 2736-ZB, and 2731-ZA Buildings.

The 241-Z Complex. A description of this complex is provided in Section 5.2.4. The 241-Z Complex is referred to as the Liquid Waste Treatment Facility. The 241-Z Building consists of five below-ground concrete enclosures with concrete cover blocks, each containing a 4,300-gal tank and covered at grade level by a corrugated metal building (a weather cover to permit all-weather operation of the vent and electrical systems; the concrete coverblocks of the below-grade tank enclosures serves as part of the flooring of the metal building). These tanks accumulate RLW from various PFP process and laboratory sources. The building is located approximately 330 ft south of the 234-5Z Building. The 241-ZA, 241-ZB (scheduled for removal) and 241-ZG Buildings are corrugated metal structures. The 241-Z-RB is a concrete waste water retention basin (and is scheduled for removal).

Special Hazards. There are no special hazards associated with these buildings other than the presence of RLW. There are no exposure hazards. The tank sumps are constructed of noncombustible materials and are belowgrade. The 241-Z Building houses the tanks containing RLW and has essentially no combustible contents. The roof, exterior walls, and interior walls are corrugated metal. The floor is poured concrete.

The 242-Z Building. This building is located between and attached to the 234-5Z and 236-Z Buildings. The building contains some unused process equipment. See Section 5.2.5 for a detailed description of this building.

Fire Exposure Hazards. The 242-Z Building is subject to exposure from fires in adjacent structures or objects (see Figure 5-1). The building is protected from exposure hazards because the 234-5Z, 236-Z, and 242-ZA (TC-66) Buildings are protected throughout by automatic sprinklers.

The 291-Z Building. The exhaust fan house, also called the compressor and fan house, is a reinforced-concrete structure with an interior finish of noncombustible materials. It is located approximately 25 ft south of the 234-5Z Building. The 291-Z-1 stack is an auxiliary structure to the 291-Z Building. The 291-Z Building houses ventilation exhaust fans for the 234-5Z, 242-Z, 232-Z, and 236-Z Buildings. There are seven electrically-driven exhaust fans. In addition, there are two deactivated steam-driven fans that were formerly used for emergency exhaust (the function originally provided by the steam-driven exhaust fans has been replaced by providing backup power from diesel-generators to two of the seven electrically-driven exhaust fans). The building also houses vacuum pumps, process and instrument air pumps, evaporative coolers, and two oil-cooled, 1,000-kVA transformers. See Section 5.2.6 for a detailed description of this building.

Special Hazards. Two oil-cooled, high-voltage transformers in the building present a special hazard.

Fire Exposure Hazards. The 291-Z Building is subject to exposure from fires in adjacent structures or objects (see Figure 5-1). There are no unacceptable fire exposure hazards to the 291-Z Building because of its location belowgrade, its fire resistive construction, and the presence of automatic sprinklers in the 234-5Z, 243-Z, and 2736-ZB Buildings.

The 291-Z Building has a construction classification of fire resistive and has a polyurethane coating over a built-up tar and felt roof on a concrete

deck. The deck is supported by concrete beams and columns. The ceiling, walls, and floor are reinforced poured concrete.

The most notable fuel load in Building 291-Z is located in the electrical room where there are two oil filled transformers. Each of the transformers contains 1,890 L (500 gallons) of oil. A worst case evaluation was made in the FHA assuming the entire content of one of the transformers spills on the floor and ignites. Structural failure of the ceiling is possible for large spill diameters. A deluge system is available to mitigate fires in the transformer but would not entirely prevent damage from an oil spill fire. The damage from the oil spill fire would however be limited to the transformer room (Room 500) and possibly some thermal damage to equipment in Room 501.

The 2736-Z Building. The 2736-Z Building consists of four vaults used for the storage of plutonium material. A corridor running the full length of the building divides the vaults and connects to the 2736-ZB Building. See Section 5.2.8.1 for a detailed description of this building.

Fire Exposure Hazards. The 2736-Z Building is subject to exposure from fires in adjacent structures or objects (see Figure 5-1). There are no unacceptable exposure hazards to the 2736-Z Building since the 234-5Z, 2736-ZA, and 2736-ZB Buildings are protected with automatic sprinklers, and the 2731-Z Building is constructed of noncombustible materials. In addition, the east wall of the 2736-Z Building serves as a fire wall.

The 2736-Z Building contains four vaults designated 1, 2, 3, and 4. Between vaults 1 and 2, as well as between vaults 3 and 4, are fire walls. The building has a construction classification of fire resistive. The building has a tar and gravel buildup roof on a concrete deck. The ceiling, floors, interior and exterior walls are poured concrete. The FHA concluded there are no credible fire scenarios which present a hazard to the structure or to the plutonium material stored in the vaults.

The 2736-ZB Building. The primary function of the building is shipping and receiving waste containers, plutonium oxide powder, and plutonium metal. The product is received from the 234-5Z Building and offsite and is transferred to the 2736-Z Building. It then goes through the NDA laboratory where it is counted for various values (isotopic and heat content). The product is either stored in the 2736-Z Building or shipped offsite.

The 2736-ZB Building has an NDA laboratory; a staging, shipping, sorting and receiving room; a changeroom; a mechanical equipment room; offices; a repackaging room; and a lunchroom. The NDA laboratory contains all the NDA and computer equipment. The equipment includes a calorimeter, a segmented gamma scan assay system, a gamma energy analysis system, a neutron-well coincidence counter, and associated minicomputers. Repackaging activities are carried out in a glovebox in room 636. See Section 5.2.8.3 for a detailed description of this building.

Fire Exposure Hazards. The 2736-ZB Building is subject to exposure from fires in adjacent structures or objects (see Figure 5-1). The building is protected from exposure hazards as follows.

- The 2736-ZA and 2721-Z Buildings are protected throughout with automatic sprinklers. The 291-Z Building has fire-resistive construction and is basically located belowgrade, and the joining wall between the 2736-Z and 2736-ZB Buildings is of fire-resistive construction. The fire alarm service in 232-Z remains in operation to alert the necessary personnel although the water to the automatic sprinklers has temporarily been capped.

- The east and south walls of the 2736-ZB Building are of fire-resistive construction, which mitigates the exposure hazards of the buildings on these sides.

The 2736-ZB Building has a construction classification of fire resistive. The roof consists of built-up tar on a reinforced concrete deck, supported by concrete columns. The exterior walls are reinforced poured concrete and the interior walls are poured concrete and gypsum wallboard. The gypsum wallboard is sealed, taped, painted, and supported by metal studs. The ceiling varies throughout the building. The office area has a suspended lay-in acoustical tile assembly. The locker rooms, laboratories, staging, shipping, sorting, and receiving areas have a suspended gypsum board assembly. The remaining areas are open to the underside of the roof. The floor is poured concrete and is finished with tile and paint. There is an extension on the south side of the building that consists of a prefabricated metal structure (2736-ZC).

The heaviest fuel loading in Building 2736-ZB is in the office space and the NDA lab. The worst case fire scenario is considered to be bounded by the fire scenario for the office/lab spaces in Building 234-5Z, which did not result in structural failures. Fire spread into the storage vaults is not anticipated because of the solid concrete walls separating these areas. The NDA lab contains plutonium bearing materials and therefore a fire in the lab can potentially contaminate the building. Contamination to the outside is not expected since the fire will be contained within the lab and office spaces, and there are no direct openings to the outside.

Auxiliary Facilities. In most cases, fire scenarios in these facilities result in minor damage and no contamination spread. Exposure hazards from these structures are discussed under the individual main process buildings.

5.4.11.1.2 Seismic Requirements. Details and results of seismically induced fire scenarios are discussed in Chapter 9.0

5.4.11.1.3 Codes and Standards. Codes and standards used in the design of the fire protection system for the PFP are considered in Chapter 4.0.

5.4.11.1.4 Fire Hazards During Construction. Construction consists of upgrades to the facilities and maintenance activities. The upgrade and maintenance activities pose a hazard by the introduction of excess quantities of combustibles (solids and liquids) not normally found in the operating facilities on the plant site. Also, disturbance of electrical systems, including temporary hookups, can serve as fire initiators.

5.4.11.2 System Description. The fire protection systems for the PFP consist of many individual communication and operating systems that inform or provide some action in regard to fires and fire fighting. The system also includes

compartmentalization and placement of fire barriers to protect against exposure hazard and provide for fire isolation to limit damage and allow personnel egress. The systems include the following:

- Piping systems that contain and transport the extinguishing agents
- Fire alarm systems, some of which notify the HFD when initiated
- Heat or products of combustion detection systems that initiate an alarm and/or initiate a suppression system
- Automatic wet-pipe, dry-pipe, pre-action, and deluge sprinkler systems
- Halon suppression systems (RMC Line gloveboxes, 2704-Z vault and 2701-ZA Buildings)
- Dry-chemical suppression systems
- Portable fire extinguishers and MgO sand
- Limited water suppression systems for hoods and gloveboxes
- Supervised valves in the water supply system
- Fire barriers to isolate parts of buildings, thus slowing progress of fire, reducing damage, and providing personnel safety in the means of egress.

5.4.11.2.1 Water Supply. The water supply and distribution system is described in Section 5.4.7. Water for both fire protection and domestic requirements is provided from connections to the water supply and distribution system 8-in. sanitary water service loop. The PFP facilities are serviced by 8 hydrants. Water flow tests for hydrant 10Z indicated a flow of 1170 gpm. This flow meets the requirements of DOE Order 6430.1A which requires a 1000 gpm. Tests to determine if the sprinkler water supply was adequate indicated a total demand of 718 gpm at 235-RZ second floor, primary filter and duct area, and a total demand of 854 gpm for 236-Z, fourth floor, Rooms 41 to 44. The water supply for fire protection service for the PFP complex satisfies the requirements contained in NFPA 13 in terms of required flow for the sprinkler systems.

Supply lines to the sanitary water service loop are fitted with check valves upstream of their service loop tie-ins. The check valves help maintain service loop water pressure and prevent loop drainage if a supply line breaks. Isolation valves in the supply lines and service loop ensure that a line break will not cause a lengthy loss of the PFP water supply.

The fire hydrants and the 8-in. sanitary water service loop are shown in Figure 5-59. The service loop is also provided with isolation valves and post indicator valves. All the post indicator valves are equipped with tamper switches that alarm at the HFD and the 234-5Z Building.

5.4.11.2.2 Normal Power Supply. The power distribution system is described in Section 5.4.2. The fire protection system is normally powered by mains from the 251-W substation feeds. The 13.8-kV supply is stepped down to 480 V by a transformer in the 234-5Z Building and fed to switchgear bus 300. A normally closed breaker then feeds to the emergency distribution bus, bus 400. This breaker opens on loss of normal power supply.

5.4.11.2.3 Backup Power. Backup power distribution to the fire protection systems is normally provided by batteries. Some fire control panels also get power from panels supplied from the backup power system supplied by the diesel-generators.

5.4.11.2.4 Fire Alarm System. The 234-5Z Building is equipped with a Flex 500A fire alarm control panel located in corridor 14A (see Figure 5-6, sheet 1 for location of the corridor). This panel also serves fire zones in the 236-Z, 242-Z, 2727-Z, 2729-Z, 2734-ZA, 242-ZA (TC-66), 234-ZC, 234-5ZA, and 2734-ZC Buildings. Each fire zone is transmitted to the HFD by radio fire alarm reporters (numbers 2780 and 2781). The fire-alarm control panels (FACPs) and remote fire alarm relays (RFARs) associated with other PFP buildings are shown in Table 5-27. The fire alarm and protection systems located in PFP auxiliary facilities are shown in Table 5-28.

Local and remote alarms may be initiated by heat detectors, smoke detectors, activation of any automatic fire suppression/extinguishing, and manual pull boxes. In addition, electrical and physical supervisory systems are provided to monitor electrical performance and critical component position. Electrical supervision consists of using alarm circuits to provide trouble signals when a circuit problem occurs. Physical supervision uses switches (valve tamper, low pressure, etc.). The electrical system will cause annunciation locally at the supervisory control panel located at 14-A and at the HFD for off-normal events.

5.4.11.2.5 Sprinkler Systems. Several types of sprinkler systems are employed in PFP building locations. They include wet-pipe, dry-pipe, preaction, limited water for hoods and gloveboxes, and deluge systems. Most of the sprinkler systems are pipe schedule designed rather than hydraulically calculated, which provides more conservatism. Foam is not used in PFP sprinkler systems. Sprinkler coverage for PFP buildings is shown in Figure 5-63. Fire protection features for all other buildings are described in Section 5.4.11.3.

Hardware included in the sprinkler systems meets NFPA codes and standards. Components are UL listed or FM approved for their intended use. The sprinkler systems were installed to meet design basis event analysis. The sanitary water supply to the fire system, however, is not seismically qualified. Several areas have glycol antifreeze loop systems.

5.4.11.2.6 Special Protection Systems. Systems or components not described above, but common to all PFP facilities, are discussed in this section. Some buildings are equipped with portable fire extinguishers. These extinguishers are approved for the type of application where they are located, inspected regularly, and meet all other NFPA 10 requirements (NFPA 1979b).

A Halon 1301 system provides fire protection inside RMC Line gloveboxes. The system is actuated in individual gloveboxes by heat detectors and is completely separate and independent of other fire suppression systems. Actuation does not cause pressurization, as demonstrated by the acceptance test procedure, and provides a 5% concentration for 10 min. The Halon system is interlocked with the RMC emergency exhaust fire damper.

Many other gloveboxes and hoods in the 234-5Z Building that are not protected by Halon 1301 are equipped with limited water bottle stations or heat detectors. Banks of water storage containers are located on the duct level of the building and provide a nominal 5-gal water supply to a glovebox or hood. A N_2 system provides pressure to each limited water bottle station to compensate for air leaks. Water flow will initiate fire alarm annunciation. Special inerting atmospheres are not used in place of automatic fire suppression systems at PFP.

A dry chemical system is installed in glovebox HA-21I in room 235B of the 234-5Z Building and is maintained in accordance with NFPA requirements, though the manual pull station and control panel for the dry chemical system are currently out of service. The MgO sand is also available in gloveboxes to aid in extinguishing plutonium metal fires.

Fire hose stations are located throughout the 234-5Z Building, served from sprinkler riser 1 (located in corridor 14B; see Figure 5-6, sheet 1 for location of corridor). As part of a site-wide policy change, the fire hoses have been removed from these locations, though the water supply still remains. The hose station valves and piping are still maintained and are available for manual fire suppression by HFD fire fighters.

5.4.11.3 Individual Facility Descriptions. Fire protection system features and other information unique to individual buildings located in the PFP facility are discussed in this section. In addition to the material provided in this chapter, information on building construction and process function is located in Section 5.2 of this document.

Discussions pertaining to DOE Order 5480.7 (DOE 1987) compliance, including loss amounts, are discussed in an internal memorandum from Taylor (1989). Specific DOE Order 6430.1A (DOE 1989) compliance items are addressed in WHC (1990).

5.4.11.3.1 The 234-5Z Building. In addition to the previous discussions and the discussion in this section, fire protection features located in the PFP AL, standards laboratory, and PPSL are detailed in Section 5.4.14.

The 234-5Z Building has four levels: one level belowgrade, one level on grade, and two levels above grade. The building is equipped with floor drains, but most of these are inoperable. Liquid run-off from the upper floors would flow to the levels below, primarily through the stairwells. The exception to this is the duct level. Liquid run-off from this level would penetrate the metal floor and enter the concealed space above the first floor ceiling. This would cause additional damage, especially in the contaminated areas of the building.

The building is equipped with wet-pipe, dry-pipe, and deluge sprinkler systems. The areas covered by sprinklers is shown in Figure 5-63.

The 234-5Z Building is in compliance with the potential-property-loss requirements of DOE (1987). The MPFL has been determined to be $27,000,000. The MCFL is $4,300,000. The maximum-possible property loss has been determined to exceed $25M (Taylor 1989), which is not in full compliance with DOE (1987) requirements. The programmatic loss of 3 months from the potential-property-loss fire is in compliance with DOE (1987). Because of the magnitude of the dollar loss in the maximum possible property loss fire, it is questionable if the plant would be refurbished. Project B-631, "PFP Fire Safety and Loss Limitation," corrected these noncompliance issues so that the building would meet DOE Order 5480.7 (DOE 1987). The following plant upgrades done under Project B-631 consisted of the following:

- Installing automatic sprinkler system with flow alarms
- Modifying or constructing new personnel emergency egress routes
- Upgrading the plant fire alarm system
- Providing fire area separations by upgrading wall structures and duct protection.

5.4.11.3.2 The 236-Z Building. The building is not equipped with any special liquid run-off control features. The run-off from the upper floor levels would be to the levels below, and would run down the stairs and through the floor openings. Therefore, on/off type heads were installed to reduce water flow.

Both interior stairwells are provided with smoke-detector-operated fire dampers. The east stairwell is also equipped with fusible-link-activated fire dampers in the ventilation openings that penetrate the stairwell from the outside. The building is in compliance with "improved risk" criteria established in DOE (1987).

The MPFL and MCFL have both been determined to be approximately $1,800,000. These losses are in compliance with DOE (1987). The 94-1 stabilization project would be shut down by a first floor fire affecting the thermal stabilization line. A delay of approximately 6 months is estimated.

5.4.11.3.3 The 232-Z Building. This building is awaiting decontamination and decommissioning. The maximum loss for this building is less than $100,000. Because of the low loss from the maximum fire, this building complies with all loss-limitation provisions of DOE (1987). The building also complies with all life-safety requirements and improved risk criteria.

5.4.11.3.4 The 241-Z Complex. A detailed description of the 241-Z Complex is given in Section 5.2.4. The 241-Z Building consists of five separate concrete sump cells, each containing one stainless steel waste tank. The cells and cell covers are built of reinforced concrete, with the covers located at approximately grade level. A pre-engineered corrugated metal

building houses support equipment and provides weather protection. The remaining buildings are made of corrugated metal and/or concrete.

The 241-Z Building is not normally occupied by personnel. The very low consequence of a fire in the 241-Z Building ($250,000 loss for either the MPFL or MCFL) or the rest of the complex does not warrant a special fire analysis. Based on the above considerations, the building complies to applicable portions of DOE (1987) for loss limitation, life safety, and improved risk.

5.4.11.3.5 The 242-Z Building. The latest fire protection survey (McKinnis 1998) indicates an MPFC of $5,300,000 and an MCFL of $16,000.

5.4.11.3.6 The 291-Z Building. The building has one level belowgrade. Liquid run-off from the probable fire scenario is expected to remain in the room because this area is provided with curbs. These curbs can retain up to 2,220 gal of fire water.

The MPFL and MCFL are the same,with a loss of approximately $530,000. The amounts are in compliance with DOE (1989). The downtime is about 2 weeks.

5.4.11.3.7 The 2736-Z Building. The building is constructed entirely of concrete and contains four vaults designated 1, 2, 3, and 4. Vaults 1 and 2, as well as vaults 3 and 4, are separated by a fire wall. A corridor divides the building in half. A general fire survey has determined that the fire protection systems are adequate to protect the building.

Vault 2 is provided with scuppers 0.5 in. above the floor. The scuppers discharge to the corridor, which has a sealed drain. The drain is sealed to prevent the discard of contaminated water. If the water is determined to be within specification requirements for waste water discharge, the seal can be removed.

The MPFL and MCFL are each associated with the security system wire raceway. The loss for either the MPFL or the MCFL would be $800,000, which is in compliance with DOE (1987).

The potential programmatic loss for both scenarios would be basically the same. There would be an inconvenience to the building security operations; however, it would not have a significant impact on the function of the building.

5.4.11.3.8 The 2736-ZB Building. The building has one level on grade. Liquid run-off would be to adjacent rooms and to the exterior. There are no special control features in the building. A general fire survey has determined that the fire protection systems are adequate to protect the building.

The MPFL is approximately $2,227,000 and the MCFL is equal to the MPFL. These potential programmatic losses are in compliance with DOE (1987). The building also complies with improved risk and life-safety criteria established by DOE (1987). There would be no operational loss since other laboratory facilities could be used to maintain programmatic schedules.

5.4.11.3.9 The 243-Z Building. This structure consists of a total of five rooms. Room 401 is a vestibule; room 402 is a changing room; room 403 is a drum washing room; room 404 is a drum turning room; and room 405 is the process room for waste water filtration. See Section 5.2.9 for more details of the building and Chapter 7.0 for details of the building processes.

The 243-Z Building has adequate exposure protection from fire in other buildings because of the fire protection measures in these other buildings and the distance separating the 243-Z Building from adjacent buildings. The 243-Z Building does not contain large quantities of combustible materials, is built of noncombustible materials (e.g., concrete and corrugated metal) and the process material of the facility is noncombustible (e.g., waste water). The 243-Z Building is covered by a wet-pipe automatic sprinkler system. Upon activation of the automatic sprinkler system, the fire alarms will be indicated at the local fire alarm control panel and transmitted to the HFD by the radio fire alarm reporter. The MPFL is $500,000 and the MCFL is <$500,000. The building complies with DOE 1987.

5.4.11.3.10 Auxiliary Facilities. The compliance of these facilities is shown in Table 5-29.

5.4.11.4 Inspection and Testing Requirements. The plant fire protection systems are inspected and tested in accordance with NFPA and DOE Order 5480 series criteria and HNF-PRO-351, *Fire Protection System Testing/Inspection and Maintenance*. A routine preventive maintenance program for fire protection systems meets the requirements identified in the documents named above. Procedures are in place to provide assurance that fire system inspection and testing requirements are met.

Loss-prevention programs are established at PFP to assure proper operation and maintenance of fire system equipment. These programs include routine procedural visual inspections, preventive maintenance, and other activities as specified in HNF-PRO-351, *Fire Protection System Testing/Inspection and Maintenance*, HNF-PRO-352, *Fire Protection System Discrepancies*, HNF-PRO-345, *Fire Protection Corrective Actions* and HNF-PRO-371, *Hanford Fire Department*.

5.4.11.5 Personnel Qualification and Training. The HFD maintains a training program for fire fighting, fire testing, and fire inspection. These training programs have been designed to meet NFPA and DOE Order 5480 series criteria.

A separate work force provides maintenance activities associated with fire protection systems. This work force is provided on-the-job training, which is augmented by vendor-supplied training and instruction. The vendor training is also available to anyone involved with the fire protection systems.

5.4.12 Maintenance Systems

Maintenance for the PFP is provided by its own maintenance group reporting to the PFP Plant Manager. Certain craft specialties such as vent and balance are obtained by work order, and work to PFP-approved work orders

and instructions. Training of the staff is outlined in Chapter 10.0. All maintenance is performed under ALARA guidance as outlined in Chapter 8.0.

5.4.12.1 Major Components and Operating Characteristics. During the initial design and construction phases of the PFP, the nationally recognized allowable radiation exposure was higher than today. The guidance came from (NBS 1938) (NBS 1949) and (NBS 1953). While the allowable exposure was higher, there existed a caveat that all radiation exposure be kept to the minimum. In 1954, as low as possible, the predecessor of ALARA, became the design guidance (see Chapter 8.0).

Routine maintenance has been conducted since the PFP went into operation in 1950. Since that time, there has been a continuous effort to ensure that the exposure to operators and maintenance personnel alike be maintained ALARA. While it is not possible to characterize all of the design features that have been included in the plant over the years to accomplish this, the following are examples of some of them.

- A major feature of the plant that minimizes exposure during maintenance is the small size and the compartmentalization of the process lines. This feature localizes the source term to that in the immediate maintenance area. This is important when contact maintenance is required.

- Remote maintenance of process equipment in the 236-Z Building. The facility was designed for conducting the majority of the maintenance work in a designated maintenance cell or glovebox.

- Service connectors to gloveboxes are protected with nontestable HEPA filters or sealed to prevent contamination of the service lines.

- The RMC Line high-use gloveboxes were retrofitted with gloveports that provide a higher degree of containment during glove change out.

- The gloveports on new gloveboxes are located to permit ease of maintenance of process equipment.

- Coving and the use of special interior surface finishes for gloveboxes minimizes the buildup of contamination and makes decontamination easier.

- A vacuum cleaning system is installed in some of the RMC Line gloveboxes and was used for removal of residual powders to reduce exposure from surface contamination. The vacuum cleaning system is partially dismantled.

- Movable radiation shields, known as ALARA panels, are available for installation to reduce the exposure to operators and maintenance personnel.

5.4.12.2 Safety Considerations and Controls. Required maintenance activities routinely involve work in contaminated and/or radiation areas. Controls associated with the ALARA program are described in Chapter 8.0, and cover all operations including maintenance.

Examples of measures in place to ensure work is performed with the lowest reasonable radiation dose to the workers includes the following.

- All work is formally planned. A work plan is required for any work. A job safety analysis/hazards analysis of the work planned indicates the potential problems. Based on the analysis, additional precautions are identified and added to the work plan. The work plan is coordinated between maintenance, radiation protection, quality assurance, and operations to ensure complete support of the plan. When the job safety analysis dictates, an additional review is performed by Nuclear Facility Safety. An ALARA management worksheet is needed for work plans above 2K dpm and nonroutine work.

- Extensive use is made of greenhouses (plastic containment tents) to provide containment during maintenance. These operations are tightly controlled and discussed in Chapter 8.0, Section 8.5.2.

- When required in the work plan, additional radiation shields, known as ALARA panels, are installed (Chapter 8.0, Section 8.3.2).

- The source term in processing equipment and gloveboxes is removed to the extent possible, thus minimizing the exposure to operating and maintenance personnel.

- Quality assurance (QA) is provided to ensure that acceptable materials are used and that the replacement or repairs function properly.

- Preventive maintenance is scheduled into the operations plan to minimize production downtime. Scheduled production shutdowns are used for equipment maintenance, repair, and replacements.

In all cases, emphasis is placed on personnel safety and ALARA. The PFP management integrates all phases of operations, maintenance, and engineering to accomplish these goals consistent with personnel safety, ALARA, and environmental protection.

5.4.13 Cold Chemical Systems

Cold (nonradioactive) chemical systems consist of storage, transfer, and makeup of chemical solutions that were used in plutonium processing and are currently used in plutonium material stabilization and laboratory functions. Small quantities of chemicals stored and used in the laboratories present no significant hazard other than that normally associated with industrial laboratories.

Chemical storage for the PFP is located in both external and internal areas of the facility. Accidental release of chemicals from a storage container could endanger the integrity of the building or its occupants. External storage is limited to the 2734 series of gas storage buildings (discussed in Section 5.4.4), DR876, E Dock, G Dock, and W Dock.

Inside storage in the 234-5Z Building is limited to rooms 392 and 338 for dry and wet chemical storage, respectively, and the chemical makeup areas (rooms 336 and 337). Small quantities of chemicals normally associated with industrial uses (such as industrial laboratories) are typically stored in the following areas: rooms 141, 154, 302, and 321, and corridor 4, 4B, and 4D. Additional chemical storage areas in the laboratories are identified by room in Section 5.4.14.

Chemical makeup areas are located in rooms 336 and 337 of the 234-5Z Building (Figures 5-6, sheet 3 and 5-20), and room 40 of the 236-Z Building (Figures 5-6, sheet 4 and 5-64). Chemical makeup involves mixing chemicals to provide solutions or organic mixtures for various processes supporting plutonium operations at the PFP.

5.4.13.1 Chemical Prep Room 336/337 (234-5Z Building). Facilities in rooms 336 and 337 (Figure 5-20) were used to prepare and supply chemicals to the RMC Line and may be currently used to prepare solutions for acid dissolution processes. Tanks are arranged along the south wall of the rooms in a low-walled sump. Room 336 contains tanks H, I, F1, F-2, C, D, D-1, D-2, G-1, G-2, E-1, E-3, and HF1-1. Room 337 contains tanks KOH-1 (TK-1), KOH-2 (TK-2), D-15, J-11, S2-X, HN-8, D-34, D-16, HN-A, and K-3. Both rooms are hooded and ventilated through roof exhausts. The room is equipped with safety showers, floor drains, and fire sprinklers. Walls and ceiling are constructed of 0.75 in. thick plaster on metal lath. Motor controls for outside chemical pumps are located in room 337. An overview of the chemical makeup activities in rooms 336 and 337 is provided as follows.

- Strong HNO_3 solution--Concentrated HNO_3 (57 wt%) was received and stored in a 7,000-gal tank outside and east of the 234-5Z Building. The inventory of HNO_3 in the PFP was reduced by removing excess HNO_3 from the tank during FY 1996 and transferring 350 L of acid to the chemical prep room 40. Any future need of concentrated HNO_3 would be met by bringing 55-gal drums into the PFP and transferring the solution to the 7,000-gal tank for distribution. When needed, 57 wt% HNO_3 is pumped from this tank through a pipeline to tank C, located in room 336, where the concentration is verified by sampling and analysis or by measuring the density with a hydrometer. Acid from tank C is pump transferred to tanks G-1 and G-2 for production of dilute HNO_3 solution.

- Dilute HNO_3 Solution--Dilute HNO_3 (1.8-2.2 M) is made up in tanks G-1 and G-2, which are located in room 336, by first adding the specified volume of distilled water to the tank. Concentrated HNO_3 (57 wt%) is then added by pump transfer from storage tank C. The solution is agitated, sampled, and analyzed for HNO_3 molarity. Dilute HNO_3 is piped by gravity-drain to gloveboxes HC-227S to be used for adjustment of process solution acidity and as a flush solution during the cleanup phase of the tanks and floors of the PRF. Either tank G-1 or G-2 is valved in to the process while the second tank is being refilled or in standby.

5.4.13.1.1 Potassium Hydroxide Solution. The potassium hydroxide (KOH) solution is purchased as 45 wt% solution, in 55-gal drums. The major drum inventory is stored outside of the 234-5Z Building, with several drums

stored in room 336. The KOH is pumped from the drums, by either a small electrically or air operated pump inserted into the drum bung, to one or two 900-gal stainless steel tanks (KOH-1 and KOH-2; also identified as K-1 and K-2, respectively) located in room 337. The 45 wt% KOH solution was gravity-transferred through piping to the KOH scrubber in glovebox HA-46. One of the tanks (KOH-1 or KOH-2) normally was used for supplying KOH while the second tank contained water used for flushing the line from the tank to the KOH scrubber after each transfer. The tank containing water also received water flushes of the pump after the desired number of drums had been emptied to the makeup tank.

5.4.13.1.2 Chemical Hazards Mitigation. The rooms are equipped with eyewash stations and safety showers for water flushing should operators come in skin or eye contact with chemicals. Two operators are required for chemical makeup so that one can assist or call for aid should an accident occur to the other.

Activities performed in chemical makeup rooms 336 and 337 have personal protective equipment designated by the applicable work procedure, or on a job-by-job basis by the work plan. The procedures and work plans are reviewed by industrial safety specialists to ensure adequate protection of workers and compliance with applicable regulations and controls. Required protective equipment is dependent on the inherent hazards of the chemicals handled and might include face shields, goggles, acid suits, rubber gloves and boots, and/or supplied air respirators.

Each group of tanks is situated in a concrete sump to catch spills or liquid from ruptured tanks. Elevated floor drains in the sump allow an accumulation of liquid, with excess liquid being drained to the 2735-Z Catch Tank. The 2735-Z Catch Tank rests in a sump to collect its overflow. An NO_x monitor is positioned over room 336 tanks C, G-1, and G-2

5.4.13.2 Chemical Prep Room 40 (236-Z Building). This room contains the tanks, scales, and associated equipment used to prepare the organic solvent and other chemicals that were used in solvent extraction and other processing activities in the 236-Z Building (Figures 5-6, sheet 4 and 5-64). All makeup vessels are closed and vented to the E-3 ventilation system. All vessels are located within a diked area for spill control that empties to a catch tank for collection. The diked area accommodates the contents of the largest vessel. All PRF processes are currently inactive remaining in the PRF tanks and process lines are managed and dispositioned in accordance with HNF-2977, *Plutonium Reclamation Facility (PRF, Building 236-Z) Layup Plan* (BWHC 1998). Electrical power to instrumentation in the room has been isolated.

The following is a list of the tanks and their former uses:

- Tank A-103 formerly contained NaOH Solution
- Tank A-105 formerly contained HNO_3 Solution
- Tank A-106 formerly contained Aluminum Nitrate Nonahydrate Solution

- Tank A-116 formerly contained Antifoam solution
- Tank A-117 formerly contained B-acid and C-acid.

5.4.13.3 Indoors Chemical Storage. The main chemical storage area within the processing buildings is room 338 (Figure 5-20). Chemical makeup rooms 336 and 337 store drums of KOH solution and DOW antifoam 1410. Reducing and oxidizing chemicals are stored separate from each other.

5.4.13.3.1 Room 338--Chemical Storage. The following chemicals are stored in room 338:

- Oxalic acid--$C_2O_4H_2$ Activated carbon
- Sodium carbonate--Na_2CO_3.

5.4.13.3.2 Rooms 334 and 335--Former Calcium Storage. Each room is 8 ft by 9 ft with an 8 ft 9 in. high ceiling. The interior walls of rooms 334 and 335 are constructed of 0.75 in. thick vermiculite plaster on metal lath on metal studs. The walls of adjoining rooms are ordinary plaster installed similarly. These walls are not load-bearing and have a fire resistance rating of 1 h. The floor of rooms 334 and 335 is constructed of 4 in. thick reinforced concrete with a fire-resistance rating of more than 1.75 h. Automatic sprinklers are installed in the concealed space above the ceilings of rooms 334 and 335 to protect the roof from ignition. The ceilings are constructed of vermiculite plaster on metal lath on suspended metal studs. A nonflammable waterproofing material was applied to the ceilings of rooms 334 and 335 when the sprinkler system in the attic was installed. The bays enclosed by the waterproofed ceilings above rooms 334 and 335 are equipped with drains that will limit the water level in the bay to less than 2 in. These drains discharge to the corridor immediately south of rooms 334 and 335, which are not themselves equipped with sprinklers. Fire detection equipment consists of two fixed-temperature heat detectors in room 335, and one combination rate-of-rise/fixed-temperature detector in room 334. Air supply vents near the fire-rated doors and gravity vents to the roof are equipped with fire dampers. The room is equipped with metal shelves with front rails that are attached to the walls.

5.4.13.3.3 Room 165. Room 165 is 9 ft 6 in. by 12 ft 3 in. and serves as an anteroom to vault room 166. The north, east, and west walls and ceiling are made of 0.75 in. thick plaster on metal lath with lighting fixtures recessed in the ceiling. The south wall is an 8-in. concrete wall. The room is equipped with wet-pipe sprinklers and rate-of-rise heat detector. A ceiling diffuser delivers the S-3 room air, which can exit the room to some extent through a 0.38-in. space under the 40-in.-wide door. The room is used as a local supply room. Piping connected to the argon supply system is available in the room and was once used to provide an argon atmosphere inside a stainless steel vessel that held a can of calcium. Though calcium has been removed from the room, the argon supply has not been capped and is available to provide 15 lb/in^2 (gauge) pressure of argon. The argon piping is equipped with a pressure regulator set at 15 lb/in^2 and a pressure reducing valve set at 18 lb/in^2.

5.4.13.3.4 Chemical Hazards Mitigation. Activities performed in rooms 336, 337, and 338 have personal protective equipment designated by the

applicable work procedure, or on a job-by-job basis by the work plan. The procedures and work plans are reviewed by industrial safety specialists to ensure adequate protection of workers and compliance with applicable regulations and controls. Required protective equipment is dependent on the inherent hazards from the chemicals handled and might include face shields, goggles, acid suits, rubber gloves and boots, and/or supplied air respirators.

5.4.13.3.5 Room 165--Argon. Argon was supplied to the room and is not currently used.

Argon Handling. Argon piped to room 165 was used for purging the atmosphere in calcium storage cans. Since a hazardous condition could develop in the form of an oxygen depleted atmosphere, the following precautions are taken.

1. The room is ventilated and heavier than air gases (argon) are swept out under the door by air pressure from the S-3 air supply.

2. Argon flow is regulated to a maximum of 200 ft^3/h.

3. It is normally unoccupied and entry is administratively controlled.

5.4.13.4 Outside Chemical Storage. The following chemicals are stored in outside storage facilities at the PFP (see Figure 5-54).

5.4.13.4.1 East End of the 234-5Z Building. The 2735-Z Facility consists of the following:

- The ANN bulk storage tank (7,000-gal ANN)
- The HNO_3 bulk storage tank (7,000-gal 57% HNO_3)
- The 2735-Z ANN/HNO_3 containment basin.

Truck shipments were transferred directly to the ANN and HNO_3 storage tanks. The ANN was transferred to PRF chemical makeup tank A-106. The HNO_3 was transferred to PRF chemical makeup tank A-105 and the RMC Line chemical makeup tank.

5.4.13.4.2 Loading Docks East of the 236-Z Building (Drum Storage). Various drums of chemicals are stored on the loading dock east of the 236-Z Building as listed below.

- Propylene glycol
- Ferrous sulfamate
- Caustic potash (45% solution KOH)
- Tributyl phosphate
- Anhydrous Na_2CO_3
- Waste drums of crushed fluorescent light tubes and polychlorinated biphenols (PCB) ballasts.

5.4.13.4.3 Gas Bottle Storage, 2734-Z Building. The 2734-Z Building is empty and scheduled for replacement.

5.4.13.5 Chemical Hazards of the PFP Chemicals. A list of the principal chemicals used in PFP processing is shown in Table 5-30 and for other large

quantities of chemicals used in the PFP in Table 5-31. These tables provide the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) and NFPA health, fire, reactivity, and persistence hazards rating for each chemical. This information was obtained from material safety data sheets for the chemicals. Sheets for all chemicals used at the Hanford Site are available from the Records Management Information System (RMIS) and from Waste Management Federal Services of Hanford Inc. (WMH). These data sheets also provide fire and explosion data and toxicity, health effects and first aid information, as well as applicable transportation regulations. The Chemical Management Programs are discussed in Section 10.4.5.

Most of the other materials at PFP (not listed in Tables 5-30 and 5-31) are used in small quantities in the laboratories. The material safety data sheets are also available for these materials from the RMIS or WMH.

5.4.13.6 Chemical Spill Management. A chemical spill management program is in place at the PFP. A trained response team is available at the PFP, as are approved procedures for handling leaks or spills of hazardous materials. In any large spill, (e.g., tank failure or drum puncture) this team would be supported by the hazardous materials response team of the HFD. Members of the response teams have completed generator hazards safety training.

The PFP has design features that will contain or mitigate a spill. The chemical preparation areas of PFP are equipped with diked-in sump areas that would contain the contents from any one tank failure. Leaks resulting from a water hose, nitric acid, or ANN pump left running may exceed the level of the sumps. A spill exceeding the capacity of the sump would overflow into the 2735-Z catch tank. Leaks or spills from the chemical makeup area and the sinks also drain to the 2735-Z catch tank. Before authorization is given to dispose of wastes generated from spill response actions to the waste water effluent stream, process engineering and plant management, interfacing with site solid waste engineering, shall determine whether the waste is regulated. Regulated wastes are packaged for disposal. Release/spill notification and reporting is performed in accordance with applicable federal, state and local regulations and DOE Orders.

5.4.14 Laboratory Facilities

There are three laboratory facilities in the 234-5Z Building: PFP AL, the standards laboratory, and the PPSL. The PFP AL, located in rooms 131 through 157A of the 234-5Z Building (Figure 5-6, sheet 1), is used to perform analytical and physical test analyses on plutonium samples supporting process control, product quality verification, and nuclear material accountability. The samples come from PFP plant processes, the research laboratory within PFP, and a few special test samples from other locations. The standards laboratory in rooms 221C, 221D, and 221E (Figure 5-6, sheet 1) is devoted to the formulation, verification, packaging, and distribution of actinide-containing destructive and nondestructive standards needed in the laboratories.

The PPSL is located in the southwest corner of the 234-5Z Building in rooms 179B through 191, room 202, and room 235C (Figure 5-6, sheet 1). The laboratory is chartered to operate chemical demonstration facilities involving both nonradioactive and radioactive materials. The PPSL also analyzes

nonroutine samples for process support and develops new methods which are then transferred to other organizations after the methodology is well established and the need becomes routine. The PPSL also processes limited quantities of plutonium material to demonstrate processes whenever the PPSL has exclusive expertise.

Chemical safety for laboratory operations is governed by *PFP Chemical Hygiene Plan*, ZAP-000-010. (See Section 10.4.5)

5.4.14.1 Functions, Equipment, Services, and Safety Considerations. In the subsequent sections, these definitions apply.

- Hood (open-faced and fume)--A standard laboratory hood is a stainless steel, open-faced fume hood that exhausts out the top. A pull-down front is provided in glass, reinforced glass, or Plexiglas™ to protect workers. The front of a fixed-faced hood is fixed in place with open ports to provide access.

- Glovebox--A typical laboratory glovebox is a stainless steel glovebox with rectangular viewing windows and 8-in.-diameter gloves. Gloveboxes are usually about 3 ft wide at the base, 3 ft high, and about 4 ft above the room floor; the length varies. A slight indent is provided partway up the sides to provide easy viewing of the glovebox floor.

- Trouble alarm--This is a foot-activated switch located along the floor of the room, on the bottom outside edge of the gloveboxes and hoods, to allow the worker to signal an alarm without exiting from the gloves. A buzzer sounds simultaneously in the office area indicating the affected area when the switch is hit to summon help in the labs.

- CAMs--CAM Physical description, functions, and location are provided in Chapter 8.0.

5.4.14.1.1 PFP Analytical Laboratory Layout. All laboratory open-faced hoods and gloveboxes are exhausted through the E-4 system. While no HEPA filters are attached directly to open-faced hoods, they are isolated from the environment by two stages of independent testable HEPA filtration. The amount of uncontained plutonium in dry, solid form is limited to 0 g in all open-faced hoods. Two gloveboxes in rooms 143 and 144 are also limited in the amount of uncontained plutonium in dry, solid form to 0 g and less than 0.2 g, respectively. These unique gloveboxes are also isolated from the environment by two independent and testable stages of HEPA filtration. All gloveboxes and hoods designed to be supplied with air from the dry air system (which currently supplies non-dry air; see Section 5.4.3) and have inlet nontestable HEPA filters. All gloveboxes are isolated from the environment by at least two independent stages of testable HEPA filtration. Placement of CAMs in the Analytical Laboratory is discussed in Section 5.4.10.1.6.

Room 131, Chemical Assay Laboratory.

Function and Equipment. Room 131 is used to analyze samples by weight for plutonium concentration. It contains one glovebox (supplied by the dry

air system; see Section 5.4.3) made up of three sections used for dissolution and analysis of product quality plutonium as follows.

- Section 1 contains a muffle furnace used for fusing plutonium oxide samples.
- Section 2 provides a working area where samples are dissolved, heated, titrated, and liquid waste is accumulated.
- Section 3 contains an argon-purged balance used in the titrations.

This is a standard laboratory dry air glovebox with an outlet HEPA filter. All HEPA filters on laboratory gloveboxes are pretested for efficiency before installation. In-place testing is not possible based on design limitations; however, in-place testing of primary filterbox HEPA filters servicing all laboratory gloveboxes and open-faced hoods is performed annually. The glovebox is exhausted through the building E-4 exhaust system and is supplied with vacuum.

Alarms and Protective Features. Room 131 has a smoke alarm and is protected by the building fire sprinkler system. A trouble alarm, located in room 131, will sound in the shift office (room 151). Alpha survey instruments are provided for detection of plutonium contamination.

Services. Room 131 is provided with vacuum, argon, 220-Vac, and process air (to Section 3) services.

Room 132, Mass Spectrometer Laboratory.

Function and Equipment. Room 132 contains two thermal ionization mass spectrometers for the isotopic analysis of extremely small quantities of plutonium and uranium. There is one E-4 drop to the mass spectrometers.

Alarms and Protective Features. Room 132 has one breathing air sampler. One room air sampler and a portable fire extinguisher are located in the room. Alpha survey instruments are provided for detection of plutonium contamination.

Services. Room 132 is provided with instrument air, nitrogen, water, and 120- and 220-Vac services.

Room 133, Dark Room.

Function and Equipment. Room 133 contains the grating and camera portions of a 2-m emission spectrograph and equipment for developing the film. It also contains an explosion-proof refrigerator for film storage. No radioactive materials are allowed in the room.

Alarms and Protective Features. No CAMs or passive air samplers are in the room.

Services. Room 133 is provided with water and 120-Vac services.

Room 134.

Function and Equipment. Room 134 is used to prepare samples for analysis on the mass spectrometer. It contains four open-faced hoods used as follows.

- Hood 1 is used to contain the equipment that mounts samples onto filaments for analysis by mass spectrometry.
- Hood 2 is used to purify samples for the mass spectrometer anion exchange resin columns. The anion resin columns are 3 in. long and contain 2 mL of resin.
- Hoods 3 and 4 are laminar downflow open-faced hoods with testable HEPA filters used for chemical preparation and sample mounting. These hoods are used for single filament mounting (e.g., pulse counting) using only nanogram quantities of plutonium filament. Both hoods are exhausted to the E-4 exhaust system.

Hoods 1, 2, 3, and 4 are typical laboratory hoods and are exhausted through the E-4 exhaust system.

Alarms and Protective Features. The four hoods in room 134 have installed fire suppression systems. In hoods provided with fire suppression systems, each hood or glovebox is equipped with a temperature-sensitive head. When the temperature in the hood activates the sprinkler head, approximately 5 gal of water is discharged into the glovebox from an individual pressure water tank pressurized with air to provide the necessary motive force. These tanks are alarmed to indicate low air pressure and annunciate through the fire detection system. The room also has a trouble alarm and alpha survey instruments.

Services. Room 134 is provided with vacuum and 120-Vac services.

Room 135.

Function and Equipment. Room 135 is used to store and mount samples in support of the mass spectrometer laboratory. It contains four hoods used as follows.

- Hood 1 provides mounting of samples to be analyzed on the mass spectrometers.
- Hood 2 provides temporary storage of samples to be analyzed throughout the laboratory.
- Hood 3 is used for chemical preparation of samples in support of the mass spectrometer laboratory (not used).
- Hood 4 is used for chemical preparation of samples in support of the mass spectrometer laboratory (not used).

All hoods are typical laboratory hoods and are exhausted through the E-4 system.

Alarms and Protective Features. The four hoods in room 135 have installed fire suppression systems provided by limited-volume sprinkler heads. No shielding is required. The room is provided with a smoke alarm, an intrusion alarm (not active), and a workstation trouble alarm. Alpha survey instruments are provided for detection of plutonium contamination.

Services. Room 135 is provided with vacuum, P-10 to the alpha counter, and 120-Vac services.

Rooms 136 and 137.

Function and Equipment. Room 136 contains an emission spectrophotometer and a quantometer. Room 137 contains the arc stand for the two-m film spectrograph. These instruments are used in trace element analyses of plutonium and uranium products. Each room contains a glovebox made up of three sections, used as follows.

- Section 1 contains equipment for sample preparation. Plutonium metal, nitrate and oxide samples are heated to 950 °C in a muffle furnace. Samples are then moved to Section 2.
- Section 2 contains equipment for the preparation and weighing of sample electrodes, after which they are transferred to Section 3.
- Section 3 contains the arc stand where the sample electrodes are shot in a moist argon-oxygen atmosphere.

This is a standard laboratory glovebox with both inlet/outlet HEPA filters and is exhausted through the E-4 system.

Alarms and Protective Features. Each room has a smoke alarm, trouble alarm, and intrusion alarm (not active). Section 1 of each glovebox contains a fire detection tube. Alpha survey instruments are provided for detection of plutonium contamination.

Services. Rooms 136 and 137 are provided with vacuum, oxygen, and argon services and includes an Applied Research Laboratory power supply with an output to 1,000 Vdc.

Room 139.

Function and Equipment. Room 139 contains six interconnected gloveboxes supplied with air from the dry air supply system (see Section 5.4.3). These gloveboxes are used to process and store all plutonium oxide powder and plutonium metal received by the laboratory for analysis. The gloveboxes are used as follows.

- Glovebox 1 contains the airlock for the entire system. Equipment and samples may be entered into the hood through the airlock.
- Glovebox 2 contains a balance that was used to weigh plutonium metal and plutonium oxide samples for analysis.
- Glovebox 3 is used for storage.

- Glovebox 4 contains a V-blender. The plutonium oxide samples are blended in this hood before the start of analysis.

- Glovebox 5 is a storage hood containing 50 racks, each capable of holding 42 25 to 35 mL glass or plastic sample bottles.

- Glovebox 6 contains two balances and a programmable furnace used for loss-on-ignition analysis. Samples for other analyses are weighed in this hood.

The room contains a storage rack with three storage positions (each storage position may contain up to 400 g), and a bench where three electric can sealers for 7-in. food pack and soup cans are located. These are standard laboratory gloveboxes with nontestable outlet HEPA filters that are exhausted through the E-4 system.

Alarms and Protective Features. Room 139 is provided with a smoke alarm and intrusion alarms (active with category II only). No shielding is provided. Each workstation has a trouble alarm. Alpha survey instruments are provided for detection of plutonium contamination.

Services. Room 139 is provided with 120-Vac services and vacuum.

Room 141, Cold Laboratory (Storage Area).

Function and Equipment. Room 141 is used to analyze cold samples that support the building process (e.g., aqueous makeup samples and viscosity on elevator oil). It contains a partitioned cold (nonradioactive) hood that is exhausted through the E-4 exhaust system, a sink, and a water purifier. Additional equipment, a hot plate, and muffle furnace are located in the hood. The room contains additional furnaces. No radioactive material is allowed in the room. The room also contains an acid storage cabinet that stores the main supply of laboratory concentrated acids.

Alarms and Protective Features. The room 141 hood is equipped with a limited-volume sprinkler head fire suppression system.

Services. Room 141 is provided with vacuum, water, and 120-Vac services.

Room 142.

Function and Equipment. Room 142 consists of four vented storage cabinets, the first two shelves per cabinet being used to store standards for the radiochemical standards laboratory and the other two for standards and sources for the PFP AL. The four vented storage cabinets are used to store up to 250 g plutonium (oxide, metal, and nitrate) and/or ^{233}U per shelf. All standards or samples are double contained. Each cabinet is equipped with built-in spacers to adhere to the criticality prevention specification. The cabinets are 0.13 in. stainless steel. All four exhaust through the E-4 system. No HEPA filters are located in the cabinets.

Alarms and Protective Features. No shielding is used.

Services. Room 142 is provided with 120-Vac service.

Room 143.

Function and Equipment. Room 143 is used for handling liquid waste that is not compatible with the waste recovery system and disposal of low-level waste to 241-Z Building. Room 143 contains four hoods and one glovebox. The hoods and gloveboxes are used as follows.

- Hoods 1 and 2 are used by PFP AL waste-handling personnel to store liquid wastes (flammable and organic). These are open-faced hoods.
- Hood 3 and Glovebox 4 were used to treat plutonium solutions with $H_2C_2O_4$ to form a plutonium oxalate precipitate.
- Hood 5 is no longer used. The hood contains a waste aspirator to transfer the waste from the 4-L bottles to the sink drain.

These are typical laboratory hoods and glovebox, and they are exhausted through the E-4 system. There are no HEPA filters provided at the hood or glovebox.

Alarms and Protective Features. Shielding is not normally used. For samples with high dose rates, extension tools and/or smaller size samples are used. The room includes station trouble alarms, and all hoods and the glovebox have limited-volume sprinkler head fire suppression devices. Alpha survey instruments are provided for detection of plutonium contamination.

Services. Room 143 is provided with vacuum, water, and 120-Vac services.

Room 144, Plutonium Chemistry Laboratory.

Function and Equipment. Room 144 contains eight hoods and one glovebox. The work performed in this room provides the primary analytical support for the PFP and PPSL plutonium samples. Among analyses performed are plutonium concentration, visual percent solids, americium concentration, uranium laser, and acid/base determination. Both aqueous and organic samples of high- and low-level plutonium concentrations are analyzed. This room also has facilities to dissolve plutonium metal and plutonium oxide. The hoods and glovebox are used as follows.

- Hood 1 is used to package/repackage samples for shipment.
- Hood 2 is used for temporary storage.
- Hood 3 (storage hood) is used for sample storage. It contains one 4-L waste bottle and one 500-mL trap bottle connected to a 26-in. mercury vacuum.
- Glovebox 4 (breakdown glovebox) is used to break down samples received from customers, dissolve plutonium oxide, plutonium metal samples, and solids contained in process samples. All high-level solutions (greater than or equal to 60 g/L plutonium) are disposed of in a 500-mL glass bottle.

- Hoods 5 and 6 are used for oxalate and KOH analysis and uranium laser analysis. Hood 5 has reagents while hood 6 has the uranium laser.

- Hood 7 is used for temporary storage.

- Hood 8 (storage hood) is used as temporary storage.

- Hood 9 contains two 4-L waste bottles connected to a 26-in. mercury vacuum and electrical outlets.

Hood 9 is subdivided into six hoods. These hoods provide routine process support to include americium, low- and high-level plutonium analysis, density, and acid and base titration. The following analyses are done in hood 9.

- High-level (greater than 60 g/L plutonium) radioassay--The sample is placed in a vial and the vial is sealed and taken to the counting room for analysis. Analyses are done by the solution counter method.

- Low-level (less than 60 g/L plutonium) radioassay--The sample is placed in a vial and the vial is sealed and taken to the counting room for analysis. Analyses are done by the solution counter method.

- Americium analysis--The sample is placed in a vial and the vial is sealed and taken to the counting room for analysis. Analyses are done by the solution counter method.

- Organic sample--Acid and base titrations.

- Low-level plutonium extraction hood--The samples are placed in vials and the vials are sealed and taken to the counting room for analysis. Analyses are done by the solution counter method.

- Specific gravity by densitometer--The samples are taken into the chamber of the densitometer, their specific gravities are measured, and the samples are discarded as waste.

All open-faced hoods are typical laboratory equipment and are exhausted through the E-4 system. HEPA filters are not provided in the hoods and glovebox in this room.

Alarms and Protective Features. Shielding is not provided. Extension tools or smaller sample sizes are used to reduce exposure for samples of high dose rates. Each hood and glovebox is equipped with installed limited-volume sprinkler head fire suppression. Each workstation includes a trouble alarm and intrusion devices that are currently not active. Alpha survey instruments are provided for detecting plutonium contamination.

Services. Room 144 is provided with 120-Vac, vacuum, and water services.

Room 145.

Function and Equipment. Room 145 contains a glovebox that is no longer in use. This glovebox originally was used in support of sinterability and bulk and tap density measurements on plutonium oxide, and for preparation of plutonium oxide standards for the emission spectrometer. This glovebox was supplied with dry air. The glovebox contains two sections, used as follows.

- Top section--Contains a programmable furnace (normal operating temperature of 1600 °C), balance, sintering press, bulk and tap density equipment, mortar and pestle, and screens.
- Bottom section--Was used to prepare plutonium standards for emission spectrograph analysis. It was supplied with dry air.

This is a typical laboratory glovebox and is exhausted through the E-4 system.

Alarms and Protective Features. No shielding is installed. Each workstation has a trouble alarm.

Services. Room 145 is provided with process air, vacuum, and 120-Vac services.

Room 145-A, Stockroom.

Function and Equipment. Room 145A is used to store supplies routinely used in the laboratory.

Alarms and Protective Features. None provided.

Services. None provided.

Room 146.

Function and Equipment. Room 146 is used for waste repackaging and analyzing percentage organic samples.

- Glovebox (hood 5) is used for waste repackaging.
- Hoods 1 through 4 are used to prepare and analyze samples for percentage organics.

These are typical laboratory gloveboxes and hoods and are exhausted through the E-4 exhaust system.

Alarms and Protective Features. Room 146 is protected by the building fire sprinkler system, two laboratory trouble alarms, and a glovebox dry powder extinguishing system. Alpha survey instruments are provided for detection of plutonium contamination.

Services. Room 146 is provided with process water, nitrogen, oxygen, compressed air, vacuum, and 120-Vac services.

Room 147. Room 147 is used as an office.

Room 148.

Function and Equipment. Two cleaned-out open-faced hoods are located in the room. The remainder of the room is used as the laboratory chemical satellite area. The gloveboxes are exhausted through the E-4 exhaust system.

Alarms and Protective Features. Room 148 hoods have installed limited-volume sprinkler head fire suppression. Each workstation has a trouble alarm. No shielding is installed. Alpha survey instruments are provided for detecting plutonium contamination.

Services. Room 148 is provided with 120-Vac and 440-Vac services.

Room 149.

Function and Equipment. Room 149 is used for packing and unpacking shipping containers. This room contains an open-faced hood, a hood converted into a glovebox, and a scrubber hood. Because relatively large amounts of plutonium compounds were to be dissolved in the glovebox, the glovebox exhaust was engineered to pass through a scrubber (in addition to the nontestable HEPA filter set in the exhaust duct of the glovebox). The glovebox has not been used to date since it was converted. These are typical laboratory hoods and gloveboxes and they exhaust through the E-4 system.

Alarms and Protective Features. Room 149 has a trouble alarm. The glovebox has wire-mesh glass windows. Alpha survey instruments are provided for detection of plutonium contamination.

Services. Room 149 is provided with vacuum, 120-Vac, and hot/cold water services.

Rooms 150 and 151, Counting Room/Shift Office.

Function and Equipment. Room 151 serves as the shift office and 150 as the counting room.

Alarms and Protective Features. Rooms 150 and 151 are not provided with CAMs or passive air samplers. No shielding is provided.

Services. Rooms 150 and 151 are provided with electrical, vacuum, and liquid nitrogen services. P-10 gas (available from gas lines) is used in the counting instruments of this room. Liquid nitrogen is contained in dewars (which are filled from cart-portable liquid nitrogen tanks).

Room 152, Waste Laboratory.

Function and Equipment. Room 152 contains a load-in hood and a glovebox. It is used to reprocess liquid laboratory plutonium wastes. The hood and glovebox are used as follows.

- Open-faced hood 551 initially receives the waste container. The waste is sampled for H+ and plutonium and visually inspected for organic content (phases).

- Glovebox 552 (no longer in use) consists of three storage tanks, a distillate tank, vacuum trap, steam concentrator, caustic scrubber, water condenser, and a load-out tank.

These are a typical laboratory hood and glovebox and are exhausted through the E-4 system.

Alarms and Protective Features. Room 152 has an installed sprinkler head fire suppression system. The glovebox is equipped with a heat detector and the hood is equipped with a limited-water-supply sprinkler system. No shielding is provided. Each workstation is provided with a trouble alarm. Alpha survey instruments are provided for detection of plutonium contamination.

Services. Room 152 is provided with vacuum, 30-lb steam, and water services.

Room 153.

Function and Equipment. Room 153 consists of four open-faced hoods and one glovebox. The open-faced hoods are used to support PPSL projects. This work is performed in the four hoods and glovebox described below.

- Hood 1 is used to analyze samples in support of PPSL processes. This hood can have up to 150 g plutonium present. It also is used as a storage hood.

- Hood 2 contains apparatus for measuring total inorganic carbon.

- Hood 3 is used to analyze total organic carbon samples using a tube furnace. The samples are injected with a syringe and needle into the system in the hood. There is a CO_2 calumniator and printer outside the hood.

- Hood 4 is used for storage of plutonium oxalate waste.

- Glovebox 5 (no longer in use) contains equipment to perform surface area analysis. The instrument is located on a bench outside the hood and the line runs into the hood. This glovebox may contain up to 250 g plutonium, and liquid nitrogen is used inside the glovebox during the analysis.

These are typical laboratory hoods and gloveboxes. The HEPA filters are on the inlet/outlets of the glovebox. All are exhausted through the E-4 exhaust system.

Alarms and Protective Features. The hoods and glovebox are protected by individual fire suppression systems (limited-volume sprinkler heads in the hood). The room includes a smoke alarm, intrusion alarm (not active), and trouble alarm. Alpha survey instruments are provided for detection of plutonium contamination.

Services. Room 153 is provided with vacuum service and contains high-purity oxygen bottles.

Room 154.

Function and Equipment. Room 154 contains a glovebox partitioned into three sections and is used for both oxide and metal samples. Carbon, sulfur, and nitrogen are analyzed in this glovebox. The glovebox contains two carbon, sulfur and nitrogen analyzers with furnaces. The plutonium samples are placed in a furnace and fired to 1200 °C, The glovebox and Section 2 are not authorized for any activity. Section 3 can contain up to 150 g plutonium. The glovebox is exhausted through the E-4 exhaust system.

Alarms and Protective Features. The glovebox includes an individual fire suppression system (sprinkler head in box distributes 5 gal of water when activated). The room also includes a smoke alarm, intrusion alarm (not active) and trouble alarm. Alpha survey instruments are provided for detection of plutonium contamination.

Services. Room 154 is provided with 220 Vac, vacuum, oxygen and compressed air (piped in from outside to support C analysis), helium (not used), and nitrogen (not used) services.

Room 155.

Function and Equipment. Room 155 contains four hoods and associated equipment.

- Hood 1 contains an ultraviolet spectrometer for measuring trace quantities of nitrate and nitrite.
- Hood 2 is used to measure nitrate and nitrites.
- Hoods 3 and 4 use the infrared spectrometer to analyze specific samples for organic content.

Alarms and Protective Features. The hoods include individual fire suppression systems equipped with a temperature-sensitive, limited-volume sprinkler head. The room includes a smoke alarm and an intrusion alarm (not active). Each workstation has a trouble alarm. Alpha survey instruments are provided for detection of plutonium contamination.

Services. Room 155 is provided with vacuum and 120-Vac services.

Room 156.

Function and Equipment. Room 156 contains two hoods and one glovebox partitioned into two sections. The glovebox, which is vacant,is HEPA-filtered and exhausted through the E-4 systems. Hoods 3 and 4 are used for specific ion analyses of PPSL samples using fluoride and chloride ion concentrations.

Alarms and Protective Features. The hoods and glovebox are covered by individual fire-suppression systems. Each hood is equipped with a temperature-sensitive, limited-volume sprinkler head. The room includes a smoke alarm and an intrusion alarm (not active). Each workstation has a trouble alarm.

Services. Room 156 is provided with vacuum and 120-Vac services.

Room 157.

Function and Equipment. Room 157 consists of four gloveboxes with furnaces and a sample cell, which are used to support plutonium oxide work. The function and equipment of these gloveboxes are described below.

- Gloveboxes 1 and 2 have been sealed and are no longer in service.
- Gloveboxes 3 and 4 contain equipment for particle size determination. Particle size is anticipated to be in the range of 0.1 to 1 μm. These gloveboxes are new and have not been used yet. Future use of these gloveboxes would be for temporary storage.

Alarms and Protective Features. The gloveboxes in room 157 are covered by individual limited-volume sprinkler head fire suppression systems. The room includes a smoke alarm and an intrusion alarm (not active). By each workstation is a trouble alarm. Each glovebox has access to alpha survey instruments.

Services. Room 157 is provided with 220-Vac, water, and vacuum services.

Room 157A. Room 157A contains a sink.

5.4.14.1.2 PFP Standards Laboratory.

Room 221B. Room 221B is dedicated for use by Radiological Control.

Room 221C.

Function and Equipment. Room 221C contains a glovebox supplied by the dry air system. This glovebox is used to prepare ultrapure plutonium oxide standards for the PFP AL. The glovebox is equipped with a balance and oscillating blender. Various materials are blended with plutonium oxide to produce quality control standards. Initial preparation of oxide material will also occur in this box. The glovebox is equipped with both inlet and outlet HEPA filters. The glovebox is exhausted through the building E-4 exhaust system. A hygrometer is also located in the glovebox to measure the dew point of the air. Room 221C also contains two hoods and a vented storage cabinet. Their purposes are as follows.

- Hood 1 is used for decontamination of glassware. It contains a sink.
- Hood 2 uses plutonium to 350 g/L (sheet standards).
- Vented storage cabinet is used to store radioactive materials.

All hoods are exhausted through the E-4 system.

Alarms and Protective Features. Room 221C is protected by the building fire sprinkler system, a fire alarm on the glovebox, a CAS, an alpha survey meter and a safety shower. Room 221C also handles the criticality detection

and alarm system for rooms 221C, 221D, and 221E. The glovebox is equipped with a heat detector.

Services. Room 221C includes hood sinks that drain to the 241-Z Building (currently inoperable). The room is also provided with 26-in. mercury vacuum, process air to glovebox, nitrogen and oxygen (neither are used), and 120-Vac services.

Room 221D.

Function and Equipment. Room 221D contains equipment used for makeup of plutonium standards and for characterizing plutonium nitrate. It contains four hoods and a glovebox used as follows.

- Hoods 1 and 2 (southwest wall of 221-D) are used as open-faced hoods for the pipetting of plutonium solutions. Hood exhaust is HEPA-filtered.
- Hoods 3 and 4 (southeast wall of 221-D) are used for plutonium nitrate characterization. Hood exhaust is HEPA filtered.
- The glovebox is for storing plutonium nitrate (but is not currently used).

The glovebox is equipped with both inlet and outlet HEPA filters, and is exhausted through the building E-4 exhaust system.

Alarms and Protective Features. Room 221D is protected by the building fire sprinkler system, fire alarm in glovebox, an alpha survey meter and a safety shower.

Services. Room 221D includes hood sinks (drain to the 241-Z Building; not currently operable) and is provided with vacuum, process water/demineralized water, nitrogen and oxygen (not used), and 120-Vac services.

Room 221E.

Function and Equipment. Room 221E contains equipment for the preparation of thorium and uranium standards, low-level plutonium, low-level sheet, and ampulizing applications.

Alarms and Protective Features. Room 221E is protected by the building fire sprinkler system. Alpha survey instruments are provided for detection of plutonium contamination.

Services. Room 221E is provided with 120-Vac, vacuum, deionized water to glovebox (from laboratory deionizing unit), nitrogen, and hot water tank and dishwasher (not used) services.

5.4.14.1.3 Plutonium Process Support Laboratories. In general, gloveboxes and hoods are connected to the building E-4 ventilation system except where noted. All gloveboxes except glovebox 179-1 are served by building water, pressurized air, and vacuum utilities. Pressurized air is

supplied at 90 lb/in^2 (gauge) but can be controlled to lower pressures. Much of the equipment in the PPSL is portable and may be relocated, as required, to support laboratory activities.

The PPSL has no equipment on backup power and no need for backup power is foreseen. Equipment could be connected to backup power in the future on a case-by-case basis. Room 202, corridor 10, room 179, room 183 (located in Figure 5-6, sheet 1), and other strategic locations have emergency lighting.

Room 179.

Function and Equipment. This room is used for working with plutonium and other transuranic chemicals in support of DOE needs. The room contains six gloveboxes and three hoods used for general and frequently changing purposes as existing work is completed and replaced by new projects.

Typical activities in gloveboxes 179-4, -6, -9, -10, and -12 are dissolutions, precipitations, chemical mixture preparations, chemical alteration reactions (e.g., hydrolysis of organic chemicals), calcination or similar decompositions, ion exchange studies, archive sample storage, particle size analyses, and equipment analysis, troubleshooting, and adjustment. Glovebox 179-1 was dedicated to the PPSL radioactive thermal analysis system but the thermal analyzer cooling water has been isolated and can no longer be operated. Satellite accumulation areas for waste radioactive chemicals are set up within gloveboxes whenever needed.

The gloveboxes contain electrically heated furnaces, hot plates, and small rotary mixers. Personnel using the furnaces and hot plates normally remain working in the area so that access to any hot surfaces by other personnel is impeded. Verbal warnings and signs are used when a furnace or hot plate must be left unattended temporarily. In addition, work projects in this room seldom require access to the same work area by personnel working on different projects. Rotary mixers are used only when submerged magnetic stir bars cannot be used. The same warnings and/or signs used for hot plates are employed.

Typical activities in hoods 179-2, -3, and -11 include access to glovebox air locks for equipment/chemical entries, plutonium storage, sample preparation and storage, and equipment decontamination. All three hoods in room 179 are currently restricted to use only for access to the glovebox air locks because the exhaust ventilation no longer meets current requirements. Work plans are in place to modify ventilation from these hoods to provide required double filtration of hood exhaust which will allow these hoods to be returned to active use.

These are typical laboratory hoods and gloveboxes and are exhausted through the E-4 exhaust system. The HEPA filters are installed on the inlets/outlets of the gloveboxes.

Alarms and Protective Features. Room 179 is protected by the building fire sprinkler system. There is an alarmed door to the outside. Room 179 has two safety showers and one alarm activation device. Hoods and gloveboxes are equipped with individual limited-volume fire-suppression systems that include pressurized water containers, low-pressure alarms, piping, sprinkler heads,

and heat detectors. Alpha survey instruments are provided for detection of plutonium contamination.

Services. Room 179 is provided with vacuum, 120- and 220-Vac, gas cylinder station, telephone/PAX system, water, and D-4 drain services. A flammables cabinet is kept here.

Room 180.

Function and Equipment. Room 180 is used for a nonradioactive thermal analysis system. The thermal analysis system includes a mass spectrometer, which is used to assist in determining decomposition products and can run radioactive sample cells for radioactive analyses from otherwise nonradioactive lab instruments. There is a hood in this room in which processes involving radioactive materials are allowed. This room also contains an ultraviolet-visible light (UV-VIS) spectrometer for aiding in organic chemical identification. This unit is mounted on a cart for mobility and is moved to other rooms frequently, as needed.

Alarms and Protective Features. Room 180 is protected by the building fire sprinkler system. It is also equipped with an alpha CAM, alpha survey instruments, and a record air sampler.

Services. Room 180 is provided with E-4 ventilation, argon cylinder stand, and D-3 drain services (not in use).

Room 182.

Function and Equipment. Room 182 is used to house the scanning electron microscope and its accessories (e.g., energy dispersive X-ray microanalysis capabilities for elemental analysis.)

Alarms and Protective Features. Room 182 is protected by the building fire sprinkler system.

Services. Room 182 is provided with hot/cold water, 120-Vac, and D-4 (taped) services.

Room 183.

Function and Equipment. Room 183 is used for liquid scintillation counting and storage of waste drums before they are removed from the building. The room contains one glovebox that is currently not in use.

Alarms and Protective Features. Room 183 is protected by the building fire sprinkler system, one fire extinguisher and a safety shower. This room holds a chemical carcinogens/flammablse cabinet.

Services. Room 183 is provided with 120- and 220-Vac and RLW drain (drains to the 241-Z Building; not currently in use) services. This room has eight cabinets for chemical storage: two storage cabinets, a corrosives cabinet, two acids cabinets (north and south wall), flammables cabinet, acid/corrosive cabinet, and a resin cabinet.

Room 186.

Function and Equipment. Room 186 houses only electronic switches and wiring for the vertical calciner seismic shutdown system. Due to the safety class nature of this equipment, additional uses are forbidden while this system remains in use.

Room 187.

Function and Equipment. Room 187 is used for smaller-scale and general radioactive activities for various DOE needs. Room 187 contains five open-faced hoods. The open-faced hoods (designated 1, 2, 3, 4, and 5) are used for general plutonium support. Typical activities in these hoods include small-scale radioactive dissolutions, precipitations, chemical mixture preparations, chemical alteration reactions, calcinations or similar decompositions, ion exchange studies, sample preparation and storage, and equipment analysis, trouble shooting, and adjustment. Equipment contained in the room includes hot plates, other heating devices, and centrifuges. These are typical laboratory hoods that are HEPA-filtered and exhausted through the E-4 exhaust systems.

The room also contains a high-gradient magnetic filter unit (with associated recirculating chiller) for studying solution decontamination by paramagnetic migration. The unit contains fixed internal cobalt contamination.

Alarms and Protective Features. Room 187 is protected by the building fire sprinkler system, one safety shower and one alarm activation device.

Services. Room 187 is provided with vacuum, hot/cold water, gas cylinder station, 120-Vac, telephone/PAX system, and D-4 drain (not currently in use) services. A storage cabinet is located here.

Room 188.

Function and Equipment. Room 188 contains one glovebox, designated 188-1, that contains the Laboratory Prototype Calciner which is not authorized for operation at this time. The laboratory calciner is used for the direct denitration of various types of plutonium-bearing solutions to a stable, storable solid and to test materials of construction to contain those processes. The laboratory calciner consists of (1) a vertical denitration calciner and (2) ancillary support equipment. The Laboratory Prototype Calciner addendum to this FSAR provides a detailed description of the equipment and process associated with the laboratory calciner. Glovebox 188-1 is a typical laboratory glovebox that is HEPA-filtered (inlet and outlet). Ventilation is supplied by room air and is exhausted to the E-4 exhaust system.

Alarms and Protective Features. Room 188 is protected by a fire sprinkler system, a motion detector for security purposes, a CAM, a fixed head air sampler, high voltage alarm, lights and a safety shower. Glovebox 188-1 contains a fire detector but does not contain fire sprinklers. Alpha survey instruments are provided for detection of plutonium contamination.

Services. Room 188 is provided with vacuum, hot/cold water, 120- and 480-Vac, dedicated high quality compressed air, D-4 drain system, and telephone/PAX system services. The 55-gal drums of scrubbing reagent (30% NaOH) are carted into the room to supply the calciner offgas scrubber in the glovebox with reagent.

Room 189.

Function and Equipment. Room 189 contains an ion chromatograph and houses the "carbon sputterer" for coating scanning-electron-microscope samples.

Alarms and Protective Features. Room 189 is protected by a room fire sprinkler system, a fire extinguisher, a safety shower, and a motion detector for security purposes.

Services. Room 189 is provided with vacuum, hot/cold water, 120-Vac, and D-3 Drain (not currently in use) services.

Room 190 (Vault).

Function and Equipment. Room 190 is used to store stable plutonium material that is not currently needed for ongoing projects and demonstrations. The equipment is limited to storage racks for fissile material.

Alarms and Protective Features. Room 190 is protected by the building fire sprinkler system and an alarm (criticality incident alarm siren). A security alarm is also provided.

Services. Room 190 is provided with 120-Vac service.

Room 191.

Function and Equipment. Room 191 is used as a cold (nonradioactive) laboratory for solution makeup and chemical preparation. There are three hoods and two countertop areas used for solution makeup to support projects in the radioactive laboratories. These are typical laboratory hoods and are exhausted through the E-3 exhaust system. This room also serves as chemical storage.

Alarms and Protective Features. Room 191 is protected by a room fire sprinkler system and an eyewash station.

Services. Room 191 is provided with vacuum, hot/cold water, gas cylinder station, 120-Vac, and D-4 and D-6 drains (not currently in use) services.

Corridors 8 and 9.

Function and Equipment. These corridors provide access to the laboratory rooms and make several safety devices available.

Alarms and Protective Features. These corridors are protected by the building fire sprinkler system, surveillance camera, an alarmed outer door, a fire alarm bell and system control, a radiation detector, a criticality horn,

and a trouble-alarm panel. Alpha survey instruments are provided for detection of plutonium contamination.

Services. Corridors 8 and 9 are provided with 120 Vac and telephone/PAX system services.

Rooms 81 through 90 and Dock 5. These rooms are used as offices. Dock 5 is used for equipment storage.

Room 202.

Function and Equipment. Room 202 is the nonradioactive pilot plant area and can be used for cold support for a wide variety of programs. The room contains one walk-in hood and two large countertop areas. Most of the room is or can be occupied by multiple pilot plants or process demonstrations. The 15 ft 9 in. ceiling allows projects to be considerably larger than in other PPSL rooms. Furnaces, hot plates, and rotary mixers are used in the open in this room whenever required by a project. Other types of heating are also used on rare occasion. Signs warning of hot surfaces are kept and used in this room to warn others of the potential thermal hazards. Rotary mixers are used only when submerged magnetic stir bars are inadequate. Equipment includes the following:

- Fume hood with a dedicated ventilation duct
- A mezzanine for additional floor space and use with tall equipment
- General laboratory work.

Functions for room 202 include chemical preparation and properties investigations; equipment testing, cleaning, and troubleshooting; materials testing; and flowsheet verification or improvement studies that include heating/cooling and the various unit operations of chemical engineering, which include fluid flow, heat transfer, extraction, distillation, calcination, precipitation, drying, diffusion, and phase separation.

Alarms and Protective Features. Room 202 contains a room sprinkler system, a safety shower, two eyewash stations, and a smoke detector.

Services. Room 202 is provided with compressed air, instrument air, 120- and 480- Vac, telephone/PAX, cold/hot water, and liquid waste drain (drains to the 241-Z Building) services.

Rooms 205, 250, and 251-A. These rooms are used as offices.

Table 5-1. Plutonium Finishing Plant Buildings and Structures.
(3 sheets)

Building number	Contents/purpose
200-Z	Maps, outside and underground facilities
207-Z	Retention basin
216-Z-1[c]	Crib (isolated: pipe has been capped or removed)
216-Z-1A[c]	Tile field, sanitary tile field (isolated: pipe has been capped or removed)
215-Z-1AA[c]	Tile field (isolated: pipe has been capped or removed)
216-Z-1AB[c]	Tile field (isolated: pipe has been capped or removed)
216-Z-1AC[c]	Tile field (isolated: pipe has been capped or removed)
216-Z-7[c]	Crib (isolated: pipe has been capped or removed)
216-Z-8[c]	French drain (isolated: pipe has been capped or removed)
216-Z-9[b,c]	Crib (isolated: pipe has been capped or removed)
216-Z-9A[b,c]	Contaminated soil removal facility
216-Z-9B[b,c]	Industrial building; prefab building
216-Z-9C[b,c]	Industrial building; prefab building
216-Z-10[c]	Reverse wells (isolated: pipe has been capped or removed)
216-Z-11[c]	Ditch (isolated: pipe has been capped or removed)
216-Z-12[c]	Crib (isolated: pipe has been capped or removed)
216-Z-13	French drain
216-Z-14	French drain
216-Z-15	French drain
216-Z-16[c]	Crib (isolated: pipe has been capped or removed)
216-Z-18[c]	Crib (isolated: pipe has been capped or removed)
216-Z-19	Ditch (abandoned)
216-Z-20[c]	Crib (isolated: pipe has been grout-capped), Z8 manhole grouted
216-Z-21[c]	Pond (isolated: pipe has been grout-capped)
231-Z[b]	Materials Engineering Laboratory/Building (200 ADP facility - contains Plutonium Finishing Plant Plutonium material)
232-Z[a]	Waste Incinerator Facility (not used)
234-5Z[a]	Plutonium Finishing Plant; plutonium conversion facility
234-5ZA	Change room and MICON™ control station
234-ZB	Miscellaneous storage for construction forces (FFS-owned) acetylene, propane, oxygen, argon, nitrogen storage
234-ZC[a]	Loading dock for waste drums and special nuclear material containers (West End)
236-Z[a]	Plutonium Reclamation Facility (not used). Temporary storage of in-process material in access gloveboxes.
241-Z[a]	Liquid waste storage and treatment tanks in underground concrete cells
241-Z-RB	Waste water retention basin (not used)
241-ZA	Sample building: sample/loadout building
241-ZB	Curbed concrete pad housing the D-9 caustic tank
241-ZG	241-Z change room
241-Z-361	Underground liquid waste settling tank (no longer used)
242-Z[a]	Waste Treatment facility (not used)
242-ZA	Monitoring building (also known as TC-66)
243-Z[a]	Low-Level Waste Treatment Facility
243-ZA	Tank
243-ZB	Cooling towers and concrete pads for closed-loop cooling water system
252-Z-1	Electrical transformer (North of 234-5Z)
252-Z-2	Electrical transformer (in 291-Z Building)
2607-W-8	Septic tank
2607-WA	Septic tank
2607-WB	Septic tank

Table 5-1. Plutonium Finishing Plant Buildings and Structures. (3 sheets)

Building number	Contents/purpose
2607-Z	Septic tank
2607-Z-1	Septic tank
267-Z	Valve house for water supply to a 234-5Z sprinkler system (Riser #9 valve house)
270-Z	PFP support facility (office building) (houses emergency control center)
291-Z[a]	Ventilation exhaust fan house
291-Z-1[a]	Ventilation exhaust stack for 232-Z, 234-5Z, and 242-Z Buildings
296-Z-3[a]	Ventilation exhaust stack for 241 cells and tanks
296-Z-5[a]	Ventilation exhaust stack for 2736-ZB Building
296-Z-6[a]	Ventilation exhaust stack for 2736-Z Building
296-Z-14[a]	Ventilation exhaust stack for 232-Z Building
296-Z-15[a]	Ventilation exhaust stack for 243-Z Building
2503-Z	Electrical distribution system for PFP (switch yard)
2701-ZA	Central station alarm facility (criticality alarm portion)
2701-ZD	PFP badge house
2702-Z	Microwave tower
2704-Z	PFP support building (office building)
2705-Z	Operations control facility
2706-Z	Septic tank
2712-Z	291-Z-1 stack sampler and monitor shack
2715-Z	Paint shop (paint, oil, and solvent, and drum storage)
2721-Z[a]	Backup electric power generators (diesel driven)
2722-Z	Concrete pad for truck load-out station
2727-Z	Storage of miscellaneous operations and laboratory equipment
2729-Z	Storage of miscellaneous maintenance materials
2731-Z	Storage of empty flushed plutonium drums
2731-ZA	Laundry storage
2734-Z	Gas bottle storage (not used)
2734-ZA	Empty cylinder storage
2734-ZB	Breathing air (compressed gas) cylinder storage
2734-ZC	Oxygen and P-10 gas cylinders, P-10 gas supply
2734-ZD	Empty non-flammable gas cylinder storage
2734-ZF	Standby gas bottle storage (not used)
2734-ZG	Nitrogen storage
2734-ZH	Argon and nitrogen storage (not used)
2734-ZJ	Liquid nitrogen storage
2734-ZK	Argon, P-10, nitrogen, propane, acetylene, helium and miscellaneous flammable gas
2734-ZL	HF gas bottles and supply piping (not used)
2735-Z	Chemical storage of HNO_3, and ANN (not used)
2736-Z[a]	Plutonium material storage
2736-ZA[a]	2736-Z exhaust fans
2736-ZB[a]	Shipping and receiving plutonium material
2736-ZC[a]	Loading dock
2736-ZD[a]	Experimental Breeder Reactor II cask storage
2900-Z	Underground lines
2901-Z	Water tower
2902-Z	Elevated sanitary water tank and valvepit (not used)
2904-Z	Monitoring building
2904-ZA[b]	Sheet metal structure that housed 216-Z-20 crib stream effluent sampling, flow measurement, pH and alpha monitoring equipment (not used)

Table 5-1. Plutonium Finishing Plant Buildings and Structures.
(3 sheets)

Building number	Contents/purpose
2904-ZB[b]	Sheet metal structure that housed 216-Z-20 crib stream effluent sampling, flow measurement, pH and alpha monitoring equipment (not used)
225-WC[b]	Houses the sampling and monitoring equipment for the waste water discharge to Treated Effluent Disposal Facility
MO-011[b]	200 W Patrol headquarters trailer
MO-014[b]	Mobile office building; office trailer
MO-015[b]	Mobile office building; office trailer
MO-016[b]	Mobile office building; office trailer
MO-017[b]	Mobile office building; office trailer
MO-031[b]	Mobile office building; office trailer
MO-032[b]	Mobile office building; office trailer
MO-244[b]	Mobile office building; Patrol change trailer
MO-249[b]	Mobile office building; office trailer
MO-250[b]	Mobile office building; office trailer
MO-290[b]	Mobile office building; IRM computer hub trailer
MO-428	Mobile office building; office trailer
MO-429	Mobile office building; office trailer
MO-432	Mobile office building; office trailer
MO-544[b]	Mobile office building; field trailer at carbon tetrachloride site
MO-834	Mobile office building; FFS lunchroom/office trailer
MO-839	Mobile office building; FFS lunchroom/office trailer
MO-939	Mobile office building; office trailer
No #s	Hazardous waste staging areas (various locations)
No #s	Fenced material control areas
No #s	Storage shed (West of 234-Z8 Building)
No #s	Moveable storage structures
HS-045	Hazardous waste storage unit - No. 2 (West of MO-432)
HS-043	Hazardous waste storage unit - No. 3 (West of MO-432)
HS-047	Hazardous waste storage unit - No. 1 (East of 234-5Z Building); Recyclable oil and miscellaneous absorbents storage
HS-046	Hazardous waste storage unit - No. 4 (East of 234-5Z Building); Temperature controlled chemical storage unit
E Maintenance Conex	Miscellaneous maintenance supplies storage
G Maintenance Conex	Miscellaneous maintenance supplies storage
Material Control Conex #1	Filter storage
Material Control Conex #2	JCS job-related hardware and components
Maintenance D Conex	-
Maintenance F Conex	Oil storage
234-5Z-BA (Oil-fired packaged boiler)[b]	Dedicated boiler provides steam supply to the PFP buildings for various uses. (Boiler operated and maintained by separate DOE-RL contractor)

[a]Major PFP structures: Those structures that were identified as having a source term and/or containing major processing equipment or one of the confinement systems.
[b]These items are located outside of the PFP Exclusion Area.
[c]Under jurisdiction of River Protection Project.

2736-ZB	1979	1982	UBC 1976 SDC 4.1	Static Dynamic	Goakey 1980 Giller 1991 Weiner 1994	Goakey 1980 WHC 1990 Giller 1990	Giller 1990 Goakey 1980	Building can withstand DBE (0.25 g), extreme wind, and snow.

[a] Wind analysis included study of both extreme wind and wind-driven missile.
[b] Analyses for combined loading of snow plus ashfall and for ashfall only, were not performed since these natural phenomena hazards are required only for new safety class 1 (safety class) facilities as per SDC 4.1, Rev. 11 (DOE-RL 1989).
[c] This facility, though it is not a high hazard facility, is included in the list because the building serves as a focal point to which a significant portion of PFP liquid effluents is directed before release from the PFP.
[d] This facility was analyzed for combined load of snow plus ashfall and for ashfall.
[e] This facility was designed for ash loading, as required under SDC 4.1, Rev. 12 (DOE-RL 1993).

Table 5-3. Major Plutonium Finishing Plant Building Construction Summary.

Building	Structure	Roof	Roof cover	Exterior walls	Interior walls	Floors	Interior finish	Fire resistance

Building	Seismic analysis performed		Design response spectra		Critical damping (%)	Soil structure	Conclusions
	Analysis type	Chapter 4.0 Reference	PHGA (g)	PVGA (g)			
234-5Z	Rigorous dynamic using 3D nonlinear model	URS, 1987	0.3	0.17	7	Considered	Building can withstand DBE without collapse. Four beam-to-column connections yield.
236-Z	Rigorous dynamic using 3D lumped-mass beam model	URS, 1988	0.3	0.17	5	Neglected	Building can withstand DBE and meets code.
232-Z	None	--	--	--	--	Neglected	Failure assumed.
241-Z	None	Ocoma et al., 1988	0.3	0.17	--	Neglected	Coverblock can withstand DBE.
242-Z	Dynamic, modal analysis	Giller, 1988	0.3	0.17	7	Neglected	Building can withstand DBE without collapse.
291-Z	Dynamic, rigorous finite element	URS, 1980	0.3	0.17	5	Considered	Building can withstand DBE.
291-Z-1 Stack	Dynamic, equivalent static	URS, 1988a	0.3	0.17	7	Considered	Stack can withstand DBE.
2736-Z	Dynamic, single degree-of-freedom	Anderson, 1971	0.3	0.17	--	Neglected	Building can withstand DBE.
2736-ZB	Static	Goakey, 1980	0.3	0.17	--	Neglected	Building can withstand DBE.
2721-Z	Static	WHC, 1990	0.3	0.17	--	Neglected	Building can withstand DBE.
2734-ZL	Static	WHC, 1990	0.3	0.17	--	Neglected	Building can withstand DBE.
2736-ZA	Static	WHC, 1990	0.3	0.17	--	Neglected	Building can withstand DBE.

PHGA = peak horizontal ground acceleration.
PVGA = peak vertical ground acceleration.

Table 5-6. Inactive Glovebox Functions.

Glovebox	Functions
HC-4	Feed solution staging. This glovebox was used for the staging of plutonium solutions to be fed to the RMA and RMC Lines.
HC-6	Feed solution staging. This glovebox was used for the staging of plutonium solutions to be fed to the RMA and RMC Lines. Feed solutions were pumped through this glovebox, which served as a way station between HC-4 and tanks HA-7A and HC-7.
HA-7A	Solution treatment. This glovebox prepared plutonium nitrate feed for transfer to the reactor in H-9A.
HC-3 HC-4 HC-5 H-8A HC-10	Conveyors. These gloveboxes served as plenums that delivered air to all the adjoining gloveboxes, as well as transporting material in the RMA Line plutonium production processes.
H-9B	Plutonium metal production. (Not available)
H-9C	Product weighing. This glovebox was used to weight full powder pans of plutonium oxide.
H-9D	Plutonium metal production. (Not available)
H-9E	Product handling. This glovebox was used to blend plutonium oxide.
H-11	MgO Heater. This glovebox was used to heat the MgO sand that was used to fill the space between crucibles and pressure vessels..
H-12S	Pressure vessel sanding. This glovebox was used to dispense sand to pressure vessels.
HC-13MD	Crucible loading. The equipment in this glovebox was capable of receiving the PuF_4 powder and the reduction chemicals for mixing and transfer to a sanded crucible (now used for seal-in/seal-out for thermal stabilization processes).
H-13G	Gasket Installation. This glovebox was used to install gaskets to the charged pressure vessels.
H-13ABC	Reduction to metal. This glovebox holds the induction furnaces used to reduce PuF_4 to plutonium metal. This glovebox is divided into three vertical sections labeled A, B, and C. Each of the sections was provided with identical equipment and instrumentation to perform the reduction.
H-14CC	Crucible cutter. This glovebox was used to break MgO slag and crucibles to release the plutonium buttons.
H-14DC	Pressure vessel dumper. This glovebox was used to remove the contents of pressure vessels.
H-14P	Pickling. This glovebox was used to clean and pickle plutonium buttons.
H-14S	Sampling. This glovebox was used for sampling of the plutonium metal buttons.
H-15B	Weighing. A balance was used for weighing of RMA material.
H-15	Plutonium metal production. (Not available)
H-16CS	Conveyor storage.
H-16BS	Button storage. This glovebox was used for storage of plutonium buttons.
H-16L	Plutonium metal production. (Not available)
HA-19	Storage.

Table 5-7. Equipment Design Basis and Equipment for Interim Storage and Plutonium Material Handling Remote Mechanical C Line Gloveboxes.

Glovebox	Function	Equipment	Material	Design pressure lb/in^2 (gauge)	Design temperature °C

Table 5-8. Miscellaneous Treatment Equipment. (2 sheets)

	Material	Diameter (in.)	Length (in.)	Volume (L)
Glovebox MT-1: inspection				
Funnel screen (cone of 1/8-in. wire cloth)	stainless steel	6.0	5	1.0
Glovebox MT-3: dissolution of bulk metallic plutonium				
Two dissolvers	Glass	6.0	6	2.7
Basket	Fluorocarbon	4.75	0.0625	
Electrodes	Tantalum	4.0	0.063 + 0.01	
Anode coated with	Platinum	4.0		
			36	
Two holding tanks	Glass	6.0		16.0
			18	
Two primary exchangers	stainless steel	6.4	~36	10.0
75 Double pass tubes	stainless steel	0.25		
			60	
Secondary exchanger	stainless steel	6.0	~60	
150 Tube exchanger	stainless steel	0.25	12	
Chemical addition	Glass	6.0		5.5
			8	
Gas sample exchanger	stainless steel	3.0	30	0.9
Coil exchanger	stainless steel	0.375		
			12	
Gas scrubber	Glass	4.0		2.5
			12	
With 1/2-in. saddles	stainless steel	4.0		2.5
			18	
Vacuum trap	Glass	6.0	3	8.2
Demister pad	Fluorocarbon	6.0		
Glovebox 4: decarbonization				
Cube still	Quartz tube	4.0	34	6.8
Cube furnace	Inconel™ tube	4.0	52	10.4
Receiver	Glass	6.0	6	2.7
Scrubber	Glass	3.0	18	2.0
Two coolers	stainless steel	0.5	25	
Exterior coil	Copper	0.25		
Boats	Nickel sheeting			
Styrene transfer	Glass	6.0	12	5.6
Vacuum trap	Glass	4.0	10	2.0
Cube crusher	stainless steel			
Glovebox 5: dissolution				
Five dissolver hot plates				
Five dissolver beakers	stainless steel	6.0	9	4.7
Five condensers	stainless steel	5.0	12	3.9
Double coils	stainless steel	0.375	~300	
Three pan filters	stainless steel	12.0	2	3.7
Chemical addition	PVC	6.0	25	11.5
Chemical addition	PVC	6.0	19	8.7
Sump receiver	Glass	4.0	18	3.6
Vacuum trap	Glass	4.0	10	2.0

Table 5-8. Miscellaneous Treatment Equipment. (2 sheets)

	Material	Diameter (in.)	Length (in.)	Volume (L)
Glovebox 6: separation and cementing of nonleachable solids				
Centrifuges (3)	stainless steel	10.5	6	8.0
Bowls (3)	stainless steel	3.8-ID	4	2.5
Two receivers	Glass	8.0D	30	14.4
Vacuum trap	Glass	6.0	12	2.5
Water reservoir	Glass	4.0	24	11.0
With cooler	stainless steel	6.0	8	3.7
Double coil	stainless steel	6.0	500	
Drying pan	stainless steel	0.375	1.88	1.5
Hot plate	--			
Vacuum pump	--	8.0		
236-Z Cell: clarified solution receiving				
Two holding tanks Tank 25, Tank 26	stainless steel	5.0 (4-barrel)	45	57.0
Glovebox HA-40F: dissolution of plutonium-bearing solids				
Furnace (2)	Ceramic	--	6.0	--
Glovebox HC-46F				
Four hot plates		6.0	9.0	4.0
Four dissolver beakers	stainless steel	6.0	9.0	4.0
Four reflux condensers (single pass)				
Inner tube	stainless steel	1.0	20.75	0.27
Shell	stainless steel	1.5	19.0	0.31
Four rotameters (0 to 5 gal/min)				
Three pan filters with Kynar™ 25-micron media	stainless steel	10.0	4.0	5.0
Two demister/scrubbers (with 1/2 Raschig rings)	stainless steel	6.0	30.0	13.9
One receiver	stainless steel	6.0	36.0	16.5
One vacuum trap	Glass	4.0	12.0	3.0
One cartridge filter housing (with 2-micron media)	stainless steel	3.0	10.0	1.0
Glovebox HC-60: hydroxide stabilization of organic residues				
Two hot plates (2 kW)				
Two dissolver beakers	stainless steel	6.0	9.0	4.0
Vacuum flask (2)	Glass			1.0
Vacuum trap	Glass	4.0	12.0	3.0
Two buchner funnels	Ceramic	--	--	0.5
Chemical addition funnels	stainless steel	3.0	6.0	

Table 5-9. Hanford Piping Standards (1960).

Standard	Application
H-6	N_2 Compressed air
H-9	Instrument air
H-12	Instrument air, dry air, and breathing air
H-22	Waste lines
H-33	Acid feed lines and process lines
H-34	Hydrogen fluoride gas

Table 5-10. American Society for Testing Materials Codes.

ASTM Code	Application
A 312-59T	Seamless and welded austenitic stainless steel
A 358-56T	Chrome-nickel high temperature steel
A 371-53T	Chrome-nickel welding rod
A 262-55T	Boiling HNO_3 test

Table 5-11. Major Plutonium Reclamation Facility Equipment.
(4 sheets)

Equipment number	Location	Function	Description* (diameter by length) (construction materials)	Working volume (L)	Overflow capacity (L)

Table 5-16. Support System Configuration Compared with Regulatory Guide 3.39 Requirements.*

Plant system/process	Operating condition	Maximum hypothetical occurrence shutdown mode
The Plant (PFP complex)	5.3.1 Load	5.3.1 Load
Ventilation	Reduced	---
Environmental surveillance and alarms	Reduced	Emergency
Fire protection and alarms	Reduced	Emergency
Balance of plant	Reduced	---
Process lines	5.3.1 Load	5.3.1 Load
PRF (236-Z)	Line normal process	---
RMC Line (234-5Z)	normal process	---
Product handling (2736-Z) (ventilation)	normal process	Emergency

*NRC 1976

Table 5-17. Analysis of System Loads for the Plutonium Finishing Plant.

System/location	Loads		
	Normal process	Reduced	Emergency
Electrical			
Ventilation	1,787 kW	1,787 kW	150 kW
Environmental surveillance	66 kW	66 kW	66 kW
Fire protection	15 kW	15 kW	15 kW
Balance of plant	390 kw	390 kW	0 kw
Subtotal	2,258 kW	2,258 kW	231 kW
PRF	0 kW	0 kW	0 kW
RMC Line	0 Kw	0 kW	0 kW
Product handling	10 kW	10 kW	10 kW
Total	2,268 kW	2,258 kW	241 kW
Steam			
Plant	50,000 lb/h	50,000 lb/h	0.00
PRF	0.00	0.00	0.00
RMC Line	0.00	0.00	0.00
Product handling	0.00	0.00	0.00
Sanitary water			
Not metered, assumed daily release to TEDF equivalent to or less than requirements	10,000 gal/day	10,000 gal/day	0.00
PRF*	0.00	0.00	0.00
RMC Line*	0.00	0.00	0.00
Product handling	0.00	0.00	0.00
Process air			
Total plant	250 ft^3/min	250 ft^3/min	0.00
Instrument air			
Total plant	200 ft^3/min	200 ft^3/min	0.00
Dry air			
Total plant, mainly for RMC Line whether operating or not	0 ft^3/min	0 ft^3/min	0.00

*Engineering estimate of intermittent process water requirement.

Table 5-18. Ventilation Zones and Associated Differential Pressures.

Zone	Ventilation system	Damper	Set pressure (in. w.g.)
1	S-1	A	+0.14 to +0.16
3*	S-3*	B	-0.14 to -0.17
3	S-3	C	-0.14 to -0.17
3A	S-3A	D	-0.11 to -0.14
3B	S-3B	E	-0.03 to -0.10
4	-	-	-1.1

*Note that zone 3 includes those rooms formerly balanced as zone 2.

Table 5-19. Typical Plutonium Finishing Plant Ventilation System Air Supply Flowrates.

Supply system	Damper	Airflow (ft^3/min)	Areas supplied
S-1	A	91,000	Zone 1
S-3	B	28,000	Zone 3
S-3	C	38,000	Zone 3
S-3A	D	72,000	Zone 3A
S-3B	E	10,000	Zone 3B
S-3B	F	49,000	236-Z Building
Total	-	288,000	-

Table 5-20. Plutonium Finishing Plant Compressed Gas Storage Facilities.

Facility	Compressed
2734-Z	Gas bottle storage (not used)
2734-ZA	Empty cylinder storage
2734-ZB	Breathing air (compressed gas) cylinder storage
2734-ZC	Oxygen and P-10 gas cylinders, P-10 gas supply
2734-ZD	Empty non-flammable gas cylinders
2734-ZF	Standby gas bottle storage (not used)
2734-ZG	Nitrogen storage
2734-ZH	Argon bottle supply (not used)
2734-ZJ	Liquid nitrogen storage tank
2734-ZK	Argon, propane, acetylene, and gas bottle storage
2734-ZL	HF gas bottles and supply piping (not used)

Table 5-21. Sanitary Water Service Connections. (2 sheets)

	Location	Size	Service
1.	234-5Z Building under north wall at column 5-1/4	4-in. dia	Riser 1 to sprinklers. Deluge for 252-Z-1 substation.
2.	234-5Z Building under north wall at column 9-1/2	6-in. dia	Building sanitary water. Building process water through backflow preventers. Serves building water loops in duct level.
3.	234-5Z Building under north wall at column 13-1/2	8-in. dia	Riser 2 to second floor sprinklers. (Originally for filter room sprinklers, but not installed.)
4.	234-5Z Building under north wall at column 16-1/3	8-in. dia	Riser 3 for east roof sprinklers (under roof). Also first floor sprinklers.
5.	234-5Z Building under north wall at column 16-1/2	6-in. dia	Riser 4 for ventilation, supply, plenum chamber, deluge sprinklers.
6.	234-5Z Building under west wall at 5 ft north of column E	8-in. dia	Riser 5. Roof sprinklers west end.
7.	234-5Z Building under west wall at 3 ft 1-1/8 in. south of column E	8-in. dia	Riser 6. West end sprinklers including office addition sprinklers.
8.	234-5Z Building office addition at southwest corner; 14 ft south of 234-5Z Building south wall	1-1/2-in. dia 1.5-in.	Sanitary water only to office addition.
9.	Line comes from elevated tank valve pit, runs south to north side of 234-5Z Building, west side of 234-5Z, south to about 40 ft south of 234-5Z, and slants east by slightly north to northwest corner of 291-Z Building	2-1/2-in. dia 2.5-in.	Provides 291-Z Building service water if water loop service pressure decreases below a set pressure.
10.	Southwest side of 2736-ZA Building 2736-ZA plutonium storage	6-in. dia	Fire protection.
11.	South side of 232-Z Building incinerator building	3-in. dia	Sanitary water service (line has been capped).
12.	South side of 232-Z incinerator building through a special valve house	4-in. dia	Provides fire protection water for sprinklers (water is provided to riser in building, but riser has been capped).
13.	Southeast corner of 291-Z Building to machinery room	3-in. dia	Used only for sanitary water and for machinery. Seal water, inter and after coolers on compressors, etc.
14.	Northeast corner of 291-Z Building into 252-Z-2 substation	4-in. dia	Used only for deluge system for 252-Z-2 substation.
15.	Southeast corridor of 236-Z Facility	3-in. dia	Both sanitary and fire water risers.
16.	Southeast corridor 236-Z Facility	3-in. dia	Sanitary water and safety showers.
17.	Northeast corner of 236-Z Facility at 6 in. north of south wall of stair 1	3-in. dia	Sanitary water.
18.	Northeast corner of 236-Z Facility at 6 in. south of north wall of stair 1	6-in. dia	Riser 7. Fire protection for 236-Z Building sprinklers for all floors.

Table 5-21. Sanitary Water Service Connections. (2 sheets)

Location	Size	Service
19. 242-Z Building at east side of control room	2-in. dia	Sanitary water for safety showers.
20. 234-5Z Building on east side at 12 ft south of column G	8-in. dia	Riser 8. Serves sprinklers for entire engineering laboratory plus additional spaces in southeast area of building. Also branch into 242-Z.
21. 234-5Z Building under north wall at column	6-in. dia	Fire protection water for east end duct level sprinklers.
22. East side of 270-Z Building	6-in. dia	Fire protection water for the 270-Z Building.
23. East side of 270-Z Building	2-in. dia	Sanitary water supply for the 270-Z Building.
24. West side of 2736-ZB Building	6-in. dia	Fire protection water for the 2736-Z and 2736-ZB Buildings.
25. West side of 2736-ZB Building	4-in. dia	Sanitary water supply for the 2736-ZB Building.
26. South end of 2721-Z Building	4-in. dia	Riser. Fire protection water for the 2721-Z backup power generation building.
27. Under north wall at column 19 of 234-5Z Building	8-in. dia	Fire protection riser for the duct level, west end.

PLUTONIUM FINISHING PLANT
FINAL SAFETY ANALYSIS REPORT

CHAPTER 6.0

PROCESS SYSTEMS

FEBRUARY 2001

This page intentionally left blank.

PREFACE

Revision 2 of Chapter 6.0 of the Plutonium Finishing Plant (PFP) Final Safety Analysis Report (FSAR) includes modifications for the following:

- Clarification of PR Can description and PR can handling
- Clarification of Seal-in/bag-out operations
- Incorporation of the Magnesium Hydroxide Precipitation Process
- Incorporation of the Bagless Transfer System

Other minor changes include editorial changes and additional clarifications.

The following summarizes the active and inactive processes performed at the PFP. Process and systems descriptions are provided for both active and inactive processes. The active systems are currently or will be authorized for operation following approval of the FSAR revision 2 and controls implementation. The inactive descriptions are retained for historical purposes to support future D&D activities.

Active Processes.

- Plutonium material storage and support activities in the 2736-Z, 2736-ZA, and 2736-ZB Buildings, 2736-ZD vault, and the gloveboxes and vaults in the 234-5Z Building
- Reactive plutonium-bearing material stabilization in the 234-5Z Building using Glovebox HC-21C and HA-21I
- Waste packaging and reactive residue storage
- Transfer operations in gloveboxes HC-227S/T in the 234-5Z Building
- Low-level waste and waste water treatment in the 241-Z Complex and 243-Z Building, respectively
- The PFP Analytical Laboratory (PFP AL), Standards Laboratory, and Plutonium Process Support Laboratory (PPSL) in the 234-5Z Building
- Facility support systems [e.g., heating, ventilation, air conditioning (HVAC), radiation monitoring, steam, electricity, etc.].
- Bagless Transfer System operations in Glovebox HA-53BTS in the RMA Line in the 234-5Z Building
- Magnesium Hydroxide Precipitation Process operations in Gloveboxes HC-230C-3 and HC-230C-4 in the RMC Line in the 234-5Z Building.

Inactive Processes.

- Plutonium-bearing solution stabilization using the Production Vertical Denitration Calciner and Laboratory Prototype Calciner in the 234-5Z Building
- Plutonium recovery in the 236-Z Building
- Plutonium conversion in the 234-5Z Building
- Waste treatment in the 242-Z Building
- Laboratory waste concentrator.

It is noted that various sections of Chapter 6.0 present information concerning plutonium-bearing solution stabilization operations using the Production Vertical Denitration Calciner located in the RMC Line and the Laboratory Prototype Calciner in the Plutonium Process Support Laboratories. Operation of either the production calciner or laboratory calciner for solution stabilization is not authorized at this time and the related portions of Chapter 6.0 will be updated, if necessary, prior to initiation of operations.

The new packaged boilers operated by Johnson Controls, Inc. which provide steam to the PFP were previously incorporated in the FSAR. This included switching the emergency exhaust fans from those which are steam-driven to those which are connected to the standby power system. However, the conversion from using steam-driven fans to standby power driven fans has not been fully implemented. The emergency exhaust fans are currently run by the new steam supply system installed under the Hanford energy conservation program. Electrically-driven emergency exhaust fans are planned to be connected to the diesel-generator standby power supply at some future date. The emergency exhaust fan functions are unchanged from that described in the FSAR regardless of the type and source of power.

The significant areas of change in Revision 2 are indicated by vertical bars in the margin of each page.

6.0 PROCESS SYSTEMS

6.1 INTRODUCTION

Since the beginning of operations in 1949, the Plutonium Finishing Plant (PFP) has performed numerous diversified plutonium processing, handling, storage, and support operations. All operations at PFP are conducted in accordance with reviewed and approved operating procedures, which are listed in Table 6-1. Current operations include the following:

- Plutonium material shipping/receiving
- Plutonium material storage
- Remote Mechanical A (RMA) and Remote Mechanical C (RMC) Line operations, including reactive plutonium-bearing material stabilization, plutonium-bearing solution stabilization using the Production Vertical Denitration Calciner (VDC) and the Magnesium Hydroxide Precipitation Process and plutonium material packaging using the Bagless Transfer System
- Laboratory support
- Facility cleanout activities
- Radioactive waste handling.

These operations (with the exception of radioactive waste handling, which is discussed in Chapter 7.0), and their associated support systems are described in this chapter. Discussion of two inactive operations, the former RMA and RMC Line processes for plutonium conversion and the Plutonium Reclamation Facility (PRF) process systems for plutonium recovery, is presented. These operations are included as plutonium recovery and conversion, and were historically the principal operations conducted at the PFP. The residual quantities of radioactive material remaining from these operations are important considerations of the safety basis. The 232-Z Waste Incinerator Facility and the 242-Z Waste Treatment Facility are also addressed.

The operations, process chemistry and associated support systems for the Magnesium Hydroxide Precipitation Process are described in the Magnesium Hydroxide Precipitation Process addendum to this FSAR (Carson 2000). The operations associated with packaging of stabilized plutonium using the Bagless Transfer System (BTS) are described in the calculation notes for the BTS (FH 2000). No further discussion of either process is provided in this chapter.

6.2 PLUTONIUM MATERIAL SHIPPING/RECEIVING

6.2.1 Process Description

6.2.1.1 Narrative Description.

6.2.1.1.1 Shipping. Only solid plutonium-bearing materials are shipped offsite. The materials are contained in sealed cans in compliance with the certificate of compliance (COC). The steel cans are of the food packaging type, referred to as "food pack cans" (see Section 6.3.3.1). The cans containing metal buttons, which have been held in storage for an extended period of time, are transferred to room 636, Building 2736-ZB, and moved into the repackaging glovebox. The plutonium metal button is removed from the package, inspected, and any loose oxide is removed by brushing with a paint brush. The button is then weighed, recanned, bagged out, and overpacked in two food pack cans.

The PuO_2 packages are also inspected. If required, the can is repackaged in the repackaging glovebox.

The packages to be shipped are placed in shipping containers and moved to the 2736-ZC loading dock where they are placed in cargo restraint transporters, which are secured in the safe secure transport (SST) truck or the Exclusive Use Vehicle for shipment.

6.2.1.1.2 Receiving. Most shipments of plutonium material are received at the 2736-ZC loading dock. One exception is the Fast Flux Test Facility (FFTF) fuel, which is stored in shipping containers in vault 192-A, and received at the door 135 dock of the 234-5Z Building. Offsite shipment to the PFP requires a preapproved shipping plan that complies with the PFP storage specifications. Shipment is made by SST truck. The shipping documents are checked, and the shipping containers are brought into the 2736-ZB Building for inspection, weighing, and nondestructive analysis (NDA) measurement of fissile material contents (see Section 6.5.1.1.4 for a description of the NDA Laboratory). If the material requires repackaging, this is also done in the 2736-ZB Building. If the materials are determined to be unstable (gas evolution, liquid, etc.), a recovery plan is developed and implemented that provides for interim safe storage and stabilization of the material. Stable materials are moved to the vaults in the 2736-Z Building for storage until final disposition. Section 6.2.3 provides details of this operation.

Load-In/Load-Out Process. The load-in/load-out (LI/LO) of plutonium nitrate [$Pu(NO_3)_4$] solutions is performed in the 234-5Z Building, room 227, in glovebox HC-227S and hood HC-227T. Hood HC-227T is primarily used for the vacuum transfer of solutions between product receiver (PR) cans and other containers in the hood and tanks in glovebox HC-227S. Glovebox HC-227S is used to blend and transfer plutonium nitrate solutions to smaller containers (e.g., 4.2 L polyjugs) for transport to the Plutonium Process Support Laboratories (PPSL). The glovebox is also used to blend, sample and transfer Pu nitrate solutions to glovebox HC-230C-2 in room 230C for solution stabilization operations using the Production VDC process. Solutions may also be transferred from glovebox HC-230C-2 to glovebox HC-227S. Additional

information on the LI/LO of plutonium nitrate solutions is found in Section 6.2.3.

Glovebox HC-227S is also the source of plutonium nitrate solutions for processing in the Laboratory Prototype Calciner in Glovebox 188-1 in the PPSL. The equipment and process involved in the transfer of solutions to the laboratory calciner are described the Laboratory Prototype Calciner addendum to this FSAR.

6.2.1.2 Flowsheets. Plutonium material is routinely shipped from and received at the 2736-ZC Building, the loading dock of the 2736-Z Support/Storage Complex. The overall schematic flow diagram for dry SNM material handling at the PFP is shown in Figure 6-1.

6.2.2 Process Chemistry and Physical Chemistry Principles

There is no process chemistry associated with plutonium material shipping/receiving.

6.2.3 Mechanical Process Systems

6.2.3.1 Functional Description. The major mechanical process activities for the 2736-Z Support/Storage Complex are shown in the simplified flow diagram, Figure 6-1. The major areas of activity are shown in the cutaway view of the 2736-ZB Building in Figure 6-2.

6.2.3.1.1 Shipping. Packages containing plutonium material designated for offsite shipment (off of the Hanford Site) are prepared for shipment as follows:

- Packages are placed in shippable form, meeting all specifications for shipping
- Packages undergo NDA
- Packages are transported to staging room 638 in the 2736-ZB Building
- Packages are loaded in DOT-6M (see Figure 6-11) or other approved shipping containers according to procedure, are inspected, and sealed.

Shippable forms are loaded into shipping containers according to type and destination. The containers are surveyed, moved out of the building to loading dock 2736-ZC, placed on the transport vehicle, and secured for shipment.

6.2.3.1.2 Receiving. Offsite transfers of solid plutonium material (metal, oxide, or other plutonium-bearing materials) are made in DOT-6M shipping containers in a SST vehicle. The SST vehicle is received at the loading dock 2736-ZC. Before receiving any plutonium material, requirements for receipt listed in Table 6-2 must be met.

Material containers are transferred to room 641 in the 2736-ZB Building for sorting. Sorted containers are transferred to staging room 638, where they are prepared for repackaging, shipping, or storage in the 2736-Z Building. Staging area activities include inspection and weighing; pneumatic, hydrostatic, and leak testing of shipping containers when necessary; and decontamination of empty shipping containers.

While N Cell was in operation at the Plutonium-Uranium Extraction (PUREX) Facility, AL-M6 and DOT-6M shipping containers were used for shipping plutonium oxide to PFP. During weapons production, PR container drums were received from the PUREX Facility. Nuclear material item transfer (NMIT) records were checked to ensure the shipment was correct, and a Radiological Control Technician (RCT) surveyed the process truck to ensure that radiation levels were within the limits of less than 50 mrem/h at contact around truck and less than 6 mrem/h in the truck cab. The transfers were made with security and RCT escorts. Upon receipt, the containers of plutonium oxide were transported to the 2736-Z Building for vault storage. The PR container drums that contained the Mark IV/V and Emergency PR cans (see Figures 6-3 and 6-4) were transported to the 234-5Z Building, room 236, for storage.

Load-in/Load-out Process In Glovebox HC-227S and Hood HC-227T. The LI/LO of plutonium nitrate solutions is performed in the 234-5Z Building, room 227, in glovebox HC-227S and hood HC-227T. Hood HC-227T (see Figure 6-5) is an open-faced hood that covers the south half of the east wall in room 227, while glovebox HC-227S covers the north half of the same wall.

Hood HC-227T was used to LO material from the PRF. Hood HC-227T is now used for the vacuum transfer of solutions between containers (e.g., PR cans and 10 liter polyethylene bottles) and tanks in glovebox HC-227S and can be used for venting PR cans. Glovebox HC-227S was used to blend and sample plutonium nitrate and to transfer solutions to the PRF or to nitrate staging tanks in glovebox HC-4 in room 166 of the 234-5Z Building. Glovebox HC-227S is now used to transfer plutonium nitrate solutions to containers (e.g., 4.2 liter and 3 liter polyethylene bottles) for transport to the PPSL and for transfer of solutions to and from the Production VDC.

Various activities are associated with LI/LO. The LI activities include LI of solutions from transport storage container assemblies (e.g., PR, 10-L, L-10, and FL-10) in hood HC-227T, solutions from flushing of containers in the hood, accounting for solution volume, and blending and sampling in glovebox HC-227S.

The LO activities include LO of solution from glovebox HC-227S to transport container assemblies (e.g., PR, 10-L, L-10, and FL-10) in hood HC-227T, accounting for volume transferred, and transferring solution from glovebox HC-227S to storage containers (4.2 liter, 3 liter polyethylene bottles, and other small containers). Solutions transferred to storage containers are removed from the glovebox through seal-out ports and transported to plant process areas or to storage in designated containers. Bottles containing plutonium solutions may be placed into an isolated transport container (ITC) for transport. Long-term storage in ITCs is not permitted. Other solution containing 3 liter polyethylene bottles are transported and stored utilizing the PR container rack and drum assembly

equipped with a 6 inch diameter sleeve to support the bottle within the drum rack (see supplement to Figure 6-3).

Miscellaneous activities include accepting solution from the Plutonium Finishing Plant Analytical Laboratory (PFPAL) into glovebox HC-227S (note the plutonium nitrate transfer line from the Analytical Laboratory entering room 227 has been capped), flushing glovebox HC-227S and hood HC-227T equipment, sampling PR can contents for plutonium assay purposes, and performing emergency shutdown in room 227 in case of malfunction.

The LI/LO activities are essentially the same regardless of which process is operating. The principal differences are in the type of solution and the final destination of the solution.

RMC Line operation for Pu metal production is currently an inactive and unauthorized process. Plutonium nitrate feed solution was loaded into batch tanks in glovebox HC-227S from PR cans via hood HC-227T. In glovebox HC-227S, nitrate solutions were blended and sampled, and the plutonium nitrate feed was transferred to staging tanks in glovebox HC-4. Occasionally, during RMC Line operation, LO of concentrated filtrate solution was required. The concentrated filtrate was transferred from glovebox HC-7 to glovebox HC-227S for LO into PR cans (via hood HC-227T) for storage, until it was used as feed for the PRF operation. RMC Line operations currently consist of reactive material stabilization using the thermal stabilization process and Pu-bearing solution stabilization using the vertical denitration calciner process.

The PRF operation is also currently an inactive and unauthorized process. Concentrated filtrate removed to PR cans during RMC processing was loaded back into glovebox HC-227S and transferred to tank TK-49 for use as PRF feed. The plutonium nitrate solution produced during PRF processing was transferred from tanks TK-45, TK-128, and TK-46 to glovebox HC-227S for LO into PR cans. This solution was stored until RMC Line resumed operation and then it was used as feed for the RMC Line process.

The transfer of solution from the PFPAL to glovebox HC-227S via the transfer line is also currently an inactive and unauthorized process. The PFPAL has, in the past, transferred solution from the laboratory concentrator (located in glovebox 552 of room 152) to glovebox HC-227S. This solution was loaded out or sent to the PRF, depending on solution storage and/or PRF operating status. Historically, transfers from the PFPAL were infrequent and usually involved relatively small volumes (less than 10 liters).

Other containers may be stored next to or along the pathway between the designated PR can storage room and room 227. Therefore, operators in room 227 may need to use transportation devices such as the L-10 cart, PR can carts or the drum/barrel carts.

The L-10 cart suspends the container being transported by a cradle and chain device that supports the container. The steering bar on the cart is used to raise and lower the container. The cart is designed to minimize any swinging motion; however, a second operator is assigned to steady the container during transport.

The PR can cart is a commercially available flatbed type of cart used to transport containers and is equipped with channel bar skids. All three types of PR cans can be transported using these carts. The PR can carts have either mechanically leveraged or hydraulically operated decks that are operated from the handle.

Two types of commercial drum/barrel carts are used at the PFP. One type has two wheels and is like a hand truck. The other type has four wheels, which allows the transport of heavy barrels. These carts are used to transport 30- to 50-gal drums. The foot pads on these carts support the drums from the bottom, and a hook mechanism locks the drum securely in place during transport. The hook mechanism releases when the drum is set on the floor.

Transfers of plutonium material from offsite are made in SST vehicles and are coordinated by transportation personnel. After receipt, the material at the 2736-ZC Building is handled as an onsite transfer.

6.2.3.2 Safety Features. Safety features related to criticality, radiological, and industrial safety are discussed in the following sections.

6.2.3.2.1 Criticality Safety. The requirements of the criticality safety program are established in *Criticality Safety General Requirements*, HNF-PRO-334. Each room, glovebox, and shipping container has been analyzed by the methods outlined in Section 6.2.9.1 to ensure compliance with the criticality safety criteria presented in Chapter 4.0, Section 4.4.4. Criticality safety features incorporated into the design of the SNM shipping and receiving operations include the following.

- Shipping containers and inner containers are equipped with gaskets or sealed to prevent water inleakage
- Inner packages of shipping containers are designed to be geometrically favorable even for flooded conditions
- Spacers are used in shipping containers to ensure the required spacing between adjacent containers is maintained
- Process containers used in repackaging operations are designed to be subcritical even if overbatched and moderated
- Vaults and transport carts provide physical barriers to separate inner packages from other fissile material in storage
- Concrete shielding walls in vaults reduce neutron interaction between SNM stored in adjacent storage cubicles
- Storage racks and contents are secured to withstand a design basis earthquake (DBE).

Administrative practices are also documented and applied to the operations for criticality safety control (CSC). For example, each room, glovebox, and storage area has specific criticality prevention specifications (CPSs), postings, and operating procedures that incorporate the criticality safety requirements. In addition, incoming miscellaneous plutonium materials

are assayed with NDA equipment, either at the PFP or at their source. This provides not only an accountability check, but also a check for criticality safety inventory control.

6.2.3.2.2 Radiological Safety. The requirements of the radiological control program are established in HSRCM-1, *Hanford Site Radiological Control Manual* (DOE 1994). Exposure to radiation is controlled to as low as reasonably achievable (ALARA) standards. Specific actions taken to achieve this include the following:

- Radiation surveys of all incoming shipments of plutonium are performed to ensure that the materials are contained
- Radiation surveys of workstations and areas are performed to detect releases of plutonium and to assess radiation levels
- Shielding is provided at work locations as needed.

At the PFP, personnel exposure is administratively controlled to 500 mrem/yr, although higher exposures (5 rem/yr) are permitted by U.S. Department of Energy (DOE) regulations. Lead shielding, water walls, or Lexan™ plastic are used to reduce exposure. Shielding is strategically located so that the average exposure rate at workstations is approximately 0.5 mrem/h. See Chapter 8.0, Section 8.3 for more details.

Internal deposition of plutonium and other transuranic (TRU) radioisotopes is of particular concern. Internal deposition of plutonium (and other radioisotopes) can occur through injection via cuts, through inhalation of airborne particulates, and (more uncommonly) through ingestion. Actions taken to reduce the probability of internal deposition include the following:

- Opening containers with plutonium solutions only in designated hoods and gloveboxes
- Ensuring that operation is shut down if negative pressure is 0.3 in. w.g. or less (glovebox negative pressure relative to room pressure must normally be more negative than the 0.5 in. w.g. alarm setting)
- Ensuring that operation is shut down if pressure drop across high-efficiency particulate air (HEPA) filters reaches 4 in. w.g. or higher (pressure drop across HEPA filters must normally be less than 3 in. w.g.)
- Replacing failed glovebox gloves before starting or continuing inspection or repackaging of plutonium-bearing material
- Using leather gloves over rubber gloves when handling some plutonium-bearing materials
- Inspecting and changing out gloves on a prescribed frequency
- Training personnel to use special care when handling material that could have sharp edges, or working in the vicinity of equipment having sharp edges

- Carefully inspecting containers for bulging or other indications of internal pressure buildup

- Using respiratory protection when handling containers suspected of holding reactive material or having internal pressure, or opening solution containers in room 227

- Using vacuum transfer of solutions whenever possible.

Continuous air monitors (CAMs) are provided to monitor breathing air in occupied areas where a person without respiratory protection is likely to be exposed to a concentration of radioactive materials in the air exceeding 1 derived air concentration (DAC) over a prolonged period of time or where there is a need to alert potentially exposed workers to significant increases in the level of airborne radioactive material levels, which could result in 40 DAC-hours in a typical work shift. Portable CAMs are used when working in a greenhouse or other areas not adequately covered by a CAM. The CAMs alarm locally, with both audible and visual alarms. Personnel are required to immediately evacuate a room when a CAM alarms. Air-purifying respirators are available, if needed.

6.2.3.2.3 Industrial Safety.

Fire. The requirements of the fire protection program are established in *Fire Protection Program Overview, Fire Protection Policy Statement* and *Responsibilities* (HNF-PRO-340, HNF-PRO-341, and HNF-PRO-342, respectively). The amount of combustible material in a glovebox is administratively controlled to the minimum required for the operation. Plastic bagout material around cans is removed and placed at least 1 ft from containers and metal buttons, and are moved from the glovebox before an additional button or container is brought into the glovebox.

The glovebox in the 2736-ZB Building is equipped with combustion and/or heat detectors. The glovebox is equipped with sand (MgO) and Halon fire extinguishers. The operator is trained to take action to extinguish small fires. The fire department responds whenever a fire alarm is sounded.

Glovebox panels where fires could occur are fabricated of metal/glass construction or of fire-resistant plastics such as Lexan™. Glovebox gloves are made of fire-resistant neoprene. The gloves are normally tied off outside the glovebox.

Personnel Injury. The requirements of the personnel safety program are established in *Integrated Environment, Safety and Health Management System Plan*, HNF-MP-003. Sharp objects or heavy equipment can cause personnel injuries. Operators are required to use leather gloves over the neoprene gloves when unloading miscellaneous solid materials from containers. Operators are trained to use care when working near sharp objects or using tools that could cut or pinch their hands or arms. Hoists are used to remove heavy PR inner containers when unloading solutions. Bulged containers that could generate missiles when opened are carefully punctured with appropriate tools before the lids are removed.

Appropriate equipment is used when moving shipping or storage containers. This includes use of PR can carts, L-10 carts, and drum/barrel carts. Hoists and pulleys are used to move heavy containers from carts onto shipping pallets, etc.

6.2.4 Chemical Process Systems

There are no chemical process systems associated with plutonium material shipping/receiving.

6.2.5 Process Support Systems

6.2.5.1 Instrumentation. This section describes the instrumentation systems common to all process systems and those specifically supporting plutonium material shipping and receiving. A listing of process instruments and their function, location, and calibration information is provided in the Preventative Maintenance and Surveillance (PM&S) system. The PM&S is a computer program for instrumentation calibration and preventative maintenance (PM) programs.

Common to all process systems are CAMs and the criticality alarm system (CAS). Chapter 8.0 Section 8.3.4 describes the CAS, and the CAMs are described in Section 8.3.5. The CAMs are required in all areas where there is a possibility of airborne radioactivity. The CAS is required to cover all areas where at least a minimum critical mass of plutonium could exist, unless criticality is precluded by fissile material physical form or distribution (as determined by an approved safety analysis).

General area radiation detectors and alarms are not provided. A general area radiation level detector and alarm system is not cost effective due to relatively low workplace dose rates and processes that do not create rapidly changing radiation levels. RCTs establish dose rates in work areas during routine and special surveys.

The primary instrumentation systems required for plutonium material shipping and receiving are to ensure personnel safety, accountability, safe condition of material, and security. Instrumentation systems for the handling processes are general safety class instruments, which are common to most of the PFP facilities (CAM, CAS, fire detection).

The LI/LO process of plutonium nitrate solutions from PR cans in the 234-5Z Building, room 227, has alarms for several parameters. The alarms include, the NO_x monitor, chemical addition tank high level, vacuum trap liquid detection, the glovebox HC-227S sump probe changes in HC-2275 Vacuum (trap liquid detection or sump). The trap and sump liquid levels can be visually boserved by an operator.

Containers of plutonium material are inspected, both visually and with radiation detecting instruments, to ensure proper exterior conditions exist before an NDA can be performed. An NDA of these containers determines the total mass of isotopes by measuring the radioactive emissions and/or the heat output of each package. The NDA Laboratory equipment is discussed in

Section 6.5.1.1.4. Data from this equipment provides the information needed for accountability of SNM.

6.2.5.2 Repackaging. Containers that have either failed or have been damaged are repackaged. Repackaging activities occur primarily in the 2736-ZB Building, room 636, and include the following steps:

- Transfer of the suspect package to the repackaging glovebox
- Opening of the container
- Extraction of the contents
- Disposal of failed containers
- Evaluation of the plutonium material (inspection of contents for signs of moisture, excessive heat, consistency with label), taking corrective actions as necessary
- Placement in new inner containers
- Sealing of inner container and verification of seal
- Bagging of sealed inner container out of the glovebox, and survey
- Addition of final containment (normally two more cans)
- Sealing of outer cans, and verification of seals
- Return of the package to storage, after NDA.

Glovebox 235-B2 in room 235-C is used to repackage large containers that do not fit into the other gloveboxes.

6.2.5.2.1 Plutonium-Bearing Materials. Plutonium-bearing materials are divided into three categories. Stable/Shippable Plutonium-Bearing Materials are plutonium-bearing materials that have well-defined characteristics and are safe for shipment. Reactive Plutonium-Bearing Materials are plutonium-bearing materials that are known to generate gas sufficient to pressurize the packages. Potentially Unstable Plutonium-Bearing Materials are plutonium-bearing materials that are insufficiently characterized to place them in either of the previous two categories.

The plutonium-bearing materials are either generated at the PFP, received from other onsite contractors, or received from offsite generators. They are typically packaged in "lard cans" (shown in Figure 6-6), contained in "A" bird cages (shown in Figure 6-7). These are staged in rooms 192-B and 192-C, and vault 174. Shipments of FFTF fuel arrive at the 234-5Z Building in Radial Reflector Shipping Containers and Model 60 shipping containers (shown in Figure 6-8 and 6-9, respectively). The driver fuel assemblies and fuel pins transported in these shipping containers are stored in their shipping containers in vault 192-A. Liquid plutonium-bearing materials are shipped/received only from onsite facilities in approved containers. The

adequacy of the containers for onsite/offsite shipment, and the shipping requirements, are addressed by specific safety analysis reports for packaging.

Containers (see Figure 6-10) that have failed or have been damaged are repackaged. Only stable/shippable plutonium-bearing materials are repackaged in the 2736-ZB Building. Repackaging/stabilization of potentially unstable plutonium-bearing materials takes place in the 234-5Z Building in rooms 228-C, 230-A,230-B, and 235-B.

Current plutonium-handling operations at the PFP are directed toward shipping and receiving stable/shippable materials and maintaining the inventory of reactive and potentially unstable plutonium-bearing materials in a safe condition until they can be stabilized. The stabilization of reactive plutonium-bearing materials as well as Pu-bearing solution stabilization constitute the primary plutonium-processing operations. The stabilized materials are repackaged for storage or shipment.

Plutonium-bearing material repackaging (recanning) is instituted if there is a gain or loss in gross package weight, a package is damaged, an improper or questionable container is identified, package contents are not well characterized, or management deems it to be appropriate.

Repackaging activities for plutonium-bearing material include prerequisites specified by operating procedures for criticality, radiological, and Safety and Quality Assurance.

6.2.5.2.2 Plutonium-Beryllium Sources. Plutonium-beryllium sources are brought to the repackaging glovebox in room 636 for repackaging. The source containers (type 3-L) are opened and, the sources are withdrawn and the serial number of each source verified using remote handling devices. After repackaging, they are transferred to shipping containers (see Figures 6-11 and 6-12) for radiation survey and shipment.

6.2.5.2.3 Plutonium Metal and Oxide. Packages in storage in the 2736-Z Building are normally in "shippable form." However, the shipping of plutonium metal requires that they be inspected and any loose oxide removed prior to repackaging for shipping. Should this activity be performed, the selected package would be transferred from storage to the 2736-ZB Building, room 636. Repackaging activities would include removing the metal from the old cans, preparing the metal for repackaging, resealing the clean metal in a tuna fish can, verifying the seal, and decontaminating the can. The last three steps would be repeated for the second and third containers (cans). The package would be placed in a shipping cask, inspected, and sealed. The casks would then be moved out of the building to the loading dock (2736-ZC) packed in cargo restraint transporters, placed in a SST, and secured for shipment.

6.2.6 Control Rooms and Control Areas

There are no control rooms or control areas associated with plutonium material shipping/receiving.

6.2.7 Analytical Sampling

Analytical sampling of plutonium-bearing materials may be required for packages with contents that are not well characterized. The sampling of plutonium-bearing material and oxide in gloveboxes is done by following specific steps outlined in an operating procedure. The procedure provides instructions for weighing, bottling, and transporting samples to the laboratories. Instructions for reweighing and/or recanning of the material after sampling are also contained in operating procedures.

6.2.8 Product Handling

Product handling is addressed in Sections 6.2.1 and 6.2.3.

6.2.9 Identification of Items for Safety Analysis

6.2.9.1 Criticality Prevention. The criticality safety evaluation (CSE) analyzes the handling of fissionable materials under normal and credible abnormal conditions, and establishes the limits, controls, and engineered features necessary to ensure that an acceptable margin of subcriticality is maintained. Principal design guidance for the CSE is described in Chapter 4, Section 4.4.4.

Consistent with the requirements of DOE Order 5480.24, *Nuclear Criticality Safety*, the CSC is primarily provided by some combination of: (1) limiting the dimensions of plutonium-containing process components and containers used to transport and store plutonium (geometry controls); (2) limiting the mass of fissionable material per workstation; (3) spacing of fissionable units at workstations, including in-process storage arrays; and (4) limiting moderating materials.

The design of processes and equipment uses the most positive practical method to prevent a criticality accident. The following methods are listed in order of decreasing safety assurance: geometrically safe equipment; geometrically favorable equipment; fixed poisons; nuclear blanks; instrumentation; soluble poisons; and administrative controls. Deviations from this guidance must be justified with clear technical reasoning, particularly if administrative controls are proposed. Criticality safety limits (SLs) for workstations are posted before loading plutonium into the gloveboxes.

6.2.9.1.1 Double Contingency Principle. The process design is analyzed for possible abnormal events to ensure that at least two unlikely, independent and concurrent errors, accidents, or equipment malfunctions would have to occur before a criticality is possible (the double contingency principle). A new process or change to an existing process is analyzed, before startup.

In stating the double contingency principle, "unlikely" means not expected to occur in the lifetime of the facility. For example, a major fire in a process facility is unlikely. While a fire could occur, a major fire is not expected; it is expected that the facility will be decommissioned in a planned and orderly way. Therefore, a major fire meets the definition of an

unlikely event. Events that are unusual or abnormal, but do not meet the test of an "unlikely" event, are not considered contingencies. They are analyzed as part of the base ("normal") condition, or as part of a single contingency based on multiple errors.

The term "independent" means that there is no common mode or common cause for the two events. For example, a fire and the actions of the fire department in response to that fire are interrelated. For criticality safety purposes, the action and reaction are one event.

The term "concurrent" means at the same time and place. For criticality to be possible, the second event must occur before the first event is discovered and corrected. The double contingency principle states that two contingencies must occur "before criticality is possible." This means that no one error, accident, or equipment malfunction will make the system critical. It does not mean that only two controls are applied. To meet the double contingency principle, appropriate controls must be applied to guard against all credible errors, accidents, and equipment malfunctions. The principle also states that the second error, accident, or equipment malfunction must be as serious and as unlikely as the first. The two events must both be unlikely, must independently occur at the same place, and the second must occur before the first is discovered and corrected.

Prevention of "errors, accidents, and equipment malfunctions" is the subject of many safety program elements. Operators receive extensive formal and on-the-job training. Written procedures, reviews, prejob planning meetings, and double or triple checks of work are used to prevent errors. The NDA programs and material balance programs are used to prevent the buildup of fissionable material in an unexpected place. Regular safety meetings are conducted to maintain a high degree of safety awareness. An extensive PM program is used to prevent equipment malfunction. Operators inspect their workstations often to ensure that work is within specified limits. Managers, as well as facility management, the Criticality Safety Representative (CSR), the Nuclear Safety Representative, and multi-disciplinary teams of safety specialists also perform inspections. Representatives of the DOE, from both the U.S. Department of Energy-Richland Operations Office (DOE-RL) and U.S. Department of Energy-Headquarters Office (DOE-HQ) in Washington, D.C., perform inspections of the workplace. In spite of all these efforts, however, the safety program assumes that people make mistakes, accidents occur, and equipment fails. The safety margins have been established so that the system remains subcritical by a comfortable margin for any possible event.

6.2.9.1.2 Criticality Safety Evaluations. The CSEs are performed by criticality safety engineers on all operations involving significant quantities of fissionable material. The criticality safety engineer works with the process engineer and operations to determine the worst possible normal operating conditions, and to identify any accidents that might occur. The accidents are severe enough to meet the description of "unlikely events" given above.

The criticality safety engineer compares normal operations and accident scenarios to known critical systems, based on critical mass experiments performed in critical mass laboratories around the world. The engineer may model normal operations and accident scenarios using computer codes or other

calculational techniques which have been determined to be accurate by comparison to critical mass experiments. Any normal or accident condition must be shown to be subcritical, with a comfortable margin of safety.

The work performed by one criticality safety engineer is documented in Criticality Safety Evaluation Reports and is always verified by at least one other criticality safety engineer. If the work is complicated, the second engineer recalculates some or all of the results using a different method to verify the results.

The engineer then selects operating limits that provide large safety margins between normal operations and any of the accident scenarios that were evaluated. Actual violation of the limits most likely will be less severe than the events defined by the contingency analysis (for example, a partial overbatch instead of a double batch). Therefore, a criticality safety "limit infraction" is distinct from a contingency.

To meet the double contingency principle, it may be necessary to establish limits and controls on any or all of the following, as appropriate:

- Fissile and fissionable material
- Neutron moderation
- Neutron interaction
- Neutron reflection
- Concentration
- Density
- Geometry
- Heterogeneity
- Neutron absorbers.

The proposed operating limits are reviewed by the operations organization to ensure that the limits will be practical to implement. The list of control features above demonstrates that there are many possible control points, and different combinations of limits can be applied to achieve the same safety margin. The criticality engineer works with the operating groups to ensure that the features selected will not only provide the required safety margins, but will be practical to apply. If a limit is not practical, another control feature or set of features can be evaluated, maintaining the margin of safety.

The limits are documented in CPSs, incorporated into operating procedures, and summarized in postings placed in the work area. The CSR provides interpretations of the CPS and reviews procedures and postings as discussed in Chapter 10.0.

Criticality Safety Evaluation for Shipping and Receiving. Analytical methods normally rely extensively on the DOE or Nuclear Regulatory Commission (NRC) COC for the subject shipping container, or the U.S. Department of Transportation (DOT) shipping container approval documents. The DOT limits on materials received require that all shipments be subcritical, even if completely submerged in water.

In addition, mechanical engineering analyses may be requested, or special Monte Carlo criticality calculations performed, to evaluate specific situations to ensure that the double contingency principle will be met.

Qualified contractors selected by PFP perform the criticality calculations. The contractor has personnel which are qualified and documented as having met appropriate DOE and industry standards. The PFP administration manual and training manual contain requirements that ensure those qualified suppliers and personnel are used to perform criticality analysis and manage these activities. The following are examples of situations that may be evaluated:

- Loss of container contents to the ground
- Variation of array size
- Water leakage into the space between the containment vessel and outer package
- Leakage from the containment vessel, where the leakage is moderated by water
- Close water reflection
- Interspersed water moderation
- Density or concentration changes in the fissionable material.

These cases consider undamaged or damaged arrays, as appropriate. Analytical methods include the use of well-referenced data or Monte Carlo calculations.

Implementation of Criticality Safety for Shipping and Receiving. The DOT labeling regulations provide package content identification of items received from offsite. Onsite transfers require equally precise identification. Upon receipt, NDA measurements assist in the confirmation of the fissionable content of these shipments.

Placement into storage is required and verified as part of the administrative control of the facility. Damaged containers are normally returned for repackaging.

Appropriate limits are placed on container content and packaging method, the number of containers that may be shipped, how many may be stacked, and spacing with other fissionable material. Specific safety features of the packaging and shipping process are described in Section 6.2.3.2.1.

During onsite transport, the probability of having an accident severe enough to rearrange the fissionable material are extremely small. However, the following administrative controls are applied, as required, to minimize the possibility of a vehicular accident with criticality safety significance:

- Limiting truck speed
- Use of additional traffic control, preferably convoy operation that requires vehicles ahead and behind the transporting truck. (This has the advantage of having speed controlled by both the lead vehicle and by the transporting truck. In addition, the vehicles ahead and behind provide anti-collision barriers. The lead vehicle

may also be instructed to stop the convoy if an approaching vehicle is sighted at an intersection on the route where the transporting truck would be vulnerable to a side collision. This provides many of the advantages of blocking roads, without the disadvantages.)

- Use of an overpack that meets DOE requirements
- Limiting the number of containers on the truck
- Requiring vehicle inspection to verify that it is in proper operating condition
- Requiring a second employee to accompany the driver, to provide backup traffic warning and emergency response.

Offsite transport control is provided by the DOE.

6.2.9.2 Chemical Safety. Two operators are required when handling hazardous chemicals. Chemical safety showers, sinks, and eyewash stations are available in the event of chemical exposure. Spills/leaks are cleaned up before continuing with chemical transfers, equipment is repaired as necessary, and operating procedures are in place for all chemical handling [e.g., acquisition, use, storage, disposition (see Section 10.4.5)].

6.2.9.2.1 Nitric Acid. Nitric acid (HNO_3) is used in LI/LO of plutonium nitrate solutions. Concentrated HNO_3 (57% HNO_3) was provided from the 7,000-gallon acid storage tank outside and east of the 234-5Z Building. The inventory of HNO_3 in the PFP was reduced by removing excess HNO_3 from the tank during fiscal year 1996. Any future need for concentrated HNO_3 would be met by purchasing HNO_3 in 55-gallon drums. Tank C located in room 336 of the 234-5Z Building stores concentrated HNO_3. Acid from tank C is pumped to tanks G-1 and G-2 (also in room 336) for production of a dilute HNO_3 solution. This dilute HNO_3 is piped by gravity drain to glovebox HC-227S for use as a flush solution. Since it can cause severe burns to the skin and/or eyes, operators are required to wear eye goggles, full-face shields, acid suits, and rubber gloves when transferring the acid. Emergency response materials are provided to neutralize small spills.

6.2.9.2.2 Potassium Hydroxide. Potassium hydroxide (KOH) is used to neutralize spills of acidic solutions. Since it is a strong base and can cause severe burns to the skin, operators are required to use protective equipment in accordance with the work plan and procedures. If the material is spilled, the operators must put on full-face air-purifying respirators. Large spills are pumped into plastic drums (DOT-34) and diatomaceous earth is used to absorb small spills.

6.2.9.3 Process Shutdown Modes. Emergency shutdown of glovebox equipment can be accomplished in several seconds by shutting off power to the gloveboxes. Short-term shutdown (one day to several weeks) of the 2736-Z Support/Storage Complex operation involves placing plutonium in safe storage. This can be accomplished in an hour or less, depending on the number of packages involved and if any contain reactive materials that would need to be moved to gloveboxes in the 234-5Z Building. Normal surveillance would continue, including verification to ensure that proper ventilation of gloveboxes is

maintained with negative pressure at or below -0.5 in. w.g., pressure drop across filters is less than 3 in. w.g., and radiation surveys.

Long-term shutdown (years) is not an option until all of the plutonium has been moved out of the PFP. This option would involve packaging and shipping all plutonium out of the PFP, either offsite or to a new facility at Hanford. It would take months to accomplish a full cleanout. Surveillance requirements would be minimal, primarily ensuring ventilation is adequate for areas containing residual plutonium, and performing area radiation surveys until decontamination and decommissioning (D&D) of the facility is completed. Additional information on facility shutdown and cleanout activities is provided in Section 6.7.

6.2.9.4 Instrumentation. There is no instrumentation associated with SMN shipping/receiving that requires identification for safety analysis purposes.

6.2.9.5 Remote and Contact Maintenance. There is no remote or contact maintenance associated with plutonium material shipping/receiving that requires identification for safety analysis purposes.

6.3 PLUTONIUM MATERIAL STORAGE

6.3.1 Process Description

6.3.1.1 Narrative Description. As discussed in Section 6.2.5.2.1, plutonium-bearing material is categorized as stable/shippable material, reactive material (generates gas), and potentially unstable material. The stable/shippable material category includes plutonium metal, PuO_2, spent nuclear fuel, and unirradiated nuclear fuel. The reactive material includes plutonium nitrate solutions. Potentially unstable material needs additional identification for categorization as either stable or reactive material.

The stable/shippable materials, such as plutonium metal and PuO_2, are stored in the 2736-Z Building vaults (1 through 4). The cans containing plutonium material are stored on pedestals inside cubicles. The concrete walls of the cubicles isolate the plutonium material from neutron interaction with material stored in other cubicles. Thermal loading for the cans of material in storage is limited to 15 W each, at the time of storage. The heat output is determined by calculations based on isotopic analytical data and weight of the material. The amount of plutonium in a can is reduced if it generates more than 15 W.

Spent nuclear fuel and unirradiated fuel are stored at the PFP in a stable/shippable form. Spent nuclear fuel is contained in three Experimental Breeder Reactor (EBR)-II storage casks [as described in WHC-SD-RE-SAP-054, *Safety Analysis Report for Packaging 21PF-1 Overpack/EBR-II Spent Fuels Storage Cask System for Transport* (WHC 1994b)]. The casks are stored in the 2736-ZD facility (refer to Chapter 5.0, Section 5.2.8.5, for a description of the 2736-ZD facility). The EBR-II casks were relocated from a Hanford Site solid waste management burial ground to the 2736-ZD facility to utilize security measures in place at the PFP, and to comply with DOE Order 5632.1C, *Protection and Control of Safeguards and Security Interests*.

The EBR-II containers are constructed of carbon steel and utilize 5 in. of poured lead for shielding. The payloads of irradiated metal fuel are within guide tubes which are doubly encapsulated in 10.2 cm (4 in.) and 12.7 cm (5 in.) diameter, schedule 40, stainless steel pipe which is welded shut and leak tested. These are placed in the 6-inch diameter central cavity of the cask. The cask is closed and sealed with a gasketed cover plate. All necessary shielding and containment is provided by the casks themselves. Details on the cask, including precise dimensions and material specifications for the containment vessels, are found in *Hazard Class and Facility-Use Determination for Irradiated Fuel Storage in EBR-II Casks in the 200 West Area* (Van Fleet 1989). References for analysis of the EBR-II Cask system performed in 1979 and 1980 are provided in *Safety Analysis Report for Packaging 21PF-1 Overpack/EBR-II Spent Fuel Storage Cask System for Transport*, (WHC 1994b).

The material within the EBR-II casks is metallic reactor fuel from the Los Alamos Molten Plutonium Rector Experiment (LAMPRE). It is further described in WHC-SD-SQA-CSA-20381, *CSER 94-014; Storage of Metal-Fuel Loaded EBR-II Casks in Concrete Vault on PFP Grounds* (Hess 1994). No cooling mechanisms are required for the fuel in the casks.

Unirradiated FFTF fuel is temporarily stored in vault 192-A. It consists of Driver Fuel Assemblies (DFAs) stored in Radial Reflector Shipping Containers (RRSCs), and fuel pins stored in Model 60 shipping containers. No cooling mechanisms are required for the fuel stored in these containers.

Each RRSC contains four DFAs. Each DFA contains 217 fuel pins (fuel pin bundle assembly). The fuel composition of each DFA pin is a pelletized and sintered mixture of plutonium and uranium oxide sheathed in stainless steel cladding. A maximum of seven RRSCs can be stored in vault 192-A.

There are 4,997 additional fuel pins that contain fissile material such as plutonium oxide, uranium oxide, plutonium metal, carbide compounds, and thorium oxide. These fuel pins are contained in 68 Model 60 shipping containers. One Model 60 shipping container can hold a maximum of 120 fuel pins. A maximum of 70 Model 60 shipping containers can be stored in vault 192-A. The Model 60 shipping containers have security seals for easy verification that no shipping container has been opened. All 10,205 fuel pins currently being stored are chemically stable and designed for use in high temperature environments.

Unless the fuel pins contained in the Model 60 shipping containers are being inspected for accountability reasons, all fuel pins remain in their shipping containers during storage in vault 192-A. The RRSCs will never be opened while being stored in vault 192-A. The design and analysis of the two shipping containers is provided in *Safety Analysis Report for Packaging, Radial Reflector Shipping Containers* (Carlstrom 1990), and *Model 60 Shipping Container Safety Analysis Report for Packaging* (Ferrell 1990).

The packaging of fissile material and the storage of the material within the seismically qualified restraint system of vault 192-A prevent its release to the environment under all credible accident conditions, including natural hazards. The seismic and design basis wind evaluations of vault 192-A, room 192-B, and room 192-C are given in *Natural Hazards Evaluations (Seismic and Design Basis Wind) for PFP Vaults 192-A, B, and C* (Baxter 1991). *Test Report*

for Modified Compression Test of Model 60 Shipping Container (Barlow 1991) shows that the Model 60 shipping containers are structurally adequate for stacking seven high. The criticality analysis is documented in *Relocation of Fuel Pins and Assemblies from 308 Building to PFP* (Hess 1991). *Calculations for Project C-125, Modification for Storage of FFTF Fuel* (KEH 1991) provides the calculations and design for the restraint structure and devices used to prevent the shipping containers in vault 192-A from moving during a design basis seismic event.

Reactive plutonium-bearing materials are moved to an active glovebox in the 234-5Z Building for interim storage (see Section 6.4.2). The material is confined within a ventilated control barrier until it can be processed to a stable form.

Plutonium nitrate [$Pu(NO_3)_4$] solutions are stored in PR cans, 3 liter polyethylene bottles, and 10 liter polyethylene bottles that are specifically vented to prevent pressurization. The PR, 10-L, L-10, and FL-10-1 containers are shipping containers that are also used for long-term vault storage. The PR container is a stainless steel drum encasing a PR can which can hold 10 liters (controlled to 8.5 liters) of $Pu(NO_3)_4$. The PR can is held in place by a rack inside of the PR container. PR containers are also used as storage containers for 3 liter polyethylene bottles of $Pu(NO_3)_4$. The PR can is removed from the PR container and a 6 inch diameter metal sleeve is inserted to position and support the 3 liter polyethylene bottle. The 10-L, L-10, and FL-10-1 containers consist of pairs of stainless steel drums that have been joined end to end. These drums each encase a cylindrical pipe, which in turn secures a 10 liter polyethylene bottle (controlled to 8.5 liters) of $Pu(NO_3)_4$. The 10-L container has no space-filling material, two holes in the lid for pressure relief (each packed with angel-hair), and a pair of I-beams welded on the base. The L-10 container has vermiculite space filling material, Schedule 80 pipe, a single gasket for sealing the lid, and a needle valve for pressure relief. The FL-10-1 container has molded phenolic foam space filling material, Schedule 40 pipe, two concentric gaskets for sealing the lid, and a needle valve for pressure relief. Other than the differences noted above, the 10-L, L-10, and FL-10-1 containers are identical.

Potentially unstable plutonium-bearing material is inspected in the 2736-ZB Building, and the source data is reviewed to determine whether it should be handled as reactive or stable/shippable material.

6.3.1.2 Flowsheets. The overall schematic flow diagram for dry SNM material handling at the PFP is shown in Figure 6-1.

6.3.2 Process Chemistry and Physical Chemical Principles

The radiolytic decomposition of hydrogenous material generates hydrogen gas. Alpha decay produces helium gas. The decomposition of organic compounds also evolves gas. The pressure of an unvented container will increase as these processes occur. In addition some of the decomposition products are corrosive. If sufficient gas is generated the container will fail.

Energy is released as material undergoes radioactive decay. Plutonium-bearing material which is low in ^{240}Pu (less than 7 weight percent) has a heat

generation rate of 2.5 W/kg. Plutonium-bearing material which is high in ^{240}Pu (more than 16 weight percent) has a heat generation rate of 6 W/kg. Irradiated nuclear fuel continues to generate heat from fission product decay even after the fuel is removed from the reactor. The rate at which energy is released affects the strength of the storage container. If the decay heat generation rate is greater than the rate at which the container can dissipate heat then the temperature of the container will increase. The material properties of the container degrade as the temperature increases. Limits on thermal loadings for storage containers are established to ensure container integrity is maintained.

6.3.3 Mechanical Process Systems

6.3.3.1 Functional Description. Storage specifications for plutonium material require complete identification, packaging information, shipping information, and receiving approvals before placement. The thermal loading of containers when first placed in storage, is limited to 15 W (does not apply the EBR-II or FFTF fuel containers). The decay heat generated by the LAMPRE fuel is conservatively estimated at less than 15 W per cask, well within the limit of 300 W per cask. The 2736-ZD facility can hold up to 7 EBR-II casks. The content of each EBR-II cask is limited to 4,000 g of total dry fissile material. The Model 60 shipping containers are structurally adequate for stacking seven high.

Containers are inspected for corrosion, dents, penetrations, and faulty seams or seals before being placed into storage. Containers holding solid plutonium material (not including the EBR-II casks or the FFTF fuel containers) are inspected monthly for bulging and corrosion. Containers that do not meet any of the above specifications are repackaged.

Extraordinary precautions are taken in the handling and storage of SNM because of its unique properties. Varying quantities of plutonium metal, PuO_2, plutonium compounds, recoverable plutonium-bearing material, salts, and unirradiated reactor fuel are stored in vault and "vault type" rooms at the 234-5Z, 2736-Z, and 2736-ZB Buildings. Also, drums containing TRU waste are temporarily stored. The areas for storage of plutonium material are shown in Table 6-4.

Storage specifications address material not allowed in storage, loss-on-ignition (LOI), enclosure requirements, use of plastics, food pack cans, and thermal loading.

Materials not allowed in storage includes liquid or damp materials of any kind, materials that may easily generate gases, corrosive salts and other materials that react with iron, and plutonium metal pieces with radiolytically sensitive material present (such as fabricating oil).

Materials may be stored or shipped if an LOI analysis of a sample is favorable. The LOI analysis involves heating a sample for a period of time and measuring the change in the mass of the sample. The allowable change in mass, and other specific requirements of the analysis are presented in OSD-Z-184-00013, *Special Nuclear Material Storage* (WHC 1995a).

Materials in storage are contained in a minimum of two (one container sealed inside the other) contamination-free, mechanically sealed containers (food pack cans) (refer to Figure 6-10).

No plastic comes in direct contact with stored SNM except for polystyrene cubes. Polyethylene (6 mil thick) is used to seal inner containers. PVC plastic (12 mil thick) may be used for material with a heat-generation rate of less than 3 W per container.

Specifications for food pack cans require that the can (and lid) be a commercially available, double-seam can of steel construction. The can (and lid) is tin coated on the inside and outside, and the inner surface may be further coated with phenolic or epoxy. Can-sealing gaskets are of synthetic rubber, and side seams, if present, are either welded or soldered.

The thermal loading of containers being stored for the first time does not exceed 15 W decay heat. LOI, process parameter, storage container, wattage, and/or enclosure requirements may be waived, after technical bases demonstrating an acceptable level of risk are prepared by PFP Process Engineering, and approved by appropriate PFP management.

6.3.3.1.1 Reactive Plutonium-Bearing Material Storage. Reactive plutonium-bearing materials are temporarily stored in active gloveboxes in the 234-5Z Building until they can be stabilized. Any active glovebox can be used for temporary storage, including those containing inactive process equipment. In Chapter 5.0, Table 5-5 provides a listing of active and inactive gloveboxes at the time of the preparation of the FSAR. The current listing of active and inactive gloveboxes is provided in WHC-SD-CP-OSR-010, *Plutonium Finishing Plant Operational Safety Requirements*.

Reactive plutonium-bearing materials are placed in polyjars (polypropylene or polyethylene), which serve as primary containers. The quantity of material in each container, and the position of the container in the glovebox, is administratively controlled to ensure criticality safety. Each glovebox is maintained at a negative pressure with respect to the surrounding room, and is equipped with combustion and/or heat-sensing devices and alarms.

6.3.3.1.2 2736-Z Support/Storage Complex. Storage specifications require complete information on material identification, packaging, shipping, and receiving approvals. Containers are inspected for corrosion, rusting, dents, penetrations, and faulty seams or seals before receiving approval for storage in Building 2736-Z. Containers that do not meet specifications are repackaged. During storage, containers are visually inspected on a monthly basis for abnormal conditions such as bulging. A straight edge is placed across the top of each container to check for pressurization.

Vault 3 contains plutonium material which is monitored by the International Atomic Energy Agency (IAEA). IAEA personnel review video tapes from eight video cameras which are located in vault 3, and inspect the security seals on the SNM containers once per month. The containers are randomly sampled (by IAEA personnel) once per year to verify the contents (see Section 6.3.7). The samples are sent to Vienna, Austria, for analysis. Room

642 of Building 2736-ZB is used by the IAEA to support their monitoring activities.

6.3.3.2 Safety Features. The safety features addressed in Section 6.2.3.2 are also applicable to plutonium material storage.

6.3.4 Chemical Process Systems

There are no chemical process systems associated with plutonium material storage.

6.3.5 Instrumentation and Control Systems

This section describes the instrumentation systems supporting plutonium material storage. The primary purpose of the instrumentation systems required for plutonium material storage are to ensure personnel safety, accountability, safe condition of materials, and security. Instrumentation systems for the handling processes are associated with general safety class instruments, which are common to most of the PFP facilities (CAM, CAS, fire detection).

A vault safety and inventory system is installed in vaults 1, 2, 3, and 4 of the 2736-Z Building. This system monitors container temperature, ambient air temperature, dimensional changes of the container, container presence, and container identification number. Data processing equipment located in the 2736-Z Building log and process the information received from the container monitors. Vault inventory system anomalies are annunciated in rooms 104 and 306A of the 234-5Z Building.

Temperature detectors (thermocouples) are provided above each cubicle in the 2736-Z Building vaults. Temperature detectors are also provided in the exhaust plenum for each room. Temperature readout devices for the 2736-Z Building are located in Building 2736-ZA. The maximum temperature difference allowed between the inlet and outlet air temperature of each cubicle is 70 °F. The facility manager is contacted if the temperature difference is greater than 25 °F (per the Operating Specifications), the outlet temperature is higher than 140 °F, or the display flashes (indicating that there is an open circuit).

6.3.6 Control Rooms and Control Areas

There are no control rooms or control areas associated with plutonium material storage.

6.3.7 Analytical Sampling

The IAEA requires preparation of sample-sized quantities of plutonium-bearing powders, which is performed with an approved operating procedure. The procedure provides instructions for sampling, mixing, splitting, weighing, and bottling samples. The loading of sample bottles into air-transportable shipping containers is covered by a separate operating procedure, and

instructions for reweighing and/or recanning of the material after sampling are contained in additional operating procedures.

6.3.8 Product Handling

Product handling is addressed in Sections 6.3.1 and 6.3.3.

6.3.9 Identification of Items for Safety Analysis

6.3.9.1 Criticality Prevention.

6.3.9.1.1 Criticality Safety Evaluation for Storage Facilities. A variety of analytical methods are used to evaluate storage facilities, including Monte Carlo calculations, the Surface Density versus Shape Factor Method, the use of well-referenced data, DOE or NRC COC analyses for shipping containers, and DOT shipping container approval documents.

Often the material is conservatively modeled by assuming that the ^{240}Pu content is zero, that the material is spherically shaped, or that the material is optimally moderated using plastic or water. Reflectors may be concrete, water, steel, or soil, depending on the location of the array. Various densities and hydrogen to fissile material (H/X) ratios are evaluated to determine the most reactive cases.

Abnormal conditions include the following, as they apply to the storage array:

- Water addition from a sprinkler system
- Bunching of units in pairs (organized off-centering)
- Double batching (in a single or two adjacent positions) at the center of a row
- Variations in the size, number, composition, and position of units
- Two units in place of a single unit
- Placing a container on top of a storage rack
- Spilling the contents of a shelf onto the floor
- Overstacking containers, or placing containers in the wrong location
- Filling a single unit with water between the inner package and the outer container
- Inadvertent addition of moderated unit(s) to unmoderated arrays

- Fissile solution leakage with either a dry outer drum or a water-filled outer drum which is not geometrically favorable
- Crushing of containers
- Overconcentration
- Flooding
- Making the array too large
- Units shaken out of their storage positions and scattered or heaped on the floor.

The analysis may require the use of drains, neutron absorbers, or leak-resistant containers. The effect of varying parameters that define the storage array are also explored. These parameters include the following:

- The effect of walls
- The effect of hydrogen (water) in the concrete
- The difference between staggering the storage locations and having the storage locations on the same level
- The interaction between storage locations
- The effect of thick iron around the fissile units
- The effect of opening all storage unit doors
- The effect of interspersed water fog
- The effect of reducing the concrete density by 5% to simulate voids and nonstandard thicknesses.

In addition to the storage area parameters, other parameters dealing with the fissile material itself are also studied. These parameters include the following:

- The difference between equilateral or flattened units
- The effect of ^{240}Pu in the plutonium
- The effect of positioning the units within the storage location from the centered position to the closest spacing to each other
- The effect of the number of layers, units per layer, and can size
- The effect of omitting layers versus decreasing the number per layer
- The effect of material composition on the allowed unit mass
- The effect of intermixing various types of units

- The effect of a uniform versus nonuniform distribution on each layer in tray-style storage locations

- Combinations of several of the above.

6.3.9.1.2 Implementation of Criticality Safety in Storage Facilities. Storage cubicles or locations are designed to be geometrically favorable for criticality safety. In many cases, the geometry is ensured by fixed storage locations providing well-defined reflection and interaction potential. Specific safety features are described in Section 6.2.3.2.1. As appropriate, the following limits are applied:

- Volumes of containers
- Moderation controls
- Individual unit mass limits
- Fixed spacing within the array
- Spacing of units being brought into or out of the array
- Unit density
- Total mass in the array
- Piece count controls
- Limits on the compounds or form.

Administrative controls such as "only one unit may be entered into or removed from the array at one time" may also be applied to ensure that limits are not exceeded.

Plutonium in staging areas is contained within geometrically favorable shipping containers. Reactive scrap is stored in gloveboxes, and the posted limits for the glovebox apply to quantity and spacing between containers.

6.3.9.2 Chemical Safety. There is no chemical safety associated with plutonium material storage that requires identification for safety analysis purposes.

6.3.9.3 Process Shutdown Modes. Process shutdown modes are addressed in Section 6.2.9.3.

6.3.9.4 Instrumentation. There is no instrumentation associated with plutonium material storage that requires identification for safety analysis purposes.

6.3.9.5 Remote and Contact Maintenance. There is no remote or contact maintenance associated with plutonium material storage that requires identification for safety analysis purposes.

6.4 REMOTE MECHANICAL A AND REMOTE MECHANICAL C LINE PROCESSES

6.4.1 Reactive Plutonium-bearing Material Stabilization and Plutonium-bearing Solution Stabilization Using the Production VDC.

Miscellaneous plutonium-bearing materials were produced during previous PFP operations. This inventory of plutonium material is in the form of pure

and mixed oxides, fluorides, oxalates, silicates, and organic-based sludges and residues. Reactive plutonium-bearing materials must be stabilized prior to long-term storage to prevent the formation of excessive hydrogen or nitrated organic compounds. These materials are stabilized in the RMA and RMC Lines using a thermal stabilization process which converts the material to a stable Pu oxide and assures a dry product suitable for long-time storage.

The PFP also contains significant quantities of plutonium-bearing solutions that are in a form considered unsuitable for long-term storage. These solutions primarily consist of the following:

- Product plutonium nitrate solutions
- Concentrated filtrate solutions
- Flush solutions.

As part of the PFP cleanout operations, these solutions are stabilized by conversion to plutonium oxide which is suitable for long term storage. The Production VDC process is used to stabilize the solutions by heating the material to a temperature of 1000 °C. Only the product plutonium nitrate solutions are suitable for direct stabilization using the Production VDC process. The other two solutions require pretreatment prior to processing in the VDC. Therefore, only processing of the plutonium nitrate solutions in the Production VDC are covered by the PFP FSAR. The pretreatment and processing of the other two solutions will be added in a future revision of the FSAR.

Plutonium nitrate solution stabilization operations are also performed with the Laboratory Prototype Calciner in Glovebox 188-1 in the PPSL. The Laboratory Prototype Calciner addendum to this FSAR provides a description of the equipment and processes associated with laboratory calciner operations.

6.4.1.1 Process Description - Reactive Material Stabilization and Solution Stabilization Using the Production VDC.

6.4.1.1.1 Narrative Description - Reactive Material Stabilization. Thermal stabilization of reactive Pu-bearing materials is performed in gloveboxes HC-21C and HA-21I, located in rooms 230A and 235B of Building 234-5Z (see Chapter 5.0, Section 5.2.1.2). These gloveboxes were originally used to support the plutonium conversion processes in the RMA and RMC Lines (see Section 6.4.3). Thermal stabilization consists of converting reactive plutonium-bearing materials into a stable form (Pu oxide) by heating the material to high temperatures in a furnace.

Process Feed. There are five categories of plutonium-bearing material containing less than 10 g of organic per charge which are thermally stabilized in the HC-21C muffle furnaces to meet long term storage requirements: PRF sludges from the last PRF campaign, mixed uranium and plutonium oxides (MOX), floor sweepings, plutonium oxalates, and plutonium oxide. Note that plutonium oxalate [$Pu(C_2O_4)_2$] degrades, from exposure to alpha radiation, to plutonium oxycarbonate ($PuOCO_3 \cdot 2H_2O$) with a reaction half-life of 64 days. Since the RMC Line sweepings have been in storage in excess of four years, essentially all of the plutonium oxalate has degraded to the oxycarbonate form. Plutonium oxide (PuO_2) may also be processed in the furnace with the compound simply being dried with no chemical reactions taking place. These feeds are representative of the materials processed in the furnaces in glovebox HC-21C.

The furnaces in glovebox HA-21I are used to thermally stabilize all of the categories of reactive plutonium-bearing material that are stabilized in Glovebox HC-21C except PRF sludges. Plutonium oxides consist of both "clean" and non-product quality plutonium oxides. "Clean" plutonium oxide is defined as materials containing no organic contaminants, plastic, debris or pyrophoric material whereas non-product quality plutonium oxides may contain some of these contaminants.

Stabilization. Processing operations are initiated with the selection of containers from storage. Only containers meeting the type A or B definitions shown in Figure 6-28 may be selected for processing to minimize the amount of hydrogen potentially available for reaction when opening the container. The containers of plutonium-bearing materials are sealed-in using either glovebox HC-13MD, HC-21A or conveyor glovebox HA-28, unpackaged, and loaded into a previously weighed Hastelloy X™ container referred to as a "boat." When processing "clean" plutonium oxide, the material is run through a sieve as the boat is loaded. This assures that any chunks of contaminants are removed before stabilization in the furnace. The boat is reweighed and the weights are recorded. The charge size is limited to 1.5 in. in depth in the boat and, for items other than "clean" plutonium oxide, to less than 10 g of organic content. The charge size is also limited to 2500 g Pu content for criticality control. A single boat is inspected for contaminants, placed into a furnace, and the covergas flow rate (required for PRF sludges only to limit the buildup of butene gas to less than 25% of the lower flammability limit [WHC 1996a]) and furnace offgas flow rate are adjusted as required (e.g., $\geq$ 30 scfh CO_2, 120 scfh offgas). Covergas flow is required only with PRF sludges, which are processed in glovebox HC-21C exclusively (HA-21I can't be used to process PRF sludges because it does not have cover gas available to its furnaces). For PRF sludges, the covergas is required for the heating period before the furnace reaches 300 °C on ramp-up. Offgas flow is used to ensure oxygen is drawn into the furnace and is available for combustion of impurities and removal of pyrolysis generated gases during the heating cycle. Offgas flow is maintained after the heating cycle is complete to aid in cool-down of the furnace. There are staging areas for an additional boat next to each furnace, but the maximum number of boats allowed in glovebox HC-21C is limited to two and the maximum number of boats allowed in glovebox HA-21I is limited to three.

Heating time and temperature for the furnaces in glovebox HC-21C are controlled by individual microprocessor-based controllers. These controllers are programmed to ramp the temperature to the setpoint, hold the furnace temperature at the setpoint for a specified time period, and then shut off the furnace. The furnaces located in glovebox HA-21I are operated with a Programmable Logic Controller (PLC) rather than individual controllers. Offgases generated during the stabilization process are drawn off and passed through a ceramic filter before entering a vacuum system that feeds into the E-4 ventilation system. High temperature interlocks and alarms are provided to maintain furnace temperatures below 1050 °C and glovebox temperatures below 70 °C.

Following stabilization, the furnace is allowed to cool before the exhaust flow is shut off and the furnace door is opened. The boat is removed from the furnace with a handling tool and positioned in the glovebox to cool further. When the process material reaches approximately room temperature, it

is transferred to glovebox HC-18M via conveyor glovebox HC-2 and glovebox HC-18BS when the material is processed in HC-21C. Material processed in HA-21I also utilizes HC-2/3 airlock, HC-3, HC-4 and HA-2B conveyers.

The processed material is scraped from the boat, sieved, crushed using the mortar and pestle (if necessary), sampled for loss-on-ignition (LOI) testing, and placed in a slip-lid product can for interim storage in Glovebox HC-18BS. Upon confirmation of acceptable LOI results (WHC 1995a), the product can is transferred from Glovebox HC-18BS to Glovebox HC18M or Glovebox HC-13MD and is removed from the glovebox (bagged-out) and packaged for storage. For unacceptable LOI, the product is recycled through the process.

6.4.1.1.1A Narrative Description - Plutonium-bearing Solution Stabilization Using the Production VDC. Plutonium-bearing solution stabilization using the Production VDC is performed in glovebox HC-230C-2 in room 230C of the 234-5Z Building (See Chapter 5.0, Section 5.2.1.2). Solution stabilization consists of converting plutonium nitrate solutions to plutonium oxide by processing the solutions through the Production VDC in glovebox HC-230C-2. The VDC process takes plutonium nitrate solutions, removes the liquids, destroys the nitrates, and oxidizes the solid residues at 1000 °C to render a stable plutonium oxide powder suitable for packaging and long-term storage. A process flowsheet and material balance for the VDC process is shown on Figure 6-24 and a flow diagram is shown in Figure 6-25. The equipment used in the Production VDC process for plutonium-bearing solution stabilization is described in Chapter 5.0, Section 5.2.1.2.

Product plutonium nitrate solutions suitable for calcination in the Production VDC are transferred from glovebox HC-227S through a double encased transfer line to a feed tank located in glovebox HC-230C-2 in room 230C. The nitrate solution is then pumped and mixed with an atomizing air flow into a preheated bed of plutonium oxide (PuO_2) powder in the calciner. The calciner agitates and heats the injected mixture between external and internal heaters to 1000 °C to form PuO_2. The calcination of the plutonium nitrate produces nitrogen oxides (NO_x), nitric acid gas (HNO_3), and steam.

The NO_x, HNO_3, and steam by-products from the production of plutonium oxide flow upward through the bed and out the top of the calciner using the 26-in. Hg process vacuum system as motive source. The offgases are filtered prior to exiting the calciner through ceramic filters and then bubbled through a gas scrubber system filled with caustic solution (sodium hydroxide). The scrubber is designed with an internal cooling coil, which receives chilled water from a chilled water supply unit. The acidic gases are condensed and neutralized with the sodium hydroxide and the water vapor is condensed. Non-condensable gases and partially spent caustic solution flow from the scrubber to a phase separator tank. The treated gas flow is then removed through a vacuum trap into the 26-in. Hg vacuum system. The radioactive offgas stream is filtered through two stages of HEPA filters in the 26-in. Hg vacuum system prior to discharge to the atmosphere.

The scrubber is designed to operate around 1.0 - 1.5 M NaOH. The caustic solution in the scrubber is depleted over time by the reactions with the acidic offgases which consume hydroxide and reduces the pH of the solution. The scrubber solution is continuously removed and circulated through the phase separator tank and returned to the scrubber tank to provide mixing.

Concentrated sodium hydroxide is added directly to the scrubber to maintain the desired concentration. The phase separator tank has a portion of the scrubber solution pumped to the spent scrub solution receiver tank (SSSRT) bank for disposal. The system is designed to have one SSSRT bank filling while the other bank is sampled and analyzed prior to discharge to tank TK-D8 in Building 241-Z via the PFP liquid drain lines. The liquid waste is ultimately transferred to tank farm facilities.

Product from the Production VDC process is PuO_2. The stabilized product from the Production VDC process is subjected to the same sampling, testing and packaging as described in other subsections of Section 6.4.1 for reactive material stabilization operations. The stabilized material is transferred in a slip-lid product can to Glovebox HC-18M and sampled to verify the LOI meets vault storage specifications (WHC 1995a). LOI testing is performed in the PFP Analytical Laboratory. If the LOI sample results are acceptable, the product can is bagged-out of glovebox HC-18M, placed into two more hermetically sealed cans, and the cans are transferred to the Building 2736-Z vaults for storage. If the LOI sample results are unacceptable, the material is processed through thermal stabilization (reactive material stabilization) until the LOI is acceptable and then it is packaged for long term storage.

Feed Preparation. The plutonium nitrate solution used for feed to the vertical denitration calciner is received from PR cans stored within the PFP. The PR cans contain approximately 8 to 9 L per can. The liquid is transferred via hood HC-227T in room 227 into the three batch load-in tanks in glovebox HC-227S designated BT-1, BT-2, and BT-3 (Batch Tank). Each PR can is emptied and rinsed with 2 M nitric acid. The plutonium nitrate is blended with Pu nitrate solutions from other PR cans and sampled for Pu accountability, acidity (H^+), density, organic (phases) and other characteristics as shown in Table 6-6.

Plutonium nitrate solution is then pumped in 9 to 10 L draws to the feed receipt tank in glovebox HC-230C-2 in room 230C. The solution is then gravity transferred to the feed pump tank. The feed receipt tank is refilled from the designated batch tank.

Feed Injection. Plutonium nitrate solution is gravity transferred from the feed receipt tank (FRT) into the feed pump tank (FPT). Plutonium nitrate solution is pumped from the feed pump tank to the vertical denitration calciner at a nominal flow rate of 2 to 4 L per hour at approximately 25 psi. The feed is then mixed and atomized with air from the air bottle rack located in the corridor outside room 230C at a rate of approximately 40 ft^3/h at 50 psi prior to entering the vertical calciner.

Feed Rate Limits. The feed rate to the Production VDC is limited by two operating factors:

- Plutonium throughput is restricted to about 600-700 g-Pu/h so that the product plutonium oxide residence time within the calciner is sufficient to meet the LOI specifications for SNM storage (WHC 1995a)

- To maintain an acceptable pressure drop across the offgas filters, the liquid flow rate is limited to approximately 2-4 L of feed per hour.

Calcination. The Production VDC is loaded or pre-charged with approximately 3 kg of PuO_2 and slowly preheated to approximately 1000 °C with agitation. Atomized plutonium nitrate solution is injected at a nominal rate of 2 to 4 L/h into the vertical calciner through the bottom plate once the calciner has reached 1000 °C. The plutonium oxide product drops from the top of the oxide bed into a collection vessel through an adjustable weir system within the calciner. When the collection vessel is full, the product is placed into a half-liter, lead-lined, slip-lid can. When the slip-lid can is filled, the product is transferred to glovebox HC-18M where it is sampled and weighed. The sample of the product is transferred to the PFP Analytical Laboratory for LOI testing. If the sample is acceptable (WHC 1995a), the product is placed into a slip-lid product can. Oxide product is collected until the production accumulates approximately 5 kg at which point it is transferred to the Building 2736-Z storage vaults. If the sample is unacceptable, it is processed through thermal stabilization furnaces (reactive material stabilization) which are discussed in other subsections in Section 6.4.1.

Offgas Treatment. Plutonium oxide production from the direct calcination of plutonium nitrate generates several acidic gases that must be removed from the offgas stream before it enters the PFP process vacuum system. These offgases include HNO_3, NO_x and water vapor from the decomposition of plutonium nitrate and vaporization of the liquid component of the feed solution.

The 26-in. Hg vacuum system pulls the hot Production VDC offgases at 300 °C from the vertical calciner through a parallel set of ceramic offgas filters mounted in the top of the calciner unit. The filters are periodically back-washed by a pulse of air to remove accumulated particulates and reduce clogging. The offgases flow to a 15 L, 1.5 M sodium hydroxide scrubber tank. Gases entering the tank are aspirated through a sintered stainless steel plate located at the bottom of the tank. The scrubber tank is cooled to 10 °C using an internal cooling coil and external cooling unit (chiller). The cooling reduces the 300 °C offgas temperature to 10 - 25 °C and, at the same time, the sodium hydroxide reacts with the NO_x and HNO_3 to form various amounts of sodium nitrate and sodium nitrite salts in solution.

Sodium hydroxide solution from the Scrubber Tank (ST) is continuously recirculated into the phase separator tank (PST) and back into the ST at 25 L/h with Pump P-230-C. The ST solution is accumulated in the PST until the high liquid level probe is activated. Solution pumped from the PST to the ST is stopped and PST solution is pumped to SSSRT 1 or 2. When the PST low liquid level probe is activated, solution transfer to the SSSRT is terminated and the recirculation of solution from PST to the ST is resumed.

Offgas Scrubber Solution. The offgas scrubber system solution, ie., the sodium hydroxide, is consumed as the reactive NO_x and HNO_3 are mixed into the scrubber tank. The scrubber is initially charged with a sodium hydroxide concentration at 8.0 M from a solution drum station via pump P-230-B. The scrubber unit operates at 1.0 - 1.5 M sodium hydroxide. A pH element is

located in the recirculation pump (P-230-C) discharge line. The pH element starts the caustic addition pump, P-230-B, depending on solution pH.

Process Cycle Time. Process cycle time regulates process support activities required to maintain the process in continuous operation. Below are listed items needed to be maintained to operate the process in a continuous manner.

- Feed Receipt Tank - Tank filling is required every 3-5 hours depending upon a Feed Pump Tank Rate.
- Product Storage - The Production VDC generates approximately 680 gm/h PuO_2. The product can is allowed 5 kg which requires sampling, testing, final canning, and storage every 7 hours.
- Spent Scrub Solution Receiver - The process has two spent scrub solution banks, each containing two tanks. Each 40 L bank will allow approximately 6 hours of calciner operation before sampling is performed and transfer to Tank TK-D8 in Building 241-Z. The sample results must be received prior to transfer.
- Sodium Hydroxide Feed - Sodium hydroxide solution is pumped into the scrubber tank from a 55-gallon drum. At the process flow sheet rate, the drum would need replacement approximately every 30 to 40 hours of system operation.
- Bottled Process Air - Bottled air is injected into the vertical calciner at approximately 40 ft^3/h. At the process flow sheet rate, one bottle containing 250 ft^3 of compressed air is used every six hours. The bottled air rack contains four compressed air bottles.

6.4.1.1.2 Flowsheets - Reactive Material Stabilization. The thermal stabilization of reactive plutonium-bearing materials is a batch process. Containers holding in-process material are staged in glovebox HA-23S or containers of material to be processed may be staged in fixed array wagons in Room 230B. A quantity of plutonium-bearing material is placed into a boat in glovebox HC-21A. The boat is covered and then transferred through the conveyers to glovebox HC-21C or HA-21I. The boat is uncovered and placed into a muffle furnace and the temperature controller is started. The stabilized material is transferred to glovebox HC-18M for sieving, LOI sampling and product can makeup. The cans are stored in Glovebox HC-18BS until the LOI results are obtained. Upon receiving acceptable results (WHC 1995a), the cans are sealed out of glovebox HC-18M or HC-13MD and sealed into two outer cans before being sent to the vaults for storage.

Heat balances are not provided because the amount of heat varies depending on the amount and type of material being processed. The heat input is controlled by automatic temperature controllers. Most of the heat generated is dissipated to the ventilation system, primarily to the E-4 (offgas) system, and discharged to the atmosphere via the 291-Z-1 stack.

6.4.1.1.2A Flow Sheets - Plutonium-Bearing Solution Stabilization Using the Production VDC. The stabilization of plutonium-bearing solution by the Production VDC process is a continuous operation. Solution is continuously

fed from the feed pump tank to the calciner by the feed pump, P-230-A. As the solution is depleted from the feed pump tank, additional solution is gravity transferred from the feed receipt tank to the feed pump tank. Similarly, as solution is depleted from the feed receipt tank, additional solution is pumped from glovebox HC-227S in room 227 to the Production VDC process glovebox, HC-230C-2. A process flow sheet and material balance are shown in Figure 6-24. The plutonium oxide product from the calciner is essentially processed as described in Section 6.4.1.1.2 for reactive material stabilization. The product is transferred to the HC-18M glovebox for sampling. The sample is transferred to the PFP Analytical Laboratory for LOI testing. If acceptable, the product in glovebox HC-18M is packaged and transferred for long term storage in the Building 2736-Z storage vaults. If unacceptable, the product is processed through the thermal stabilization furnaces in the same manner as discussed in Section 6.4.1.1.1 for reactive material stabilization.

6.4.1.2 Process Chemistry and Physical Chemistry Principles - Reactive Material Stabilization. Five categories of plutonium-bearing material are thermally stabilized to meet long term storage requirements: PRF sludges from the last PRF campaign, mixed uranium and plutonium oxides (MOX), floor sweepings, plutonium oxalates, and plutonium oxide. When heated, PRF sludges dry and then oxidize to an impure plutonium oxide powder. The floor sweepings include plutonium oxide, plutonium oxalate, and plutonium oxycarbonate. The plutonium oxide simply dries with no chemical reactions occurring. Plutonium oxalate [$Pu(C_2O_4)_2 \cdot 6H_2O$] degrades from exposure to alpha radiation to plutonium oxycarbonate ($PuOCO_3 \cdot 2H_2O$) with a reaction half-life of 64 days. Since the floor sweepings have been in storage for over four years, essentially all of the Pu oxalate has degraded into the oxycarbonate form. Plutonium oxycarbonate, when heated above 100 °C, forms an intermediate phase. As the temperature rises (or is held at an elevated level), the aqueous portion is driven off and the remaining material is oxidized to plutonium oxide powder. Plutonium oxide is simply dried in the furnace to meet LOI requirements for long term storage. Currently, all five categories of "clean" and non-product plutonium-bearing material mentioned above may be processed in the furnaces in glovebox HC-21C. Four of the five categories of "clean" and non-product plutonium-bearing materials (excluding PRF sludges) may be processed in the furnaces in glovebox HA-21I.

6.4.1.2A Process Chemistry and Physical Chemistry Principles - Plutonium-Bearing Solution Stabilization Using the Production VDC. The objective of the plutonium-bearing solution stabilization program is to convert the plutonium in Pu nitrate solutions to Pu oxide using the Production VDC process. The acidic offgases produced by the conversion process are treated in the scrubber prior to being released to the atmosphere. The process technology is described below.

Plutonium Oxidation. The Pu nitrate, $Pu(NO_3)_4$, at an acid concentration of at least 1.3 M HNO_3 or greater is decomposed to plutonium oxide when heated in the calciner to an overall process temperature of 1000 °C in excess oxygen/air. A reactor residence time of at least 4 hours assists in heating the product further to obtain the desired product which meets LOI requirements.

The decomposition of the Pu nitrate to Pu oxide follows a reaction similar to:

$$Pu(NO_3)_4 \text{ ---------> } PuO_2\downarrow + 0.6\ NO\uparrow + 3.4\ NO_2\uparrow + 1.6\ O_2\uparrow$$

The overall process heat in the Production VDC is achieved through heating the outer portion of the reactor and the inner core to 1000 °C.

Air is injected into the system at 40 ft^3/h at 50 psi from an air bottle rack to atomize the feed solution and provide the excess O_2 required to oxidize the Pu nitrate to the oxide form of the element (Pu) with no valence change. Offgases produced from the reaction are a mixture of oxides of nitrogen (NO_x) compounds with nitric acid vapor and water as steam.

Offgas Treatment. The NO_x compounds discharged from the calciner unit are drawn through the offgas treatment scrubber using the 26-in. Hg vacuum system. The offgas scrubber uses a box constructed of sintered stainless steel plate that disperses the gas into small bubbles. This dispersion increases the reaction area in the scrubber and reduces NO_x emission.

The neutralization of the NO_x compounds follows reactions:

1) $2\ NO_2 + H_2O \text{ ---------> } HNO_3 + HNO_2$

2) $HNO_3 + NaOH \text{ ---------> } NaNO_3 + H_2O$

3) $HNO_2 + NaOH \text{ ---------> } NaNO_2 + H_2O$

4) $3\ HNO_2 \text{ ---------> } HNO_3 + 2\ NO + H_2O$

5) $2\ NO + O_2 \text{ ----------> } 2\ NO_2$

The NO_x compounds are converted to mostly sodium nitrate, per reaction 2, in the liquid phase as determined from the material balance in Figure 6-24. The reaction consumes a portion of the sodium hydroxide and lowers the pH, or sodium hydroxide concentration, as sodium salts of nitrate/nitrite and water are formed.

Offgas Scrubber pH. The scrubber is designed to operate around 1.0 - 1.5 M NaOH. The reactions shown above consume sodium hydroxide which reduces the pH of the scrubber solution. The hydroxide ion is forced to form water to maintain a chemical balance in the system. The scrubber solution is recirculated from the phase separator tank to the scrubber tank to provide mixing. The phase separator tank, at the same time, has a portion of the sodium hydroxide pumped to the SSSRT for disposal. The scrubber tank volume and pH is adjusted by adding 8.0 M fresh sodium hydroxide solution. The sodium hydroxide (NaOH) addition maintains the scrubber at a pH of approximately 14.1 at 1.0 - 1.5 M NaOH. Lower pH values (below 13.5) will permit NO_x in the vacuum system lines and seal water which will cause low pH discharges to the Low Level Waste Treatment Facility, Building 243-Z.

6.4.1.3 Mechanical Process Systems. There are no mechanical process systems associated with the RMA and RMC Line processes involving reactive material stabilization or plutonium-bearing solution stabilization using the Production VDC.

6.4.1.4 Chemical Process Systems - Reactive Material Stabilization and Plutonium-bearing Solution Stabilization Using the Production VDC. Thermal stabilization of reactive materials is performed in gloveboxes HC-21C and HA-21I, located in rooms 230A and 235B of Building 234-5Z (see Figure 6-27). The thermal stabilization process is supported by charge makeup in glovebox HC-21A. Sampling and product can makeup is conducted in HC-18M. Feed lag storage is in glovebox HA-23S, and product lag storage is in glovebox HC-18BS. LOI analysis is performed in the PFP Analytical Laboratory. Conveyor gloveboxes HC-1, HC-2, HC-3, HC-4, and HA-28 are used to transfer material between gloveboxes.

Plutonium-bearing solution stabilization using the Production VDC process is performed in glovebox HC-230C-2 (see Figure 6-26) located in room 230C of Building 234-5Z (see Figure 6-27). The Production VDC process converts Pu nitrate solutions into Pu oxide. Solution stabilization operations are supported by the following:

- LI/LO hood HC-227T/glovebox HC-227S for Pu nitrate solution LI, blending, sampling and transfer to glovebox HC-230C-2 and LO of solutions from glovebox HC-230C-2
- Gloveboxes HC-18BS and HC-18M for Pu oxide product storage, sieving, grinding, sampling for LOI testing, and initial packaging for long term storage
- Conveyor gloveboxes HC-1, HC-2 and HC-3 for transfer of materials between gloveboxes.

6.4.1.4.1 Functional Description - Reactive Material Stabilization. Thermal stabilization is used to stabilize reactive plutonium-bearing materials. The stabilized plutonium is then packaged for long-term storage.

Thermal stabilization is accomplished by heating the plutonium-bearing materials to high temperatures in furnaces. A pre-programmed controller is used to ramp the temperature to the setpoint, hold the furnace temperature at the setpoint for a specified time period, and then shut off the furnace. Following stabilization, the material is cooled, crushed (if necessary) and sampled to verify compliance with the vault storage criteria (WHC 1995a). The processed material is then packaged for long-term storage.

6.4.1.4.1A Functional Description - Plutonium-bearing Solution Stabilization Using the Production VDC. The Production VDC process (not currently authorized) is used to stabilize plutonium-bearing solutions. The process converts Pu nitrate solutions to Pu oxide for long term storage by heating the solutions to approximately 1000 °C in the calciner. The dried product, Pu oxide, is continuously collected from the calciner which overflows into a collection jar. The product is transferred to other gloveboxes where it is sieved, ground, sampled for LOI testing and packaged for long term storage. The Production VDC process is described in Section 6.4.1.1.1A and the process flow is presented in Section 6.4.1.1.2A.

6.4.1.4.2 Major Components - Reactive Material Stabilization. The major components associated with thermal stabilization of reactive plutonium-bearing materials are identified and described below for each glovebox. These

gloveboxes were originally used to support plutonium conversion operations, as part of RMA or RMC Lines. Additional information can be found in Chapter 5, Section 5.2.1.2.2.

Gloveboxes HC-1, HC-2, HC-3, HC-4, HA-28. These gloveboxes are conveyer gloveboxes and therefore contain no process equipment. Gloveboxes HC-1, HC-2, HC-3, and HA-28 are equipped with 4-1/2-in.-wide electrically powered slat conveyors that travel between 5/8-in.-high guide rails that are separated by a distance of 7-5/8 in. A series of rollers are used for transporting items through glovebox HC-4.

Gloveboxes HC-1 and HC-2 serve as plenums that deliver air to all the adjoining gloveboxes, except for the top and bottom sections of HC-9B and HC-17P (see Figure 6-14). Glovebox HC-2 extends from Glovebox HC-18BS to an airlock in Room 230-B. Glovebox HA-28 also serves as a plenum to deliver air to adjoining gloveboxes. Air is exhausted through HEPA filters located in the gloveboxes and out of the E-4 gas system. At least -0.5 in. w.g. pressure is maintained in the gloveboxes by the exhaust system.

Air enters the system at the top of the glovebox HC-2 conveyor adjacent to glovebox HC-18BS, through a 4-in. self-governing regulating valve rated at 250 std ft^3/min. Flow is regulated between 25 to 250 std ft^3/min. The sensing pressure is applied directly to the diaphragm chamber to control pressure to -0.5 to -1.2 in. w.g., and can cycle from full-open to full-closed within 3 s. Air also enters the system at the west end of glovebox HA-28, through a 4-in. self-governing regulating valve. As pressure increases to greater than -0.5 in. w.g., the supply valves close, avoiding loss of negative pressure, overpressurization, or discharge of air through an open port (see Section 5.2.1.2.2 for more details).

A differential pressure switch connected to an annunciator in the power control room (room 321) monitors the pressure in the gloveboxes, and alarms if it exceeds -0.3 in. w.g. The power operator in room 321 announces the loss of sufficient differential glovebox pressure to the affected area.

Two valves regulate exhaust on an emergency basis. Each parallel 4-in., 200 std ft^3/min valve connects to a common, locally unfiltered 8 in. diameter duct to exhaust a total of 400 std ft^3/min. The valves are closed tight for any upstream pressures less than -0.5 in. w.g. They are set to start opening at -0.45 in. w.g. and be opened fully before upstream pressure becomes positive. The resulting flow of unfiltered air goes to the 12-in.-diameter E-4 header in room 263 (above the RMC Line), and to four primary filterboxes connected in parallel. The increased exhaust flow helps to maintain the glovebox confinement in the event of a glovebox glove failure.

An electrically controlled valve located on the 8-in.-diameter emergency exhaust duct is interlocked with the glovebox heat detectors. If a fire with sufficient heat to activate the heat detectors occurs, the emergency duct valve would close, reducing heat load on the first-stage filters and reducing the flow of air that could feed the fire.

A 12 in. diameter unfiltered duct, equipped with a manual valve, is located on the west end of glovebox HC-2. This valve is used to regulate airflow during glovebox panel changes.

Gloveboxes HC-1, HC-5, and HA-23S are equipped with criticality drains. A criticality drain is a 3 in. diameter bag port attached to the side of the glovebox with the bottom lip of the port just below the maximum allowed depth of liquid accumulation on the glovebox floor. An open-ended plastic bag is attached to the port. The open end is closed for confinement purposes by a precision-finished steel roller balanced on a polished steel plate. Liquid exceeding the maximum slab depth drains out of the glovebox into the plastic bag. The weight of the liquid pressing against the steel roller moves it off of the plate, freeing a path for drainage to the room floor. The resulting contamination is a less severe hazard than a criticality incident.

Glovebox HC-18BS. Glovebox HC-18BS is used as a transfer and product lag storage area. The low, broad glovebox frame is level with glovebox HC-1. There are no panels on the north and south sides, where it connects to the HC-2 and HC-1 conveyor platforms. Glovebox HC-18BS contains 20 storage sites. The storage sites are on a chain-driven slotted belt conveyor, situated horizontally around five large sprockets.

Glovebox HC-18BS was originally used to store and transfer metal buttons using the serpentine conveyor belt during production operations in the RMC Line. The conveyor belt is used during thermal stabilization operations to transfer furnace boats between conveyor Glovebox HC-2 and Glovebox HC-18M for further processing. A new boat holder has been specifically designed to accommodate use of the serpentine conveyor with furnace boats. The conveyor is also used for lag storage of the plutonium oxide product while waiting for LOI analysis results.

Glovebox HC-18M. The glovebox is equipped with gloveports on three sides, and connects with glovebox HC-1 on the north side. The glovebox top is mostly polymethyl methacrylate paneling. The glovebox contains a sieve pan, sieve screen, sieve shaker, mortar & pestle, a weigh scale, electric bag sealer, furnace boats and covers, funnel, and tongs. Beneath the glovebox are the two hydraulic pumps that serve the RMC Line. All of the electric valves (EVs) that control the hydraulic fluid to the equipment in the gloveboxes are housed in a separate compartment beneath the glovebox on the south end. This section is ventilated by room air that is exhausted by a dedicated duct. The electric blower that served the line vacuum cleaner is located beneath the north section of the glovebox. The electric blower, which is no longer in service, exhausted into the E-4 system by a dedicated duct.

There are two levels in the glovebox with the second level floor at 45 in. above the room floor. The lower level is not used for stabilization operations. The upper level houses the sieve, mortar and pestle, and a weigh scale. Glovebox HC-18M is used to sieve the stabilized plutonium oxide material to obtain a particle size of less than 1/4 inch. This ensures that a representative sample is obtained for LOI testing. Larger particles are broken up by use of a mortar and pestle. A sample of material is obtained and bagged-out for LOI testing in the PFP Analytical Laboratory and the remainder of the material is placed in a slip-lid can, taped closed, and transferred for temporary storage in Glovebox HC-18BS. For samples that pass the LOI test, the slip-lid container corresponding to that sample is retrieved from Glovebox HC-18BS, weighed, bagged-out of Glovebox HC-18M, and transferred to storage. Samples that do not pass the LOI test are returned for additional processing through the furnaces.

Glovebox HC-21A. The equipment in glovebox HC-21A is used for sealing-in/out plutonium-bearing materials, opening containers, loading boats, and weighing (See Figure 6-15). Filled boats are covered and transferred to Glovebox HC-21C for thermal stabilization processing in one of the muffle furnaces. The glovebox contains an electronic balance for determining the mass of plutonium-bearing material before and after thermal stabilization. A glass mortar and pestle are available (if needed) for crushing large chunks of thermally stabilized material. Thermally stabilized material is passed through a sieve to uniformly size the material. The sieving is performed to ensure that a representative sample can be taken for LOI analysis. The processed material is placed into slip-lid cans and stored on a storage rack in glovebox HC-21A or in HC-18BS until the LOI results are obtained. For acceptable LOI results, the cans are sealed out of glovebox HC-21A and sealed into two outer cans before being sent to the vaults for storage. Any material that not meeting the LOI limits is resampled and recycled if necessary. Slip-lid cans are used for holding the stabilized material. Note that Glovebox HC-18M is the primary location for processing of thermally stabilized material and sealing out, although the option of using Glovebox HC-21A has been retained for back-up purposes (e.g., Glovebox HC-18M out-of-service). Glovebox HC-21A will require a review/revision of the glovebox posting and associated procedures to provide adequate material control prior to initiating thermally stabilized material processing in glovebox HC-21A.

Glovebox HC-21C. Glovebox HC-21C houses two muffle furnaces that are used for thermal stabilization. The glovebox is linked on the north side with conveyor glovebox HC-2. The furnaces have chamber dimensions of 13 in. in length, by 5.5 in. in width, and 5 in. in height. The 4.1 kW furnaces have an operating temperature range of ambient to 1093 °C. The furnaces are equipped with CO_2 purge systems that are used to dilute butene, which could be generated while processing PRF sludge to $\leq$ 25% of the lower flammability limit (WHC 1996a). The CO_2 is supplied by a station located in room 230A. The station consists of a cabinet that houses two liquid CO_2 cylinders. A manifold automatically switches to the second cylinder when the first one is empty. Each cylinder is equipped with a vent that releases approximately 2 lb of CO_2 per day, to reduce cylinder pressure.

The exhaust line from each furnace in Glovebox HC-21C ties into the 26-in.-Hg process vacuum system. The exhaust air passes through a stainless steel housing with ceramic filter media, to filter out suspended particles greater than 2 microns in diameter. The filter is followed by a needle valve that is used to adjust the exhaust flowrate. The flow rate is indicated on rotameters and differential pressure gauges. Inconel tubing is used between the furnace and filter housing to withstand the high temperatures. Once the exhaust gas passes through the filter housing, the gas has cooled sufficiently so that stainless steel may be used. The stainless steel offers greater resistance to corrosion.

There are two stainless steel desiccators that may be present in the glovebox. The sides and door are made of tempered glass. The desiccator has a positive-latch door with a neoprene gasket. A manual relief valve allows for chamber pressure equilibration. The outside dimensions of the desiccator are 12.5 in. in length by 12.5 in. in width and 12.25 in. in height. The desiccant is a silica gel contained in a small canister that can be regenerated. The current feed types do not require the use of a desiccator

following thermal treatment but the new feed types being tested may require a desiccator.

Glovebox HA-21I. Glovebox HA-21I contains three muffle furnaces used for thermal stabilization (see Figure 6-16). The south end of glovebox HA-21I connects to conveyor glovebox HA-28. The same type of muffle furnace is used as in glovebox HC-21C. The furnaces in HA-21I do not have a CO_2 purge system, therefore, HA-21I is not used to treat PRF sludges. The exhaust line from each furnace in HA-21I ties into a dedicated 5-in. mercury process vacuum system. Similar to the HC-21C system, the exhaust flows through a ceramic filter followed by a needle valve, which is used to adjust the exhaust flowrate. The flow rate is indicated on differential pressure gauges. This glovebox is equipped with a criticality drain.

The HA-21I glovebox is provided with a criticality drain to prevent liquid accumulation and fissionable material from reaching a depth that could result in exceeding an allowable criticality limit.

Glovebox HA-23S. Lag storage of feed material is provided in glovebox HA-23S. The south end of glovebox HA-23S connects to conveyor glovebox HA-28. This glovebox is equipped with a criticality drain.

6.4.1.4.2A Major Components - Plutonium-bearing Solution Stabilization Using the Production VDC. The major components in the Production VDC process used for solution stabilization are the glovebox, calciner, scrubber, process tanks, and process pumps. These components are described in detail in Chapter 5.0, Section 5.2.1.2.2 under the headings "Remote Mechanical C Line Glovebox for Solution Stabilization Using the Production VDC" and "Remote Mechanical C Line Glovebox Equipment for Solution Stabilization Using the Production VDC".

6.4.1.4.3 Design Description - Reactive Material Stabilization. The gloveboxes used for thermal stabilization operations are part of the RMC/RMA Line which was designed for converting plutonium nitrate solutions to plutonium metal. The gloveboxes are fabricated of stainless steel frames with top and side panels of clear plastic or leaded glass with wire mesh. The large windows provide visibility for the operators. The window panels are penetrated by gloveports, glovebox bag-in/bag-out ports and sphincter seals. Most of the gloveboxes are also provided with leaded glass for shielding. Glovebox HA-23S has a water wall for neutron shielding.

6.4.1.4.3A Design Description - Plutonium-Bearing Solution Stabilization Using the Production VDC. The process design for the solution stabilization operations using the Production VDC is provided in Section 6.4.1.1.1A and the equipment design is provided in Chapter 5.0, Section 5.2.1.2.

6.4.1.4.4 Safety Criteria and Assurance - Reactive Material Stabilization and Plutonium-Bearing Solution Stabilization Using the Production VDC. The primary safety concerns associated with the stabilization process are:

- criticality safety
- radiological safety
- process upsets
- industrial safety.

Criticality Safety. The gloveboxes and processes used in the stabilization processes have been analyzed by the methods outlined in Section 6.4.1.9.1 to ensure compliance with the criticality safety criteria presented in Chapter 4, Section 4.4.4. Criticality safety features incorporated into the design of the gloveboxes include the following:

- The process equipment is designed to be geometrically favorable, even if it is filled with plutonium at the maximum credible moderation.
- Process containers such as boats, slip-lid cans and product receiver jars are designed to be subcritical, even if overbatched and moderated.
- Gloveboxes HC-1, HC-5, HA-21I, and HA-23S are each provided with a criticality safety drain to ensure that a critical depth cannot be achieved, even if material is spilled and the gloveboxes are flooded.

Administrative limits are included in the criticality safety programs for stabilization operations. These limits include restrictions on plutonium mass, the number and size of containers, material type, and spacing limits between containers. Specific administrative limits for reactive material stabilization operations are specified in WHC (1995b) and, for solution stabilization operations, are specified in BWHC (1997a). The total dispersible Pu in Glovebox HC-18BS is limited to 50 kg as metal or 20 kg as powder (BWHC 1998). Criticality specification limits for the various process gloveboxes are shown in Chapter 5.0, Table 5-5.

Criticality detection and alarm systems are located in the areas used for stabilization operations. Personnel are required to rapidly evacuate the areas if the alarms sound. Criticality drills are conducted annually. The detection and alarm equipment is checked on a scheduled basis and redundancy is provided. This system must be functional to perform stabilization operations.

Radiological Safety. All gloveboxes are maintained at negative pressure with respect to room pressure (-0.3 to -1.5 in. w.g.), to confine plutonium to the gloveboxes if a small break in the confinement barrier occurred. Three stages of HEPA filtration (one non-testable at the glovebox and two that are testable in the exhaust system) are provided in the E-4 exhaust system before offgases are discharged to the atmosphere via the 291-Z-1 stack.

Strategically located CAMs alarm if airborne plutonium is detected in the work space and prompt evacuation of the affected airspace is required. The CAMs must be functional to perform stabilization operations. Criticality detectors and alarms are also required to be operational. The layout of CAMs and criticality detectors is provided in Chapter 8.0, Figures 8-13 and 8-27, respectively.

Process Upsets. Process upsets can potentially lead to loss of confinement, criticality, equipment damage, or high plutonium losses to waste. These events were considered when developing the process flowsheets, equipment design, and instrument and control (I&C) systems. The stabilization systems

were designed to maintain the process within operating limits (see Section 6.4.1.4.5). Instrumentation and controls are provided to monitor process parameters and alarm abnormal conditions. Interlocks are provided to automatically place equipment in a safe condition in the event of process upsets.

Industrial Safety. High temperatures could melt glovebox gloves. The gloves are pulled out of the glovebox and tied together when the thermal stabilization furnaces or the calciner are in use and work is not being performed.

Fire in a glovebox is a potential hazard that could breach confinement barriers (glovebox panels, gloves) and disperse plutonium powders. The potential sources of fire are primarily ignition of gloves by high temperature equipment, and accumulation of combustibles (gloves, rags, paper, etc.) in a glovebox (particularly during maintenance activities) with subsequent ignition.

Administrative controls require that combustibles in a glovebox be kept to a minimum. Criticality prevention specifications limit the number of rags per glovebox for cleaning purposes. All gloveboxes are administratively limited to control combustible material. Gloves are fabricated of fire-resistant and chemical-resistant Hypalon™ material and are not permitted to accumulate in gloveboxes when removed. Maintenance activities are monitored to ensure that there is no excessive accumulation of combustibles.

Each glovebox has heat detectors that alarm if a fire starts. The Hanford Fire Department also receives an alarm. Some of the glovebox panels are fabricated of Lexan™ (a self-extinguishing material) and the remainder are plexiglass or wire-reinforced glass. Hand-operated dry chemical fire extinguishers with bayonets to penetrate gloves and MgO sand are also available to extinguish fires. An automatic Halon system is provided in thermal stabilization glovebox HC-21C. Thermal stabilization glovebox HA-21I and Production VDC solution stabilization glovebox HC-230C-2 have sensors that are set to activate dry-chemical fire protection systems.

6.4.1.4.5 Operating Limits - Reactive Material Stabilization and Plutonium-bearing Solution Stabilization Using the Production VDC. The thermal stabilization process for reactive materials has operating limits controlling feed type, furnace operation, offgas and purge flow, fire safety concerns, product specifications, and glovebox plutonium inventory. These limits and their related safety/operational considerations are shown in Table 6-5. The solution stabilization operations using the Production VDC have operating limits on feed materials, process conditions and product quality which are shown in Table 6-6.

6.4.1.5 Instrumentation and Control Systems - Reactive Material Stabilization and Plutonium-bearing Solution Stabilization Using the Production VDC.

6.4.1.5.1 Functional Description - Reactive Material Stabilization. Reactive plutonium-bearing materials are thermally stabilized in muffle furnaces located in gloveboxes HC-21C (in room 230A) and HA-21I (in room 235B). Most of the instrumentation, controls and alarms for the thermal stabilization process are located on a control panel and on a personal

computer (PC) control station located in room 230A, near the HC-21C glovebox. The control panel is used for operating the muffle furnaces in glovebox HC-21C. The furnaces in HA-21I are controlled with the PC. A CO_2 cabinet is also located in room 230A. Rotameters are located near glovebox HC-21C. Differential pressure gauges are located both in and near gloveboxes HC-21C and HA-21I.

Thermocouples are used to determine furnace and glovebox temperatures. If the furnace temperature exceeds a preset value, an alarm is activated and power to the furnace is automatically shut off. Offgas flow rate and CO_2 purge are manually set at the glovebox (CO_2 purge is only available in glovebox HC-21C). Covergas flow is required only with PRF sludges, which are exclusively processed in glovebox HC-21C. For PRF sludges, the covergas is required for the heating period before the furnace reaches 300 °C on ramp-up. Offgas flow is used to ensure oxygen is drawn into the furnace and is available for combustion of impurities and removal of pyrolysis generated gases during the heating cycle. Offgas flow is maintained after the heating cycle is complete to aid in cool-down of the furnace. Offgas flow is used during the whole operation cycle.

6.4.1.5.1A Functional Description - Plutonium-bearing Solution Stabilization Using the Production VDC. Solution stabilization is performed in glovebox HC-230C-2 in room 230C of the 234-5Z Building. The stabilization operations consist of processing solutions of plutonium nitrate through the Production VDC to convert the solutions to plutonium oxide. Most of the instrumentation and controls for the Production VDC process are located in panels in room 230C and a programmable logic controller (PLC) and modular automation system (MAS) located in room 235B. The panels, PLC, and MAS are summarized in Chapter 5.0, Section 5.2.1.2.2. The Production VDC process is monitored and controlled by the PLC which monitors process parameters and actuates appropriate equipment and controls. The principal process parameters of interest are the glovebox pressure (negative) relative to the room, glovebox temperature, calciner temperatures and pressures, calciner offgas differential pressure, agitator operation, scrubber pH and levels of the various process tanks. Section 6.4.1.5.3A discusses the instrumentation, controls, interlocks and alarms in detail.

6.4.1.5.2 Major Components - Reactive Material Stabilization. Glovebox HC-21C has two muffle furnaces, and three muffle furnaces are located in glovebox HA-21I. Temperature elements are used to measure furnace temperature and provide feedback to the programmable electronic controllers for the furnaces in glovebox HC-21C. The temperature elements in glovebox HA-21I are connected to a PLC. Thermocouples are used to determine glovebox temperature. Orifices with differential pressure gauges are used to control offgas flow rate and, for the furnaces in HC-21C, CO_2 purge. In addition valved rotameter are located near glovebox HC-21C.

6.4.1.5.2A Major Components - Plutonium-bearing Solution Stabilization Using the Production VDC. The major components in the instrumentation and control system for solution stabilization using the Production VDC are those that monitor and control system pressures, temperatures and levels. In addition, power input for the calciner heaters is controlled to provide process temperature control. Pressures are monitored through direct reading gauges and switches for control and/or alarm. Self-contained pressure

regulating valves are generally used for pressure control. Most other process valves are of the open-close type.

Process temperatures of interest are associated with the calciner and are monitored by thermocouples, some of which control the power to the calciner heaters. Process tank levels are monitored by either conductivity probes or weight factor instrumentation. Specific information on significant process instrumentation and control is provided in Section 6.4.1.5.3A.

6.4.1.5.3 Detection Systems and Locations - Reactive Material Stabilization. Each muffle furnace in glovebox HC-21C is equipped with two temperature elements. The temperature elements provide information to the local controllers, which control the power to the furnaces. If the furnace temperature exceeds 1050 °C an alarm is activated and power to the furnace is shut off. Glovebox temperature is measured by three thermocouples placed in representative areas in the glovebox. The measured temperatures are sent to an instrument that digitally displays the temperature in each zone for several seconds. An alarm is activated at 70 °C and the power to each furnace is shut off. An independent detector system is used for the Fire Suppression System. At 93 °C a Halon fire suppression system is activated. A differential pressure gauge measures the negative pressure in the glovebox relative to the room.

Similar to glovebox HC-21C, each muffle furnace in glovebox HA-21I has two temperature elements, and there are three thermocouples placed in HA-21I to monitor glovebox temperature. The information from the temperature elements is sent to the PLC, which controls power to the furnaces. If the furnace temperature exceeds 1050 °C an alarm is activated and power to the furnace is shut off. The measured glovebox temperatures are also sent to the PLC, where the high temperature is selected and displayed on the PC control station. An alarm is activated at 70 °C and the power to all furnaces is shut off. An independent detector system is used for the Fire Suppression System. At 93 °C, a dry chemical fire suppression system is activated. A differential pressure gauge measures the negative pressure in the glovebox relative to the room.

6.4.1.5.3A Detection Systems and Locations - Plutonium-bearing Solution Stabilization Using the Production VDC. The following subsections present information on the major process instrumentation, controls, interlocks and alarms associated with solution stabilization operations using the Production VDC process. A flow diagram for the Production VDC process is provided in Figure 6-25. Operating specification limits for various parameters in the process are provided in Table 6-6.

Calciner Temperature. The calciner has several temperature control and monitoring points. For temperature control, the calciner temperature is measured by a thermocouple which provides temperature information to the PLC system. Temperature controllers control power to the silicon-controlled rectifiers (SCR) which supply power to the calciner heaters. The calciner temperature controller is part of the modular automation system (MAS) with set point programming which receives input from the thermocouple and, based on a comparison with the setpoint, sends output to SCRs. The SCRs control power to the calciner heaters based on the input from the controller. The SCRs use the input from the controller to establish the output current to the heating coils

(dome and shell heaters) on the calciner. A shorted SCR provides full power to the connected heater. On heater A, the SCR provides an alarm contact which is annunciated on the control console. Additionally, an LED on the shorted SCR will indicate the failure at the SCR box located in the control area. The heater B SCR has only an LED which indicates the level of the control signal by its intensity. In addition, heater current readings are provided on the control panel.

Several temperature elements provide temperature information during calciner ramp-up/soak time and control information during calciner operation. One temperature element feeds an interlock to provide high temperature annunciation and calciner operations shutdown. The high temperature alarm annunciates when the calciner outer temperature exceeds 1050 °C and notifies the operators that the Production VDC temperatures are deviating from program parameters and action may be necessary.

Calciner Pressure. The Production VDC uses pressurized air to atomize the feed solution and to provide the oxygen to oxidize the plutonium nitrate at high temperatures. The calciner differential pressure is monitored with a differential pressure transmitter (DPT) installed between the calciner internal compartment and the calciner glovebox. The DPT senses the calciner pressure versus the vacuum of the glovebox within a specified range (<5 inches W.G.) and when activated, annunciates VDC Low Vacuum Alarm. This alarm activates an interlock to shutdown the feed pump, the atomizing air, and the offgas filter blowback air.

Calciner Offgas Filter Differential Pressure. The Production VDC process uses pressurized air to atomize the feed solution and to provide the oxygen to oxidize the plutonium nitrate at high temperatures. The system relies on the 26-in. Hg vacuum system to remove this air to prevent pressurization of the calciner and provide offgas control. The offgas filter differential pressure is monitored with a DPT installed between the vacuum source and calciner internal compartment. The DPT senses the calciner pressure verses the vacuum within a specified range and, when activated, annunciates an alarm. Following an alarm, the operator checks the filter dP on the operator control screen. If the dP is >90 in. W.G., then the feed pump, atomizing air and offgas filter blowback air are stopped (manual response).

Calciner Agitator Stopped. The calciner agitator is monitored for operation and annunciates when not in operation. An agitator stall is detected by a sensor which shuts down the calciner feed pump, P-230-A.

Glovebox Temperature. The glovebox high temperature control system ensures that calciner operations are not allowed to continue if high temperatures in the glovebox are occurring. Discontinuing the calciner operations prevents the Dry Chemical Fire Suppression System from tripping.

The temperature for glovebox HC-230C-2 is measured by one thermocouple in the upper level of the glovebox. When the temperature from the thermocouple reaches a setpoint of 70 °C, a temperature switch actuates an alarm to notify operators that glovebox temperature is high and shuts down the Production VDC operations. An interlock automatically shuts off power to the calciner heaters (dome and shell heaters), the feed pump and the offgas filter blowback air when the glovebox temperature exceeds the limit. The temperature setpoint

of 70 °C is well below the 93 °C automatic trip point for the glovebox dry chemical fire suppression system to prevent inadvertent actuation of the system.

Glovebox Differential Pressure. The differential pressure between glovebox HC-230C-2 and room 230C is monitored to assure that the glovebox is always at a negative pressure relative to the room. This prevents contamination of the room should the glovebox confinement be breached. The differential pressure is read on a local indicator and if negative pressure is lost, the Production VDC operations are manually terminated.

Glovebox Fire Detection System. A heat detection system is provided for the glovebox and automatically activates the dry chemical fire protection system if the temperature exceeds 93 °C.

Calciner Offgas Scrubber Tank pH. The offgas scrubber pH is controlled using a pH sensing element in the discharge line of the phase separator tank pump, P-230-C. The pH probe activates an interlock which starts the sodium hydroxide pump, P-230-B, when the pH drops to $\leq$ 13.0. The probe activates the pump to supply fresh 8.0 M sodium hydroxide to increase the scrubber tank pH to approximately 14.

Phase Separator Tank Level. The phase separator tank (PST) pump, P-230-C is running whenever the offgas scrubber is operating. The PST pump recycles solution from the PST to the scrubber or transfers spent sodium hydroxide solution to the Spent Scrub Solution Receiver Tank (SSSRT) depending on the PST level. The PST level is monitored by conductivity probes. Once the PST level reaches the probe, the transfer to the SSSRT is started. When the level in the PST drops below the level high probe, the recycle to the scrubber is started. Level control in the scrubber is by use of an overflow tube from the scrubber to the PST.

Spent Scrub Solution Receiver Tank Level. Levels in the SSSRTs, SSSRT-1 or -2, are monitored through weight factor transmitters (WFT). The WFTs actuate alarms which warn of high liquid levels in the tanks. The corrective action for an alarm from either tank is to manually switch operations to use the other tank. Corrective actions by operations will prevent liquid spillage to the floor from the tank vents. Tanks overflowing to the glovebox floor will activate the sump level switch which actuates an alarm.

Vacuum Trap Level. Two vacuum trap conductivity probes (a high and a high-high level) actuate an alarm and a solenoid actuated valve on the vacuum trap to isolate the 26-in. Hg vacuum system from the glovebox HC-230C-2 vacuum line when there are high levels of liquid in the trap. One of the conductivity probes detects the presence of liquid in the vacuum trap and actuates an annunciator so corrective action may be taken. The second conductivity probe detects higher levels of liquid in the vacuum trap and, after a time delay, closes a valve to isolate the vacuum trap from the 26-in. Hg vacuum header. The delay before the valve closes allows the feed pump, the feed pump supply isolation valve, the atomizing air, the caustic pump, the PST recirculation pump, and the offgas filter blowback air system to shutdown. The alarm is on the MAS system.

Feed Receipt Tank Level. The FRT level is monitored by a conductivity probe. Upon receiving a high level signal, feed solution transfer from glovebox HC-227S to the FRT is automatically terminated by closing the FRT inlet valve.

Feed Pump Tank Level. The FPT level is monitored by a WFT. Upon receiving a high level signal, feed solution transfer from the FRT to the FPT is automatically terminated by closing the FPT inlet valve.

Emergency Shutdown Switch. An emergency shutdown switch is provided at the local control panel in room 230C. The switch provides for manually terminating the Production VDC process when abnormal conditions arise which require shutting down operations. Actuation of the switch results in shutdown of the following:

- Calciner heaters (dome and external)
- Feed pump, P-230-A
- Caustic (sodium hydroxide) pump, P-230-B
- Phase separator tank pump, P-230-C
- Offgas filter blowback air
- FRT outlet valve closed
- Atomizing air
- Calciner agitator.

Seismic Shutdown Switch. The Production VDC process is interconnected with the existing PFP HVAC supply fan seismic shutdown switch. When actuated, the seismic switch will result in shutdown of the same calciner equipment as described above for the emergency shutdown switch. The seismic shutdown switch also shuts down the normal power to the calciner fire control panel and forces it onto its battery backups.

6.4.1.5.4 Operating Characteristics - Reactive Material Stabilization. Heating time and temperature for the furnaces in glovebox HC-21C are controlled by individual microprocessor-based controllers. These controllers are programmed to ramp the temperature to the setpoint, hold the temperature for a specified time period (soak), and shut off the furnace. Each controller is programmed with six ramp/soak regimes; one for PRF sludges, one for plutonium metal, one for plutonium oxide, and recycled feed, one for regenerating desiccant, and two for restarting the furnaces at elevated temperatures. The controllers can be programmed with additional ramp/soak regimes as new feeds are approved for processing in the furnaces.

The furnaces located in glovebox HA-21I are operated with a PLC rather than individual controllers. The PLC is currently programmed for processing plutonium oxide, and recycled feed, and for restarting the furnaces at elevated temperatures. The PLC can also be programmed with additional ramp/soak regimes.

Because PRF sludges potentially contain organics, the furnaces in Glovebox HC-21C are ramped up to 175 °C and held for 1.5 h. This keeps the rate of butene generation outside of the flammable range. The temperature is then increased to 1000 °C and held for 2 h. The controller then shuts off the furnace. This sequence of operations removes essentially all of the volatiles.

For plutonium metal the furnace is ramped up to 550 C and held for 12 hours. The material in the boat is examined and if all metal is oxidized the material is sieved and returned to the boat. the sieved material is then processed as oxide.

The following are typical process programs for thermal stabilization. The parameters can be changed and programs added for variations in the process feeds.

For plutonium oxalate charges, the furnace is ramped up to 110 °C and held for 1 h. This removes most of the water of hydration, and allows the liquid portion of the charge to evaporate without foaming over the edge of the cake pan. The temperature is then increased to 175 °C and held for 0.5 h to allow separation of the remaining water of hydration from the oxycarbonate (oxalate) and continued evaporation of the free liquids. The temperature is then increased to 1000 °C and held for 1 h. The controller then shuts off the furnace. This removes essentially all of the volatiles.

There are no intermediate temperature hold points required for plutonium oxide and recycled feed charges. The furnace is ramped up to 1000 °C and held for 1 h. The controller then shuts off the furnace. This removes essentially all of the volatiles.

Each furnace door is interlocked to shut off the furnace whenever the door is opened. When the door is closed, a red light on the panel illuminates or an illuminated icon on the PC indicates that a heating cycle can be started.

6.4.1.5.4A Operating Characteristics - Plutonium-bearing Solution Stabilization Using the Production VDC. The principal operating characteristics for solution stabilization using the Production VDC process is to heat the feed solution to approximately 1000 °C to convert the Pu nitrate into Pu oxide. The offgas from the process are run through a scrubber to remove and neutralize undesirable constituents prior to release to the atmosphere. The instrumentation and controls for the Production VDC process are designed to assure that the desired operating conditions are obtained and abnormal process conditions are detected and appropriately mitigated. Section 6.4.1.5.3A provides a discussion of the principal process instrumentation, controls, interlocks, and alarms. Section 6.4.1.1.1A provides a description of the Production VDC process for solution stabilization. Chapter 5.0, Section 5.2.1.2.2, provides a description of the equipment used for solution stabilization operations using the Production VDC.

6.4.1.5.5 Safety Criteria and Assurance - Reactive Material Stabilization. The ramp rates are pre-programmed into the controller for each specific feed type. The furnace is ramped up slowly to avoid damaging the furnace heating coils. If temperature deviates greater than 20 C° from the ramp setpoint, a deviation band controller alarms and the control system alarm interlock shuts off the furnace. This is accompanied by an audible alarm, and an illuminated window on the annunciator panel or a display on the PC.

The high temperature alarm system provides an independent backup to prevent over-heating the furnace if the controller fails. When the furnace temperature exceeds 1050 °C, the alarm is activated, an interlock shuts off

the furnace, an audible alarm sounds, and a window will illuminate on the annunciator panel or display on the PC.

When any one of the three glovebox thermocouples reaches 70 °C, the furnace is shut off, an audible alarm will sound and a window will illuminate on the annunciator panel or display on the PC. The Halon fire suppression system for glovebox HC-21C is activated when the independent detector system associated with the Fire Suppression System detects a temperature of 93 °C. The Halon fire suppression system can be restrained by pressing the Halon ABORT button and holding it constantly, or by pressing it at intervals of less than 30 s. The dry chemical fire suppression system for glovebox HA-21I is activated when the independent detector system associated with the Fire Suppression System detects a temperature of 71 °C.

If the furnace door is opened within a heating cycle, the furnace is shut off. This interlock prevents the furnace from being on while a boat is being put into or removed from the furnace. This interlock also minimizes heat loading to the glovebox during heating cycles.

6.4.1.5.5A Safety Criteria and Assurance - Plutonium-bearing Solution Stabilization Using the Production VDC. Safety criteria and assurance for solution stabilization operations using the Production VDC process is provided by establishing limits for various process parameters and by the use of instrumentation, controls, interlocks and alarms to monitor and warn of parameter deviations. The operating specifications for important variables are shown in Table 6-6. Section 6.4.1.5.3A provides a discussion of the principal detection systems and resultant interlocks and alarms which assure safety in the operations.

6.4.1.6 Control Rooms and Control Areas - Reactive Material Stabilization. Most of the instrumentation, controls and alarms for the thermal stabilization process are located on a control panel, and on a PC that are located in room 230A, near the HC-21C glovebox. A CO_2 cabinet is also located in the room. Differential pressure gauges are located both in and near gloveboxes HC-21C and HA-21I. Valved rotameters are also located near glovebox HC-21C. If the local controls are disabled, power can be shut off at the main electrical breaker box. In general, shutting off power to a glovebox results in an immediate safe-shutdown condition. A longer term safe shutdown requires cleanout of plutonium bearing-materials from the gloveboxes.

6.4.1.6A Control Rooms and Control Areas - Plutonium-bearing Solution Stabilization Using the Production VDC. There is no control room dedicated to the solution stabilization operations using the Production VDC. Control panels and related control devices (MAS and PLC) are located in rooms 230C and 235B. A local panel with an operator display screen is provided in room 230C near the Production VDC process equipment and glovebox. The MAS and PLC, located in room 235B, provide the control components for the operations. Additional discussion of the control panels and associated equipment is provided in Chapter 5.0, Section 5.2.1.2.2. Details of the instrumentation and controls associated with the Production VDC process are provided in Section 6.4.1.5.3A.

6.4.1.7 Analytical Sampling - Reactive Material Stabilization. Feed material originating in the PRF, or material of unknown origin is sampled and analyzed

in accordance with procedures before processing. Charges containing less than 10 g of organic material may be processed through the muffle furnaces in glovebox HC-21C. Feed material is NDA'd for plutonium content to ensure that glovebox mass limits are not exceeded.

Each full can of processed material is sampled in Glovebox HC-18M for LOI analysis. Approximately 11 g of material is removed from a slip-lid can and the can is defined to be full when the processed material is 3/4 inches from the top. The weight of the sample is determined and entered on a data sheet for the sample. The sample is transferred to the Analytical Laboratory for LOI analysis. For transfer to the Analytical Laboratory, a Nuclear Material Item Transfer Form is obtained for each item to be transferred. The sample is sealed out of Glovebox HC-18M or HC-13MD for LOI in accordance with procedures. If the LOI does not meet the storage specification (WHC 1995a), the material is processed per the manager's instructions. If the LOI meets the storage specification, (WHC 1995a) the material is packaged for storage and sent to the vaults.

6.4.1.7A Analytical Sampling - Plutonium-bearing Solution Stabilization Using the Production VDC. The PR cans of plutonium nitrate to be processed for solution stabilization by the Production VDC process have been previously characterized prior to placing them in storage at the PFP. The PR can contents are loaded into glovebox HC-227S through the load-in head in hood HC-227T. The contents of several cans are blended in the glovebox and a sample is removed for testing to assure compatibility with the Production VDC process. The testing assures that the Production VDC process feed solution meets the acid concentration, organic content, solids content and Pu concentration limits shown in Table 6-6. The plutonium nitrate solutions are then transferred by pumping through a double contained line to glovebox HC-230C-2 for stabilization using the Production VDC process.

The Pu oxide product resulting from the VDC process is transferred from glovebox HC-230C-2 via conveyor gloveboxes HC-2 and HC-3, to glovebox HC-18M or HC-21A, where it is accumulated in a slip-lid can. When the can is full, approximately 5 kg, the contents are mixed and sampled. The sample is transferred to the PFP Analytical Laboratory for LOI testing. If the sample meets the LOI requirements of the storage specification (WHC 1995a), the product material is packaged for long term storage. This consists of taping the slip-lid product can closed and bagging-out the can from the glovebox. The unit is then packaged and sealed in two more cans and transported to the nondestructive assay laboratory in Building 2736-ZB. After assaying the contents, the can is transferred to the Building 2736-Z vaults for long term storage.

If the product material does not pass the LOI test, it is considered reactive material and processed through the thermal stabilization furnaces for additional stabilization. It is then transferred to glovebox HC-18M or HC-21A for additional sampling, LOI testing and packaging, and then transferred for assaying and storage.

6.4.1.8 Product Handling - Reactive Material Stabilization. The stabilized plutonium-bearing material generated by thermal stabilization is handled, packaged, and stored in accordance with the process descriptions contained in Sections 6.2, 6.3, and 6.4.1.

6.4.1.8A Product Handling - Plutonium-bearing Solution Stabilization Using the Production VDC. Handling of the plutonium nitrate solutions during the Production VDC stabilization process and after conversion to plutonium oxide is included in the discussion in Section 6.4.1.7A. Additional discussion is also provided in Section 6.4.1.1.1A.

6.4.1.9 Identification of Items for Safety Analysis.

6.4.1.9.1 Criticality Prevention - Reactive Material Stabilization and Plutonium-bearing Solution Stabilization Using the Production VDC.

Criticality Safety Evaluation. Activities associated with thermal stabilization of reactive materials include inspecting, splitting, weighing, heating, sampling, crushing, mixing and packaging. Thermal stabilization takes place in gloveboxes that were used as "dry gloveboxes" for plutonium metal production. Activities associated with stabilization of plutonium nitrate solutions using the Production VDC include solution transfers, blending, sampling, VDC processing, LOI testing and packaging. The process occurs in a new glovebox (HC-230C-2) added to the RMC Line. Criticality prevention specifications (CPS) based on Criticality Safety Evaluation Reports (CSER) have been prepared for all of the gloveboxes and activities/processes used in the stabilization processes.

Analytical methods used include the use of well-referenced data, Surface Density versus Unit Shape Factor method, Monte Carlo calculations, and all plutonium is assumed to be ^{239}Pu, unless the isotopic content is specifically controlled by analysis and administrative procedures. All moderated mixtures are assumed to be metal-water or oxide-water.

The analyses consider available containers, maximum fissionable material densities, credible moderators, glovebox floor surface area, the presence of criticality safety drains, reflectors near the glovebox (floors, walls, or ceiling), and normal maximum process limits.

Contingencies are developed for each operation in the gloveboxes. These contingencies include the following, as appropriate to the operation analyzed:

- Addition of fissile material in excess of that allowed by the CPS, either as additional units (overloading) or larger units (overbatching or double batching).
- Addition of a moderator
- Intermixing of units of various types
- Violation of spacing rules
- Spills
- Equipment failure
- Equipment volume or depth larger than expected
- Accumulations of fissionable material
- Density of materials increased
- Addition of a reflector.

The controlling (worst-case) contingency for most gloveboxes is the introduction of a moderator (e.g., water used in fire fighting). Specific analyses demonstrate that the operation remains acceptably subcritical even if fully moderated.

Implementation of Criticality Safety. Process equipment and containers used in stabilization gloveboxes are designed to remain subcritical even in the event of accidental flooding. Criticality safety drains are also provided to limit the depth of liquid in a flooding event. Storage gloveboxes are designed to provide spacing between plutonium units. Specific safety features are described in Section 6.4.1.4.4.

Process glovebox limits are established for moderators, liquids in the glovebox, container size, batch or unit mass, spacing and, spills or accumulations of fissionable material. CSERs have been prepared and appropriate CPSs have been established for stabilization gloveboxes. The glovebox inventory limits are shown in Chapter 5.0, Table 5-5.

6.4.1.9.2 Chemical Safety - Reactive Material Stabilization and Plutonium-bearing Solution Stabilization Using the Production VDC. At elevated temperatures, heavy metal nitrate-tributyl phosphate (TBP) complexes (and associated dibutyl and monobutyl phosphate complexes) decompose exothermically. If the rate of reaction is such that heat is generated faster than it can be removed, the reaction becomes autocatalytic. The accompanying rapid evolution of butane gas may lead to an explosion. Additional details regarding the decomposition of heavy metal nitrate-TBP complexes are provided in Chapter 9.0, Sections 9.2.1.2 and 9.2.9.1.

Tributyl phosphate/nitric acid reactions are possible during stabilization operations. The probability and magnitude of such reactions are reduced to an acceptable level primarily by limiting the organic content of the material being processed and by controlling process temperatures. The probability of a rapid organic reaction during thermal stabilization in glovebox HC-21C is reduced by limiting the feed material to a charge with less than 10 g of total organic content. In addition, when processing organic materials, an inert covergas (CO_2) is introduced into the furnace to ensure flammable gas concentrations (butene) remain $\leq$25% of the lower flammability limit (WHC 1996). Covergas ($\geq$45 scfh) is required for the heating period before the furnace reaches 300 °C on ramp-up. Offgas flow (120 scfh) is used to ensure oxygen is drawn into the furnace and is available for combustion of impurities and removal of pyrolysis generated gases during the heating cycle.

The plutonium nitrate solutions to be stabilized are limited to less than 1% organics. A discussion of reaction potential is provided in Chapter 9.0, Section 9.2.9.1.

6.4.1.9.3 Process Shutdown Modes - Reactive Material Stabilization and Plutonium-bearing Solution Stabilization Using the Production VDC. The stabilization processes have emergency shutdown switches. For thermal stabilization, a manual switch is located in the control console, and will shut off the furnace in glovebox HC-21C until the manual reset button is pulled out. During an emergency shutdown, the control system will continue to function. A manual switch is located on the exterior of glovebox HA-21I, which shuts off power to all three furnace elements in the glovebox when the button is depressed. The PC station contains an icon for emergency shutdown of the furnaces in glovebox HA-21I from the Control Computer.

For solution stabilization using the Production VDC, a manual shutdown switch is located on a local control panel in room 230C near glovebox

HC-230C-2 which houses the Production VDC equipment. This switch shuts down the Production VDC operations as described in Section 6.4.1.5.3A. The local control panel is described in Chapter 5.0, Section 5.2.1.2.2.

6.4.1.9.4 Instrumentation - Reactive Material Stabilization and Plutonium-bearing Solution Stabilization Using the Production VDC. This section provides an overview of the parameters used to detect process conditions. More details are provided in Section 6.4.1.5.

Process-specific operating parameters that are monitored for thermal stabilization of reactive materials include temperature and flow rate (offgas and CO_2 purge). Each of the five muffle furnaces has two temperature elements to measure the furnace temperature. Glovebox HC-21C and glovebox HA-21I each have three thermocouples to provide representative glovebox temperature measurements. Orifices with differential pressure gauges are used to control the offgas flow rates for glovebox HC-21C and HA-21I. Glovebox HC-21C also has valved rotameters for controlling offgas flow rates and a CO_2 purge system.

Process specific parameters that are monitored for solution stabilization operations using the Production VDC process include calciner and glovebox temperatures, process tank levels, calciner and glovebox pressures, and scrubber pH. A description of specific instrumentation associated with the Production VDC process is provided in Section 6.4.1.5.3A. Important process parameter limits are shown in Table 6-6.

The instrumentation systems provide information to the operators about process or support equipment under their control, to alert them to off-normal conditions. Sensing devices for these parameters are located within the process equipment. They transmit signals to locally situated recorders/controllers. The controller is used to control the process within the limits for the parameter. The recorder displays and records how the equipment is performing with respect to the parameter of concern. Operating procedures outline the specific actions for the operators to take. Typical responses for thermal stabilization operations include adjusting offgas flow rate to maintain required flow, interrupting power to the furnace temporarily if the furnace temperature is higher than the program temperature, interrupting power to the furnace if the furnace temperature fails to rise or minimum required offgas flow cannot be maintained, and pausing the program if the program temperature is higher than the furnace temperature. For solution stabilization operations using the Production VDC, either manual or automatic response to abnormal conditions provide mitigative actions. Responses for abnormal conditions are included in the discussion in Section 6.4.1.5.3A.

Instrumentation is provided wherever plutonium materials are handled to assure personnel safety and material accountability. The NDA Laboratory has special equipment to determine the amount of plutonium being received or shipped. Sampling, mass spectrometer analyses, and weighing of plutonium materials are the primary methods used for accountability.

Radiation monitoring instruments (stack CAMs and CAS instruments) used in the plutonium materials handling facilities are safety class or safety significant instruments (see Chapter 5.0, Section 5.4.10 and Chapter 4.0,

Tables 4-7 and 4-8). They are controlled by engineering personnel and maintained by maintenance personnel under the PFP PM program.

Airborne plutonium concentration is a personnel health and safety concern. Differential pressure gauges, located in all gloveboxes, measure the negative pressure in the gloveboxes relative to the room. A negative pressure must be maintained on the gloveboxes to contain and control airborne radioactive particles.

Stack effluent samplers and monitors provide proportional samples and real-time gross radioactivity monitoring (see Chapter 7.0, Section 7.1.2). Waste water discharges to the Low-Level Waste Treatment Facility (LLWTF) at 243-Z for treatment (see Chapter 7.0, Section 7.2). The treated stream from the LLWTF is monitored in-line (pH, conductivity, and flow rate) and proportionally sampled by an automatic composite grab sampler at the 225-WC Building. The stream is routed to the Treated Effluent Disposal Facility (TEDF) for discharge to the environment. Radioactive liquid waste to the 241-Z underground tanks is sampled before transfer, and manual records of the amount of liquid pumped and its contents are maintained (see Chapter 7.0, Section 7.2).

A listing of all instrumentation is maintained within the PM program. It provides a schedule for calibration and testing of the instrumentation and the maintenance requirements. Instrumentation is tested and calibrated before installation. Radiation detection instrumentation is tested on a scheduled basis. The NDA equipment is also calibrated on a frequent and scheduled basis. The process instrumentation is important to operations personnel safety.

6.4.1.9.5 Remote and Contact Maintenance. Maintenance of equipment in gloveboxes normally involves replacing the equipment, and repairing the failed item in a "hot" maintenance area or discarding it to solid waste. Instruments or small pieces of equipment are replaced using the rubber gloves and viewing panels of the gloveboxes. The new (or repaired) item to be installed, and the tools required (if not already in the glovebox), are introduced through a sphincter seal, bag-in or airlock and moved to the position requiring maintenance. The failed item is replaced with a new unit, and the failed item is removed from the line and bagged-out in plastic bags.

Larger equipment requires open glovebox maintenance. Normally the equipment is replaced with a new or repaired unit. A temporary plastic containment tent known as a "greenhouse" (or glovebag, if the component being replaced is small) is placed around the glovebox and work area for contamination control. The containment is normally fabricated in a rectangular shape from 12-mil fire-retardant sheet plastic. Irregular shapes may be fabricated as the job dictates. For some jobs, portions of containment may be fabricated from clear plastic for increased visibility. A second smaller containment is installed at the entrance to the containment tent, with an opening between the two. The smaller containment is called an annex and is made of same type of material as the primary containment. It serves as a buffer zone between the room and the primary containment, and as an area for personnel clothing removal when exiting the primary containment. Separate ventilation is supplied to the greenhouse, and portable air monitors are used inside the greenhouse and just outside the entrance. Workers are required to

use multiple layers of protective clothing and respirators, as a minimum. A fresh air supply may also be required.

6.4.2 Other Remote Mechanical A and Remote Mechanical C Line Processes

6.4.2.1 Process Description.

6.4.2.1.1 Narrative Description. As previously discussed in Section 6.1, the plutonium conversion process is inactive and operation is not authorized. However, all gloveboxes (except those physically removed or declared inactive) are authorized for interim storage of plutonium-bearing material. A list of active and inactive gloveboxes is provided in Chapter 5.0, Table 5-4. Inactive gloveboxes cannot store or receive containers of plutonium, but residual quantities of material remain in these gloveboxes.

6.4.2.1.2 Flowsheets. There are no flowsheets associated with other RMA and RMC Line processes.

6.4.2.2 Process Chemistry and Physical Chemistry Principles. There is no process chemistry associated with other RMA and RMC Line processes.

6.4.2.3 Mechanical Process Systems.

6.4.2.3.1 Functional Description. Gloveboxes which were once used for the plutonium conversion process are now used for the interim storage of plutonium-bearing material. The containers are sealed in and sealed out of the gloveboxes in accordance with established operating procedures. The material for interim storage also complies with established CPSs.

6.4.2.3.2 Safety Features. Safety features related to criticality, radiological, and industrial safety are discussed in the following sections.

Criticality Safety. Each room, glovebox, and container has been analyzed by the methods outlined in Section 6.4.2.9.1 to ensure compliance with the criticality safety criteria presented in Chapter 4.0, Section 4.4.4, and criticality safety features are incorporated into the design of the RMC Line.

The process equipment is designed to be geometrically favorable, even if filled with plutonium at the maximum credible concentration and optimum moderation. Process containers such as powder pans and pressure vessels are designed to be subcritical, even if overbatched and moderated. Physical spacers are provided in storage gloveboxes to minimize interaction between plutonium batches. Criticality safety drains are provided to ensure that a critical depth cannot be achieved, even if material is spilled and the glovebox is flooded. The stainless steel discs have been placed in the sumps, where appropriate, to prevent the accumulation of large amounts of solution. Raschig rings (neutron absorbers) have been placed in the sump in room 166 for criticality safety in the event of a large spill of solution. Vacuum traps are instrumented to detect liquid. Interlocks shut off the vacuum supply to prevent plutonium solutions from being syphoned to geometrically unfavorable equipment.

Administrative limits are included in the criticality safety program for the RMA and RMC Lines. These limits include restrictions on the number and size of containers, spacing limits between containers where physical restraints are not provided, and restrictions on fire-fighting practices for most gloveboxes.

A criticality detection and alarm system is located in the RMC Line area. Personnel are required to rapidly evacuate the area if the alarm sounds. Evacuation drills are conducted regularly. The detection and alarm equipment is checked on a scheduled basis, and redundancy is provided. This system must be functional to perform work in the gloveboxes in the RMC Line.

Radiological Safety. Exposure to radiation is controlled to ALARA standards. Lead shielding, water walls, or Lexan™ plastic are used to reduce exposure. Shielding is strategically located so that the average exposure rate at workstations is approximately 0.5 mrem/h. See Chapter 8.0, Section 8.3, for more details.

All gloveboxes are maintained at negative pressure (-0.3 to -1.5 in. w.g. relative to the room) to confine plutonium to the gloveboxes if a small break in the confinement barrier occurred. Differential pressure gauges, located in all gloveboxes, measure the negative pressure in the gloveboxes relative to the room. Three stages of filtration (two of which are testable) are provided before offgases are discharged to the atmosphere via the 291-Z-1 stack.

CAMs are provided to monitor workplace breathing air in occupied areas where a person without respiratory protection is likely to be exposed to a concentration of radioactive materials in the air exceeding 1 DAC over a prolonged period of time or where there is a need to alert potentially exposed workers to significant increases in the level of airborne radioactive material levels, which could result in 40 DAC-hours in a typical work shift. Portable CAMs are used when working in a greenhouse or other areas not adequately covered by a CAM. The CAMs alarm locally, with both audible and visual alarms. Personnel are required to immediately evacuate a room when a CAM alarms. Air-purifying respirators are available, if needed.

Industrial Safety. The amount of combustible material in a glovebox is administratively controlled to the minimum required for the operation. Gloveboxes are equipped with combustion and/or heat detectors. The operators are trained to take action to extinguish any small fires. The fire department responds whenever a fire alarm is sounded.

Glovebox panels where fires could occur are fabricated of metal/glass construction or fire-resistant plastics such as Lexan™. Glovebox gloves are made of fire-resistant neoprene. The gloves are normally tied off outside of the glovebox.

6.4.2.4 Chemical Process Systems. There are no chemical process systems associated with other RMA and RMC Line processes.

6.4.2.5 Instrumentation and Control Systems. Functioning I&C systems remain in place to monitor glovebox differential pressures. The RMA and RMC Line gloveboxes are designed to provide confinement of dispersible radioactive materials. The glovebox design requires a operating range of

-0.5 to -0.7 in. w.g. relative to room pressure. Each glovebox has a differential pressure gauge to monitor interior pressure relative to the room. The gauges are oriented to provide easy viewing for operating personnel.

6.4.2.6 Control Rooms and Control Areas. There are no control rooms or control areas associated with other RMA and RMC Line processes.

6.4.2.7 Analytical Sampling. There is no analytical sampling associated with other RMA and RMC Line processes.

6.4.2.8 Product Handling. There is no product handling associated with other RMA and RMC Line processes.

6.4.2.9 Identification of Items for Safety Analysis.

6.4.2.9.1 Criticality Prevention. While plutonium metal is no longer produced in the RMA or RMC Lines, there are residual quantities of fissile material in the gloveboxes. In addition, active gloveboxes may be used for interim storage of plutonium-bearing material. The established CPS limits are still valid for gloveboxes that are not in routine use. Gloveboxes HC-1, HC-2, HC-3, HC-4, HC-13MD, HC-18BS, HC-18M, HC-21A, HC-21C, HA-21I, HA-22B, HA-23S, HA-28, and HC-230C-2 are used for reactive plutonium-bearing material stabilization and plutonium-bearing solution stabilization operations using the Production VDC.

Dry Process Gloveboxes. Analytical methods used include the use of well-referenced data, Surface Density versus Unit Shape Factor method, Monte Carlo calculations, and all plutonium is assumed to be ^{239}Pu unless the isotopic content is specifically controlled by analysis and administrative procedures. All moderated mixtures are assumed to be metal-water or oxide-water. The analysis considers available containers, maximum fissionable material densities, credible moderators, glovebox floor surface area, the presence of criticality safety drains, reflectors near the glovebox (floors, drains, or ceiling), and normal maximum process limits.

Contingencies are developed for each operation in these gloveboxes. These contingencies include the following, as appropriate to the operation analyzed:

- Addition of fissile material in excess of that allowed by the CPS, either as additional units (overloading) or larger units (overbatching or double batching)
- Addition of a moderator
- Intermixing of units of various types
- Violation of spacing rules
- Spills
- Equipment failure
- Equipment volume or depth larger than expected

- Accumulations of fissionable material
- Density of materials increased
- Addition of a reflector.

The controlling (worst-case) contingency for dry gloveboxes is the introduction of a moderator (e.g., water used in fire fighting). Specific analyses demonstrate that the operation will remain acceptably subcritical even if moderated.

Wet Process Gloveboxes. The criticality safety engineer determines which conditions result in exceeding solution depth must be considered as part of the evaluation. Since leaks of plutonium solution and the addition of water to the floor cannot be precluded, the floor and container mixtures are assumed to be ^{239}Pu-water. Reflection from actual materials of construction, such as "Hanford" concrete with 0.68 wt% hydrogen and the 304-L stainless steel floor of the glovebox, are evaluated. Top reflection is assumed to be nominal (1 in.) water. Interacting tanks, containers, and other plutonium-bearing equipment are specially modeled.

In general, when plutonium nitrate is present, it is assumed that there is no excess nitrate ion present. This assumption yields conservative results, tends to overestimate the value of k^{eff}.

The presence of criticality drains, sumps, or sloping glovebox floors are considered. Abnormal conditions evaluated by the criticality safety engineer in establishing margins of safety include exceeding container mass and volume limits, violating spacing between containers and tanks, violating the sludge depth limit in the tanks, substituting plutonium-water for plutonium nitrate in the tanks and containers, and exceeding the solution depth on the hood floor. Examples of abnormal conditions that could be evaluated are described in the following paragraphs.

An operator could introduce solution containing more than 450 g/L of plutonium into a feed line and transfer the solution into the storage tanks. One or both of the storage tanks could receive more than its mass limit of plutonium.

Two containers, each having a maximum volume of 1.5 L and containing a maximum of 400 g plutonium, are permitted inside the glovebox. One of the containers is allowed to be moved within 25 cm of a storage tank for sampling purposes. A single credible operator error could result in both containers being placed against a storage tank.

Activation of the sprinkler system could introduce water into the room. Water mist could be introduced between the storage tanks and could enter the glovebox through a broken window.

If two storage tanks were full and one of the pipes connected to the lower tank cracked or failed, the contents of both tanks could drain to the hood floor. The maximum permissible depth of solid accumulations in the bottom of any tank is established. However, long-term operations involving the tanks might result in a thicker layer of solid accumulations.

Containers in a hood could exceed the allowable volume limit, or mass in a container could exceed the limit. The spacing requirement between tanks and container could be violated, or plutonium solution in one tank might be of higher concentration than allowed (600 g/L of plutonium versus a 450 g/L plutonium limit). Solution on the floor could also exceed depth limits (possibly 2.5 in. deep versus a 0.5-in. limit).

In some cases, incredible conditions may be analyzed to provide additional information, such as addition of spectral reflection equals 1.0 in the +x direction (full-water reflection) along the side of two tanks or material in tanks or containers being more reactive (plutonium-water versus plutonium nitrate).

Support Gloveboxes. Activities evaluated in the support glovebox analyses are decanning, inspecting, weighing, recanning, transport, and maintenance. Other associated activities may be included, but in each case the equipment and process steps are carefully defined in the evaluation document.

Evaluation methods used are Monte Carlo calculations, the Surface Density versus Unit Shape Factor method, or the use of well-referenced data. Other calculational methods may be selected in some cases.

Accident and abnormal conditions considered include addition of fissile material in excess of that allowed with additional units (overloading) or larger units (overbatching or double batching), addition of a moderator, and violation of spacing rules. Plutonium is assumed to be ^{239}Pu, unless otherwise specified, and moderated mixtures are assumed to be plutonium metal-water or PuO_2-water.

Implementation of Criticality Safety in Other RMA and RMC Line Processes. Process equipment and containers used in the dry process gloveboxes are designed to remain subcritical, even in the event of accidental flooding. Criticality safety drains are also provided to limit the depth of liquid in a flooding event. Storage gloveboxes are designed to provide spacing between plutonium units.

Dry process glovebox specification establish limits for moderator limits, liquids in the glovebox, container size, batch or unit mass, spacing, and spills or accumulations of fissionable material.

Wet process glovebox specifications establish limits on equipment size, shape, and location for fissionable material concentration and masses, acid concentration, number, size, and spacing of containers that may be used, and spills or accumulations.

Support gloveboxes specifications establish limits for number of units, size of containers, fissionable content of containers, allowed moderation levels, spacing, spills or accumulations.

6.4.2.9.2 Chemical Safety. The cold chemical preparation areas in the 234-5Z Building (rooms 336 and 337 on the third floor) are no longer used to support plutonium conversion in the RMA and RMC Lines. Dilute nitric acid solutions are prepared for the LI/LO of plutonium nitrate solutions (see

Section 6.2.9.2.1). Potassium hydroxide solution may still be prepared for use in neutralizing spills of acidic solutions (see Section 6.2.9.2.2). The PFP chemical management program is discussed in Section 10.4.5.

6.4.2.9.3 Process Shutdown Modes. Emergency shutdown of glovebox equipment can be accomplished in several seconds by shutting off power to the gloveboxes. Short-term shutdown (one day to several weeks) involves placing plutonium in safe storage. This can be accomplished within one hour or less, depending on the number of packages involved. Normal surveillance would continue. This includes checking to ensure that proper ventilation of gloveboxes is maintained, with negative pressure at or below -0.5 in. w.g., pressure drop across filters less than 3 in. w.g., and radiation surveys.

Long-term shutdown (years) is not an option until all of the plutonium has been moved out of the PFP. This option would involve packaging and shipping all plutonium out of the PFP, either offsite or to a new facility at the Hanford Site. It would take months to accomplish a full cleanout. Surveillance requirements would be minimal, primarily ensuring ventilation is adequate for areas containing residual plutonium, and performing area radiation surveys until D&D of the facility is completed. Additional information on facility shutdown and cleanout activities is provided in Section 6.7.

6.4.2.9.4 Instrumentation. There is no instrumentation associated with other RMA and RMC Line processes that requires identification for safety analysis purposes.

6.4.2.9.5 Remote and Contact Maintenance. Remote and contact maintenance is addressed by Section 6.4.1.9.5.

6.4.3 Previous Remote Mechanical A and Remote Mechanical C Line Processes

The previous RMA and RMC Line processes are inactive and operation is not authorized. Reactivation of any portion these processes would require the performance, documentation, review, and approval of new hazard and accident analyses, with revision as required to this Final Safety Analysis Report (FSAR). However, all gloveboxes (except those physically removed or declared inactive) are authorized for interim storage of plutonium-bearing material. A list of active and inactive gloveboxes at the time of preparation of the FSAR is provided in Chapter 5.0, Table 5-5. A current list of active and inactive is maintained in WHC-SD-CP-OSR-010 (WHC 1994a). Inactive gloveboxes cannot receive containers of plutonium, but residual quantities of material remain in these gloveboxes. Several of the gloveboxes are now used for the thermal stabilization process (see Chapter 6.0, Section 6.4.1).

A historical detailed description of the former processes can be found in Revision 0 of this FSAR. In addition, historical information can be found in previous PFP Safety Analysis Reports (SAR)s which analyzed different facets of operations at the PFP:

6.4.3.1 Narrative Description. The nitric acid solutions of plutonium were converted to plutonium metal in the RMA and RMC Lines. The RMA Line was also once used for converting plutonium nitrate to plutonium oxide powder. The plutonium conversion process is inactive and operation is not authorized. The RMA and RMC Lines are located on the first floor (near the center) of the 234-5Z Building.

The plutonium conversion process consisted of preparing plutonium nitrate feed, precipitating plutonium oxalate from the plutonium nitrate solutions (approximately 250 g/L of plutonium), filtering the oxalate, calcining it to PuO_2, and fluorinating the PuO_2 to form PuF_4 (see Figure 6-18). The PuF_4 powder was loaded into a MgO crucible with elemental calcium and iodine,

charged to a pressure vessel, and fired to produce metallic plutonium and a slag containing CaF_2, calcium, iodine, and small amounts of unreacted PuF_4. The slag was removed from the metallic plutonium button and sent to slag and crucible (S&C) dissolvers (along with the remains of the MgO crucible), to recover the residual plutonium. The metal button was cleaned, pickled, sampled, weighed, and placed in metal cans for storage.

The RMA Line operations were conducted in 6 "wet" gloveboxes where plutonium solutions were present, and in 28 "dry" gloveboxes where plutonium powders and metal were present. The process was semi-remotely controlled from the RMA control room 233. The "wet" gloveboxes include the following:

- Glovebox HC-4 - Feed Solution Staging
- Glovebox HC-6 - Feed Solution Staging
- Glovebox H-7A - Solution Treatment
- Glovebox HA-9A - Powder Production
- Glovebox H-14P - Pickling
- Glovebox HA-46 - Potassium Hydroxide Scrubber.

The "dry" gloveboxes include the following:

- Glovebox HC-3 - Conveyer
- Glovebox HC-4 - Conveyer
- Glovebox HC-5 - Conveyer
- Glovebox H-8A - Conveyer
- Glovebox H-9B
- Glovebox H-9C - Powder Weighing
- Glovebox H-9D
- Glovebox H-9E - Product Handling
- Glovebox HA-10 - Conveyer
- Glovebox H-11
- Glovebox H-12S - Pressure Vessel Sanding
- Glovebox H-13MD - Crucible Loading
- Glovebox H-13G - Gasket Installation
- Glovebox H-13ABC - Reduction to Metal
- Glovebox H-14CC - Crucible Cutter
- Glovebox H-14DC - Pressure Vessel Dumper
- Glovebox H-14S - Sampling

- Glovebox H-15B - Weighing
- Glovebox H-15
- Glovebox H-16CS - Conveyor Storage
- Glovebox H-16BS - Button Storage
- Glovebox H-16L
- Glovebox HA-19 - Storage
- Glovebox HA-20MB - Machining
- Glovebox HA-21I - Reactive Material Stabilization (See Section 6.4.1.4.2)
- Glovebox HA-22B - Weighing (now used for seal-in of plutonium material for transfer to Glovebox HA-23S for storage and for staging items into and from glovebox HA-21I)
- Glovebox HA-23S - Reactive Material Stabilization (See Section 6.4.1.4.2)
- Glovebox HA-28 - Conveyor.

The RMC Line operations were conducted in 6 "wet" gloveboxes where plutonium solutions were present, and in 15 "dry" gloveboxes where plutonium powders and metal were present. The process was semi-remotely controlled from the RMA control room 229. The "wet" gloveboxes include the following:

- Glovebox HC-4 - Feed Solution Staging
- Glovebox HC-6 - Feed Solution Staging
- Glovebox HC-7 - Solution Treatment
- Glovebox HC-9B - Powder Production
- Glovebox HC-17P - Pickling
- Glovebox HA-46 - Potassium Hydroxide Scrubber.

The "dry" gloveboxes include the following:

- Glovebox HC-1 - Conveyer
- Glovebox HC-2 - Conveyer
- Glovebox HC-10 - Powder Weighing
- Glovebox HC-11 - Powder Pan Storage
- Glovebox HC-12S - Pressure Vessel Sanding
- Glovebox HC-13MD - Crucible Loading (now used for seal-in/seal-out of plutonium-bearing material for thermal stabilization processes)

- Glovebox HC-15 - Reduction to Metal
- Glovebox HC-16CC - Crucible Cutter
- Glovebox HC-17DC - Pressure Vessel Dumper
- Glovebox HC-17SBB - Sampling/Weighing
- Glovebox HC-18BS - Reactive Material Stabilization (See Section 6.4.1.4.2)
- Glovebox HC-18M - Reactive Material Stabilization (See Section 6.4.1.4.2)
- Glovebox HC-21C - Reactive Material Stabilization (See Section 6.4.1.4.2)
- Glovebox HC-21A - Reactive Material Stabilization (See Section 6.4.1.4.2).

6.5 LABORATORY SUPPORT

6.5.1 Process Description

6.5.1.1 Narrative Description.

6.5.1.1.1 Plutonium Process Support Laboratories. The PPSL are chartered to operate nonradioactive and radioactive chemical process and equipment demonstration laboratories. These laboratories support numerous programs across the Hanford Site and occasionally on other DOE sites. The PPSL facilities include necessary connections to essential building services, including ventilation, drains, vacuum, electricity, water, compressed air, and compressed gas. The PPSL support processing facility flowsheet evaluation, troubleshooting, new technology implementation, and process demonstration. The above activities are performed on bench scale and pilot-plant scale. The PPSL also analyze nonroutine samples for process support, and develop new methods that are transferred to other organizations when the methodology is well established and the need becomes routine. The PPSL also processes plutonium materials to demonstrate processes in cases where they have exclusive expertise.

The PPSL facilities allow several approved, independent projects or experiments to proceed simultaneously. Administrative procedures and controls for PPSL operation are discussed in general in Chapter 10.0. All changes to configuration and design, such as installation of a new piece of equipment are done in accordance with FSP-PFP-5-8, *Plutonium Finishing Plant Administration* Section 2.27, "Senior Supervisory Watch Program." Part of the analysis requires a review of the FSAR to determine if the change or activity is covered in the existing safety analysis. If not, a revision to the FSAR is required before the work can proceed.

The specific laboratory rooms of the PPSL within the PFP, and their capabilities, are described in the following sections.

Room 179. This room contains a particle counter and an inactive TGA instrument. The TGA is located in a dedicated glovebox, with five other gloveboxes and three hoods available for general alpha-radioactive chemistry projects. All three hoods in room 179 are restricted to glovebox air lock access, because the exhaust ventilation no longer meets the airflow requirements. All glovebox drains in the room are connected to the D-4 drain line.

The gloveboxes contain electrically heated furnaces, hot plates, and small rotary mixers. Personnel using the furnaces and hot plates normally remain in the area, so that access to any hot surface by others is impeded. In addition, work in this room seldom requires access to the same work area by personnel working on different projects. Rotary mixers are used only when submerged magnetic stir bars cannot be used.

Room 180. This room contains a thermal analysis system with simultaneous mass spectroscopy (used to identify decomposition products) and one mobile ultraviolet-visible light spectrometer (used to identify unknown materials). The room contains a hood connected to a glovebox, to permit the analysis of radioactive and nonradioactive samples.

Room 182. This room contains a scanning electron microscope (SEM) for examining minute quantities of solids. The SEM includes energy dispersive X-Ray microanalysis capabilities for elemental analyses.

Room 183. This room is currently used for storage of scintillation counting equipment and waste drums.

Room 186. This room is used only for electronics and for the vertical calciner seismic shutdown system.

Room 187. This room contains five hoods for small general radioactive chemistry projects. Two of the hoods are connected to the normally nonradioactive D-3 drain line.

Room 188. This room contains a production-scale prototype vertical denitration calciner that is used to develop direct denitration techniques. The Laboratory Prototype Calciner is also used to evaluate equipment performance and operating parameters. The equipment and process used in laboratory calciner operations are described in detail in the Laboratory Prototype Calciner addendum to this FSAR. The laboratory calciner is not currently authorized for operation.

Room 189. This room contains an ion chromatograph used to examine non-radioactive samples. The room will be upgraded by adding a hood for a radioactive sample cell for the chromatograph.

Room 190. This room is a vault-type room used for storing stable plutonium material that is not currently needed for ongoing projects and demonstrations.

Room 191. This room is a chemistry laboratory used for general, nonradioactive chemistry projects and chemical preparation. The room contains three hoods and two countertop areas. The hoods in this room are connected to the E-3 ventilation system. The drains in this room are also connected to the D-3 drain line.

Room 202. This room is the nonradioactive pilot-plant laboratory, and contains one walk-in hood and two large countertop areas for general chemistry projects. The hood has a dedicated ventilation system that can also be used for tanks or other equipment in room 202. This ventilation system exhausts to the atmosphere through exhaust fan EM-15. The room also contains a small mezzanine area. Most of the room is (or can be) occupied by multiple pilot plants or process demonstrations. The 4.8-m ceiling allows projects to be considerably larger than in other PPSL rooms. Drains in this room are connected to the D-3 drain line.

Furnaces, hot plates, and rotary mixers are used in the open in this room whenever required by a project. Other types of heating are also used occasionally for specific process demonstrations or other needs.

General. Gloveboxes and hoods are connected to the E-4 ventilation system, except where noted above. All gloveboxes (except glovebox 179-1) are served by building water, pressurized air, and vacuum utilities.

Pressurized air is supplied at 90 lb/in^2 (gauge), but can be controlled to lower pressures. Much of the equipment in the PPSL facilities is portable and may be relocated, as required, to support laboratory activities.

The combined sum of all dispersible plutonium in the PPSL, the PFPAL, and the Standards Laboratory is administratively controlled to 12.45 kg by WHC-SD-CP-OSR-010, *Plutonium Finishing Plant Operational Safety Requirements* (WHC 1994a). Although individual room limits do not exist, the CPSs for the gloveboxes and hoods within the rooms restrict the amount of material within any room. Fissionable material is kept in room (vault) 190 except when in use, or in a nonstable form such as solution or moist solids.

Radioactive nonstable materials are stored in gloveboxes. Chemicals are stored in approved containers on shelving in a storage area. Flammable liquids are stored in flammable material storage cabinets.

The PPSL have no equipment receiving emergency power, and no need for backup power is foreseen. Equipment could be connected to backup emergency power in the future, on a case-by-case basis. Emergency lighting is available in room 179, room 183, room 202, corridor 10, and other strategic locations.

6.5.1.1.2 Plutonium Finishing Plant Analytical Laboratory. The PFPAL is located in the east end of the 234-5Z Building and is used to perform analytical and physical test analyses on plutonium samples. The samples come from the PFP operations, the PFP research laboratory, and a few special test samples from other locations.

The PFPAL is located in rooms 131 through 157 of the 234-5Z Building, with quality control standards being formulated and dispensed from rooms 221-C, 221-D, and 221-E. Plant air samples are counted in room 221-G.

The samples received and analyzed represent process control, material accountability, and product analysis. Both chemical analyses and physical tests are performed. The samples may be liquid, solid (metal and oxide), or substrate captured (filter media).

Chemical analyses are performed to determine major and minor element content, isotopic ratios, radiochemical characteristics, and pH. Physical tests to determine LOI and density are also performed.

All laboratory activities are conducted by trained personnel using approved procedures. Laboratory performance is controlled and monitored by a quality control program that includes analysis of standards, compliance overchecks, and audits.

All laboratory open-faced hoods and gloveboxes are exhausted through the E-4 system. The open-faced hoods and gloveboxes are isolated from the environment by two stages of independent and testable HEPA filtration. No uncontained plutonium in dry form is allowed in any of the open-faced hoods, or in the glovebox in room 143. The glovebox in room 144 is limited to less than 0.2 g uncontained plutonium powder or solid form material for PuO_2 and metal sample dissolution only.

All other laboratory gloveboxes, with the exception of gloveboxes 1 through 5 in room 139 and the single glovebox in room 145, contain both inlet and outlet HEPA filtration. Gloveboxes 1 through 5 in room 139 contain only inlet HEPA filters, and the single glovebox in room 145 contains only outlet HEPA filters. Gloveboxes 1 through 5 in room 139 are interconnected. The normal flow of exhaust from these gloveboxes is via a pass-through to glovebox 6. Glovebox 6 contains outlet HEPA filtration. Gloveboxes 1 through 5 are also connected to an emergency exhaust system. A normally closed valve on the emergency exhaust system opens when the gloveboxes start to pressurize. The emergency exhaust is HEPA filtered before connecting to the E-4 exhaust system. The single glovebox in room 145 is also equipped with an emergency exhaust system. A normally closed valve on the emergency exhaust system opens when the glovebox starts to pressurize. The emergency exhaust is HEPA-filtered before connecting to the E-4 exhaust system.

Room 131. Room 131 is used to analyze samples, by weight, for plutonium concentration. It contains one glovebox made up of three sections used for dissolution and analysis of product quality plutonium. Section 1 contains a muffle furnace used for fusing PuO_2 samples. Section 2 provides a working area where samples are dissolved, heated, titrated, and liquid waste is accumulated. Section 3 contains an argon-purged balance used in the titrations.

Room 132--Mass Spectrometer Laboratory. Room 132 contains two thermal ionization spectrometers for the isotopic analysis of extremely small samples of plutonium and uranium.

Room 133--Dark Room. Room 133 contains the grating and camera portions of a 2-m emission spectrograph and equipment for developing the film. It also contains a refrigerator for film storage. No radioactive materials are allowed in the room.

Room 134. Room 134 is used to prepare samples for analysis on the mass spectrometer, and it contains four open-faced hoods. Hood 1 is used to mount plutonium and uranium by electrodeposition, for analysis by thermal ionization mass spectrometry. Hood 2 is used to purify samples for the mass spectrometer via anion exchange resin columns. The anion resin columns are 3 in. long and contain 2 mL of resin. Hoods 3 and 4 are laminar downflow open-faced hoods with exhaust HEPA filtration. These hoods are used for single filament mounting of nanogram quantities of plutonium, for analysis by thermal ionization mass spectrometry.

Room 135. Room 135 is used to store and mount samples in support of the mass spectrometer laboratory, and it contains four hoods. Hood 1 is used to mount plutonium and uranium by electrodeposition, for analysis by thermal ionization mass spectrometry. Hood 2 provides temporary storage of samples to be analyzed throughout the laboratory. Hoods 3 and 4 are not in use at this time.

Rooms 136 and 137. Room 136 contains an emission spectrophotometer and a quantometer. Room 137 contains the arc stand for the 2-m film spectrograph. These instruments are used in trace element analyses of plutonium and uranium product. Each room contains a glovebox made up of three sections. Section 1 contains equipment for sample preparation. The plutonium metal, nitrate, and oxide samples are heated to 950 °C in a muffle furnace. Samples are then moved to Section 2, which contains equipment for the preparation and weighing of sample electrodes. The samples are moved to Section 3, which contains the arc stand where the sample electrodes are shot in a moist argon/oxygen atmosphere.

Room 139. Room 139 contains six interconnected gloveboxes. It is used to process and store all PuO_2 and plutonium metal received by the laboratory for analysis. The gloveboxes are as follows. Glovebox 1 contains a balance and the airlock for the entire system. Samples are weighed, and equipment and samples may be entered into the glovebox through the airlock. Glovebox 2 contains a balance and is used to weigh plutonium metal and oxide for analysis. Glovebox 3 is used for storage, and glovebox 4 contains the V-blender. The PuO_2 samples are blended in this hood before the start of analysis. Glovebox 5 is a storage hood containing 50 racks, each capable of holding up to 42 25-mL to 35-mL glass or plastic sample bottles per tray. Glovebox 6 contains two balances and a programmable furnace used for LOI analysis. There is a hygrometer located in glovebox 6 which is no longer functioning. Samples for other analyses are weighed in this hood.

The room contains a storage rack with three storage positions (each storage position may contain up to 400 g Pu), and a bench with three can sealers (one manual, two electric) for 7-in. food pack and soup cans.

Room 141--Cold Laboratory. Room 141 is used to analyze cold samples that support the building process such aqueous makeup samples and elevator oil viscosity. It contains a cold hood partitioned into two sections, a sink, and a water purifier. Additional equipment (a hot plate and muffle furnace) is located in the hood. The room also contains additional furnaces. No radioactive material is allowed in the room. Part of this room is set up as a satellite area for chemicals that have not been introduced into the controlled areas.

Room 142. Room 142 consists of four vented storage cabinets. The first two shelves in each cabinet are used to store standards for the radiochemical standards laboratory, and the other two store standards for the PFPAL. The four cabinets store approximately 250 g plutonium (oxide, metal, and nitrate) and/or ^{233}U per shelf. All standards or samples are double contained. Each storage cabinet is equipped with built-in spacers to comply with the CPS. The storage cabinets are 1/8-in. stainless steel. All four cabinets exhaust through the E-4 system, and do not contain HEPA filters.

Room 143. Room 143 is used for the handling of liquid waste that is not compatible with the waste recovery system and disposal of LLW to tank D-8 in 241-Z. Room 143 contains four hoods and one glovebox (glovebox 4). Hoods 1 and 2 are used by PFPAL waste handling personnel and are open-faced (ported hoods). Hood 3 and glovebox 4 were used to treat plutonium solutions with $C_2H_2O_4$ to form a plutonium oxalate cake. This solution was filtered, and the cake was disposed of as reactive scrap. The scrap was counted on the Segmented Gamma Scan Assay System (SGSAS) and transferred to operations for processing. The hood and glovebox are currently used for storage. Hood 5 was used to dispose of LLW via a drain system to the D-8 tank in the 241-Z Building, for transfer to tank farms. The hood contained a waste aspirator to transfer the waste from the 4-L bottles to the sink drain. This hood is no longer used to dispose of LLW. The hood is usable, but it is not being utilized. The sink in the hood is inoperable.

These are standard laboratory open-faced hoods with ports, to which gloves could be attached (if needed) for additional radiological safety. The single glovebox does not provide total containment since it is directly connected to an open-faced hood. For this reason, the glovebox is controlled by radiological posting consistent with open-faced hoods (0 g uncontained plutonium powder or solid-form material). There are no HEPA filters provided at the hoods or glovebox. The exhaust ducting from the hoods and glovebox leads to a filterbox in the E-4 ventilation system.

Room 144. Room 144 contains eight hoods and one glovebox. The work performed in this room provides the primary support for PFP and PPSL plutonium samples. Analyses that are performed include plutonium concentration, visual percent solids, americium concentration, and acid/base determination. Both aqueous and organic samples of high-level and low-level sample concentrations are analyzed. This room also has facilities to dissolve plutonium metal and PuO_2.

Hood 1 is used to package/repackage samples for shipment, hood 2 is used for temporary storage, and hood 3 is used for sample storage. Hood 3 contains one 4-L waste bottle and one 500-mL trap bottle connected to a 26-in. Hg vacuum. One-liter polybottles containing process organic may also be present. During peak operations the samples are disposed of every 24 h. At the beginning of every day shift, the waste recovery technician checks and removes all full bottles to room 152.

Glovebox 4 is used to break down samples received from customers, and to dissolve PuO_2, plutonium metal samples, and solids contained in process samples. All high-level solutions (>60 g/L plutonium) are disposed of in a 500-mL glass bottle. All low-level samples (<60 g/L plutonium) are disposed of in a 4 L bottle.

Hoods 5 and 6 are used for uranium analysis by kinetic phosphorescence. Hood 5 contains reagents, while hood 6 contains the uranium analyzer.

Hood 7 is used for temporary storage, and hood 8 is used for storage of high-level waste samples (>60 g/L plutonium). Samples are segregated plutonium density for criticality control.

Hood 9 contains two 4-L waste bottles and is connected to a 26-in. mercury vacuum and electrical outlets. This hood also has an organic waste bottle. Various analyses, or sample preparations, are performed in hood 9. For high-level (greater than 60 g/L plutonium) and low-level (less than 60 g/L plutonium) radioassay, the sample is placed in a vial, the vial is sealed, and taken to the counting room for analysis. Analyses are performed by the solution counter method.

For americium analysis, the sample is placed in a vial, the vial is sealed, and taken to counting room for analysis. Acid and base titration and low-level plutonium extraction are also performed. For plutonium extraction, the sample is contacted with tributyl phosphate/normal paraffin hydrocarbon and aqueous solutions are sent to the 222-S Laboratory for inductively coupled plasma emission spectroscopy/Dionex. A specific gravity densitometer is also used, where a sample is taken into the chamber of the instrument, measured, and discarded to waste.

Room 145. Room 145 contains a glovebox that was used to analyze sinterability, bulk and tap density of PuO_2, and for the preparation of PuO_2 standards for the emission spectrometer. The glovebox contains two sections. The top section contains a programmable furnace with a normal operating temperature 1600 °C, a balance, a sintering press, bulk and tap density equipment, a mortar and pestle, and screens. The bottom section was formerly used to prepare plutonium standards for emission spectrograph analysis.

This is an older laboratory glovebox, constructed in the early 1970's. It is no longer in use, and the plutonium inventory in this glovebox is 0 g.

Room 145-A. Room 145-A is used to store supplies routinely used in the laboratory. There are no special alarms, protective features, or services provided for this room.

Room 146. Room 146 has four open-faced hoods and a glovebox. The hoods are used for percent organic analysis and storage. The glovebox is used for waste repackaging. All laboratory hood waste goes through this glovebox before being placed in 55-gal drums.

Room 147. Room 147 is used as an office and is not discussed further.

Room 148. Room 148 has two hoods that are cleaned out. The remainder of this room is used as the laboratory chemical satellite area.

Room 149. Room 149 contains an open-faced hood and a hood converted into a glovebox. Since relatively large amounts of plutonium compounds were to be dissolved in the glovebox, the exhaust passes through a scrubber. The converted glovebox is also equipped with inlet HEPA filtration. The glovebox

was not used for dissolving plutonium compounds, and the room is currently used for packing and unpacking shipping containers.

Rooms 150 and 151--Counting Room/Shift Office. Room 150 serves as the counting room and room 151 as the shift office. Room 150 contains six counting systems. There are four hyper-pure germanium detector systems that are used for gamma ray spectroscopy. These detectors are continuously stored at a reduced temperature through the use of liquid nitrogen dewars. The dewars are refilled from cart-portable liquid nitrogen tanks. Room 150 contains a liquid scintillation counting system used for counting samples with very low activities. A gas flow proportional counting system is used for alpha and beta radiation. This detector utilizes a fill gas of 90% argon and 10% methane, known as P-10 gas. The fill gas is available from gas lines in room 150.

Room 152--Waste Laboratory. Room 152 contains a load-in hood and a glovebox. It was used to reprocess liquid laboratory wastes. The open-faced hood (551) initially received the waste container. The waste was sampled for H+ and plutonium analysis before being returned to the process. Currently this hood is only used for storage of high-level wastes.

Glovebox 552 consists of three storage tanks, a distillate tank (sent to D-8), vacuum trap, steam concentrator, caustic scrubber, water condenser, and a LO tank. This glovebox is out of service.

These are standard laboratory hoods and gloveboxes and are exhausted via the E-4 system.

Room 153. Room 153 consists of four open-faced hoods and one glovebox, which are used to support PPSL projects. Hood 1 is used to analyze samples in support of the PPSL, and the hood can have up to 150 g plutonium present. Hood 2 is used to analyze total inorganic carbon (CO_3). Hood 3 is used to analyze total organic carbon samples. The samples are injected through the hood and into the system with a syringe and needle. There is a CO_2 coulometer and printer outside the hood. Hood 4 is used for storage of plutonium oxalate waste. Glovebox 5 contains equipment necessary to perform the surface area analysis. The instrumentation is located on a bench outside the hood and the line runs into the hood. This glovebox may contain approximately 250 g plutonium, and liquid nitrogen was used inside of the glovebox during the analysis. This glovebox is no longer in use.

Room 154. Room 154 contains one glovebox partitioned into three sections, and is used for analysis of both PuO_2 and metal samples. At one time, carbon, sulfur, and nitrogen were analyzed in this glovebox. The glovebox contains two carbon, sulfur, and nitrogen analyzers with furnaces. The glovebox can contain up to 400 g plutonium.

Room 155. Room 155 contains four hoods and associated equipment that were used to support sludge work. Hood 1 contains an ultraviolet spectrometer for measuring trace quantities of nitrite. Hood 2 contains electrodes connected to a pH meter external to the hood, and a hot plate. These are used to measure nitrate. Hoods 3 and 4 are used to analyze for percent organic in sludge samples.

Room 156. Room 156 contains one glovebox divided into two sections and two hoods. The glovebox is no longer in service, and hoods 3 and 4 are used to analyze PPSL samples for F^- and Cl^- ion concentration.

Room 157. Room 157 consists of four gloveboxes (with furnaces) and a sample cell, which were used to support PuO_2 work. Gloveboxes 1 and 2 have been sealed and are no longer in service. Gloveboxes 3 and 4 are new and have never been used. They contain equipment for particle determination, and future use of these gloveboxes would be for temporary storage.

Room 221-G. Room 221-G contains an air filter analyzer.

6.5.1.1.3 Radiochemical Standards Laboratory. The radiochemical standards support that is provided in rooms 221-C, 221-D, and 221-E is devoted to the formulation, verification, packaging, and distribution of the plutonium-containing standards needed in the PFPAL.

Room 221-C. Room 221-C contains a glovebox used for the preparation of ultra-pure PuO_2 standards for the PFPAL. The glovebox is equipped with a balance and an oscillating blender which has been dismantled for disposal. Various materials are blended with PuO_2 to produce quality control standards. Initial preparation of oxide material also occurs in this box. The glovebox is equipped with both inlet and outlet HEPA filters. The glovebox is exhausted via the building E-4 exhaust system. A hygrometer is also located in the glovebox to measure the dew point of the dry air. The hygrometer is not working since there is no dry air supply. Room 221-C also contains two hoods and a vented storage cabinet which is no longer in use. Hood 1 is used for storage. Hood 2 is used for "cold work" with HNO_3 or millicurie level quantities of plutonium dilutions, and for decontamination of glassware. Hood 2 is also used for sheet standard (fiberous papers with mounted plutonium nitrate) preparation. Both hoods contain sinks. The vented storage cabinet is used to store radioactive materials.

Room 221-D. Room 221-D contains equipment used for makeup of plutonium sheet standards and for performing plutonium nitrate characterization. It contains four hoods and a glovebox. Hoods 1 and 2, located on the southwest wall of 221-D, are used as open-faced hoods for the pipetting of plutonium solutions. Hoods 3 and 4 located on the southeast wall of 221-D, are used for plutonium nitrate characterization. The glovebox is used for plutonium nitrate storage, but is not currently being used. This is a standard laboratory glovebox equipped with both inlet and outlet HEPA filters.

Room 221-E. Room 221-E contains equipment for the preparation of thorium and uranium standards. This room is used in conjunction with rooms 221-C and 221-D to support actinide standards used in all 200 Area analytical laboratories. The work done in this room is nonradioactive or has a low-radioactivity level. The room contains bench tops and three open-faced hoods. One hood contains a sink and an ultrasonic cleaner which is no longer used. The second hood contains an electric Bunsen burner for flaming counting disks. The torch is no longer in use and the gas bottles have been removed. A third hood contains heat lamps for drying low-level sheet standards used in NDA techniques. Additional items in the room include the q-water system (an ion exchange resin water purification system to provide low conductivity/high purity water), and an analytical balance on a balance table.

6.5.1.1.4 Nondestructive Analysis Laboratory. The NDA of containers of plutonium material indicates the total mass of isotopes by measuring the radioactive emissions and/or the heat output of plutonium-bearing material in the package. Several NDA systems are available for package evaluation. The NDA Laboratory is located in room 637 of the 2736-ZB Building.

Isotopic Counters. Material in cans (recoverable, metal, or oxide) and drums of waste may be assayed in any one of four isotopic counters in the NDA Laboratory. The isotopic counters detect and measure spontaneously emitted gamma radiation, which allows identification of TRU isotopes and the mass fractions of each isotope. Each assay requires approximately 2.5 h of counting time. The detectors are chilled with liquid nitrogen, and 15-L dewars of liquid nitrogen are kept in the laboratory for each counter.

Pre-Equilibration Bath. Before it is measured by calorimeter, a plutonium-bearing item is placed inside of a calorimeter adapter, which is then brought to a uniform temperature by immersion in the pre-equilibration bath. This temperature adjustment allows the calorimeter to measure container heat output more rapidly and accurately. The demineralized water heat sink in the bath is continually agitated by two electric mixers to ensure uniform temperature throughout the bath.

Calorimeter. The plutonium material container, following temperature adjustment, is placed in a calorimeter for the determination of container heat output. A container may be in the calorimeter from 2.5 to 4.0 h before a heat output can be assigned to the container. The performance and accuracy of the calorimeters are affected by air-space insulation around the heaters, room temperatures, and humidity. Six calorimeters are in use, each measuring a single container at a time.

Neutron Well Coincidence Counter. The Neutron Well Coincidence Counter (NWCC) may be used to determine total plutonium content of a plutonium material container instead of the calorimeter. The counter consists of a large-volume polyethylene moderator, into which the container is placed. Detectors in the polyethylene are positioned radially around the container, and measure the coincident spontaneous-fission neutrons emitted by even-numbered isotopes of plutonium. The NWCC is especially useful when large numbers of containers of similar chemical makeup require assay. Counting time is much shorter than with a calorimeter, and temperature pre-equilibration is not required.

Segmented Gamma Scan Assay System. The SGSAS counts containers of waste or recoverable material on rotating tables. Tables are sized to accommodate containers from 0.5 L polyjars to 55-gal drums. Counting time is 10 to 15 min, depending on the container. The assay system uses a germanium detector cooled with liquid nitrogen. A small ^{75}Se source is associated with the system for determining gamma ray attenuation corrections (adjusting for gamma ray attenuation due to changing matrix density). There are two small-table SGSASs in the 234-5Z Building, and one large-table and one small-table SGSAS in the 2736-ZB Building.

NaI Gamma Package Counter. The NaI package counter detects TRU holdup in waste. The counter is designed and calibrated specifically for large waste packages occasionally weighing over 300 lb, combustibles, or low-density

noncombustibles. The counter is normally used for the assay of room and glovebox waste drums, empty polyethylene bottles, and used HEPA filters. The counter is calibrated against a 300-g plutonium source before counting each item. If a waste package contains 10 g plutonium or more, it is held for recount on an SGSAS (for greater accuracy).

Portable NaI and germanium counters are used primarily for in-situ measurement of plutonium in duct work, HEPA filters, and tanks, and occasionally, for counting packages. They are calibrated by a sheet standard of dried plutonium on filter paper, triply encapsulated.

6.5.1.2 Flowsheets. The majority of laboratory support functions are batch processes. Flowsheet documents are not used in the PFPAL, Radiochemical Standards Laboratory, or the NDA Laboratory.

Flowsheets are seldom required in the PPSL. Most of the projects are small chemistry demonstrations done in batch steps. Many of the processing steps are not determined until the results of the previous step are known. Larger continuous experiments (pilot plants) frequently demonstrate process flowsheets planned for use in production facilities. These planned flowsheets can be either used full-scale for the PPSL demonstration or scaled down, as appropriate. Flowsheets are incorporated into test plan documents unless the flowsheet is so large or complex that a separate flowsheet document is required.

The flowsheet for the Laboratory Prototype Calciner using the vertical direct denitration calciner process, located in room 188 of the PPSL, is incorporated into WHC-SD-CP-TP-088, *Test Plan for Radioactive testing of a Vertical Direct Denitration Calciner* (WHC 1994c). The flowsheet for this process as well as the related equipment and process descriptions are provided in the Laboratory Prototype Calciner addendum to this FSAR.

6.5.2 Process Chemistry and Physical Chemistry Principles

A variety of chemical reactions take place in the PPSL, PFPAL, and the Radiochemical Standards Laboratory. Chemicals that are handling hazards include, but are not limited to, HNO_3, HF, H_2SO_4, NH_2NH_2, NaOH, KOH, and $KMnO_4$. The NDA Laboratory does not conduct chemical processes.

The Laboratory Prototype Calciner located in room 188 of the PPSL is used to convert plutonium nitrate solution into a stable, storable plutonium dioxide powder. The process chemistry involved in operation of the laboratory calciner is described in the Laboratory Prototype Calciner addendum to this FSAR.

6.5.3 Mechanical Process Systems

The NDA Laboratory operations are essentially mechanical in nature as described earlier.

6.5.4 Chemical Process Systems

A variety of laboratory processes involving chemical reactions take place in the PPSL, PFPAL, and the Radiochemical Standards Laboratory. Descriptions of the rooms and equipment where these processes occur are given in Sections 6.5.1.1.1, 6.5.1.1.2, and 6.5.1.1.3. One of these processes is testing the direct denitration of plutonium-bearing solutions in a production-scale prototype vertical denitration calciner. The Laboratory Prototype Calciner is used to evaluate equipment performance and process parameters for operation of the calciner. The direct denitration of plutonium-bearing solutions using the Laboratory Prototype Calciner takes place in glovebox 188-1, located in room 188 of the 234-5Z Building. The Laboratory Prototype Calciner addendum to this FSAR provides a description of the equipment and process for the laboratory calciner. The addendum includes a hazard evaluation of the process, appropriate accident analysis, designation of safety equipment and specification of controls for laboratory calciner operations.

6.5.5 Instrumentation and Control Systems

Instrumentation systems for laboratory support processes are associated with safety significant instruments which are common to most of the PFP facilities (e.g., CAM and CAS). Other instrumentation systems may be added or used per the needs described in the applicable test plan. See the Laboratory Prototype Calciner addendum for information on instrumentation and controls associated with operation of the laboratory calciner.

6.5.6 Control Rooms and Control Areas

The equipment used in the PPSL, PFPAL, Radiochemical Standards Laboratory, and the NDA Laboratory is locally controlled. It can be switched off to ensure a safe shutdown. The equipment used for the Laboratory Prototype Calciner is described in the Laboratory Prototype Calciner addendum to this FSAR.

6.5.7 Analytical Sampling

Product produced by laboratory testing is sampled in the glovebox or hood where produced. The samples are sent to the PFPAL for the desired analyses. Any stabilized product is later sent to 2736-ZB for calorimetry and storage. The plutonium content of the laboratory calciner product is determined by calorimetric measurements in the 2736-ZB Building. A sample of the product is LOI tested in the PFPAL. Additional information regarding the laboratory calciner is provided in the Laboratory Prototype Calciner addendum to this FSAR.

6.5.8 Product Handling

The product destined for storage is transferred from product receiver vessels into slip-lid cans. The stabilized plutonium-bearing material

generated by direct denitration is handled, packaged, and stored in accordance with the process descriptions provided in the *Laboratory Prototype Calciner* addendum to this FSAR.

6.5.9 Identification of Items for Safety Analysis

6.5.9.1 Criticality Prevention.

Criticality Safety Evaluation for Laboratories. The PPSL, PFPAL, Radiochemical Standards Laboratory, and the NDA Laboratory handle fissionable material on a routine basis. The laboratory CPSs establish sets of allowable limits for gloveboxes and hoods, and state where each set may be applied. Design restrictions are not always practical in laboratory gloveboxes, and criticality safety must be achieved by conservative restrictions on plutonium mass, volume, and spacing.

Abnormal conditions considered in the criticality safety evaluation are addressed in the following sections. These conditions can occur individually or as a combination of events.

Mass Limit--Mass limits are imposed in two ways. A glovebox or hood may have a single mass limit for all fissionable material stored inside, or a separate mass limit may apply to more than one unit mass of fissionable material inside the glovebox (a glovebox may have a limit of 4 unit masses with 400 g plutonium per unit mass). Violations of mass limits could occur if a worker introduced a single mass of plutonium that (by itself) exceeded the mass limit for the glovebox, hood or unit mass. A violation could also occur if a mass of plutonium was introduced to existing plutonium in the glovebox, hood, or unit mass such that the total amount of plutonium exceeded the mass limit. These violations could occur by failure to record the introduction of a package of fissionable material to the glovebox, failure to remove a package of plutonium from a glovebox after removing its record from the glovebox inventory, incorrect labeling of the amount of plutonium on a package before placing it in the glovebox, or incorrect calculation of the new total before introducing a new package with plutonium.

Volume Limit--Volume limits are imposed in three ways. There may be a limit to the allowable volume of a single container, the allowable volume of the collection of containers within a glovebox, hood or unit mass, or both. Violations of the volume limits could occur in the same manner as mass limit violations.

Introduction of Water--The presence (or use) of water may not be allowed due to the amount and form of plutonium present in a glovebox. Violations could occur if workers failed to lock out any water supply lines correctly. The potential activation of a fire extinguishing system is considered in CSEs. Water could also be introduced by firefighters using water on a fire inside the glovebox.

Spacing--Spacing limits are imposed in two ways. A glovebox may have a limit on how closely another mass of fissionable material may approach the glovebox, or there may be minimum spacing requirements between separate unit masses within a glovebox. Violations could occur if workers moved containers

of fissionable material without verifying the distance between the package being moved and any adjacent packages or unit masses.

Material--The type of material may also be limited within a glovebox, hood, or unit mass. The limits restrict the introduction of moderating materials and neutron reflectors, the use of plastics in operations, and the use of organic liquids. Violation could occur if workers introduced such materials in excess of the limits. Neutron reflectors must be controlled both outside and inside of the glovebox or hood enclosure. The unapproved installation of radiation shielding material could represent a violation, if its proximity to the fissile accumulations, or if the type of shielding used could increase neutron reflection. Another type of material violation that could occur is the addition of a plutonium container with an unacceptably high ratio of hydrogen to plutonium (H/Pu > 2).

Implementation of Criticality Safety in the Laboratories. Criticality safety is implemented in the laboratories by posting and complying with the specific limits in effect on a glovebox or hood. A CPS containing a uniform set of eight posting limits has been approved for use in the laboratories. Laboratory management and the CSR determine the necessary postings for a glovebox or hood, depending on the type(s) of work to be done and the amount of plutonium necessary to accomplish the task(s). The appropriate limits are posted on the glovebox or hood after ensuring that the current plutonium masses, spacing, and container volumes, etc., are in compliance with both the old and new set of limits.

Plutonium mass and container volume inventories are posted on the glovebox for tracking as material is moved, added, or removed. The inventory is compared with the criticality posting before work begins in any hood or glovebox. These inventories are verified and adjusted before adding and after removing plutonium or containers. The inventories and the condition of glovebox criticality drains are also verified monthly by laboratory personnel, and the results are reported to the CSR. The CSR and the laboratory management also inspect the laboratory areas quarterly for compliance with criticality safety limits.

Design features for criticality safety, such as geometrically favorable equipment, are used to the maximum extent possible. Specific safety features are described in Section 6.3.9.1.

6.5.9.2 Chemical Safety. Significant amounts of chemicals, with a variety of hazards to personnel are used in the PPSL, PFPAL, and the Radiochemical Standards Laboratory. the chemicals used that are handling hazards include, but are not limited to, HNO_3, HF, H_2SO_4, NH_2NH_2, KOH, and $KMnO_4$. Chemical safety is ensured by strict compliance with *Chemical Management* (HNF-PRO-2258) and safety requirements contained in ZAP-000-010, "PFP Chemical Hygiene Plan" (see Section 10.4.5). Safety requirements for chemicals are contained in the Material Safety Data Sheet (MSDS) provided by the chemical manufacturer and the HEHF. Complete listings of applicable MSDSs are maintained by the laboratories and copies are readily available to laboratory personnel. New or unique handling requirements are listed and discussed in all new procedures. These are approved by the appropriate safety organizations before implementation.

Nonradioactive dry chemicals received at the PFPAL from the Radiochemical Standards Laboratory are stored in room 141 for technical staff use. When one of these chemicals is used for a procedure, it is placed in the hood or glovebox where the procedure is performed. Chemicals received from the Radiochemical Standards Laboratory are clearly labeled and are in containers appropriate for the chemical mixture. The label indicates the name(s) of the person(s) preparing the chemical, the date the chemical was placed into the container, and the expiration date for the chemical. Chemical work is not allowed unless at least one other person is in the laboratory, or is aware that chemical work is underway.

Flammable and combustible liquids are stored in cabinets dedicated to flammable materials. Concentrated acid solutions and other hazardous liquids are stored separately from the flammable materials in dedicated cabinets. Spill kits are located in the laboratories.

Radioactive chemicals are handled in accordance with the applicable RWPs. The RCTs are frequently in the laboratories and ensure compliance with the RWPs.

Exposure rate varies with the amount and type of material being handled. The gloveboxes in room 139 of the PFPAL range from 10 to 80 mrem/h. The other hoods and gloveboxes of the PFPAL range from 0 to 40 mrem/h. The higher dose rates are permitted only where intermittent occupancy is required. See Chapter 8.0 for specifics on radiation protection.

Disposal of waste chemicals after testing is guided by (HNF-PRO-455), *Solid Waste Management*. Radioactive waste solutions are sent to the Tank Farms via the tanks at 241-Z. Waste that could not be sent the tanks at 241-Z was run through the waste concentrator in room 152, or converted to an oxalate in room 143. These high-level plutonium-bearing materials were then sent back to operations via tank 227 or as oxalate cake. Radioactive and nonradioactive solid wastes are packaged and disposed of in accordance with *Hanford Site Solid Waste Acceptance Criteria*, (Willis 1994).

Most chemical operations for the Laboratory Prototype Calciner occur inside the glovebox, which shields workers from chemical hazards. The Laboratory Prototype Calciner addendum to this FSAR provides information on chemical and process hazards and protective features related to laboratory calciner operation.

6.5.9.3 Process Shutdown Modes. The laboratory support projects are normally small and localized, allowing power requirements to be met with standard 110-Vac electrical outlets. Special shutdown systems are not required for these projects, with the exception of the SEM and the Laboratory Prototype Calciner. Because the SEM must operate under a high vacuum it contains an interlock built-in by the manufacturer to protect the equipment. If the vacuum is lost or is inadequate for any reason, the electron source automatically shuts down. Emergency shutdown features for the laboratory calciner are discussed in the Laboratory Prototype Calciner addendum to this FSAR.

Normal shutdown for the SEM is in accordance with the operating manual provided with the unit, and no safety hazards are involved. Normal shutdown

of the Laboratory Prototype Calciner is in accordance with PPSL operating instructions.

Larger projects may also require emergency shutdown systems. However, most projects can be shut down completely by deenergizing the process at one or two standard electrical switches or plug-ins. Special instructions for shutdown including locations of circuit breakers and essential valves outside of the laboratory area, are supplied whenever other groups provide overnight or weekend surveillance of PPSL projects.

6.5.9.4 Instrumentation. Instrument needs for laboratory support projects are determined on a case-by-case basis. Most chemistry projects require little or no instrumentation. Larger projects may require thermocouples, pH meters, gas monitors, or similar small equipment that is available from vendors for direct use. Small amounts of chemicals are normally used so that effluent monitors are not required, and nonradioactive waste solutions are collected, sampled, and analyzed by the PFPAL before disposal under PFP Environmental Compliance guidance. Radioactive effluents are disposed of through the building radioactive waste drain system under the guidance of both PFP Environmental Compliance and PFP Process Engineering.

Instruments that are required for laboratory support projects are maintained and calibrated according to the building PM&S system and/or manufacturer instruction manuals. General building instruments used in the PPSL facilities (CAMs, survey instruments, the CAS, security alarms) are controlled by Engineering Administration and calibrated by maintenance personnel under the PM&S and PM programs.

Process specific operating parameters that are monitored for the Laboratory Prototype Calciner are discussed in the Laboratory Prototype Calciner addendum to this FSAR.

6.5.9.5 Remote and Contact Maintenance. There is no remote or contact maintenance associated with laboratory processes that requires identification for accident analysis purposes.

6.6 MISCELLANEOUS PROCESSES

6.6.1 236-Z Plutonium Reclamation Facility Process Systems

The PRF process systems are inactive and operation is not authorized. Active electrical power to the PRF is limited to the 17 inch mercury vacuum system, criticality alarm system, normal lighting/receptacle panels, elevator, security systems, building support systems (e.g., HVAC), and emergency lighting/receptacle panels. A total restoration of PRF electrical power is not planned. Power to PRF process systems and equipment will remain deactivated except when required for PRF facility clean out and deactivation.

Reactivation of any portion of these process systems would require the performance, documentation, review, and approval of new hazard and accident analyses, with associated modifications (as required) to this FSAR. However, all gloveboxes (except those physically removed or declared inactive) are

authorized for interim storage of plutonium-bearing material. A list of active and inactive gloveboxes is located in Chapter 5.0, Table 5-5. Inactive gloveboxes cannot receive containers of plutonium, but residual quantities of material remain in the gloveboxes.

A historical detailed description of the former processes can be found in Revision 0 of this FSAR. In addition, historical information can be found in the previous PFP SARs, which analyzed different facets of operations at the PFP (see Section 6.4.3).

6.6.1.1 Narrative Description. The plutonium recovery process converted various plutonium-bearing materials and aqueous feeds to a purified plutonium nitrate product suitable for conversion to plutonium metal or PuO_2 (see Figure 6-22). This plutonium recovery process is inactive and operation is not authorized.

The process included recoverable material dissolution and scrap stabilization, and plutonium purification. Recoverable material dissolution and scrap stabilization [miscellaneous treatment (MT)] included hydrolysis, clarification, and calcination. Plutonium purification involved feed preparation, solvent extraction (SX) and stripping, and organic cleanup. The process also involved concentration and clarification of the aqueous product and waste streams.

Most of these process steps were located in the PRF in the 236-Z Building (see Figure 6-23). Some of the miscellaneous processing took place within the 234-5Z Building of the PFP.

6.6.1.1.1 Recoverable Material Dissolution and Stabilization. Recoverable plutonium-bearing materials (PuO_2 powders, incinerator ashes, sludge, and miscellaneous solutions) were converted to aqueous plutonium solutions in gloveboxes in the PRF and in the 234-5Z Building.

Several processes, collectively known as MT, were conducted within a complex of five gloveboxes in Room 41 of the PRF. The gloveboxes in Room 41 are numbered one through six (glovebox MT-2 has been removed). MT consisted of inspecting, weighing, sampling, splitting, burning, repacking, dissolving, precipitating, and storing operations. The glovebox operations involved batch lots of different types of materials.

Additional capacity and capabilities were provided by four gloveboxes located in the 234-5Z Building. Glovebox HC-60, located in Room 230, was used for hydrolysis of scrap containing greater than 20% organic. Glovebox HA-40F, located in Room 169, is equipped with two furnaces that were used to calcine miscellaneous solids, primarily ash from the incinerator at the Rocky Flats Plant (RFP) in Colorado. Glovebox HC-46F, located in Room 170, contains dissolver pots and support equipment that were installed (but never used) for dissolving plutonium-bearing solids. Glovebox HA-21I once contained furnaces that were used for calcining hydrolyzed plutonium-bearing materials.

Two continuous refluxing dissolver/condensers installed in the 236-Z Building process canyon were used for dissolving crushed sand and S&C from the RMC Line in the 234-5Z Building. The dissolvers were supported by three systems: acid feed, product treatment, and offgas treatment. Three

interconnected gloveboxes in room 43 of the 236-Z Building also supported dissolver operations. Cans of feed material were dropped into the dissolvers from the charging glovebox. The dissolvers contained hot nitric acid provided by the acid feed system. Gases evolved during dissolution passed through a reflux condenser and scrubber before being vented into the 236-Z process cell. The product solution flowed to a settling tank, where large entrained solids were removed. The product then flowed to a centrifuge, where the remaining solids were removed. The product solution was used as feed to the SX system.

6.6.1.1.2 Plutonium Purification. Plutonium purification was accomplished by feed preparation, solvent extraction and stripping, and organic cleanup. The first step was to prepare and sample feed from such sources as the MT dissolvers, the S&C dissolvers, the filtrate from the RMC Line, and the aqueous waste concentrator.

The plutonium extraction and stripping function took place in the process cell and the upper sections (extending up through gloveboxes on the fourth, fifth, and sixth floors) of the 236-Z Building.

An organic stream composed of 20% TBP and 80% CCl_4 was used to complex, or chemically combine, with plutonium. Because the solvent density was greater than the density of aqueous feed, the organic solvent flowed downward through the aqueous solution. As the liquids passed each other, plutonium in the aqueous feed transferred to the organic extractant. After passing through the organic phase, the aqueous solution flowed out of the top of the column and was sent to Aqueous Waste Processing. The organic phase containing the extracted plutonium continued to move downward and met with an aqueous solution that had been recycled from the stripper column. Finally, near the bottom of the column, the organic met a dilute stream of HNO_3, which removed chemical impurities from the organic.

The plutonium-bearing organic was then pumped to the top of the plutonium stripping (CC) column and flowed downward. As it flowed downward, the organic passed through a dilute aqueous solution of HNO_3 and hyrdoxlamine nitrate (HN) that entered the bottom of the column. This aqueous solution removed ("stripped") the plutonium from the organic, and was recycled back to the plutonium extraction (CA) column.

The organic, which contained impurities, went to Organic Cleanup. The organic from the CC column flowed continuously through three columns to remove trace plutonium, impurities, and organic degradation products, and a fourth column reacidified the organic before being recycled back to the CA column.

6.6.1.1.3 Aqueous Solution Concentration. There are two steam evaporators in the PRF, which are the product concentrator and the filtrate/waste concentrator.

The product concentrator is a "falling film" evaporator. Internal "stripping steam" was used to heat the product solution as it passed through a bed of Raschig rings. Steam was also supplied to a steam jacket, which surrounded the concentrator. Any organic contained in the solution was vaporized as it contacted the hot surface of the Raschig rings. The product solution was then centrifuged to remove any suspended solids, and returned to the 234-5Z Building storage to await metal conversion.

The waste concentrator is also steam-jacketed, and the solution was boiled to reduce its volume. The filtrate from the RMC Line, the organic cleanup column aqueous waste solutions, and miscellaneous solutions were pumped to the evaporator, where antifoam agents and HNO_3 were added if necessary. The concentrated aqueous waste was drained to holding tanks (TK-23 or TK-24) and transferred back to the SX feed preparation.

6.6.1.2 Design Description. The PRF was designed to confine plutonium, and meet commercial and industrial safety criteria. The design of operating area compartments (nuclear and chemical) and critical safety structures has been reanalyzed and upgraded a number of times since the facility was built.

The 236-Z process cell is constructed of noncombustible materials (concrete walls, floors and ceiling, with a stainless steel floor liner capable of holding spills from leaking piping or vessels). The process cell uses limited or controlled air in-leakage to prevent loss of containment. The cell walls and the ceiling are 2 ft thick, providing limited radiation protection in the event of a criticality. The process equipment was designed to be geometrically favorable for criticality safety. Personnel exposures were limited by minimizing "hands on" operation through extensive use of mechanical equipment. Valving and pumps are located outside of the process cell but inside gloveboxes. Major components can be replaced and repaired in the hot maintenance shop, which is located just outside of the process cell.

The process vessels and piping were designed to contain contaminated (plutonium-bearing) solutions. Generally, these streams were operated at atmospheric pressure and relatively low temperatures. Specific equipment items were designed to meet the American Society of Mechanical Engineers (ASME) *Boiler and Pressure Vessel Code* and the American Society for Testing and Materials (ASTM) Code for pressure piping.

The MT gloveboxes were designed to confine plutonium and provide for inlet and outlet air ventilation through HEPA filter systems. The process equipment was designed to provide confinement during normal feed preparation and stabilization. The spacing and size of the equipment, in conjunction with administrative controls on mass and concentration, provide criticality control. The glovebox, ventilation system, and process equipment were designed to minimize the amount of contamination in the event of a fire or explosion, by maintaining airflows and pressure drops.

6.6.1.3 Safety Criteria and Assurance. When in operation, the primary safety concerns associated with plutonium recovery operations were criticality safety, radiological safety, process upsets, and industrial safety. Because of the presence of residual radioactive materials in the process cell and in plutonium-recovery gloveboxes and process equipment, in addition to the use of plutonium-recovery facilities for the temporary storage of in-process material, criticality prevention and radiological hazards continue to be safety concerns. In addition, there are some chemical safety concerns. As discussed below, the PFP has committed to removing all remaining chemicals to alleviate these concerns by December 31, 1997.

6.6.1.3.1 Criticality Safety. The process cell and each glovebox have been analyzed to ensure compliance with the criticality safety criteria presented in Chapter 4, Section 4.3.4. The established CPS limits are still

valid for gloveboxes that are not in routine use. Criticality safety features incorporated into the design of the plutonium recovery operations include the following.

- The process equipment is designed to be geometrically favorable even if operated with plutonium at the maximum credible concentration (if the plutonium precipitates during a process upset) and optimum moderation.
- Spacing between major pieces of process equipment is fixed to reduce neutron interaction.
- Process cell tanks are spaced from the walls, floor, and ceiling to reduce neutron reflection from the concrete.
- Process containers, such as cans or polybottles, are designed to be subcritical even if overbatched and moderated.
- Liquid level on the east and west glovebox floors is physically controlled by weirs. each floor weir discharges to a lower level, and the lowest level discharges to the process cell floor bays.
- The depth of liquid in the process cell floor bays is physically controlled by weirs that direct flow of solutions from bay sections near the east and west walls to the center of the cell. The process cell floor bays can hold all the tank contents of the cell without exceeding the maximum safe depth.
- Process waste is collected in geometrically favorable tanks that are physically isolated from sources of concentrated plutonium. These tanks are connected to waste storage systems through lines operated by supervisor-controlled valves. Transfers are made only after an acceptable plutonium content in the waste is verified by sampling.
- Cooling water systems are designed to ensure that any leakage would flow into the process system and would not discharge into the waste storage system.

Operating procedures incorporate administrative criticality safety requirements. These requirements include plutonium mass limits, limits on the number and size of containers, spacing limits between containers, concentration limits, and limits on the depth of solution spills.

The PFP is equipped with an integrated criticality detector system. The detector system covers all areas where the occurrence of a criticality is considered possible. Periodic operability checks of detectors and alarms are made, and personnel response to criticality alarms is verified by drill exercises.

6.6.1.3.2 Radiological Safety. Although plutonium conversion is no longer being performed, the associated gloveboxes and process cells contain residual radioactive material and may be used for the storage of in-process material. The gloveboxes and cells provide the primary confinement barrier to the release of radioactivity. Gloveboxes are maintained at negative pressure

(-0.3 to -1.5 in. w.g.) to ensure plutonium is confined if a small break in the confinement barrier should occur. Airflow is through a nontestable HEPA filter at the glovebox exit, and at least two testable HEPA filter stages, in series, in the E-4 offgas treatment system. Pressure drop across filters is indicated by Magnahelic gauges and is periodically monitored to detect filter plugging.

The process cell tanks are shielded by a 24-in. concrete wall. Individual gloveboxes, such as at the maintenance cell, have provisions to add lead glass shielding as necessary. Leaded gloves are used in most positions to reduce gamma ray exposure to the hands and arms. Surveys are taken frequently to assess radiation levels at workstations.

The CAMs are provided to monitor workplace breathing air in occupied areas where a person without respiratory protection is likely to be exposed to a concentration of radioactive materials in the air exceeding 1 DAC over a prolonged period of time or where there is a need to alert potentially exposed workers to significant increases in the level of airborne radioactive material levels, which could result in 40 DAC-hours in a typical work shift. Portable CAMs are used when performing nonroutine maintenance activities. Air-purifying respirators and fresh-air-supplied masks are available, if necessary.

CAMs and their associated alarm function also mitigate some potential facility worker hazards at PFP. In general, during stabilization activities, the primary boundary to release of radionuclides to occupied rooms are gloveboxes, process systems, or sealed plutonium storage containers. The primary boundaries to plutonium release inside PFP can fail through several potential mechanisms, such as improper maintenance, equipment degradation, or abnormal glovebox pressurizing events. In many cases, there is no obvious indication that a plutonium release has occurred. The CAMs serve to validate the satisfactory performance of the barriers to plutonium release. If one of these primary barriers fail and plutonium is released into PFP, then alarms will be actuated when the alarm setpoint is reached. Upon actuation of the alarm, facility workers are trained to promptly evacuate the affected air space. These actions in combination serve to reduce the potential plutonium inhalation dose received by the affected facility workers. The public and onsite workers are not significantly affected by these potential plutonium releases inside PFP because the exhaust air flow is filtered by the applicable exhaust ventilation system prior to release outside of PFP.

6.6.1.3.3 Chemical Safety. The cold chemical preparation area in the 236-Z Building (room 40 on the fourth floor) is no longer used to support PRF process systems. The small quantities of chemicals remaining in the PRF tanks and process lines will be managed and dispositioned in accordance with HNF-2977, *Plutonium Reclamation Facility (PRF, Building 236-Z) Layup Plan* (BWHC 1998b).

The excess chemicals (a few hundred pounds) consist primarily of B-acid, sodium nitrate, sodium carbonate, antifoam, and TBP which are currently stored at the PRF. These chemicals have no near-term use in the PRF and present a potential chemical release hazard to facility workers should a tank or storage container leak. Certain chemicals may pose a reactivity or flammability hazard. Therefore, the PFP facility has performed a hazard assessment (BWHC

1997b) relative to chemicals within the plant and identified those items requiring mitigation. Accordingly, plans have been developed to track, monitor and remediate the hazards identified in the assessment.

6.6.2 232-Z Waste Incinerator Facility

The 232-Z Waste Incinerator Facility housed an enclosed system of gloveboxes and hoods that were used for sorting solid waste contaminated with plutonium, leaching noncombustible wastes, chopping waste for size reduction, and incinerating combustible wastes. Solutions and ash from this facility were processed for plutonium recovery in the PRF. The 232-Z Building has undergone bulk plutonium removal from the gloveboxes, hoods, and associated ventilation exhaust piping, in preparation for D&D activities. The fire alarm service in the 232-Z Building remains in operation to alert the necessary personnel, although the automatic sprinklers have been temporarily deactivated.

6.6.3 241-Z Liquid Waste Treatment Facility

The 241-Z Complex (or Liquid Waste Treatment Facility) consists of five structures: the 241-Z Building, 241-ZA Sampling Building, 241-ZB Caustic Tank (now inactive and scheduled for removal), 241-Z-RB Retention Basin (scheduled for removal), and 241-ZG Changeroom. This complex adjusts and temporarily stores PFP radioactive liquid waste (RLW) before transfer to the 244-TX Receiver Facility. The operation of the 241-Z Complex is described in Chapter 7.0.

6.6.4 242-Z Waste Treatment Facility

The 242-Z Waste Treatment Facility was used to treat PRF waste and to extract americium from the waste. On August 30, 1976, an incident occurred that involved the explosion of an ion-exchange column containing approximately 100 g of ^{241}Am. The routine use of the facility was discontinued following this incident and minimal cleanup efforts have been undertaken. In 1977, a testable HEPA filter was added to the E-3 exhaust system for the building. In 1981, the glovebox ports were sealed, nonessential services were disconnected, and contaminated surfaces were treated with a strippable coating. Entry into this building is nonroutine and strictly controlled.

6.6.5 243-Z Complex Low-Level Waste Treatment Facility

The 243-Z Complex (or LLWTF) is a low hazard process facility. It provides the best available technology for treatment of low-level contamination, both chemical and radiological, for the PFP waste that once was disposed to the 216-Z-20 crib. The facility is comprised of two buildings: the 243-ZA Building sump (containing the influent sump tank), and the 243-Z Building (containing the remainder of the equipment for the facility). The functions of the 243-Z Complex are controlled by the MICON™ operator station (see Chapter 5.0, Section 5.4.2, for more details of the MICON™ System). The operation of the 243-Z Complex is described in Chapter 7.0.

6.7 FACILITY CLEANOUT ACTIVITIES

Since startup, the PFP complex has played a historic role in ensuring that defense production needs were achieved. The history of the PFP complex has been one of continuous upgrading, renovation, replacement, and expansion of functions, processes, and buildings, to meet the changing plutonium-production and recycle requirements. The evolving regulations for nuclear operations and the improving technology for plutonium material processing, have been and will continue to be the cause for renovation. As a result, the PFP facilities occasionally have been shut down and placed in inactive status, awaiting further action (refer to HNF-PRO-1794, *Facility Shutdown, Standby, and Transfer*). Often they were restarted for a new mission. The consideration of D&D criteria for plant design was introduced to the nuclear industry after most of the PFP buildings were constructed.

Shutdown facilities first undergo terminal cleanout operations (TCO). This is intended to recover any residual plutonium-bearing material in the equipment, gloveboxes, and offgas system, and leave the area in a stable condition requiring minimum surveillance pending D&D or reactivation. The activities associated with TCO must be evaluated to determine if they are covered by the facility authorization basis. If the activities directly or indirectly affect the facility authorization basis, then the activity must be reviewed in accordance with the Unreviewed Safety Question (USQ) process specified by DOE Order 5480.21, *Unreviewed Safety Questions*. Changes to the authorization basis are incorporated into the PFP FSAR during the annual update.

Following TCO, a facility will eventually undergo D&D activities. This involves removal and disposal of the equipment, decontamination of the room or building and removal of the building if it has no alternative use. A preliminary hazard analysis and a safety analysis report, if necessary, is required before initiating D&D activities.

Shutdown facilities remain on ventilation control as long as dispersible radioactive materials are present. The CAMs are also maintained active, or portable units are used if infrequent entry is required. Fire protection and alarm systems are also maintained active. Criticality incident detection is maintained active until fissile material quantities, forms, or configurations ensure criticality prevention. Power to equipment is shut off, but room lighting is maintained.

Surveillance of the shutdown facilities ranges from once per shift to infrequently. The 242-Z facilities have been stabilized and (except for the ventilation system, wet-pipe sprinkler system, and room lighting) isolated. Surveillance of the 242-Z facilities is conducted approximately once every 6 months. Surveillance is conducted in 232-Z on a weekly basis. Surveillance of the remaining facilities within 234-5Z ranges from daily to once per shift.

Surveillance is performed to verify that conditions within the facility have not changed. The condition of gloveboxes and equipment is noted. Particular emphasis is placed on noting if water is present. Ventilation is checked to determine if it is operational. Radiological surveys are conducted at a frequency dependent on the facility. As required in FSP-PFP-5-8,

Volume 1, Section 7.1, "Hazardous Material Management Plan/EPCRA 312 and 313" (see Section 10.4.5) systems or storage locations with "hold-up" or legacy chemicals are inspected to verify system or container integrity.

Table 6-2. Receipt of Nuclear Material Requirements.

A. Nuclear Information Required for Material Receipt		
1.	Material identification	Unique identity number given to material item.
2.	ANSI Class	The ANSI classification (of unirradiated plutonium-bearing material).
3.	Material description	Chemical and physical makeup of material; presence of any radiolytic gas producing components (water, organics); and LOI. The material description should be as complete and accurate as possible.
4.	Gross weight	Weight of container, seals, and labels plus contents in grams.
5.	Net weight	Weight of contents only, in grams.
6.	Element weights	Actual weight of nuclear materials (plutonium, uranium, americium, etc.) in grams.
7.	Isotopic distribution	Weight percentages of isotopes including date determined.
8.	H/X Ratio	Categorize H/X as $\leq$2, $\leq$10, $\leq$20, or fully moderated ($\leq$20).
9.	Decay heat	Thermal energy released by decay of isotopes expressed in watts.
B. Shipper Information Required for Material Receipt		
1.	Station and location	Name and address of shipping organization.
2.	Shipper's contact (particularly necessary if information in A and B is incomplete)	Name of person knowledgeable about shipment and its contents, with telephone number.
C. Receiving Approvals Required for Material Receipt		
1.	Material scheduled to be shipped to PFP from offsite, shall be reviewed by the SNM Evaluation Team. A shipping, receiving, and storage plan shall be developed and approved prior to receipt of the material at PFP

Vault 192-A	Room 236	Vault 4	Room 642

Table 6-5. Reactive Plutonium-Bearing Material Stabilization Operating Limits.

Variables	Operating Limit	Safety/Operations Considerations
Feed Specifications		
Feeds Permitted	PRF Sludge, Plutonium oxide, Plutonium metal, (oxycarbonate), Incinerator Ash. Exception. Additional feed type items may be processed with the written concurrence of Process Engineering as long as they fall within the defined safety boundary.	Off-gas production
Feed NOT Permitted: PRF Sludges in HA-21I	Plutonium bearing materials with ≥ 10 grams or more of organic in charge.	Excessive butene production
Controller Specifications		
Furnace Ramp Rate Settings	Ramp rates controlled to prevent equipment damage.	Heating coil damage; Efficiency
Heating Cycle PRF Sludge Settings	Minimum Times: 1st Soak - 1.5 hr at 175 °C 2nd Soak - 2 hr at 1000 °C	Excessive butene production; Material stability
High Furnace Temperature Setting	Controlled to prevent equipment damage.	Heating coil damage
Off-Gas System		
Off-Gas Flow Rate for PRF Sludge Material (no flow rate required for other materials)	120 std. ft^3/hr. minimum until furnace temperature reaches 300 °C on ramp-up.	Off-gas accumulation
Purge System		
Purge Flow Rate: Purge flow rate applies only to Glovebox HC-21C	≥ 45 std. ft^3/hr. CO_2 Used only for charges with a potential for containing TBP.	Flammable gas concentration
Fire Safety		
Fire Suppression System Activation Temperature	93 °C	Fire
Combustible Materials	Kept to a minimum.	Fire
Product Specifications		
LOI	Must Meet WHC (1995a) Vault Storage Criteria	Gas generation
Glovebox Specifications		
Plutonium Limit in Glovebox HC-21C	5,000 g	Administrative Control
HA-21I, with operating limit of 8,000 g, as an administrative control		

Table 6-6. Operating Specifications for Plutonium-bearing Solution Stabilization Using the Production VDC

Variable	Specification Limit	Basis
Nitric Acid Concentration	≥ 1.6M(H^+)	Lower acid concentrations may cause Pu polymer formation which may create a criticality concern.
Organic in Feed	< 1%	Organic could provide a fire hazard.
Solids in Feed	< 1% total solids	Solids may plug calciner or other equipment.
Pu Concentration	> 30 g/l; < 450 g/l	Lower limit assures efficient calciner operation; upper limit based on criticality prevention.
Pu Nitrate Feed Rate	< 3.5 l/hr	High flow rate could cause vaporized liquids to overwhelm off-gas system.
Calciner Operating Temperature	> 950 °C	Long term storage criteria requires heating materials to ≥ 950 °C which also reduces absorptivity of the Pu Oxide.
Calciner High Temperature	1050 °C	Lower temperatures assures integrity of calciner materials of construction and increases heater life.
Calciner Vacuum	< 5 inches W.G.	Prevents overpressurization of calciner and potential release of material to glovebox. (instrumentation provides indication only)
Calciner Filter High Differential Pressure	< 100 inches W.G.	Limit pressure drop across filters to prevent calciner pressurization and release of material to glovebox.
Glovebox High Temperature	70 °C	Provides sufficient warning of impending conditions which could activate fire suppression system at 93 °C.
Vacuum Trap Level	< 6 inches	Vacuum trap prevents liquids from entering vacuum system which is not criticality safe.
Glovebox HC-230C-2 Sump Probes	Operational when handling Pu Solutions	Prevent Pu solutions on floor in excess of crit. spec.; prevent overflow through crit. drain to room 230C floor.
PuO_2 Loss-on-Ignition	< 0.5 % wt. LOI at ≥ 950 °C for 2 hours	To meet interim storage criteria to prevent pressurization of stored items.
PuO_2 Density	< 6.2 g/ml	To meet crit. spec. requirements.

PLUTONIUM FINISHING PLANT
FINAL SAFETY ANALYSIS REPORT

CHAPTER 7.0

WASTE CONFINEMENT AND MANAGEMENT

FEBRUARY 2001

This page intentionally left blank.

PREFACE

Revision 2 of Chapter 7.0 of the Plutonium Finishing Plant (PFP) Final Safety Analysis Report (FSAR) incorporates the following:

- Revisions to the liquid waste water stream general description
- Revisions to the radioactive liquid waste treatment description
- Revisions to the solid waste packaging, handling safety and criticality prevention description
- Changes in the handling of TRU HEPAs
- Changes in the drums approved for waste packaging
- Deletion of Table 7-3

Other minor changes include editorial changes and addtional clarifications.

The new packaged boilers operated by Johnson Controls, Inc. which provide steam to the PFP were previously incorporated in the FSAR. This included switching the emergency exhaust fans from those which are steam-driven to those which are connected to the standby power system. However, the conversion from using steam-driven fans to standby power driven fans has not been fully implemented. The emergency exhaust fans are currently run by the new steam supply system installed under the Hanford energy conservation program. Electrically-driven emergency exhaust fans are planned to be connected to the diesel-generator standby power supply at some future date. The emergency exhaust fan functions are unchanged from that described in the FSAR regardless of the type and source of power.

The significant areas of change in Revision 2 are indicated by vertical bars in the margin of each page.

This page intentionally left blank.

7.0 WASTE CONFINEMENT AND MANAGEMENT

Chapter 7.0 describes the systems and controls for confining and managing the waste materials generated as a result of the Plutonium Finishing Plant (PFP) operations.

PFP gaseous effluents, liquid wastes, and solid wastes are managed in accordance with procedures HNF-PRO-450 (draft), -451, -455, -456, -462, -2364, and -2595. A technical interpretation of the U.S. Department of Energy (DOE) orders and other pertinent state, federal, and local laws established to protect the environment and public is provided in these procedures. The purpose of the procedures is to establish guidelines that:

- Protect the environment from radioactive materials and other dangerous substances under Hanford jurisdiction
- Protect people from radionuclides and other dangerous substances in the environment
- Provide a tool to be used in conjunction with applicable DOE orders and other pertinent Federal, State, and local laws, rules, and regulations promulgated for Environmental Protection (EP) in accordance with the policy defined in *Management Plans* HNF-MP-001 and 003.

In June 1987, the DOE released a directive to manage radioactive hazardous constituents in accordance with the *Resource Conservation and Recovery Act (RCRA) of 1976* and subsequent *Hazardous and Solid Waste Amendments of 1984*. In July 1987, Westinghouse Hanford Company (WHC) responded with an aggressive program that called for upgraded facilities, laboratories, administrative systems, and enhanced training. Since then, PFP management has implemented upgrade programs designed to achieve compliance with applicable regulations including the *Hanford Federal Facility Agreement and Consent Order* (Ecology et al. 1994). These effluent monitoring, treatment, and disposal upgrade programs are essentially complete and the PFP is in compliance with federal, state, and local regulations governing liquid effluent discharges into the soil column.

The waste management criteria; waste characterization (form, quantity, and location); waste equipment and description; waste monitoring, treatment, and/or processing; and waste packaging, storage and/or disposal for airborne/gaseous effluents, liquid waste, and solid waste are discussed below.

7.1 AIRBORNE EFFLUENTS

7.1.1 Criteria for Control of Airborne Effluents

The requirements for the control of airborne effluents at the PFP are contained in Hanford Site procedures HNF-PRO-450, 2364, and 2595. These requirements incorporate applicable federal, state, and local regulations, DOE orders, Hanford Site best management practices, and as low as reasonably

achievable (ALARA) considerations. Airborne effluent requirements are divided into six areas: all emissions sources, non-radioactive sources, radioactive sources, source categories, new construction and modifications, and notifications. Each of these areas is summarized in the following sections.

7.1.1.1 All Emission Source Requirements. Three categories of requirements apply to all emissions sources: general requirements, stack flow measurements and calculations requirements, and effluent monitoring directives (note that not all of the requirements apply to the PFP).

7.1.1.1.1 General Requirements. Hanford Site procedures in Section 7.1.1 include requirements for the following:

- Operational requirements to control emissions to the environment to ALARA levels
- Use of reasonably available control technology
- Contaminant opacity requirements
- Emission of particulate matter
- Air pollutants from fugitive emissions
- Odor reduction policies and procedures
- Offsite air pollutant impacts
- Emission of gases containing sulfur dioxide
- Prohibition against concealment of air contaminant emissions that would violate federal, state, or local regulation or standard
- Fugitive dust generation due to construction or related activities.

7.1.1.1.2 Stack flow Measurement/Calculation Requirements. Hanford Site procedures in Section 7.1.1 include requirements for the following:

- Frequency for determination of stack flow rates in accordance with 40 CFR 60, "Standards of Performance for New Stationary Sources"
- Determination of stack flow rates after facility modifications
- Inclusion of stack flow rate measurement requirements in the *Facility Effluent Monitoring Plan for the Plutonium Finishing Plant* (HNF-EP-0476).

7.1.1.1.3 Effluent Monitoring Report Requirements. Hanford Site procedures in Section 7.1.1 include requirements for PFP emissions inventory input to the site effluent monitoring (EM) report.

7.1.1.2 Sources Requirements. Three categories of requirements apply to non-radioactive emissions sources; ventilation requirements, equipment leak

requirements, and waste unit management requirements (note that not all of the requirements apply to the PFP).

7.1.1.2.1 Ventilation Requirements. Hanford Site procedures in Section 7.1.1 include requirements for the following:

- Regulatory appraisal of process vents associated with distillation, fractionation, thin-film evaporation, solvent extraction, and air and steam stripping processes
- Determination, documentation, and reporting of current operating status emission rates for affected vents
- Installation of additional control devices on existing emission units
- Applicability of this requirement to new and active emission units.

7.1.1.2.2 Equipment Leak Requirements. Hanford Site procedures in Section 7.1.1 include requirements for the following:

- Leak detection and repair program for equipment containing or contacting hazardous waste with organic concentrations of greater than or equal to 10 ppm (by weight)
- Compliance of leak detection monitoring with 40 CFR 265.1063, "Test Methods and Procedures"
- Time requirements for reporting of leaks
- Exclusion of vacuum service equipment
- Determination of equipment as "light liquid service" or "heavy liquid service"
- For all management units containing affected equipment, a log which includes the elements required in 40 CFR 265.1064, "Recordkeeping Requirements," must be kept in the management unit record
- Availability of equipment leak information to the contractor EM for Hanford Site environmental release reports.

7.1.1.2.3 Waste Management Unit Requirements. Hanford Site procedures in Section 7.1.1 include requirements for the following:

- Assessments of waste management units to determine applicability of requirements in 40 CFR 265 Subpart CC
- Implementation of emission control requirements and placement of implementation schedules in operation records for non-exempt waste management units
- Inspection and monitoring of emission control covers for leaks

- Onsite operations records
- Treatment, storage, and disposal (TSD) facilities reporting requirements.

(Note: The PFP, as an operator of a waste management unit, is regulated under RCRA interim status, 40 CFR 265, "Standards for Owners and Operators of Hazardous Waste Treatment, Storage, and Disposal Facilities").

7.1.1.3 Airborne Radioactive Source Requirements. The requirements that the PFP must meet are predicated on the assumption that the PFP has the potential to exceed 0.1 mrem/yr effective dose equivalent (EDE) to an offsite receptor. Five categories of requirements apply to airborne radioactive sources; emission standards for all facilities and operations, continuous monitoring and alarms, emission measurements, emission filtration and treatment, and flow measurement (note that not all of the requirements apply to the PFP).

7.1.1.3.1 Emission Standards Requirements. Hanford Site procedures in Section 7.1.1 include requirements for the following:

- Offsite dose limits of Hanford Site facilities air emissions of radionuclides
- Applicability of requirements to emissions caused by emergency conditions
- Utilization of "best available radionuclide control technology"
- Hanford contractor Effluent monitoring authority to limit airborne emission concentration(s) of radioactive materials released to the environment.

7.1.1.3.2 Continuous Monitoring, Alarms, and Emission Measurement Requirements. Hanford Site procedures in Section 7.1.1 include requirements for the following:

- Continuous monitoring requirements for ventilation stacks
- Documentation of the determination of ventilation stack monitoring criteria in a FEMP
- Design of monitoring systems
- Calculation of theoretical annual emissions of radionuclides
- Calibration requirements for monitoring systems
- Monitoring sensitivity of monitoring systems
- Recording of maintenance, calibration, system anomalies, etc., for continuous monitoring instruments
- Downtime of emissions monitoring capabilities.

7.1.1.3.3 Emission Measurements Requirements. Hanford Site procedures in Section 7.1.1 include requirements for the following:

- Criteria for determination of requirements for record sampling or other emissions measurements
- Development and maintenance of emissions measuring schedules
- Limitations on gross alpha and beta measurement for sample characterizations
- Use of sample characterization for radionuclide-specific analysis
- Adequacy of gross radioactivity measurements for reports
- Emission release point and sampler tagging
- Measurement criteria for emission points and sampling systems.

7.1.1.3.4 Emissions Filtration and Treatment Requirements. Hanford Site procedures in Section 7.1.1 include requirements for the following:

- Required equipment for emissions filtration and treatment
- Testing and performance criteria for effluent filtration systems.

7.1.1.3.5 Flow Measurement Requirements. Hanford Site procedures in Section 7.1.1 include requirements for the following:

- Circumstances for flow rate determination
- Effluent flow rate measurement methods
- Time periods for flow rate measurement analysis and data logging.

7.1.1.4 Source Categories Requirements. Two categories of requirements apply to all source categories at the PFP; ozone-depleting substance control and phase-out, and asbestos requirements. The remaining requirements for fossil fuel-fired steam generators, gasoline distribution and detergent additives records, and open burning are not applicable to the PFP (note that not all of the requirements apply to the PFP).

7.1.1.4.1 Fossil Fuel-Fired Steam Generators Requirements. The requirements of this section do not apply to the PFP.

7.1.1.4.2 Ozone-Depleting Substances Control and Phase-Out Requirements. *Air Quality Program - Nonradioactive Emissions*, HNF-PRO-2595, includes requirements for the following:

- Servicing, using, record-keeping, and reporting of refrigerants
- Labeling of equipment that contain and/or use refrigerants.

7.1.1.4.3 Asbestos Requirements. *Regulated Substance Management*, HNF-PRO-451, includes requirements for removal and disposal requirements and agreements for asbestos.

7.1.1.4.4 Gasoline Distribution and Detergent Additives Records Requirements. These requirements are not applicable to the PFP because the PFP does not purchase gasoline direct from an offsite seller.

7.1.1.4.5 Open burning Requirements. The requirements of this section does not apply to the PFP because the PFP does not conduct open burning.

7.1.1.5 New Construction or Modifications Requirements. Nine categories of requirements apply to new construction or modifications; notices of construction, prevention of significant deterioration (PSD), toxic air pollutants, limitation of clean air submittals to Ecology, national emissions standards for hazardous air pollutants (NESHAP), registration of radioactive sources, portable/temporary sources of air emissions, portable/temporary radioactive airborne emission units (note that not all of the requirements apply to the PFP).

7.1.1.5.1 Notices of construction (NOC) Requirements. A notice of construction (NOC) is an application to Environmental Protection Agency (EPA), Ecology, and/or Washington State Department of Health (DOH) required to request approval for construction pursuant to the regulations given in *Environmental Notification and Reporting*, HNF-PRO-453. If a new construction or modification would constitute a regulated activity under air regulations, an advance submittal and regulatory approval of an NOC would be required. HNF-PRO-453 includes requirements for the following:

- General situations and methods dealing with the submittals of NOCs and the approval of new construction or modifications pursuant to applicable air regulations
- Application for approval of new construction or modifications that generate a new source of radioactive air emissions or impact sources of radioactive air emissions
- Provision of NOCs for construction, installation, or establishment of new sources or emissions units.

7.1.1.5.2 Prevention of Significant Deterioration (PSD) Requirements. This requirement concerns the determination of need for PSD application because of significantly increased emission of criteria pollutants from a new or modified operation or construction.

7.1.1.5.3 Toxic Air Pollutant Requirements. HNF-PRO-2595 includes requirements for the following:

- Listing of toxic air pollutants (TAPs)
- Design requirements mandated for compliance

- NOC requirements prior to the construction, installation, or establishment of any other new or modified source of toxic air emissions
- Requirements of NOC application analyses for TAPs
- Requirements, applicability, and exemptions of NOCs for TAPs.

7.1.1.5.4 Limitations of Clean Air Submittals to Ecology Requirements. These requirements deal with the number of submittals required for new sources or modifications.

7.1.1.5.5 National Emission Standards for Hazardous Air Pollutants Requirements. These requirements deal with the *Clean Air Act Amendments of 1990*, which require the EPA to promulgate, by the year 2000, an extensive number of regulations establishing maximum achievable control technologies for source categories emitting one or more of the hazardous air pollutants listed under the act. Although many of the regulations will not apply to the PFP, a regulatory analysis would still be warranted for any PFP source category for which future regulations will be promulgated.

7.1.1.5.6 Registration of Nonradioactive Sources Requirements. These requirements apply to all sources listed for registration under the WAC 173-400-100 in air emissions inventories.

7.1.1.5.7 Registration of Radioactive Sources Requirements. These requirements deal with approval of NOCs for new construction or modification of existing sources of emissions.

7.1.1.5.8 Portable/Temporary Sources of Air Emissions Requirements. These requirements deal with NOC requirements for portable emission sources at temporary locations.

7.1.1.5.9 Portable/Temporary Radioactive Airborne Emission Units Requirements. Requirements for portable/temporary radioactive airborne emission units are covered in HNF-PRO-450 (Draft), *Air Quality Program.*

7.1.1.6 Notification Requirements. There are six categories of requirements that deal with notifications for airborne effluent missions:

- Abnormal or Transient Emissions of Radioactive Airborne Material
- Planned Pre-Operational Tests
- Startup, Shutdown, or Emissions Measurement Change
- Reports of Closure
- Excess Nonradioactive Airborne Emissions

- Other Notification Requirements

  - Noncompliance with operational safety requirements (OSRs), operating specification documents, permit or approval requirements, technical specifications, or a requirement with potential to increase airborne emissions

  - Prior notification for operations that could result in exceeding the operating specification documents, permit or approval requirements, or technical specifications with the potential to increase airborne emissions

  - Shutdown of continuous effluent monitoring systems other than for maintenance, or other changes that prevent the accurate measurement of emissions to the environment

  - Failure of a required effluent treatment system test.

Requirements for notifications for these categories are given in HNF-PRO-453, *Environmental Notification and Reporting*, and HNF-PRO-2595.

7.1.2 Radioactive Gaseous Effluents Description and Stream Characterization

Gaseous effluent streams from the PFP that may contain low levels of radioactivity include are shown in Figure 7-1:

- The 291-Z-1 main stack for the 234-5Z, 236-Z, and 242-Z Buildings
- The 296-Z-3 stack for the 241-Z and 241-ZA Buildings and tanks
- The 296-Z-5 stack for the 2736-ZB Building
- The 296-Z-6 stack for the 2736-Z vaults and 2736-ZA Building
- The 296-Z-14 stack for the 232-Z Building
- The 296-Z-15 stack for the 243-Z Building (record sampler only).

The following specific radionuclides have been identified as being released from the 291-Z-1, 296-Z-3, and 296-Z-5 stacks:

- $^{239,240,241}Pu$
- ^{241}Am
- $^{238,242}Pu$ (theoretically may be present but have not been detected).

The releases from the 296-Z-6 stack are extremely low, which makes specific sampling and analysis fruitless. Routine monitoring of this stack is for gross alpha and beta. In case of a high result, a specific isotopic analysis would be performed to characterize the release. The 232-Z Building hoods and gloveboxes (which are exhausted by the 296-Z-14 exhaust system) have been cleaned of bulk radioactive material. Radionuclide emissions from the 296-Z-15 stack have not been detected because of the extremely low radioactive content of the waste water effluent and because of the efficiency of the filtering media used in the facility to extract radioactive particles.

Radionuclide discharge data are reported annually in accordance with HNF-PRO-453. Annual average concentrations are given in Table 7-1.

7.1.2.1 Sampling and Monitoring.

7.1.2.1.1 Record Sampling Capabilities. The record sampler for each of the six main PFP gaseous effluent discharge points; 291-Z-1, 296-Z-3, 296-Z-5, 296-Z-6, 296-Z-14, and 296-Z-15 (the record sampler for the sixth stack, which services the 243-Z Building, is operated on an as-needed basis) is the in-line sampler mounted downstream of the sampler line flow splitter. This sampler draws effluent through a 47-mm particulate filter by means of a vacuum pump. Sampling flow rates are designed to provide near isokinetic sampling at the flow rate of 2.0 ft^3/min (3.0 ft^3/min for the 296-Z-15 stack) through the filter media. Sample filters are collected biweekly and analyzed for gross alpha and gross beta activity. If releases in excess of the applicable limits are suspected, samples can be analyzed on a priority basis in 24 h. The minimum detection level (MDL) of the stack record sampling system is 1.0×10^{-14} μCi/mL for $^{239,240}Pu$, and 5.0×10^{-15} μCi/mL for gross alpha.

HNF-EP-0476 and plant operating procedures provide detailed operational criteria and system operating instructions. Radiological release data from the sample analyses are documented annually in HNF-EP-0527, *Environmental Releases for Calendar Year*. Risk and accident evaluations are provided in Chapter 9.0. Chapter 5.0 provides more detailed descriptions of the various ventilation systems.

Responsibilities, operation, calibrations, surveillance, reports, and record keeping are specified in the appropriate plant procedures.

7.1.2.1.2 Monitoring Capabilities. Each gaseous effluent stream is equipped with a CAM and alarm, such as an Eberline Alpha-5A CAM. The alpha CAM provides a solid-state detector and a single channel pulse height analyzer to measure only alpha particles of a specific energy. Since the principal radionuclide of concern is ^{239}Pu, which has the most restrictive DCG, setting the pulse height window for the principal ^{239}Pu alpha energy (5.16 MeV) is appropriate for the PFP exhaust system monitors. This increases the sensitivity of the CAM as the majority of the effects of the radon-thoron daughters are rejected.

The background subtraction circuit employs a separate adjustable window so that an appropriate energy window may be used to determine the amount of subtraction required. The use of a separate window for subtraction provides a more uniform background subtraction reading during rapid changes in radon concentration. The high energy ^{218}Po (Radium A) peak (6.0 MeV) was chosen for background subtraction to maximize the distance between the two functional windows. The use of an appropriate multiplier allows this peak to be used to compensate for radon and thoron daughter build up on the CAM filter so that the alarm trip point setting is a more realistic initial estimation of the stack discharge (assuming that the detected radionuclide is ^{239}Pu).

The alpha CAM has a failure warning circuit to indicate the absence of a signal from the detector along with the high level alarm. If the signal is lost, the counting light extinguishes and an external failure alarm is actuated. The instrument may be used with an external air pump or with the

facility vacuum system. Air flow is monitored with a rotameter calibrated as part of the CAM instrument and controlled with airflow regulators or needle valves where appropriate.

The alpha CAMs for each stream are normally set to alarm at an integrated activity of 40 CPM. The alarms have remote annunciators at the MICON™ control station (room 714 of the 234-5ZA Building). Although this set point may not account for the differences between individual CAM units, the basic purpose of the set point is to warn PFP Operations and Radiological Control (RC) personnel that the composition of the plant exhaust has changed and that investigative and/or remedial actions need to be initiated. This set point was selected to provide the earliest warning of changing discharge radionuclide concentrations while minimizing the number of potential false alarms as a result of rapidly changing natural radioactivity levels during certain meteorological conditions.

7.1.2.2 Analysis Continuity and Integrity. Sample integrity is maintained through implementation of procedural requirements in *Radioactive Airborne Effluent Sampling*, HNF-PRO-2364. Sample data (time collected, flow rates, collectors, time on, etc.) are noted on the sample container by the collector and/or are logged in the field using a bar-code scanner. These data and the sample are logged in at an assembly point (RC Office, Operations desk, Control Room, etc.) and then transferred to the appropriate analytical facility. At the analytical facility, the samples are logged in by the transporter and the analytical facility representative on an inventory sheet, at which time possession of the samples is transferred to the laboratory. The laboratory then implements its routine chain of custody procedures during sample analysis. The laboratory sends copies of the analytical results to the concerned parties and maintains a copy in its own files. The analytical results are used to evaluate compliance with Hanford Site and DOE requirements and are summarized in monthly, quarterly, or annual reports. The concerned parties (PFP Operations, Environmental Protection, Radiological Control, etc.) perform tracking and trending of the results based on their individual needs and requirements.

7.1.3 Nonradioactive Gaseous Effluents Description and Stream Characterization

While the majority of airborne releases from the PFP are ventilation air, other nonradiological compounds are exhausted via the heating, ventilation, and air-conditioning (HVAC) stacks. Other chemicals which could be exhausted from the stack include small quantities of TBP from the thermal stabilization process, and its degradation products of TBP: MBP, DBP, and butanol. Other gaseous releases from the PFP via the stacks and other pathways result from the routine use products such as aerosol cans, paints and thinners, laboratory chemicals, and products supporting maintenance activities. Releases associated with these products are accepted as common industrial hazards.

The $NaNO_2$ that is added to the 241-Z below-grade waste tanks before the waste is transferred to the 244-TX receiving facility has the potential for generating quantities of NO_x which could exceed the NO_x emission reporting value mandated by the *Comprehensive Environmental, Response, Compensation, and Liability Act of 1980* (CERCLA). To prevent the release of NO_x above release

limits, work control will ensure that proper review and planning of waste treatment activities is completed prior to performing the work.

7.1.3.1 Sources of Building Ventilation Exhaust.

7.1.3.1.1 291-Z-1 Stack--234-5Z, 236-Z, and 242-Z Building Exhaust.

General Description. A detailed description of the PFP complex ventilation system and 291-Z-1 stack is contained in Chapter 5.0.

Source Description. The major airborne streams contributing to the PFP 291-Z-1 main stack effluent are as follows:

- The 234-5Z E-3 system
- The 234-5Z E-4 system
- Process solution transfer vacuum pump exhaust
- The PFP air sample vacuum pump exhaust
- The 236-Z E-3 system
- The 236-Z E-4 system
- The 236-Z air sample vacuum exhaust
- 242-Z Waste Treatment Facility.

7.1.3.1.2 296-Z-3 Stack--241-Z Building Exhaust.

General Description. The 296-Z-3 stack exhausts filtered air from the sumps and vessels of the 241-Z Building, (the PFP LiquidWaste Treatment Facility). Liquid process wastes from the PFP are received in the tanks in 241-Z and are retained for batch-wise neutralization and transfer to the tank farms. The building is only a weather cover for the tanks.

The 296-Z-3 stack is 24 ft high, 14 in. in diameter, and constructed of Schedule-10 stainless steel. The flow rate averages about 1,200 ft^3/min. An isokinetic air sampling probe feeding a record sampler and an alpha CAM is located 20 ft downstream of the exhaust fans.

Source Description. Contributing sources of the 296-Z-3 stack consist of exhausts from the TK-D4, TK-D5, TK-D6 (TK-D6 is isolated from chemical transfers), TK-D7, and TK-D8 waste tanks and their surrounding cells, the sampling hood in 241-ZA, and the TK-D9 caustic tank (TK-D9 is no longer in service, but was originally used for storage of UNH and is considered to be contaminated with uranium).

7.1.3.1.3 296-Z-5--2736-ZB Building Exhaust.

General Description. The 296-Z-5 stack exhausts filtered air from the 2736-ZB Building and the glovebox in Building 2736-ZB. This building has been in service since 1984 and contains facilities for shipping, receiving, repackaging, and nondestructive assay (NDA) of plutonium and plutonium-bearing materials.

The 296-Z-5 stack is 15 ft high, 34 in. in diameter, and constructed of 14-gauge steel. The flow rate averages 12,000 ft^3/min. The stack is equipped

with two sampling probes; one feeds a record sampler, and the other feeds an alpha CAM with alarm.

Source Description. The major airborne streams contributing to the 296-Z-5 stack effluents consist of the following:

- Zone 4 exhaust
- Zone 3 exhaust
- Zone 2 exhaust
- Zone 1 exhaust
- Air sampler pump.

7.1.3.1.4 296-Z-6--2736-Z and 2736-ZA Building Exhaust.

General Description. The 296-Z-6 stack exhausts filtered air from the 2736-Z and 2736-ZA Buildings, (the plutonium storage vaults). The 296-Z-6 stack is 14 ft 8 in. tall, 36 in. in diameter, and extends 30 in. above the roof of the 2736-ZA Building. The flow rate averages 12,000 ft^3/min.

Source Description. The 296-Z-6 stack has two identical contributing streams. Each stream consists of a filter bank and an exhaust fan, and the two streams join at the base of the 296-Z-6 stack. The major airborne stream contributing to the 296-Z-6 stack effluents is from zone 2 exhaust.

7.1.3.1.5 296-Z-14--232-Z Building Exhaust.

General Description. The 296-Z-14 stack exhausts filtered air from the 232-Z Building.

The 296-Z-14 stack is 21 ft high with a 12-in. dia. The stack is constructed of stainless steel and effluents are sampled and monitored.

Source Description. The major airborne streams contributing to the 296-Z-14 stack effluents consist of the following:

- Zone 4 exhaust
- Zone 3 exhaust
- Zone 1 exhaust.

7.1.3.1.6 296-Z-15--243-Z Building Exhaust.

General Description. The 296-Z-15 stack exhausts filtered air from the 243-Z Building.

The 296-Z-15 stack is 42 ft high with a 12-in. dia and is constructed of stainless steel. This stack is not routinely sampled and monitored because of the small likelihood of any plutonium entering the 243-Z Building and then escaping the piping and train drums. The sampling and monitoring that is done is to confirm the low radioactive emissions.

Source Description. The major airborne streams contributing to the 296-Z-15 stack effluent is zone 2 exhaust airflow.

7.1.3.1.7 Drain Line Vents. Drain lines within the PFP are equipped with vent lines that exhaust out of the roof of the buildings and act as vacuum breaks. All liquid waste drains that eventually lead to TK-D8, in the 241-Z Building, have filtered vents. The filtered vent lines include the D-4, D-5, D-6, D-7, D-8 drain headers in both the 236-Z Building and the 234-5Z Building. The filters are located on the fourth floor of the 236-Z Building and the duct level of the 234-5Z Building.

7.1.3.2 Safety Features. Safety-related features are in place within this system to help reduce the possibility of significant amounts of plutonium being released into the environment and to reduce the possibility of a criticality incident. Some of these features are as follows:

- Up to three stages of HEPA filtration for zone 4 exhaust ventilation
- Continuously monitored exhaust flows
- Criticality specification limits for gloveboxes and hoods
- Backup fans for exhaust fans to prevent overpressurization
- Pressure indicators
- Fire dampers.

7.2 LIQUID WASTE

7.2.1 Criteria for Control of Liquid Wastes

Requirements for and restrictions against returning liquid waste to the environment are detailed in *Water Quality*, HNF-PRO-456. These requirements incorporate applicable federal, state, and local regulations, DOE orders, best management practices, and as low as reasonably achievable (ALARA) considerations. These water quality requirements are categorized into 11 areas; general requirements, discharges to the Columbia River (not applicable to the PFP), sanitary sewer discharges, discharges to the soil column, subsurface discharges (underground injection) (not applicable to the PFP), control standards and requirements for waste disposal sites, groundwater well installation and use (not applicable to the PFP), monitoring requirements, sampling requirements, requirements for new facilities, and drinking water supply systems (not applicable to the PFP). Items for each category of water quality requirements detailed in HNF-PRO-456 are summarized below.

7.2.1.1 General Requirements. HNF-PRO-456 includes requirements for the following:

- Regulations for discharges of liquid effluents containing dangerous wastes
- Reporting of CERCLA hazardous materials in nonradioactive liquid effluent releases to the environment

- Use of best available technology (BAT)
- Tracking and reporting releases with quantities of toxic chemicals
- Radioactive liquid effluents threshold requirements
- Limitation of dose from operations to offsite receptors via effluent release pathways (including airborne)
- Radiological concentrations limits for surface water or groundwater
- Control of discharges of radioactive liquid effluents
- Evaluation and documentation of effluent streams for the FEMP
- Effluent management system for radioactive liquid wastes (RLW)
- Isolation or reconfiguration of liquid effluent lines
- Transferal of information regarding deactivation status and method of deactivation for liquid effluent disposal sites to waste information database system (WIDS)
- Parametric values for doses.

7.2.1.2 Discharges to the Columbia River Requirements. These requirements are not applicable to PFP.

7.2.1.3 Sanitary Sewer Discharge Requirements. HNF-PRO-456 includes requirements for the following:

- Industrial waste water and toxic pollutants disposal
- Disposal limitations of dangerous waste
- Disposal limitations of waste components via septic systems
- Acceptable systems for disposal of sanitary waste
- Site characterization and planning details for the installation, repair, modification, connection to, or expansion of onsite sewage systems
- Sewerage systems operation and maintenance
- Processes for removal of septic tanks from service
- Limitations for use of holding tank sewage systems.

7.2.1.4 Discharges to the Soil Column Requirements. HNF-PRO-456 includes requirements for the following:

- Categories of waste water requiring permits

- Actions necessitating notification of Liquid Effluent Engineering
- Exclusion of water from permit applications
- Other waste water permitting methods
- Time requirements for filing engineering reports, plans, specifications, and permit applications to Ecology
- Underground injection controls; this item is not applicable to the PFP.

7.2.1.4.1 Purgewater Management Requirements. These requirements are not applicable to PFP operations.

7.2.1.4.2 RAD Limits for Releases to the Soil Column. HNF-PRO-456 includes requirements for the following:

- Compliance requirements for radioactive liquid effluents discharged to soil columns
- Use of soil columns to treat and remove suspended and dissolved radionuclides
- Establishment of administrative control values for radionuclides discharges.

7.2.1.4.3 Maintenance of Ponds Containing Radioactive Material Requirements. These requirements are not applicable to PFP operations.

7.2.1.5 Subsurface Discharge Requirements. These requirements are not applicable to the PFP.

7.2.1.6 Control Standards and Requirements for Waste Disposal Site. HNF-PRO-456 includes requirements for the following:

- Requirements for evaluation for impacts of using a waste disposal site
- Routine evaluations of liquid waste disposal sites
- Processes for notification of the Effluent Monitoring organization and Hanford Technical Services of changes in effluent streams
- Responsibility for monitoring non-RCRA/CERCLA treatment, storage, and disposal facilities for migration of contaminants to the water table.

7.2.1.7 Groundwater Well Installation and Use Requirements. These requirements are not applicable to the PFP.

7.2.1.8 Monitoring Requirements. HNF-PRO-456 includes requirements for the following:

- Determination of dangerous contents of waste water
- Monitoring requirements for waste streams
- Record monitoring system requirements.

7.2.1.8.1 Record Effluent Monitoring Requirements for Radioactive streams. HNF-PRO-456 includes requirements for the following:

- Evaluation of streams for release of radionuclides
- Effluent monitoring objectives
- Continuous monitoring requirements for emergency situations
- Continuous monitoring requirements for radionuclide release points
- Allowances for continuous sampling of emissions
- Determination and documentation of overall accuracy for continuous monitoring or sampling
- Consideration of stream characteristics for monitoring system criteria
- Environmental considerations for locating record monitoring systems
- Requirements for off-line monitoring systems
- Design and sensitivity requirements for effluent instruments and transport lines
- Continuous monitoring alarm/waste diversion requirements
- Volume, flow rate, and radionuclide concentrations measurement requirements
- Requirements for batch releases of effluent
- Detection capability requirements for laboratory methods used to analyze record samples
- Requirements for radionuclide analysis
- Statistical analyses requirements
- Contents of record monitoring programs
- Approval for sample collection regimes.

7.2.1.8.2 Calibration Requirements. HNF-PRO-456 includes requirements for the following:

- Record continuous effluent monitoring and sampling systems calibration periods
- Calibration consistency
- Calibration(s) accordances.

7.2.1.8.3 Monitor Down Time Requirements. HNF-PRO-456 includes requirements for the following:

- Corrections for loss of effluent monitoring capabilities
- Length of down time for monitoring systems
- Responsibilities of facility operations management for monitoring.

7.2.1.8.4 Notification Requirements. HNF-PRO-456 includes requirements for the following:

- Events requiring reporting to Environmental Reports
- Facility operation management reporting responsibilities for upsets or malfunctions of required effluent sampling or monitoring systems
- Reporting criteria for release levels of discharges of radionuclides.

7.2.1.9 Sampling Requirements. HNF-PRO-456 includes requirements for the following:

- Sampling for potential equivalent concentrations of dangerous waste contaminants
- Bases for representative measurements of volumes and concentrations of pollutants released to the environment
- Locations for effluent stream measurements
- Grab sampling requirements
- Sampling requirements for surface ponds
- Sampling programs for effluents affected by process configuration
- Methods for the analysis of liquid nonradioactive pollutants.

7.2.1.10 Requirements for New Facilities. HNF-PRO-456 includes requirements for the following:

- Best available technology usage

- Minimization policies of radioactive and nonradioactive liquid waste discharges
- Permit requirements for discharges of liquid effluent to the soil column
- Septic systems procedures
- Pre-operational environmental surveys requirements
- Discharge standards for effluent from domestic waste water treatment facilities
- Individual permits for activities within a Wild and Scenic River study area.

7.2.1.11 Drinking Water Supply Systems Requirements. Not applicable to the PFP.

7.2.2 Liquid Waste System Description and Stream Characterization

The PFP generates, treats, and disposes of the following liquid wastes:

- Low-level RLW collected and treated at the 241-Z Facility prior to transfer to the tank farms for storage (these wastes contain levels of radioactivity greater than allowable for release to the environment.)
- Waste water with a radioactive interface [this includes cooling water, process steam condensate, and floor drains. These liquid effluents are processed through the Low-Level Waste Treatment Facility (LLWTF) and are discharged to the offsite Treated Effluent Disposal Facility (TEDF).]
- Nonradioactive, nonhazardous streams from storm drains, roof drains, and HVAC supply fan sprayers that are sent to TEDF but do not pass through LLWTF
- Steam condensate discharged to the soil column through French drains
- Restroom, shower, and lunchroom drains sent to the 200 West Area Regional Drain Field.

7.2.2.1 Radioactive Liquid Waste. The RLW is collected in batches, sampled, and treated at the 241-Z Waste Storage and Treatment Facility before transfer through pipelines to the tank farms for storage in double-shell tanks.

The basement of the 234-5Z Building consists of a series of six tunnels that contain drain line headers for the building. The only drain line headers with active drains (i.e., have not been capped off) are drain lines D-2, D-3, D-4, D-5, and D-6. For a discussion of drain lines D-2 and D-3, see Section 7.2.3.2. The D-4, D-5, and D-6 lines combine into a new double-encased line

which leads to tank TK-D8 in the 241-Z Building. The D-6 drain line from the 236-Z Building connects to the 234-5Z Building drain line near Tunnel #3 in the 241-Z Building. The tunnels are equipped with sumps that collect any solutions that would be released in the event of a leaking drain line. The tunnels are checked daily for signs of any leaks. Following detection of liquid in a sump, the sump would be isolated from the environment and pumped out. The sumps are not geometrically favorable, as the waste solutions being transferred through these drain lines are assumed to contain a minimum amount of plutonium.

7.2.2.1.1 General Description. Liquid waste streams from various sources within 234-5Z and 236-Z (i.e., labs and process systems) are contaminated or have a high potential of being contaminated, and are therefore designated as RLW. The RLW is routed to the 241-Z Complex for temporary storage and is ultimately treated (see Section 7.2.3) with chemicals that render the wastes suitable for transport through pipelines and storage in underground tanks. A RCRA dangerous waste Part A permit application for the 241-Z Waste Storage and Treatment Facility (EPA/State identification number WA7890008967) identifies the liquid waste managed by the facility as dangerous for exhibiting the characteristics of corrosivity, metal content, and toxicity (as required in Ecology 1989).

7.2.2.1.2 Source Description. Three waste streams are or have been discharged from the 236-Z and 234-5Z Buildings are received, temporarily stored, and/or processed in 241-Z Complex tanks. These waste streams are as follows:

- The high-salt waste (HSW) from the Plutonium Reclamation Facility (PRF) (the PRF is not authorized for production operation)
- The HSW from the Remote Mechanical C (RMC) Line (the portion of the RMC Line that would generate HSW is not authorized for operation and is currently inactive)
- The low-salt waste (LSW) from laboratories, the PRF (unauthorized for operation), and the RMC Line (unauthorized for operation).

Approximately 100,000 gal/yr was discharged during previous plant processes (Remote Mechanical A (RMA) and RMC Lines, PRF operation, laboratories, etc.). This has now decreased to 3,000 gal/yr from current operations (primarily LSW).

Characterization of wastes received from the sources is based on flowsheets, practices, sample data, chemical principles, and other process knowledge which were representative of processes that are no longer authorized, but kept in this section for historical purposes (see Tables 7-2).

Plutonium Reclamation Facility Waste Streams. Waste solutions generated by the PRF was a mixture of HSW [composed of column aqueous waste (CAW), solvent cleanup waste (CXP), and CU column uranium waste (CUU)] and LSW solutions of filtrate evaporator distillate and steam jacket condensates from the filtrate and product evaporators.

The CAW stream was the highly acidic waste from the PRF extraction column (CA column). The CAW was difficult to accurately characterize because, although some components were either added or known to exist, other components were present in the waste only because they were present in the feed, which was typically only characterized with respect to plutonium content. The characterization provided in Tables 7-2 was developed assuming a PRF feed that contains RMC Line concentrated filtrate, dissolved oxide, and slag and crucible (S&C) feeds.

The CUU and CXP solutions were generated from the organic cleanup process. The CUU, although containing trace fluoride and chloride, contained high levels of uranium. When low-uranium-content feed was processed in the PRF, the CUU could be reworked and not discarded. The CXP was a carbonate solution containing degradation products from the breakdown of tributyl phosphate (TBP).

The remaining PRF-generated waste streams were filtrate concentrator distillate and steam condensate from the filtrate and product evaporators. These are reported in the tables as PRF LSW. The evaporator distillate normally contained HNO_3 and trace plutonium, but small concentrations of fluoride and chloride were present. The steam condensate was normally only water and scale inhibitor, but there was the potential for high plutonium levels in this stream in the event of a vessel failure.

Remote Mechanical C Line Waste Streams. Process wastes discharged to the 241-Z Complex from the RMC Line operation came from two sources: the potassium hydroxide (KOH) scrubber located in 234-5Z and the filtrate evaporator located in 236-Z.

The KOH scrubber solution was a HSW stream that contained KF and unreacted KOH.

The LSW stream generated by the filtrate evaporator during RMC Line operation had higher volume and lower acidity than the LSW stream generated when the PRF was in operation. Although the bulk components of the RMC LSW were the same as PRF LSW, the trace constituents were different.

Low-Salt Waste from Laboratories and Miscellaneous Facilities. This LSW contains trace amounts of HNO_3 and plutonium. The majority of this waste is generated in the Analytical Laboratory (PFP AL) and Plutonium Processing Support Laboratory (PPSL). The generation rate is nominally 10 gal/d.

Each source results in wastes that vary greatly in flow, characterization, and subsequent treatment. The major facility sources in terms of liquid volumes are given in Tables 7-2.

7.2.2.1.3 Stream Characterization. Cross-contamination between waste streams due to waste handling practices and equipment at the 241-Z Complex is likely to mask certain impurity level concentrations in some streams.

Estimates based on process knowledge of stream impurities are given in the following sections, considering the maximum allowable impurity level in essential materials.

Aluminum. Aluminum was added in the form of aluminum nitrate nonanhydrate to the acid dissolution process conducted in the MT-5 and MT-6 gloveboxes; however, this process is inactive (information provided for historical purposes only). Aluminum content of the acid dissolution preparations was 1.3 M. Contribution to aluminum concentration from entrained solids is assumed to be negligible.

Chromium and Nickel. Chromium and nickel in the PFP waste originate from corrosion products from stainless steels and impurities in cold process chemicals. Nickel and chromium do not appear in the essential material specification sampling explicitly, but could be considered by the residue on the evaporation specification of HNO_3. It is assumed that analysis is specified only for those potential impurities that can reasonably be expected. Since stainless steels are a source of chromium and nickel, all corrosive PFP liquid effluent streams are likely to be contaminated to some degree with these metals. The actual contamination level in the waste depends on very many factors (i.e., corrosivity of each liquid, relative flow rates, PRF feed contamination, age of equipment, temperatures, campaign, metal area exposed to solution, etc.). It is not practical to obtain and characterize these data. The means to estimate chromium and nickel is subject to engineering judgment at best.

Iron. There is one principal source of iron which is the chemical adjustment of the waste just prior to transfer to the tank farms (treatment). Minor sources include corrosion products and cold chemical impurities.

Iron introduced to waste from minor sources is estimated to be less than 1,000 ppm. This estimate is based on informal observations of many waste samples prior to implementation of iron addition to waste. These early samples sometimes contained clear gelatinous solids and/or tiny white solids and/or dark specks. The supernate was either clear or had a pale yellow tint. Since iron addition began, much less variability could be discerned because all samples observed ranged from light to dark reddish brown and from opaque to partially translucent. This was an expected result of iron addition. Iron forms voluminous hydroxide jelly when in a solution above a pH of about 5. The solubility of iron salts in a basic solution is extremely low (60 ppm). It is believed that if significant quantities of iron were present prior to implementation of iron addition, the presence would have been obvious. Iron (greater than 10,000 ppm) has been identified in some feeds. Therefore, to cover the uncertainty, the range of iron in CAW is estimated at 0 to 10,000 ppm. The nominal concentration is estimated at 50 ppm.

Iron nitrate is the waste additive used to provide stable solids to keep plutonium dispersed in tank 241-SY-102. Iron is presently added to all waste.

Acidity. All PFP waste streams are acidic except PRF CXP and RMC Line HSW. The HNO_3 is usually the predominant species. HNO_3 is the only strong acid used in PFP processes. Because HNO_3 is strong, its concentration is an accurate indication of acidity.

Laboratory LSW is not well characterized, but the accumulated waste is known to occasionally contain a few tenths molar HNO_3 (estimated average of 0.1 M). Since it is possible for plant acid (12.2 M) to enter the drain, the laboratory waste stream is estimated to range from 0 to 12.2 M.

Potassium. Potassium is a major contaminant of the waste streams and results from the use of NaOH as a waste neutralizer in the 241-Z waste treatment process.

Sodium. Sodium is known to be present in untreated waste streams exiting the PFP; however, these concentrations are insignificant to the composition of treated PFP liquid waste because of the addition of NaOH as part of the 241-Z waste treatment process. Accurate estimates of sodium impurities, then, are not critical to accurate characterization of total basified waste flow.

Hydroxide. Most PFP waste streams are acidic and, therefore, contain an extremely small amount of hydroxide. However, the treatment of waste streams with NaOH ensures that waste discharges to the tank farms have >0.5 M hydroxide.

Chloride. Chloride comes from many sources. All acidic wastes (all are acidic due primarily to HNO_3) will contain some chloride from the chloride impurity in the plant supply of HNO_3.

The PFP AL and PPSL LSW has no known contributors of significant amounts of chloride other than the impurity level in HNO_3. The average HNO_3 concentration of laboratory LSW is estimated at 0.7%. The impurity level is less than 0.05% of the HNO_3 concentration. The chloride concentration is estimated at 4 ppm. Based on the essential material specifications, NaOH used in waste treatment at the 241-Z Complex is expected to contain 1,500 ppm chloride.

Fluoride. Fluoride was used extensively in plutonium chemistry. Fluorine compounds were used in the dissolution of plutonium from solid forms. (Information provided for historical purposes only).

Nitrate. The majority of chemistry used at the PFP is built around nitrate systems. NO_3^-, then, originates from many sources. Because the nitrate ion is dominant in most PFP waste prior to basification, contributions from impurities in cold chemicals are considered negligible.

Normal use of the drains in the laboratories is expected to contribute some additional nitrates (<1,000 ppm). A small amount of nitrate is added to waste in the form of $Fe(NO_3)_3 \cdot 9H_2O$ at 241-Z as a part of waste treatment for criticality prevention.

Nitrite. The NO_2^- is the conjugate base of the weak nitrous acid. It has very low solubility in concentrated solutions of strong acids, and high solubility in alkaline solutions. Nitrite is detected in collected LSW in a concentration of about 0.01 M. When necessary $NaNO_2$ are added to each waste batch at 241-Z as a corrosion inhibitor.

Plutonium. Plutonium is a constituent of all RLW streams at the PFP. The estimated concentration is 0.00001 g/L for the PFP AL and PPSL LSW (the estimate is based on an average). Of course, the instantaneous concentration may be quite high during disposal of a contaminated fluid.

Americium. The PFP AL and PPSL LSW is estimated at 0.1% of the PRF LSW based, in part, on the existence of their sample evaporator.

Barium, Lead, Strontium, Phosphate, Sulfate, Ammonia, and Silica. These materials are expected to be introduced to the waste primarily as impurities in essential materials. The maximum impurity level allowed by the essential material specifications is conservatively assumed. The collective contributions of essential material impurities to each waste stream are given in Tables 7-2. The lead estimate includes all cations that precipitate upon boiling the acidified essential material with hydrogen sulfide.

It must be recognized that many of the above composition estimates are subject to variances in controlled process parameters such as certain stream flows and compositions. In cases where controlled parameters were needed, values used were nominal and tolerances were not considered.

7.2.2.2 Liquid Waste Water Stream.

7.2.2.2.1 General Description. Waste water from the PFP complex is routed to the TEDF located in the 200 East Area. This waste water stream includes all effluents that were formerly discharged to the 216-Z-20 crib and the 216-Z-21 seepage basin.

The physical arrangement of the sewer system, including the manholes, the LLWTF, the monitoring station in 225-WC, and the TEDF pump station 1 are shown in Figure 7-2.

The piping system that transports the waste water is comprised of three primary branches. The water from the building steam condensate exits the 234-5Z Building on the north side and travels through manholes S1 through S7 before reaching the TEDF tie-in at manhole C2. The supply fan condensate was part of this waste stream. The sources that formerly discharged to the deactivated 216-Z-20 crib are now tied into the TEDF at manhole C1. Of the nine manholes located along the sewer route to the defunct 216-Z-20 crib, only manholes Z1, Z2, Z3, Z4, and Z7 are still active. The new TEDF sewer line picks up the old 216-Z-20 crib sources at manhole C1.

The supply fan condensate normally flows into the JCI condensate receiver tank, from which two float activated condensate pumps pump it back to the packaged boiler. In the event the condensate receiver tank or pumps are out of service, the supply fan condensate flows into the C2 manhole via an overflow pipeline. Building steam condensate does not return to the packaged boiler and is discharged to the french drains.

Manhole Z1 receives steam condensate from the 2736-ZB Building and waste water from the duct level, second floor, and roof drains from the west end of the 234-5Z building. The 232-Z Building is also connected to manhole Z1, but all water services to this building are isolated and the building is being decommissioned. The composite stream from manhole Z1 flows to manhole Z2 via a 15-in. dia vitreous clay pipe (VCP) line.

In addition to the stream from manhole Z1, manhole Z2 receives waste from the three storm sewers south of the 234-5Z Building. In the past, manhole Z2 received steam condensate from the 241-Z Building, a source that is now out of service. The effluent from manhole Z2 flows to manhole Z7 via a 15 in. dia VCP line.

Waste streams from the 234-5Z Building drain D-1 and D-2 headers, the east end of the duct level and second floor, and the effluent from the 291-Z sump all flow to manhole Z3. The 242-Z Building is also connected to manhole Z3 but all water services to this building are shut off. All D-1 sources from the 234-5Z Building have been isolated. The composite stream from manhole Z3 flows to manhole Z4 via a 15 in. dia VCP line.

In addition to the composite effluent stream from manhole Z3, manhole Z4 receives waste from the 234-5Z Building D-3 header and from the 236-Z Building D-1, D-3, and steam condensate headers. The composite stream from manhole Z4 flows to the LLWTF via a 15 in. dia VCP line.

Manholes Z5, Z6, Z8, and Z9 are isolated (by grouting) from the waste water sewer route due to the incorporation of the LLWTF and TEDF tie-in.

The effluent streams from manhole Z2 and the LLWTF flow into manhole Z7. The 2904-ZA Sample Building is located downstream from manhole Z7 and directly over the centerline of the sewer line. The composite stream from manhole Z7 flows in a lined 15 in. dia VCP to manhole C1.

Manhole S1 is a storm drain that also receives the supply fan water and the 234-5Z Building steam condensate. It also used to receive the 2902-Z high-tank overflow; however, this water tank is drained, isolated, and out of service. Manholes S2, S3, and S4 are also storm drains. These drains are the only locations that effluent can enter the system from the north side of the PFP. The sewer lines along these manholes are 12-in. corrugated stainless steel piping.

The sewer line installed by Project W-049H to reroute the effluent to the TEDF was referred to as pipe C with the manholes being labeled C1 thru C4. Manhole C1 was added just upstream of manhole Z8 and provides the tie-in point for the 216-Z-20 crib sources. Manhole C2 is the tie-in point for the PFP's southside sources. Manhole C4 contains the flume and flowmeter and is located next to the 225-WC, Wastewater Sampling Facility. The 10 in. dia VCP pipe extends from manhole C4 to the TEDF pump station 1.

As noted above, the sewer lines from the Z-manholes are primarily 15-in. dia VCP. The original lines were installed in 1948. The pipes were laid out in 3-ft bell and spigot sections. The piping underwent a maintenance clean out in Autumn 1994 and was video-surveyed to verify the integrity of the piping. The majority of the sewer system piping is in good physical condition, but the piping between manholes Z7 and C1 and the LLWTF is known to be contaminated. The piping between manholes Z2 and Z7 show some cracks in the pipe sections and several 4 to 6 in. holes. These sections were remediated by project W-291H.

The purpose of Project W-291H was to remediate the contaminated piping between manholes Z7 and C1 and the LLWTF to allow safe discharge of waste water to the 200 Area TEDF. The pipes were "relined" with a resin-based membrane and manhole Z7 was repaired to fix contamination in-place and allow the PFP to meet the TEDF wastewater discharge requirements. This project also remediated the line between manholes Z2 and Z7 to seal up the cracks and small holes in the pipe.

7.2.2.2.2 Source Description. The waste water stream sources are widely varied. Tables 7-4 through 7-7 list a summary of sources and the facility origin.

- Eyewash stations--The drains are located in the labs. Chemical contaminants flushed off of a worker during an emergency will be heavily diluted before reaching the LLWTF.

- Storm drains--These drains are in the fenced security zone. The effluent consists of rain, slush, snowmelt, etc.

- Supply fan drains--This includes building steam condensate from the 234-5Z Building, dry air compressor cooling water (though the dry air compressor is not currently in use), and ventilation spray pan water.

- Floor drains--Floor drains throughout 234-5Z Building are located near overhead safety showers or similar potential sources of water piping. Typically, the floor drains would contain potable water, the same type of effluent as eyewash station drains.

- Condensate header--Process steam trap drains located on the third floor of the 236-Z Building have no potential for hazardous chemical contamination of the TEDF waste water stream. This is a high-pressure steam line under nearly constant operation.

- Utility water drains--These drains, located in the 236-Z Building, room 35, are normally just for water. Effluent sources include steam condensate, backflow drains, and floor drains. Hazardous chemical or radioactive contamination of these drains is considered improbable. Cooling water systems are pressurized to help ensure that any leakage would flow into the process and not discharge into the waste stream.

- The HVAC condensate drains--These drains are located in the 2736-ZB Building, room 602. The potential for radioactive or hazardous chemical contamination is very low.

7.2.2.3 French Drains (Radioactive Waste Units). French drains at the PFP are used to discharge steam condensates and floor drainage as shown in Figure 7-3. The following French drains are registered with the State of Washington as underground injection wells.

- 216-Z-13 French drain

  - Designation--Inactive RLW ground disposal unit (French drain)

  - Location/site designation--The unit is located 190 ft south of the 234-5Z Building and approximately 50 ft northeast of the 291-Z-1 stack in 200 West Area

  - Dates of waste receipt--1949 to 1998

- Waste types and amounts--The unit receives floor drainage from the 291-Z Building. It also received steam condensate from the turbine for the ET-8 emergency exhaust fan, which will be removed from service when fans ET-1 and ET-2 are connected to backup electrical power to provide emergency exhaust capability. Radiological inventories are not available; low levels of radiation are not expected, but have been assumed. In 1998, steam condensate was rerouted to discharge to LLWTF, and isolated from this drain.

• 216-Z-14 French drain

- Designation-Active RLW ground disposal unit (French drain)

- Location/site designation--The unit is located 190 ft south of the 234-5Z Building and approximately 50 ft northwest of the 291-Z-1 stack in 200 West Area

- Dates of waste receipt--1949 to present

- Waste types and amounts--It receives steam condensate from the turbine for the ET-9 emergency exhaust fan in the 291-Z building, which will be removed from service when fans ET-1 and ET-2 are connected to backup electrical power to provide emergency exhaust capability. Radionuclide inventories are not available; low levels of radiation are not expected, but have been assumed.

• 216-Z-15 French drain

- Designation--Inactive RLW ground disposal unit (French drain)

- Location/site designation--The unit is located 50 ft south of the 234-5Z Building and next to the north end of the 291-Z Building in 200 West Area

- Dates of waste receipt--1949 to 1997

- Waste types and amounts--The unit formerly received condensates from the S-12 evaporator cooler in the 291-Z Building. Radionuclide inventories are not available; low levels are not expected, but have been assumed.

7.2.2.4 Sanitary Sewer Systems.

7.2.2.4.1 General Description. The PFP sanitary sewer systems include the 234-5Z sanitary drain, the 234-5Z annex sanitary drain, and the trailer drain. These sanitary sewer systems receive liquid from restrooms, showers, and lunchroom sinks and dispose of it through septic tanks, pumpstations, and to the 2607 West Regional Drain Field located approximately one half mile away where it is percolated into the soil. The sanitary sewer systems' effluent is chemically nonhazardous and is nonradioactive according to *The Plutonium Finishing Plant Liquid Effluent Monitoring Plan* (WHC 1988). There is

virtually no potential for radioactive or hazardous chemical contamination of the sanitary sewer systems.

The requirements for disposal of sanitary waste liquids are given in *Water Quality*, HNF-PRO-456, and *On-site Sewage Systems*, WAC 246-272. No sampling or monitoring is required for facilities operating before June 15, 1987, if no corrosives are used in the system. The PFP systems are not required to be sampled or monitored since no strong acid nor bases (corrosives) are used in the systems. Small quantities of caustic cleaning solutions are used, but effluents released to the environment are noncaustic.

7.2.2.4.2 Source Description. The sanitary sewer sources are listed below.

- Sanitary drain (2607-Z)--The sanitary drain receives liquid effluents from the 234-5Z, 236-Z, 270-Z, and 2704-Z Building restrooms, lunchrooms, and the changeroom showers in the 234-5Z Building. The effluent is discharged into a tile field (2607-W1) located west of the PFP.

- The 234-5Z annex sanitary drain (2607-ZA)--This sanitary system receives waste from the 234-5Z Building annex restrooms and from the 2736-ZB Facility. The effluent is discharged into a tile field (2607-W1) located west of the PFP.

- Trailer sanitary drain (2607-ZB)--This sanitary system receives waste liquid from the restrooms, kitchen sinks, and drinking fountains located in MO trailers. The effluent is discharged into a tile field (2607-W1) located west of the PFP.

Chemicals routinely used in the sanitary system include the following:

- Toilet bowl cleaner
- Dishwashing detergent
- Pine oil disinfectant
- Cleansers (Ajax, etc.)
- Hand soap (lotion or lava)
- Shower cleaners.

7.2.2.4.3 Instrumentation and Controls. No effluent monitoring instrumentation or management procedural controls are required.

7.2.2.4.4 Stream Characterization. The sanitary waste system handles only used sanitary water, human waste discharges, and body-cleansing agents and liquids. No characterization of the streams is required.

7.2.2.4.5 Sampling and Monitoring. No waste effluent sampling or monitoring is required.

7.2.2.5 Chemical Waste System. Bulk chemicals used in the PFP for processing are prepared and transferred in the chemical makeup areas. The chemical makeup areas are located in the 234-5Z Building (rooms 336 and 337) and 236-Z Building (Room 40). All Building 236-Z Room 40 processes are currently inactive. Chemicals remaining in the PRF tanks and process lines are managed

and dispositioned in accordance with HNF-2977, *Plutonium Reclamation Facility (PRF, Building 236-Z) Layup Plan* (BWHC 1998). Electrical power supplied to instrumentation in the room has been isolated.

234-5Z Rooms 336/337 contain three active chemical tanks that are required to support future material stabilization activities.

There is a sump underneath the tanks in the chemical makeup area (room 40) that is equipped with standpipes similar to those in the RMC Line operation. All tanks are equipped with high-level alarms. A conductivity probe is installed in the drain system just below where all of the PRF drains combine. The conductivity probe gives an immediate local alarm (alert) to operators if any chemical release is detected. In addition, an interlock system is installed to prevent overfilling of tanks from the PFP bulk HNO_3 storage and feed tank. The drain systems for both of the chemical preparation areas are tied into a catch tank located within the 2735-Z impoundment. The catch tank is a 400-gal stainless steel tank equipped with sampling and loadout capabilities. Any effluents drained to this tank are sampled and loaded-out into drums for disposal or reuse.

The following are safety-related features that are in place to help eliminate the possibility of chemicals being released into the TEDF waste water stream system:

- 236-Z Building chemical preparation room, room 40--sump drain conductivity probe alarm
- Room 40--CCl_4 monitor
- Room 40--chemical makeup tank liquid-level indicators
- Room 40--spill basin leak detector
- Rooms 40, 336, and 337--spill basin risers
- Rooms 336 and 337--aqueous makeup tank liquid-level indicators and electrical interlock system.

7.2.2.6 Plutonium Finishing Plant Spill Areas. The PFP spill areas shown in Figure 7-4 include the following:

- Radioactive contamination southwest of the 236-Z Building (UN-216-W-89)
- Radioactive contamination south of the 236-Z Building (UN-216-W-90)
- Radioactive contamination near the 234-5Z Building (UN-216-W-91)
- Caustic spill at the PFP.

Areas associated with radioactive spills have been decontaminated to nondetectable levels. This effort included the removal of the contaminated ground surfaces to a depth at which the isotope was no longer detectable with

portable survey instruments. The material removed is treated as radioactive waste and packaged for disposal in UN 1A2 55-gal drums.

The caustic spill at the PFP consisted of an undetermined amount of 50% aqueous sodium hydroxide. The area affected by the caustic spill was cleaned up by removal of the soil, which was packaged and shipped offsite as hazardous waste.

7.2.2.7 Plutonium Finishing Plant Inactive *Comprehensive Environmental Response, Compensation, and Liability Act of 1980* **Sites.** The PFP has one inactive site, the 241-Z-361 settling tank, shown in Figure 7-4.

- Designation--Inactive radioactive waste storage unit (settling tank)
- Location/site designation--The unit is located south of the PFP in 200 West Area
- Dates of waste receipt--Prior to 1976
- Description--The tank is a 1 ft thick, reinforced concrete box with a 3/8-in. steel liner. The top of the tank is 2 ft below grade. Prioritization of this facility for decommissioning classifies the relative radiological hazard as high in comparison with other 200 Area surplus facilities.

7.2.3 Liquid Waste Treatment and Control

7.2.3.1 Radioactive Liquid Waste.

7.2.3.1.1 Treatment. The 241-Z Building contains six underground stainless steel tanks (five active tanks and one isolated tank), with each tank in a concrete cell (one cell contains a tank and a smaller overflow tank). Each tank is ventilated and each cell contains leak detection equipment and the capability for pumping out of solutions that may leak into the concrete cell. One of the tanks, TK-D5, is used to treat aqueous liquids collected from the process facilities. Another tank, TK-D8, is used to collect, measure, and stage the liquids for treatment. Treatment occurs in a batch process consisting of the addition of NaOH or KOH, $Fe(NO_3)_3.9H_2O$, and $NaNO_2$ to the 241-Z treatment tank (TK-D5). A flowchart for the 241-Z facility waste storage and treatment is shown in Figure 7-5. The liquid waste is sampled and analyzed after treatment to make certain that it meets the required Waste Acceptance Criteria specifications (see OSD-184-Z-00010). The remaining active tanks (TK-D4, TK-D7, and TK-D7 overflow tank) are used to supplement the capacity of the TK-D8 and TK-D5 tanks if they overflow.

Treated wastes at the 241-Z Complex are pumped through double-encased lines to the collection tank in the 244-TX Receiver Facility located approximately 1 mi north of the 241-Z Building. The ultimate destination of the waste is to double-shell tanks. Tank TK-D5 is designed to treat 5,300 gal/d of liquid. The sump tanks and their functions are shown in Table 7-8.

7.2.3.1.2 Instrumentation and Controls. The retention tanks are monitored for leaks by a leak detection system that provides audible and visual alarms when liquids accumulate within the sump areas. The tanks are also monitored by strip charts that record the liquid levels of the tanks. The tanks are also equipped with high and low liquid-level indicators that alarm both audibly and visually when liquid reaches preset levels. The alarms and strip charts are checked every shift and the tank levels are recorded; any discrepancies are reported to plant management.

7.2.3.1.3 Tank Farm Acceptance Criteria. In order for the RLW to be accepted by the tank farms, the following criteria (see OSD-184-Z-00010) must be met:

- Pu concentration < 0.033 g/L
- Solid content limited from 0.7 to 3 vol%
- Fe to Pu weight ratio > 160:1
- No separable organic phase in liquid
- pH > 8
- If $[NO_3^-] < 1.0$ M, then $0.01 \text{ M} \leq [OH^-] \leq 5.0$ M and $0.011 \text{ M} \leq [NO_2^-] \leq 5.5$ M and $[NO_3^-]/[OH^-] + [NO_2^-] < 2.5$
- If $1.0 \text{ M} \leq [NO_3^-] \leq 3.0$ M, then $(0.1)[NO_3^-] \leq [OH^-] \leq 10$ M and $[OH^-] + [NO_2^-] \geq 0.4[NO_3^-]$
- If $3.0\text{M} < [NO_3^-] \leq 5.5$ M, then $0.3 \text{ M} \leq [OH^-] \leq 10.\text{M}$ and $[OH^-] + [NO_2^-] > 1.2$ M.

7.2.3.1.4 Criticality. Because the 241-Z tanks are geometrically unsafe, criticality prevention specifications impose a 400 g plutonium limit for each tank. As a conservative measure, all plutonium passing through a tank is considered to be resident in that tank until an NDA is conducted. In addition, plutonium concentration is limited to <0.033 g/L upon transfer of the RLW to 244-TX.

7.2.3.1.5 Safety Features. Safety-related features are in place within this system to help reduce the possibility of significant amounts of plutonium being released into the environment and to reduce the possibility of a criticality incident. Some of these features are as follows.

- Tanks are located within concrete cells
- Cells are individually ventilated
- Each cell contains leak detection and the capability of pumping out solutions that may leak into them
- Two sets of HEPA filtration provide redundancy

- Transfer lines between 241-Z and 244-TX are double-encased with leak detection and cathodic protection
- Tanks are equipped with agitators to help prevent buildup of solids
- Waste tank weight factor instrumentation and recorders are present.

7.2.3.2 Waste water Treatment.

7.2.3.2.1 Treatment Process. The waste water stream at the PFP receives input from a number of sources. Some of these sources, namely sanitary water and air-conditioning or chiller water, are all chemically nonhazardous and nonradioactive and are routed directly to the TEDF. Other sources which have the potential to contain hazardous or radioactive material are routed to the LLWTF for treatment and then to the TEDF for disposal. See Chapter 5.0, Section 5.4.9, for a detailed description of the 243-Z Building.

The D-2 and D-3 drain lines from the basement of the 234-5Z Building drain to the LLWTF. The D-1 and D-3 drain line headers in the 236-Z Building drain to manhole Z-4. The LLWTF receives potentially radioactive waste water from manhole Z4. The waste water enters the 243-ZA Building through double-contained pipe into an influent sump (which is supported with a 5,000-gal influent surge tank) (see Figure 7-2) and is then pumped into the 243-Z Building, as shown in Figure 7-6. Because the incoming effluent wastes are of a pH range about that of water, the stream pH does not typically need to be adjusted to meet a desired concentration to protect downstream cation exchange contactors. Even if an accidental acid spill does enter the waste water stream, the acidic portion of the effluent stream would be in such a small amount and of such a small duration that the trains would adequately treat the effluent to meet acceptable criteria.

Two prefilters can be used to remove suspended solids, though one filter is used at any one time with the other used as a backup. The prefilters are supplied with replaceable cartridges that remove particle sizes of 10 μm and larger, as well as a pressure gauge indicator used to measure stream flow. When a differential pressure exceeds 10 lb/in^2, operations routes the effluent stream flow through the backup prefilter and the saturated filter. Saturated filter cartridges are replaced. The cartridges are then disposed of as low-level waste (LLW).

The waste water stream is routed through two identical parallel treatment trains. Each train consists of three different adsorption medias arranged in the following order; granulated activated carbon, bone-char, and a cation (IX) resin.

All adsorption media are contained in UN 1A1 55-gal drums that are placed inside frames holding the piping and valves necessary to pass waste water through the canisters. The purpose of granulated activated carbon is to remove any traces of organic chemicals (e.g., chloroform) before the stream enters the bone-char canisters. The bone-char is specifically used in the process to remove the radionuclides that could be present in the waste water stream. Bone-char is used as the adsorption media of choice because of the following characteristics:

- High adsorption distribution coefficient for plutonium and americium over the entire range of pH expected for the waste water
- Rapid plutonium and americium adsorption under anticipated waste water conditions
- Reactivity toward all plutonium and americium isotopes that are expected to be present in the waste water
- Large particle size to minimize a pressure drop across the drums containing bone-char
- High mechanical strength and chemical stability.

The final stage of the absorption process occurs when the partially cleaned effluent passes through cation exchange contactors. These drums remove cations (e.g., barium, aluminum, mercury, copper, and other cations). The cleaned water is expected to consistently meet the DCGs as well as the 200 Area TEDF influent criteria.

The maximum flow rate to the 243-Z Building is 20-25 gal/min. Each train can clean a maximum influent rate of 30 gal/min. Train 1 or train 2 can be removed from service for maintenance without stopping the maximum influent flow to the 243-Z Building. Redundant pumps, filters, and manually operated valves are included in the process for the same purpose.

The 55-gal drums are Department of Transportation (DOT) UN 1A1 hazardous waste containers and are used for the following reasons.

- They may be filled with various adsorbents of choice
- The drums are easy to handle inside the 243-Z Building and can be easily loaded and unloaded from trucks
- The operator is prevented from coming in direct contact with radionuclides and hazardous chemicals during removal of saturated drums using the drum replacement procedures
- The UN 1A1 55-gal drums can be easily disposed of as LLW.

7.2.3.2.2 Low-Level Waste Treatment Facility Waste Streams.

Solid waste. There are five types of solid wastes generated in the waste water treatment process. All five types of solid wastes will be generated within the 243-Z Building, and will be disposed of by methods outlined in Section 7.3. The five types of solid waste are listed below.

1. Replaced suspended solids filter--this occurs when a differential pressure reaches 10 lb/in^2, indicating that the suspended solids filter must be changed.
2. Saturated activated carbon contactors--the necessity of a drum change is determined by two methods: examining the weekly sample monitoring results of a material balance, and/or by noting a flow

loss at a drum (i.e., a leak or plug). If a drum change is found to be required, that drum is removed from the process piping via quick-disconnect couplings and transported by hand cart to the drum turning room inside the 243-Z Building. The drum is mounted on a drum turning machine that raises the drum so that the liquid can be drained back into the influent sump. Two valves on the drum will be opened, the water will start to drain, and the doors to the drum draining station will be closed. The exhaust fan over the drum turning machine draws off any airborne radioactive and/or nonradioactive material through a HEPA filter before exhausting to the outside air (see Chapter 5.0, Section 5.4.1, for details of the ventilation system). Screens over the valves of a turning drum will prevent any solids from leaving the drum during the draining process. The drum is then buried as LLW.

3. Saturated bone-char contactors--these drums are disposed of in the same way as activated carbon contactors.

4. Saturated cation contactors--these drums are disposed of in the same way as activated carbon contactors.

5. HEPA filters from the 243-Z exhaust system--removal and disposal of HEPA filters is performed during the normal maintenance operations at the PFP.

Gaseous waste. Any possible hazardous chemical or radioactive gases generated in the waste water piping or the process vessels in the 243-Z Building would result from an accident. During normal operation of the primary and secondary closed-loop cooling system and the waste water treatment system, neither hazardous chemicals nor radioactive gases will be generated.

Liquid waste. Sludge will build up in the influent surge tank during operation of the 243-Z Building process system. Examination of the sump interior by looking through a flange will indicate whether build-up needs to be removed from the sump. Removal of sludge requires that an access manway on tank 101 be removed to allow for a truck vacuum hose to be used to remove any built-up solids.

7.2.3.2.3 Low-Level Waste Treatment Facility Sampling and Monitoring. After the waste stream enters the LLWTF, it is sampled before undergoing the treatment process. It is sampled using a proportional pressure-fed sampler with a 5-gal capacity and an adjustable sample rate up to 2 gal/h. There is online pH and conductivity monitoring at the inlet and outlet of the treatment trains. Before the treated effluent is transferred to manhole Z7, it is continuously monitored for pH and conductivity and proportionally sampled using a second sampler. If any of the limits or ranges do not meet specifications, the stream is recycled back through the process. If the effluent is within specifications, it is transferred to manhole Z7.

7.2.3.2.4 Treated Effluent Disposal Facility Sampling and Monitoring. The primary chemical constituents or measurements of regulatory concern for the TEDF waste water stream system are (1) pH (hydrogen ion concentration), (2) plutonium (radioactive), and (3) metal ions (conductivity). The TEDF is permitted for discharges that meet state drinking water standards on chemical

constituents and 4% of the DCG for radioactive constituents. Sampling of the TEDF stream began on June 8, 1995.

In the 225-WC Building, two flow-proportional composite samplers collect samples of waste water for analysis. One sampler is set up as the continuous or main sampler. The other is set up as the pH or backup sampler. The continuous sampler is set to collect 125 mL samples at 3,000-gal intervals. The collected effluent is composited in a 15 gal sample reservoir. The reservoir is sampled once a week.

Temperature, pH, and conductivity probes are located in the 225-WC monitoring station and are immersed in the effluent stream and the ultrasonic flowmeter is mounted in manhole C4. Local alarms annunciate when pH measurements exceed the discharge limits of 6.5 and 8.5 and when the flow rate exceeds 500 gal/min. If the pH alarm annunciates, the backup sampler is activated to collect samples of the stream. The pH monitor AIT-201, conductivity monitor AIT-202, and flow computer FQ-301 send data to chart recorder UR-201. Flow diagrams of the sampling equipment are found in the PFP procedure *225-WC Facility Surveillance*, ZO-102-018.

In addition to the effluent monitors, the waste water is sampled for radionuclides and chemical contaminates in accordance with the PFP Routine Wastewater Sample Schedule, FSS-Z-080-00003. These samples include the TEDF expanded sample, the TEDF indicator sample, the environmental composite sample, and process support samples. These samples are sent to the WSCF for analyses, except for the process support samples, which can be sent to the 222-S Laboratory.

The TEDF expanded sample is collected every 6 months and consists of grab samples and composite samples. The composite samples are analyzed for chlorides, nitrates, sulfates, total dissolved solids, arsenic, cadmium, chromium, iron, lead, manganese, mercury, Bis (2-ethylhexylphthalate), and phenol. The grab samples are analyzed for cyanides, WTPH-G, oil and grease, gross alpha, gross beta, total radium, ^{226}Ra, semi-volatiles, and volatiles. The expanded sample is collected by Sampling and Mobile Labs.

The TEDF indicator sample is a composite sample collected every 2 months and is analyzed for arsenic, cadmium, chromium, iron, lead, manganese, and mercury.

The environmental composite sample is collected weekly and is composited over the entire month at the WSCF. The monthly composite is analyzed for total alpha, total beta, gamma-energy analysis, ^{238}Pu, ^{240}Pu, and ^{241}Am. The environmental composite sample is collected under procedure ZO-102-021.

Process support samples are collected on request and can be taken from the Manning Sampler or as a grab sample. The process sample is usually analyzed for total alpha and pH. The grab sample is collected under procedure ZO-102-014. Grab samples are collected from manholes C4 and Z7, but additional sampling points may be specified.

7.2.4 Administrative Controls and Responses

Manual FSP-PFP-5-8, *Plutonium Finishing Plant Administration*, contains the procedures defining action levels and response actions to be taken in the case of high or abnormal sample results on liquid effluent samples. Responses to liquid effluent monitor alarms are discussed in *Building Emergency Plan for Plutonium Finishing Plant Complex*, HNF-IP-0263-PFP. The action levels for liquid effluents can be found in FSP-PFP-5-8.

Off-Normal Conditions and Constituents. The TEDF waste water stream sources were evaluated for possible off-normal conditions of regulatory concern. A list of PFP chemical constituents is presented in Table 7-9. All of these chemicals are used in the processing of plutonium materials and become part of the RLW. They are not discarded to the TEDF stream system. The only way these chemicals can enter the sewer system is during an off-normal plant condition. With the discontinuance of the PRF operations and the RMC Line, there is no potential for off-normal conditions because solutions no longer go to the cribs. The 236-Z exhaust duct sump is normally dry. If liquid should accumulate, it must be sampled before the sump contents can be transferred by jet pump to manhole Z-4 for discharge into the LLWTF.

7.3 SOLID WASTE

7.3.1 Criteria for Control of Solid Wastes

The PFP generates and manages the following radioactive and nonradioactive solid wastes.

- **Transuranic (TRU) waste.** These wastes contain alpha-emitting radionuclides of atomic number greater than 92, with half-lives greater than 20 yr, in concentrations greater than 100 nCi/g of waste matrix.

- **Low-level waste.** Waste that contains radioactivity and is not classified as high-level waste, TRU waste, or spent nuclear fuel.

- **Mixed waste.** Waste that contains both radioactive and hazardous components as defined by the Atomic Energy Act (AEA) and by the RCRA/WAC 173-303, respectively.

- **Dangerous waste.** Dangerous wastes means those solid wastes designated in WAC-173-303-070 through 173-303-100 as dangerous, or extremely hazardous or mixed waste. Such wastes are listed and defined in WAC 173-303 as discarded chemical projects or dangerous waste sources. As used in WAC 173-303, the term "dangerous waste" will refer to the full universe of wastes regulated by WAC 173-303 (including dangerous and extremely hazardous waste). (See HNF-EP-0063, *Hanford Site Solid Waste Acceptance Criteria).*

- **Nondangerous, nonradioactive solid waste.**

Standards for control of solid wastes, including a waste minimization program, are given in *Solid Waste Management*, HNF-PRO-455 and waste acceptance criteria are given in HNF-EP-0063. These standards include segregation of wastes according to type and minimization of the volume of solid wastes.

7.3.1.1 General Requirements for Radioactive Solid Wastes. HNF-PRO-455 and HNF-EP-0063 includes the following general requirements for radioactive solid wastes:

- Smearable contamination limits for waste package exteriors
- Segregation of incompatible wastes
- Stabilization of unreacted chemicals and alkali metals
- Prohibition of disposal of nonradioactive materials in containers specifically marked for radioactive materials
- Prohibition of explosives or pyrophorics in wastes
- Venting of gas cylinders (except aerosol cans) placed in wastes
- Waste designation and waste certification.

7.3.1.2 Not Used.

7.3.1.3 Standards for Disposal of Nonradioactive Solid Wastes. HNF-PRO-455 and HNF-EP-0063 includes the following standards that apply to disposal of nonradioactive solid wastes:

- Assay and/or survey policies for suspect waste prior to disposal
- Disposal location requirements for nonradioactive solid wastes
- Waste minimization implementation requirements.

7.3.2 Nonradioactive Solid Wastes

Nonradioactive solid wastes are discussed in Section 7.3.4.1.

7.3.3 Design Objectives

All solid wastes originating from the PFP are packaged for onsite/offsite storage or disposal. The design objective for waste packaging is to safely contain the waste during temporary storage at the PFP and during transportation to storage or disposal units. The waste packages meet the criteria of the pertinent storage/disposal unit. For TRU wastes, these criteria are DOE/WIPP-069, Rev. 5, *Waste Acceptance Criteria for the Waste Isolation Pilot Plant* (WIPP WAC) and HNF-EP-0063. For LLWs these criteria are those established by the LLW burial grounds. Hazardous and mixed waste (MW) meet regulatory standards established by the EPA, DOT, and Ecology. The

objectives of solid waste management activities also include proper segregation of all types of solid wastes.

7.3.4 Equipment and System Description

7.3.4.1 Waste Management System. Solid wastes generated at the PFP are packaged and shipped to the appropriate Treatment/Storage/Disposal (TSD) facilities in accordance with site and facility policies and procedures. The PFP interfaces with Waste Management of Hanford (WMH) to ensure all waste characterization, packaging, and transportation requirements are met for each waste container.

If possible, waste management activities are planned in advance and are included in the pre-planning stages of work being performed at the facility. WMH personnel are assigned to assist the PFP personnel meet federal, state, and site requirements and policies regarding waste characterization, packaging, and transportation.

The generated waste is characterized and determined to meet a specific Waste Specification Record (WSRd). WMH personnel develop a waste profile which describes the waste stream, characteristics, and packaging. WMH personnel also develop a portfolio which includes characterization documents (i.e., sample analysis, inventory sheets, MSDSs, etc.) as well as appropriate shipping documentation. The portfolio is sent to the receiving TSD facility for approval. When the portfolio has been approved the waste is shipped to the appropriate TSD per 49 CFR (DOT) or the applicable SARP/SEP.

The WMH managed TSD facilities perform waste verification on the waste containers to ensure the waste complies with the waste profile. Waste verification varies between 5% and 100% on waste containers depending on the waste stream and waste nonconformances.

7.3.4.2 Waste Equipment. Radioactive solid wastes are packaged in metal drums or burial boxes, depending on the size of the wastes. Burial boxes are used to dispose of failed equipment, HEPA filters, and other radioactive solids too large to fit into UN 1A1 55-gal drums. Dangerous solid wastes are collected in metal drums. Nonradioactive, nondangerous solid wastes are generally collected in metal dumpsters.

Radioactive waste drums consist of UN IA2 55-gal galvanized, aluminized, or painted drums. Each drum is quality control inspected and approved before use and is provided with a trace number. Each drum contains an absorbent or a Radpad in the bottom of the drum, a minimum of a 4-mil polyethylene liner, and an absorbent in the bottom of the liner. An alternative to the liner and absorbent components is a piping component consisting of a spacer securing an inner vessel within the drum. Drums are sealed with lock ring seals whose lock bolts are tightened in accordance with vendor information. Some, but not all, drums are equipped with a filter vented lid. Those drums that present the potential for pressurization are equipped with a filtered vent lid and may also contain a hydrogen oxygen recombinant catalyst pack be added to the drum to prevent pressurization resulting from the decomposition and/or interaction of organics that may be present.

Burial boxes consist of steel boxes or wood boxes. The steel boxes are painted inside and outside so that no bare metal is exposed. Each box is lined with a 6-mil (minimum) polyethylene liner. Boxes are designed to be watertight and are kept closed when not in use. When filled, the steel boxes are bolted shut with bolts tightened to specified torques, or secured with clips and security seals are applied. The wood boxes are nailed and banded shut.

7.3.5 Operating Procedures

Packaging of Waste. TRU waste is generally sealed out of the glovebox, bagged, and loaded into approved isolated transportation containers (ITCs). The ITCs are then subjected to an NDA measurement. As each waste package is placed into a waste container, a log sheet is filled out specifying the total plutonium present. Low level waste packages may be placed directly into the waste container after contamination survey to verify that there is no surface contamination. Management must be notified if the waste package contains greater than 187 g plutonium. After NDA, the waste package is placed in the container. Waste packages are added until the waste container is determined to be full. Drums are considered full when any of the following conditions are met:

- For PFP drums other than PRF drums, when plutonium content reaches 187 g (HNF-EP-0063 limit)
- For PRF drums, when plutonium content reaches 150 g (based on PRF operating experience; in some cases, total drum assay is higher than sum of individual package assays)
- When the drum surface dose rate reaches 200 mrem/h at any point (HNF-EP-0063 limit)
- When the drum estimated gross weight reaches 300 lb (the PFP limit based on personnel safety for drum handling) or up to 500 lb with management approval
- When the drum is physically full and additional waste can not be added.

Further actions depend on the results of the assay, as follows:

- If less than 1 g, attach CAUTION radioactive materials label, remove fissile labels
- If between 1 and 10 g, attach standard package label recording identification number, type of material, gross weight, grams of fissile material, net weight, H/X, and seal number
- If greater than 10 g, transfer the drum to a segmented gamma scan assay system in 2736-ZB. Have NDA personnel count the drum. If greater than 187 g plutonium, notify management.

Waste packages and containers are also surveyed to control radiation exposure. Department of Transportation shipping regulations limit each waste package to less than 20 dpm/100 cm^2 of removable alpha contamination, however Hanford Site and PFP radiological control policies prohibit any detectable surface contamination.

Compactible solid LLW consists of paper, plastic, cloth, tape, cardboard, etc. Compactible solid LLW is collected and transferred to the 234-5Z Building, room 192. In room 192 the LLW is assayed on the Multi-Energy Gamma Assay System. If the assay is 100 nCi/g or greater, the LLW is handled as TRU room waste. All LLW is classified and segregated according to category 1 or 3, based upon HNF-EP-0063. Category 3 waste is not compacted, but category 1 waste is compacted. The waste is stored at the PFP until ready for transport to the designated TSD facility.

Non-compactible solid LLW consists of non-compactible category 1 and 3 materials. The waste may be categorized by surface contamination levels or NDA. The waste is stored at the PFP until ready for transport to a designated TSD facility.

TRU drums are vented using a carbon composite filter in the lid of the drums. If a waste drum is determined to be pressurized, it is depressurized using a specific work plan.

Some drums have been found with small amounts of liquid (as detected by radiograph) and do not meet the WIPP WAC. These are sent to the PFP for repackaging using an approved work plan or procedure. Currently, all drums have absorbent added to absorb any "free" liquid.

Mixed Wastes. Mixed Wastes (MWs) are packaged to meet HNF-EP-0063, 49 CFR, and/or SARPs, and the appropriate waste profile in accordance with facility specific procedures or work plans. MWs are stored in designated hazardous waste 90-day accumulation areas prior to shipment to the appropriate treatment, storage, or disposal facility (TSD).

7.3.5.1 Solid Waste Packaging, Handling Safety, and Criticality Prevention. Criticality safety limits for solid waste management are based on determination of the fissionable material content of each waste package placed in a waste container and on observation of fissionable material limits and handling procedures.

- Packaging
  - Fissile material content in a standard 55 gallon drum may not exceed 187 grams. This limit is consistent with the fissionable material content limits for standard 55 gallon drums contained in HNF-PRO-0063, *Hanford Site Solid Waste Acceptance Criteria*.
  - A maximum of 250 grams fissile material is allowed in a 55 gallon drum (TRU waste) which contains an unrestricted quantity of polyethylene (CPS-Z-165-80100).

- A maximum of 100 grams of fissile material is allowed in a drum if the fissile material is contained in less than 20% (one-fifth) of the drum volume.

- The maximum material allowed per SS&C cemented billet can is 100 grams.

- For discrete "packages" of plutonium (sample vials, contaminated bottles, etc.) with less than or equal to 15 grams plutonium each, spacing, location, and volumes are not controlled provided that the total accumulation of such packages shall not exceed 100 grams.

• Handling

General Spacing Limits (CPS-Z-165-80100)

Fissile material spacing limits listed below give general spacing requirements. Other specific requirements or limits can be found in this CPS (CPS-Z-165-80100) and in other CPS's which apply to specific container or storage locations.

- Minimum spacing between two storage arrays or an array and more than 100 grams fissile material (including non-isolating walls) is 3 ft.

Transition Spacing

- Minimum spacing from other transition operations is 3 ft.

- Minimum spacing from other storage arrays while in transition is 18 in.

- Minimum spacing between items in storage during transition into and out of a storage array is not required. DOES NOT PERMIT STACKING.

ITC Spacing Requirements (CPS-Z-165-80100)

- Maintain an 18-in. minimum spacing between ITCs and between ITC and any other items containing over 100 grams of fissile material including through non-isolating walls when in storage.

- ITCs containing unmeasured waste shall be spaced a minimum of 3 ft from other unmeasured waste items and from any other items containing over 100 grams of fissile material including through non-isolating walls when in storage.

- An unattended transportation array is considered to be in storage, not in transit. Minimum spacing of 3 ft between two storage arrays or an array and items containing more than 100 grams fissile material, unless specifically permitted by a CPS.

- Minimum spacing of 3 ft is required between two unmeasured items or an unmeasured items and other arrays greater than 100 grams fissile material.

- Minimum spacing of 18-in. is required between transportation array and any storage array or glovebox during movement, unless transportation array can be combined with the storage array under posted criticality limits (i.e., introduce the item into a glovebox or storage array).

- If the spacing required would extend through a non-isolating wall, then the space on the other side of the wall must be examined to determine no spacing violations would exist when items or arrays are stored near the wall.

The following criticality safety-related limits and procedures have been established for standard waste boxes (SWBs).

- Maximum plutonium content is 325 g per SWB.

- A 3-ft minimum spacing is to be kept between each SWB and other fissile material.

Additional safety procedures have been established for waste containers.

- All water-soaked rags are wrung out and dried before loading. Absorbent is added to all packages that might contain inorganic liquid to help ensure that all free liquids are absorbed.

- Sharp corners and edges are padded and taped before packages are loaded into drums and boxes.

7.3.5.2 Administrative Procedures. Administrative controls are relied upon for solid waste segregation. Separate waste containers are provided for each type of waste (i.e., TRU waste, LLW, MW, and DW). Contents inventory sheets (CISs) are used to track the inventory of each waste container to ensure that unauthorized wastes are not present. In addition, written procedures exist for each waste type and container type.

7.3.6 Characteristics, Concentrations, and Volume of Solid Waste

Nonradioactive and radioactive solid wastes are generated at a number of sites at the PFP. The sites are not fixed; they can be moved or deleted or new sites can be added.

LLW generation rate for 1996 is anticipated to be 1500 UN 1A2 55-gal drums. The LLW absorbed organic (12 L per drum) CCl_4, TBP nominal waste generation rate is 50 ft^3/yr. For low-level PCB hydraulic fluids (greater than 50 ppm and less than 70,000 ppm PCB in diesel or PYDRAUL or FYRQUEL hydraulic fluids--30 L liquid per drum) the nominal waste generation rate is 66 ft^3/yr or 90 drums per year.

The TRU-absorbed organics [CCl_4, tributyl phosphate (TBP) and its degradation products; dibutyl phosphate (DBP) and monobutyl phosphate (MBP), TBP in normal paraffin hydrocarbons, xylene, trimethyl benzene, nonionic detergent, and trioctal phosphine oxide) are placed in UN 1A2 55-gal drums.

Drums contain 12 L of liquid. The nominal waste generation rate would be 52 ft^3/yr or seven drums per year if the PRF were operating.

The TRU PCB-contaminated solid waste (rags, protective clothing, tools, hydraulic hoses, and equipment) is placed in UN 1A2 55-gal drums. The nominal waste generation rate is 30 ft^3/yr or four drums per year. The TRU PCB-contaminated burial box waste nominal waste generation rate is 50 ft^3/yr.

The TRU PCB hydraulic fluids (greater than 50 ppm and less than 70,000 ppm PCB in normal paraffin hydrocarbon or polyphenyl phosphate-based hydraulic fluids) are placed in UN 1A2 55-gal drums. The nominal waste generation rate is 50 ft^3/yr or seven drums per year.

7.3.7 Packaging

All radioactive waste, DW, and MW is packaged, transported, and stored in an environmentally safe manner. The packaging requirements for radioactive waste, DW, and MW are described in *Hanford Site Solid Waste Acceptance Criteria*, HNF-EP-0063, specific SARPs/SEPs, and/or 49 CFR.

The specific packaging, labeling, and manifesting requirements for actual waste packages or waste items are defined in *Responsibilities and Procedures for All Hazardous Materials*, HNF-PRO-154; *Radioactive Material/Waste Shipments*, HNF-PRO-157, and *Non-Radioactive Material/Waste Shipments*, HNF-PRO-156. This document is prepared in accordance with applicable state and federal dangerous waste and transportation regulations or DOE-authorized alternate criteria.

Other requirements have been established in *Radioactive Material/Waste Shipments*, HNF-PRO-157, and Non-Radioactive Material/Waste Shipments, HNF-PRO-156. These define the control of handling, storage, cleaning, packaging, preservation, and shipping of items to prevent damage or loss and to minimize deterioration. These requirements have been implemented using approved procedures, instructions, drawings, specifications, shipment instructions, or other pertinent documents or procedures.

7.3.8 Storage Facilities

Containerized LLW is stored either in radioactive material areas (RMAs) within the 234-5Z or 2736-ZB buildings or outside in the 234-5Z West Pad or South Pad waste storage RMAs.

Containerized TRU waste may be stored in the same locations. When TRU waste is stored in an outside RMA it must meet the requirements of WHC-SD-CP-OSR-010, 5.24.1, *Management of TRU Material stored in RMA Outside Facility Buildings*.

MW and DW must be stored in established satellite accumulation areas (SAAs). When a SAA accumulates 55 gallons of DW/MW or 1 quart of acutely hazardous waste it must be moved to the appropriate 90 day accumulation area within three days. 90 day accumulation areas are inspected on a weekly basis per WAC 173-303.

7.4 VENTILATION EXHAUST SYSTEMS AND OFFGAS TREATMENT

See Chapter 5.0, Section 5.4.1 for details of the HVAC system of the PFP complex.

The ventilation exhaust systems provide for the discharge of all treated airborne and gaseous effluents. These systems provide exhaust for the ventilation systems and the offgas treatment systems.

The ventilation systems at the PFP are designed and constructed to confine airborne radioactive materials within the appropriate areas of the building. The ventilation systems clean all normally or accidentally contaminated air effluent streams before release to the environment to as far below established limits as is reasonably achievable.

The ventilation systems are a safety feature of the facility. As such, they are designed to compliment the building layout and remain functional during all operational modes and fail safely during credible accident conditions where stopping is acceptable. Safety considerations and controls for the ventilation systems can be found in Chapter 5.0, Section 5.4.1.

7.5 LIQUID WASTE SOLIDIFICATION

Small amounts of sludge, glovebox floor sweepings, glovebox residue with free moisture, and other TRU waste are solidified into a cement matrix. The ingredients are mixed in accordance with approved plant operating procedures. Contents are allowed to solidify and cure for 24 h, inspected for free liquids, packaged, NDA'd, and transferred to TRU waste drums.

[a]Water utilities are shut off to this building. There are no routine contributors to the LLWTF from 242-Z.
[b]Water utilities are shut off to this building. There are no routine contributors to the TEDF from 232-Z.
[c]The cooling towers and backflow preventers drain directly to the LLWTF feed tank, Tk-101.

Table 7-8. Active Sump Tanks.

Sump tank	Location	Function	Description	Normal operating level (L)	Nominal plutonium inventory (g)	Physical form	Nominal chemical form	Criticality specification limit (g)
Tk-D4	241-Z	Radioactive mixed waste storage tank. Reserve storage capacity for tank overflows.	10-ft. x 10-ft. 3-in. stainless steel with 3/8-in. wall thickness	12,000	100	Liquid	$Pu(NO_3)_4$	400
Tk-D5	241-Z	Radioactive mixed waste storage and treatment tank. Receives waste solutions primarily from storage tank Tk-D8 with ability to receive from Tk-D7. All waste transfers to tank farms are through tank Tk-D5.	10-ft. x 10-ft. 3-in. stainless steel with 3/8-in. wall thickness	12,000	100	Liquid	$Pu(NO_3)_4$	400
Tk-D7	241-Z	Radioactive mixed waste storage tank. Reserve storage capacity for tank overflows.	10-ft. x 10-ft. 3-in. stainless steel with 3/8-in. wall thickness	12,000	100	Liquid	$Pu(NO_3)_4$	400
Tk-D8	241-Z	Radioactive mixed waste storage and treatment tank. Receives waste from PFP Laboratory and miscellaneous stabilization processes. Batch transfers are made from Tk-D8 to Tk-D5.	10-ft. x 10-ft. 3-in. stainless steel with 3/8-in. wall thickness	12,000	100	Liquid	$Pu(NO_3)_4$	400

Table 7-9. List of Plutonium Finishing Plant Chemical Constituents.

Chemical constituent	Formula
Potassium permanganate	$KMnO_4$
Potassium hydroxide	KOH
Oxalic acid	$H_2C_2O_4$
Nitric acid	HNO_3
Hydrogen peroxide	H_2O_2
ANN (aluminum nitrate nonahydrate)	$Al(NO_3)_3\ 9H_2O$
Sodium hydroxide	NaOH
Hydrazine	$NH_2 \cdot NH_2$
Tributyl phosphate	$(C_4H_8)_3\ PO_4$
Sodium nitrite	$NaNO_2$
Hydroxylamine nitrate	$NH_2OH\ HNO_3$

PLUTONIUM FINISHING PLANT
FINAL SAFETY ANALYSIS REPORT

CHAPTER 8.0

RADIATION PROTECTION

FEBRUARY 2001

This page intentionally left blank.

PREFACE

Revision 2 of Chapter 8.0 of the Plutonium Finishing Plant (PFP) Final Safety Analysis Report (FSAR) includes modifications for the following:

- Revision of the description of the solid waste stream
- Provide additional clarification of the airborne radioactivity sampling guidance documents and program responsibilities
- Clarification of the internal dosimetry programs

Other minor changes include editorial changes and additional clarifications.

It is noted that various sections of Chapter 8.0 present information concerning plutonium-bearing solution stabilization operations using the Production Vertical Denitration Calciner located in the RMC Line and the Laboratory Prototype Calciner located in the Plutonium Process Support Laboratories. Operation of either the production calciner or the laboratory calciner for solution stabilization is not authorized at this time and the related portions of Chapter 8.0 will be updated, if necessary, prior to initiation of operations.

The new packaged boilers operated by Johnson Controls, Inc. which provide steam to the PFP were previously incorporated in the FSAR. This included switching the emergency exhaust fans from those which are steam-driven to those which are connected to the standby power system. However, the conversion from using steam-driven fans to standby power driven fans has not been fully implemented. The emergency exhaust fans are currently run by the new steam supply system installed under the Hanford energy conservation program. Electrically-driven emergency exhaust fans are planned to be connected to the diesel-generator standby power supply at some future date. The emergency exhaust fan functions are unchanged from that described in the FSAR regardless of the type and source of power.

The significant areas of change in Revision 2 are indicated by vertical bars in the margin of each page.

This page intentionally left blank.

8.0 RADIATION PROTECTION

This chapter describes the Hanford Contractor and Plutonium Finishing Plant (PFP) radiation protection program, which is designed to minimize the exposure of individuals and the environment to radiation, considering all potential sources of radiation and radioactive materials.

The Hanford Site customary radiological protection units are used in this chapter. This means that "rad" is used to denote beta particulate exposures, "R" or "roentgen" denotes gamma exposures, and "rem" denotes neutron exposures or the combination of any of these units. The term "dpm" (disintegrations per minute) indicates that readout of a radiation detection device that reads in "cpm" (counts per minute) has been corrected for its detection efficiency. In the PFP, dpm indicates an alpha or beta particulate survey measurement (see Section 8.5.2). The derived air concentrations (DAC) and derived concentration guides (DCGs) are based on International Commission on Radiological Protection (ICRP) 30 considerations as expressed in 10 CFR 835 *Occupational Radiation Protection*, Appendix A (DOE 1993a) and DOE Order 5400.5, *Radiation Protection of the Public and the Environment* (DOE 1993b), respectively.

10 CFR 835 establishes radiation protection standards, limits, and program requirements for protecting individuals from ionizing radiation resulting from the conduct of Department of Energy (DOE) activities. The requirements found in 10 CFR 835 are the minimum required by law. 10 CFR 835 requires that each DOE contractor write a radiation protection program (RPP) that will implement the requirements of 10 CFR 835. Enforcement of 10 CFR 835 will be against the RPP.

The RPP was developed using requirements from the Project Hanford Radiological Control Manual, PHRCM; HNF-5173 (FH 2000), that best implement the 10 CFR 835 requirements. Therefore, the requirements are derived from the minimum requirements found in 10 CFR 835 and implemented through the RPP using the PHRCM. Implementation is described in *Fluor Daniel Hanford Radiation Protection Program Implementation of Title 10, Code of Federal Regulations, Part 835*, HNF-SP-1145.

Safety structures, systems, and components (SSCs) and procedures are required to minimize or mitigate the impact of design-basis accidents on the public, the environment, or the work force per DOE Order 6430.1A, *General Design Criteria*, Section 0111-99.0.1 (DOE 1989). Two safety categories have been defined as safety class and safety significant which are described in *Hazard and Accident Analysis Process* (HNF-PRO-704), Table 5, Safety SSC Criteria.

The use of the safety classification system aids the facility operations to establish priorities for equipment operation, maintenance, and repair. Plant SSCs related to safety are categorized as Safety Class or Safety Significant in a Safety Equipment Listing (SEL). The SEL for the PFP includes (among other systems) the stack effluent monitoring, supply ventilation seismic shutdown system, criticality alarm systems (CAS) and continuous air monitors (CAM), which are described in this chapter. Chapters 4.0, 5.0, 6.0, and 7.0 contain many of the details on how the PFP conforms to the design requirements of DOE Order 6430.1A (DOE 1989). This chapter contains

information that shows the PFP functional conformance with DOE Order 6430.1A (DOE 1989) criteria. See Section 4.4 of Chapter 4.0, "Safety Protection Systems", for additional details. See WHC-SD-CP-ES-128, *Preliminary Evaluation of PFP Conformance to DOE Order 6430.1A Principal Design Criteria* (WHC 1995a) for additional information on the PFP conformance to current design guidelines.

8.1 OCCUPATIONAL RADIATION EXPOSURES

8.1.1 As Low As Reasonably Achievable Policy

It is the site contractor policy that line management (facility manager) is responsible for the safe operation of facilities. The Radiological Control (RC) organization provides the services and overview necessary for a radiation protection program meeting the operational needs of the PFP.

The as low as reasonably achievable (ALARA) guidance philosophy required by 10 CFR 835, PHRCM, and DOE Order has been incorporated into the management policy and organizational structure. Management is committed to ALARA, and those responsible for implementing the program are alert to opportunities for reducing exposures.

The radiation dose to Hanford employees, visitors, and members of the general public originating from company operations is controlled to levels which are less than applicable DOE limits. Such radiation doses are further limited to levels that are ALARA. The following manuals describe the organizational structure and the methods for controlling and ensuring that human exposures to hazardous substances and conditions are maintained to ALARA: *ALARA Management Commitment and Policy*, HNF-PRO-1618; *ALARA Organization and Responsibilities*, HNF-PRO-1619; *ALARA Program Scope*, HNF-PRO-1620; and, *Plutonium Finishing Plant Administration*, FSP-PFP-5-8.

Facility line management has the responsibility for the implementation of and compliance with DOE safety regulations. Management has assigned the RC organization the responsibility for implementing company radiation protection standards and procedures, providing independent review and evaluation of the program, conducting the radiological support and dosimetry effort, and administering the company-wide ALARA program. The RC organization is assigned directly to plant director. See Chapter 10.0 for additional information.

The PFP line management is responsible for the radiological safety of the personnel assigned to the PFP as well as of visitors. The PFP line management and the PFP RC organization work together to identify the plant's radiation protection needs and to implement the Radiation Protection and ALARA programs.

The PFP line management has designated an ALARA Team which is a subcommittee to the ZAC, to aid the plant Manager in the application of ALARA. The PFP ALARA Team consists of representatives from various organizations such as: Engineering, Transition Operations, RC, Operations, Analytical Laboratories, Maintenance Work Control, PFP Safety, and Plutonium Process Support Laboratory (PPSL) groups, as well as the Plant Director and the ALARA Team Chairperson. The team meets as necessary to support changing plant

conditions. The ALARA team activities follow the requirements and HNF-PRO-1619, *ALARA Organization and Responsibilities.*

Plant personnel are made aware of management's commitment to ALARA via the establishment of the PFP ALARA goals, the ALARA procedure in the plant administrative manual, and pre-job meetings. Modifications have been made and will continue to be made to the facilities and plant procedures to implement ALARA improvements. Any person in the plant may submit ALARA-based suggestions for changes to plant procedures or modifications of plant facilities for reduction of personnel exposure to radiation or radioactive materials.

The ALARA representative or local contact is the interface with the function manager, functional organizations, and work package preparers/persons-in-charge (WPP/PIC). Facility management implements the formal ALARA program and acts as the interface between organizations in daily work activities within the PFP.

In addition to the ALARA program, the RC organization conducts periodic audits and appraisals of company operations. The purpose is to provide independent radiological control assessment to ensure that the applicable radiological safety standards and ALARA are being followed and are in compliance with the PHRCM (FH 2000), and 10 CFR 835 (DOE 1993a).

Sections 8.1.2 and 8.1.3 provide information on how ALARA is implemented in PFP design and operation.

8.1.2 Design Considerations

The original design for the PFP was based on the Uniform Building Code (UBC) of 1946 (ICBO 1946) and National Bureau of Standards (NBS) Handbooks 23 (NBS 1938) and 42 (NBS 1949).

Facilities were built and operated before there was a significant amount of design or ALARA guidance developed for this type of facility. The current DOE design and ALARA requirements have evolved from the design criteria developed for the PFP construction project.

The design philosophy used throughout the PFP was based on the premise that any exposure of personnel to possible internal plutonium depositions shall be avoided if at all possible. New or modified facilities, systems or equipment are designed today in accordance with current radiological design principles including ALARA. Design guidance is provided by *Radiological Design Review Process*, HNF-PRO-1622. 10CFR835 design criteria are utilized for the design of new or modification of existing shielding. The ALARA philosophy is applied to all areas of the plant. Some areas of the PFP that were designed to >1 mrem/h criteria remain. To maintain a $\leq$1 mrem/h average dose rate, administrative restrictions have been applied. Administrative control offsets higher design dose rates. This is acceptable because of the following:

- The original design was usually conservative

- Dose rates or personnel occupancy rates are lower than the designers expected

- Administrative restrictions have been implemented to minimize personnel occupancy.

The process equipment was and the new equipment is designed to provide confinement of airborne activity, completely separating the atmospheres exposed to possible plutonium contamination from air breathed by operating personnel. Since various operations performed in the different building spaces have varying potentials for external contamination spreads from a loss of confinement situation, a high degree of compartmentalization has been provided to isolate various spaces in the event of a contamination incident. Chapter 5.0 discusses how the facility structures respond to natural phenomena hazards. This chapter describes the special features that were incorporated into the design and ultimately built into the facilities to make the facilities appropriate for processing and handling large quantities of plutonium materials.

Facility management, with the aid of its ALARA program personnel:

- Review new designs or facility modifications to ensure that radiological design criteria principles include ALARA

- Ensures that facilities or modifications are designed to minimize exposure of personnel to radioactive materials or radiation

- Ensures that environmental assessments include ALARA principles so that design-based releases are ALARA

- Review technical work documents and work plans, determine the ALARA review requirements, and obtain the RC Organization concurrence in this determination [PHRCM, 312.3, 315.2 (FH 2000)].

At the time of construction there was minimal design or ALARA guidance, but the following features of the PFP have evolved as a result of ALARA and past operating experience. Lead shielding, ALARA panels, and lead-loaded rubber gloves are used in gloveboxes to reduce whole-body and extremity exposures. Gloveboxes are used in cases where handling of bare material is required or the risk of airborne contamination is high. The PFP design features and ALARA improvements have evolved over the last 40 yrs and are in functional conformance with today's standards. Some of these features are:

- The ventilation system is designed to ensure control of airborne contaminants even if normal airflow patterns may be disrupted, such as by an open glovebox access port. This system also maintains airflows from lowest to highest contamination potential and filters all radioactive material work areas and confinement device exhausts to ensure minimal escape of radioactive materials.

- The gloveports of new gloveboxes are strategically located to permit servicing of glovebox equipment.

- Service connections to the gloveboxes are protected with high-efficiency particulate air (HEPA) filter backflow preventers or are

sealed to minimize radioactive material contamination of the service lines.

- Operation and control of certain process equipment, valving, and material transfer are remote from the glovebox interior, thereby minimizing extremity and whole-body exposure.

- Supply airflow in radiological areas within process areas sweeps from ceiling to floor to maintain clean air in the breathing zone.

- Shielding is used for gloveboxes in many of the process areas for shielding neutron and gamma radiation, thereby reducing dose to personnel.

- Remote sensing penetrations have been installed in the plutonium materials storage vaults, where practical, to allow remote continuous air monitoring and sampling of storage vault atmospheres.

- The plutonium materials vault storage areas use various administrative and engineered controls to minimize dose, such as shielded pedestals and a real-time inventory system to minimize personnel dose.

- Air sampling, radiation monitors, and communications systems are provided to assist in early identification of a release to the environment and providing notification of an upset situation at the facility. All of the monitors have local alarms; some alarms have remote alarming features.

Consideration of decontamination and decommissioning (D&D) criteria for plant design was introduced to the nuclear industry after most of the PFP buildings were constructed.

Shutdown facilities first undergo terminal cleanout operations (TCO). This is intended to (1) recover any residual plutonium-bearing material in the equipment, gloveboxes, and heating, ventilation, and air-conditioning (HVAC) system and (2) leave the area in a stable condition requiring minimum surveillance pending D&D or reactivation. Following TCO, a facility will eventually be further decontaminated and decommissioned.

Shutdown facilities remain on ventilation control as long as radioactive materials remain. The CAMs are also maintained active and portable units are brought in if infrequent entry is required where there is a probability of airborne radioactivity. Fire protection is also maintained active when required by the site fire protection program. Criticality incident detection normally is not maintained since TCO results in fissile material quantities, forms, or configurations which ensure criticality prevention. Equipment is typically isolated from electrical services though support systems, such as fire protection and CAMs, may remain operational until D&D of the shutdown facility.

There was no initial requirement for incorporation of D&D features, but the following design features are an aid in the D&D of the facility: (1) compartmentalization and modularization of the facility and its processes; (2) isolated service piping and access levels for utilities and heating,

ventilation, and HVAC systems used in the various process modules and work areas; and (3) strategically located HEPA filters and filterboxes.

New or modified facilities/systems/equipment are designed in accordance with HNF-PRO-1622, *Radiological Design Review Process*, which is in accordance with accepted radiological design principles of DOE Order 6430.1A (DOE 1989) and *Radiological Performance and ALARA Goals*, HNF-PRO-1630. The Safety organization and RC is responsible for approving engineering documents for both initial release and subsequent revision based on assigned approval designators. The approval process is specified in *Engineering Release and Approval Requirements*, HNF-PRO-317.

8.1.3 Operational Considerations

The pertinent techniques of PNL-6577 (PNL 1988b) have been incorporated into the PFP procedures and methods of operation used to ensure that occupational radiation exposures are ALARA.

The Hanford contractors are responsible for the development of programs and procedures for occupational health protection in contractor-operated facilities. Whenever a new or revised DOE directive is issued, DOE-RL advises the affected contractor(s) in a formal letter. The appropriate executive is assigned the responsibility for incorporating the directive into procedures. *Managing DOE Directives*, HNF-PRO-116, establishes and maintains a controlled system of written management directives in the form of policies, requirements, and procedures. The controlled system governs the activities of the company performing work under the prime contract with the DOE. These management requirements and procedures establish the ALARA and Radiation Protection programs (see *ALARA Management Commitment and Policy*, HNF-PRO-1618, *ALARA Organization and Responsibilities*, HNF-PRO-1619, and *ALARA Program Scope*, HNF-PRO-1620).

The PFP operating and administrative procedures incorporate safeguards that help to ensure that contamination levels are ALARA. The principle of total confinement is used throughout the PFP where practical. Tasks involving resuspendable transuranic (TRU) element/compounds are performed using at least one engineered barrier between the material and personnel. If confinement cannot be achieved, administrative procedures identify requirements; for deviating from the confinement philosophy in FSP-PFP-5-8, *Plutonium Finishing Plant Administration*, Section 1.1, "Safety Policy." Appropriate approvals by the RC, Operations, and Plant Engineering functions are required.

PFP approves operating procedures and work plans. The facility team performs a hazards analysis that identifies unique hazards and incorporates methods for dealing with the hazard into the procedures as safety requirements. The PFP Safety and RC organizations review the procedures for Federal regulation, DOE order, and requirements compliance and ALARA implementation. The PFP Safety and RC organizations approve operating procedures, along with plant and transition operations.

Plant management establishes annual ALARA goals for its operations based on projected processing campaigns, proposed modifications, and anticipated work scope. These goals and quarterly status reports are provided to the

ALARA Program Office, which tracks plant status and incorporates plant reports into documentation provided to DOE-RL.

The operation of the PFP ALARA program is described in Section 8.1.1.

8.2 RADIATION SOURCES

The PFP is designed to process plutonium, a TRU element. The TRUs have the most restrictive radiological control values of any radioisotopes in the PFP. Processing TRUs requires extensive analytical capabilities for process control. Modern analytical tools (e.g., atomic absorption spectrometry, mass spectrography, gas chromatography, etc.) are used to minimize the amount of hands-on activities during routine analytical functions, which is a major source of personnel dose and a potential source for loss of contamination control. The PFP radiation protection program assumes that any alpha contamination found is plutonium and responds accordingly. This conservative assumption is applied to all operations. The PFP Analytical Laboratory (PFP AL) and the PPSL contain a wider range of radionuclides than are found in the principal facility processes. This wider range is used in analytical procedure verification, procedure and process work, and process-upset investigations. The radiation protection program is based, primarily, on controlling alpha-emitting radionuclides at or below those values established for ^{239}Pu. The program has the flexibility needed to provide similar controls for specialized PFP areas that handle and/or process nonplutonium radioisotopes such as uranium and americium. Additional information relating to the handling of plutonium materials for processing and storage is contained in Chapter 6.0.

The following is a description of the principal radiation sources and their locations in the PFP facilities.

8.2.1 Contained Sources

This section describes the existing radiation sources which were considered during the design of the PFP. The design considered radiation shielding and criticality control. The sources are categorized as follows:

- Process streams
- Nonairborne waste streams
- Storage of product and recoverable materials
- Holdup.

8.2.1.1 Process Streams.

8.2.1.1.1 Inactive Processes.

Plutonium Reclamation Facility. The Plutonium Reclamation Facility (PRF) is not operating and is not authorized for operation. The PRF was used to recover plutonium from plutonium-bearing materials and solutions. See Chapters 5.0 and 6.0 for discussion of PRF facility/equipment descriptions and operations, respectively.

The PRF tanks, vessels, and equipment are essentially empty and do not represent significant radiation sources. The remaining sources are due to holdup and heels in tanks, and general contamination on equipment, in hoods and in the canyon. Table 8-2 provides the location, function, description, working volume, and source chemical form for the equipment that contains potential radiation sources in the PRF.

Remote Mechanical A Line. The Remote Mechanical A (RMA) Line was used to produce plutonium metal. Gloveboxes HA-21I, HA-22B, HA-23S, and HA-28 are currently used during the thermal stabilization process, with the remainder of the gloveboxes being inactive.

See Chapter 5.0 for a description of active RMA Line gloveboxes. See Chapter 6.0 for a discussion of the thermal stabilization process. See Chapter 6.0, Section 6.4, for discussions of past RMA processes and glovebox functions.

High dose rates (multiple rem per hour) exist in this processing line, but it is not normally accessed, which keeps personnel doses ALARA.

Remote Mechanical C Line. The Remote Mechanical C (RMC) Line was previously used to produce plutonium metal. RMC Line gloveboxes HC-1, HC-2, HC-3, HC-4, HC-13MD, HC-21A, HC-21C, HC-18BS, and HC-18M are currently being used in the thermal stabilization process, with the remainder of the gloveboxes not currently being used.

See Chapter 5.0 for a description of RMC Line gloveboxes used in the thermal stabilization process. See Chapter 6.0 for a discussion of the thermal stabilization process and the present RMC Line operations and glovebox functions.

The location, function, description, working volume and source chemical form for the equipment that contains potential sources of radiation in the RMC Line are identified in Table 8-3.

The RMC Line radiation dose rates are subject to significant changes depending on housekeeping, operating campaign source materials, and accumulated cleanup materials.

8.2.1.1.2 Active Processes.

Thermal Stabilization. Reactive plutonium-bearing materials are converted to a stable form by heating the material to high temperatures in a furnace. See Chapter 5.0, Section 5.2.1, for details of the equipment used in the thermal stabilization process for reactive materials.

An estimation of personnel dose equivalents (DEs) were calculated for the thermal stabilization of the inventory contained within the PFP (Chew 1996). The total whole body and extremity DE for the process was determined by the summation of individual process task DEs. After the two man rule was factored into the total whole body, the values were then divided by the number of operators (who are trained on all processes and are regularly rotated) to estimate the average whole body and extremity DE over the estimated campaign duration (four years). The whole body DE/operator/yr was 1.0 rem and the extremity DE/operator/yr was 12.2 rem (Chew 1996).

The thermal stabilization process for reactive materials was analyzed for four sets of material: plutonium oxide, mixed plutonium oxide, other, and sludge. The oxide and mixed oxide material were further subdivided into low ^{240}Pu weight percent, mid ^{240}Pu weight percent, and high ^{240}Pu weight percent for oxide material, and mid ^{240}Pu weight percent, and high ^{240}Pu weight percent for mixed oxide material. Other material such as product from the 188-1 glovebox Laboratory Prototype Calciner, was considered to be low ^{240}Pu weight percent material. Sludge material was considered low ^{240}Pu weight percent.

See Chapter 5.0 for a detailed description of the equipment used in reactive plutonium-bearing material thermal stabilization operations. See Chapter 6.0 for a complete discussion of the thermal stabilization process. See the Laboratory Prototype Calciner addendum to this FSAR for descriptions of the equipment and process associated with the laboratory calciner.

Nitrate Load In/Load Out and Vertical Calcination. This process involves transfers of solution from product receiver (PR) cans and 10-L polyethylene bottles in glovebox HC-227S and hood HC-227T. See Chapter 5.0, Section 5.2.1.2.2 for details of the HC-227S glovebox and HC-227T hood. See Chapter 6.0, Section 6.2.3 for discussions of the load-in/load-out (LI/LO) operations. See the Laboratory Prototype Calciner addendum to this FSAR for interface operations between the HC-227S glovebox and the laboratory calciner.

Repackaging. This process involves the repackaging of plutonium metal from failed or damaged containers. Repackaging activities occur primarily in the 2736-ZB Building, room 636, in the 636 repackaging glovebox. See Chapter 6.0, Section 6.2.5.2 for more details of the repackaging process.

An estimation of personnel DEs were calculated for repackaging of plutonium metal contained within the PFP (Chew 1996). The total whole body and extremity DE for the process was determined by the summation of individual process task DEs. After the two man rule was factored into the total whole body, the values were then divided by the number of operators (who are trained on all processes and are regularly rotated) to estimate the average whole body and extremity DE over the estimated campaign duration (four years). The whole body DE/operator/yr was 0.1 rem and the extremity DE/operator/yr was 0.6 rem (Chew 1996).

8.2.1.2 Nonairborne Waste Streams.

8.2.1.2.1 Liquid Effluents. Four liquid effluent streams are generated by the PFP operations RLW, waste water, sanitary liquid waste, and french drains. Of these, the radioactive liquid hood and laboratory wastes [radioactive liquid waste (RLW)], collectively referred to as salt waste, are collected at the 241-Z sump tanks for eventual routing to Tank Farms. This stream is not discharged to the environment. Condensates, cooling water, and other non-contaminated streams from the PFP are routed to the 200 East Area Treated Effluent Disposal Facility (TEDF). The waste water streams that have a potential of becoming contaminated are routed through the Low-Level Waste Treatment Facility (LLWTF) before discharging to TEDF. Nonradioactive sanitary liquid waste is discharged to a tile drain field. Details of the liquid effluent facilities (LLWTF and 241-Z Complex) and their operation are contained in Chapters 5.0 and 7.0.

Prior to the startup of the TEDF, the "cold" liquid effluent streams from the PFP were transferred to the 216-Z-20 Crib and 216-Z-21 Seepage Basin for discharge to the ground. Historical data estimate that the 216-Z-20 crib has accumulated (as of December 1994) $\leq$33.7 g of ^{239}Pu and $\leq$0.3 g of ^{241}Pu since its 1981 startup. This material is in the underground lines, the distribution tile, and the soil beneath the crib.

The activity and collection points of the low-level liquid effluents are identified in Table 8-4. Chapter 5.0 contains more detailed information about this system. Chapter 7.0 contains details on the waste water effluent sources and the sampling system associated with it as well as waste water effluent treatment processes at the PFP.

8.2.1.2.2 Solid Wastes. Radioactive wastes generated at the PFP are low-level waste (LLW), TRU waste, low-level mixed waste, TRU mixed waste, and polychlorinated biphenyl (PCB)/absorbed organic waste. Isotopes commonly found in PFP wastes are typical of those found in weapons and reactor grade plutonium (^{238}Pu, ^{239}Pu, ^{240}Pu, ^{241}Pu, ^{241}Am, ^{242}Pu).

Waste Management Hanford acceptance organization is the organization within WMH that is responsible for waste acceptance, including approval of waste stream profiles and approval of individual waste packages and shipments, and for coordinating the approval of case-by-case evaluations for specific criteria and exceptions to the acceptance criteria.

DOE Order 5820.2A requires that each treatment, storage, and/or disposal facility (referred to as TSD unit) that manages low-level or transuranic waste (including mixed waste and TSCA PCB waste) maintain waste acceptance criteria. These criteria must address the various requirements to operate the TSD unit in compliance with applicable safety and environmental requirements.

The baseline criteria for acceptance of radioactive waste at TSD units operated by WMH is HNF-EP-0063," Hanford Site Solid Waste Acceptance Criteria". The criteria for each TSD unit have been established to ensure that waste accepted can be managed in a manner that is within the operating requirements of the unit, including environmental regulations, DOE Orders, permits, technical safety requirements, waste analysis plans, performance assessments, and other applicable requirements.

Acceptance criteria apply to the following TSD units: the Low-Level Burial Grounds (LLBG) including both the nonregulated portions of the LLBG and trenches 31 and 34 of the 218-W-5 Burial Ground for mixed waste disposal; Central Waste Complex (CWC); Waste Receiving and Processing Facility (WRAP); and T Plant Complex. Waste from all generators, both from the Hanford Site and from offsite facilities, must comply with these criteria. Exceptions can be granted as provided. Specific waste streams could have additional requirements based on the identified TSD pathway. These requirements are communicated in the Waste Specification Records (WSRds).

Low-level waste (LLW). Waste that contains radioactivity and is not classified as high-level waste, transuranic (TRU) waste, or spent nuclear fuel or 11e(2)-byproduct material as defined by DOE Order 5820.2A. A test specimen of fissionable material irradiated for research and development only, and not for the production of power or plutonium, could be classified as LLW provided

the concentration of transuranic materials is less than 100 nanocuries per gram.

The waste typically is room waste and consists of surgical gloves, plastic, tape, wrappers, unused containers, and protective clothing. Normally it does not contain alpha contamination detectable with a hand held alpha survey instrument. LLW is compacted where practical and placed in an approved UN 1A2 55-gal drum. Non-Compactible or large LLW packages are typically packaged and shipped in burial boxes.

Transuranic waste or TRU waste. Waste containing more than 100 nanocuries of alpha-emitting transuranic isotopes per gram of waste, with half-lives greater than 20 years, except for: (1) high-level waste; (2) waste that the Secretary (of Energy) has determined, with the concurrence of the EPA Administrator, does not need the degree of isolation required by the disposal regulations; or (3) waste that the Nuclear Regulatory Commission has approved for disposal on a case-by-case basis in accordance with 10 CFR 61 (Public Law 102-579: Waste Isolation Pilot Plant Land Withdrawal Act).

Waste Isolation Pilot Plant (WIPP) certifiable transuranic (TRU) waste (or hood waste) WIPP is the disposal facility identified for TRU waste from the Hanford Site. At the time of writing, the Hanford Site TRU waste certification program currently is being developed to meet various requirements to ship and dispose of waste at WIPP. The TRU waste certification program will identify portions of the certification process that are the responsibility of the waste generator, while other portions will be performed at WRAP. Until completion and approval of the TRU waste certification program, APPENDIX G of HNF-EP-0063 identifies the interim requirements applicable to generators. Section 3.0 of DOE/WIPP-069 presents the requirements that must be met before TRU waste can be transported to and managed and disposed of at WIPP. TRU waste is not compacted. It is placed into an approved container as specified APPENDIX D of HNF-EP-0063 for long term storage. The contact exposure rates on these drums is typically $\leq$1 mrem/h, with an average dose rate of slightly less than 0.5 mrem/h.

Alpha contaminated hood and glovebox waste is designated as TRU waste and may consist of other contaminated confinement barriers or pieces of process equipment. The TRU waste, including contaminated HEPA filters, is processed to meet the Hanford Site Solid Waste acceptance criteria. This waste will ultimately be shipped offsite for long term disposal at the Waste Isolation Pilot Plant (WIPP). TRU waste drums packaged for WIPP disposal must have a $\leq$200 g plutonium content. Criticality safety analysis for the routinely used UN 1A2 waste drum allows for higher drum plutonium inventories, however PFP administratively holds all waste drum contents to the $\leq$200 g WIPP limit.

Waste items that are too large or to heavy are loaded into steel waste boxes called Standard Waste Box (SWB). The SWB is used for the general transfer of TRU waste material within the 200 West Area boundary. The TRU waste contents of the SWB will typically consist of tank sections, pumps, greenhouses, and other miscellaneous solids. The SWB is a carbon steel container designed and fabricated at the WIPP. A maximum of 325 g of fissile material distributed over equipment or objects as contamination is allowed in a SWB. The SWB shall not contain more than 15 grams of fissile material if waste in the form of plastic (excluding wrapping and liners) is part of the payload.

It is understood that certain TRU waste might require extensive processing and/or treatment before disposal at WIPP. As a policy, however, generators of newly generated TRU waste shall generate, segregate, and package the waste to minimize the need for additional processing at WRAP. More specifically, generators shall segregate their waste by TRUCON code (DOE/WIPP-89-004) and shall attempt to meet those requirements of the Waste Acceptance Criteria for the Waste Isolation Pilot Plant (DOE/WIPP-069) identified in Table G-1 of HNF-EP-0063.

TRU waste drums packaged for WIPP disposal must have a ≤200 g plutonium content. Criticality safety analysis for the routinely used UN 1A1 waste drum allows for higher drum plutonium inventories, however PFP administratively holds all waste drum contents to the gram limit, as set by HNF-EP-0063, to comply with the regulatory, permitting, safety, environmental, and operational requirements of the Hanford Site Central Waste Complex.

Non WIPP certifiable transuranic (TRU) waste requirements are also presented in Section 3.0 of DOE/WIPP-069.

Low level mixed waste (LLMW) and TRU mixed waste - "Mixed waste" means a dangerous, extremely hazardous, or acutely hazardous waste that contains both a radioactive hazardous component and, as defined by 10 CFR 20.1003, source, special nuclear, or by-product material subject to the Atomic Energy Act of 1954 (42 U.S.C. 2011 et seq.).

The CWC is a storage unit for low-level mixed, TRU, TRU mixed, TSCA PCB waste, and other waste types requiring treatment before disposal (e.g., nonregulated low-level organic liquids, unstabilized chelating compounds, and contact-handled low-level waste that exceeds radiological disposal criteria). Waste stored at CWC will be treated and repackaged as required for disposal as treatment capabilities become available.

The CWC manages waste having characteristic waste numbers D001 through D043, all listed discarded chemical product waste numbers (U- and P- listed waste), certain F-listed waste (F001 through F005, F020 through F023, F026 through F028, and F039), and all Washington state-only waste numbers. In addition, the CWC manages TSCA PCB waste from Hanford Site generators in accordance with 40 CFR 761. The CWC also can store waste from CERCLA cleanup activities.

Polychlorinated biphenyl (PCB)/absorbed organic waste - HNF-PRO-3152 establishes requirements for activities involving polychlorinated biphenyls (PCBs). PCBs shall be managed in accordance with the Toxic Substances Control Act (TSCA) regulations (40 CFR 761) and with the Washington State Department of Ecology (Ecology) Dangerous Waste Regulations [Washington Administrative Code (WAC) Chapter 173-303]. This procedure primarily identifies general requirements and provides reference to more detailed requirements. As references are readily available, detailed descriptions of requirements are not provided. Identified references should be used in conjunction with this procedure. Packaging requirements are taken from HNF-EP-0063, Hanford Site Solid Waste Acceptance Criteria, 49 CFR, and/or the applicable SARP.

Currently TRU waste is packaged in 55-gal drums for 20-yr retrievable storage. Waste items that are too large or too heavy for 55-gal drums are loaded into steel waste boxes. These waste boxes are also placed into 20-yr

retrievable storage. TRU waste drum contact dose rates are ≤200 mrem/h by definition.

8.2.1.3 Storage of Recoverable Plutonium. Plutonium-bearing recyclable, excess, or out-of-specification material in various forms has been generated at the PFP or received for processing at the PFP for over 35 yr. This material is stored in gloveboxes and vaults in the PFP.

Some of the recoverable plutonium items have been processed in the PRF during its periods of operation. Other residual recoverable plutonium items that have known or suspected reactive characteristics are chemically stabilized.

The residual recoverable plutonium items are divided into three categories:

1. **Stable Material**--Material for which the source data contain no information that would indicate that the material may be unsuitable and the information in the source data is judged adequate to avoid undue risk and meets the requirements of plant operating specifications in *Special Nuclear Material Storage*, OSD-Z-184-00013 (BWHC 1998).

2. **Potentially Unstable Material**--Material for which the source data contain information that would indicate that material may be unstable or the information in the source data is judged inadequate to evaluate the risk (BWHC 1998).

3. **Reactive Material**--Material that has known or suspected reactive characteristics that could not be administratively controlled during shipment or is unshippable or unstorable because of its physical form (e.g., with liquids or recoverable material). A complete definition of reactive material can be found in plant operating specifications (BWHC 1998).

Table 8-5 identifies gloveboxes and hoods that contain potential plutonium sources. The table provides the location and description of the equipment and the physical and chemical forms of the plutonium materials contained therein. The gloveboxes are used for processing or interim storage of recoverable materials.

Plutonium and other radioactive materials that either have been stabilized or were received from offsite as stable material are stored in various containers approved for storage in vaults. Typical radioactive material packaging configurations for vault storage are identified in Table 8-6.

Plutonium materials in the form of nitrate, oxide, and metal that meet the specifications identified for product material are stored as plutonium product in vaults and staging areas within the PFP. Plutonium product nitrate solutions are stored in PR cans in storage vaults and staging areas awaiting conversion to stabilized PuO_2 powder. The PuO_2 and metal product are typically stored in a triple can configuration consisting of a minimum of two contamination-free, mechanically sealed food pack cans. The typical product materials that are the sources of radiation within storage vaults at PFP are

identified in Table 8-6. The various food pack cans used for the packaging of plutonium or plutonium-bearing materials are identified in Figure 8-1. The storage containers used for storage and the facilities in which they are stored meet the intent of Section 1300-5 of DOE Order 6430.1A (DOE 1989). The storage containers have been approved for this purpose by facility management in accordance with DOE guidance documents (Section 4.7 of FSP-PFP-5-8 implements this guidance).

Radioactive materials are stored in containers approved for vault storage according to plant operating specifications (e.g. Special Nuclear Material Storage (BWHC 1998), and CH-TRU Solid Waste Disposal (BWHC 1998c)). The majority of the stable material and product plutonium metal and oxide radioactive material confinement consists of packaging the plutonium in metal containers that are placed in one or two layers of polyethylene. The material is then packaged in at least two contamination-free, mechanically sealed food pack cans.

Exposure and dose rates associated with plutonium-bearing materials and products vary with chemical form, container characteristics, isotopic abundances, moisture content, specific activity, total quantity, and storage location characteristics.

The exposure rates associated with the PuO_2 1-lb storage container ranges from 40 to 80 mR/h gamma. The resulting dose rate is 5 to 10 mrem/h neutrons at contact depending on ^{240}Pu content and age. The higher dose rate is related to the higher ^{240}Pu content.

A plutonium metal button storage container normally reads ~50 mR/h gamma exposure rate with a corresponding 20 mrem/h neutrons dose rate at contact. A PuF_4 crucible charge from the RMC Line, when placed in a storage container, has a contact exposure and dose rate of ~30 mR/h gamma and 60 mrem/h neutrons, respectively.

The exposure rates associated with plutonium nitrate solutions in PR cans varied from 4 to 12 mR/h gamma. The resulting dose rate is 1 to 6 mrem/h neutrons at contact with a greater dependence on can construction than on contents. The PR cans in use vary in construction materials used [e.g., shielded or unshielded (lead-lined outer)] and with material thicknesses used. The average contact exposure and dose rates for all PR cans is approximately 6 mR/h gamma and 2 mrem/h neutrons, respectively.

These contact dose rates are established using the standard Hanford Site instrumentation.

8.2.1.3.1 Characteristics of Contained Sources in the Plutonium Finishing Plant. Plutonium decay via charged particle emission and spontaneous fission results in the generation of alpha particles, neutrons, beta particles, and electromagnetic radiations. The presence of light elements enhances the neutron radiation emissions via the alpha-n reaction. The X-ray emissions are related to bremsstrahlung from beta particle interactions and internal conversions. Gamma rays are associated with alpha emissions, spontaneous fission, and fission product decay. The even numbered isotopes (i.e., ^{238}Pu, ^{240}Pu, and ^{242}Pu) are principally considered as alpha emitters with a nominal spontaneous fission neutron generation rate of 2×10^3 neutrons per second per gram of isotope. Alpha-n neutron generation

rates vary depending on which light elements are present. Plutonium fluoride neutron emission rates are approximately two orders of magnitude higher than those observed for the plutonium oxides. ^{241}Plutonium is principally a beta particle emitter, and its daughters, ^{241}Am and ^{237}U, are alpha and internal conversion X-ray emitters. ^{239}Plutonium is considered principally an alpha emitter.

The plutonium isotopic fractions in the sources stored at the PFP are directly related to the dose rates from handling the material and criticality concerns. See WHC-SD-CP-TI-190, Rev. 0, *Technical Basis for Characterization of Plutonium for the PFP Safety Analysis* (WHC 1993c), for a description of the isotopic concentrations used in the PFP Safety Analysis.

8.2.1.3.2 Effects of Aging. Aging of the material has a small effect on neutron dose rates, much less than that associated with ^{240}Pu content. The metallic form remains at an essentially constant neutron emission rate over the first 40 yr. The oxide form increases its neutron emission rate by about 15%, the nitrate form increases about 20%, and the fluoride form increases by 40% in the same time frame. Aging does have a significant effect on gamma and X-ray dose rates from ingrowth of daughter products (principally ^{237}U and ^{241}Am). The ^{237}U component reaches 90% of its maximum contribution to dose rate in about 40 days and eventually decreases with the half-life of ^{241}Pu (13 yr). The ^{241}Am ingrowth continues until it peaks at about 45 yr and then decreases with its half-life (432 yr). Based on total X-ray and gamma ray output, the surface dose rate can increase by a factor of approximately 10 over 40 yr, when compared to the dose rate 1 day after separation.

8.2.1.3.3 Shielding Considerations. When low energy gamma photons are appropriately shielded, fast neutrons from alpha-n reactions are the principal source of personnel doses. Neutron shielding designs for the older parts of the PFP were based on empirical experiments, experience, and knowledge of this and other plutonium-handling DOE sites. Construction of the 2736-Z Building was based on early computer shielding codes and hand calculations. Later, the existing storage vaults were evaluated using contemporary neutron shielding codes. Later vault buildings were designed using neutron codes such as Monte Carlo neutron (MCN) and Monte Carlo neutron photon (MCNP) (WHC 1993a).

The X-ray and gamma energy groups and strengths for the isotopes that are the sources of radiation within the PFP are shown in Table 8-7. These values were used as input to a computer program named PUSHLD (Plutonium Shielding) developed by Battelle Northwest (BNW) Laboratories, now known as Pacific Northwest National Laboratory (PNNL). Additional information is provided in *Calculation of Gamma Dose Rates at the Surface of Plutonium Oxide Sources*, BNWL-1259 (Van Tuil 1970).

8.2.1.4 Holdup of Plutonium in Facility Systems. Table 8-8 identifies potential plutonium sources in filterboxes. These filterboxes contain HEPA filters, which are used to remove radioactive particulate from the process glovebox and cell exhaust streams. The table lists the location and function of each filterbox and the physical form of the Plutonium Oxide therein.

Several other process exhaust systems within the PFP also contain radioactive materials. They are described below and summarized in Table 8-9.

- E-4 exhaust system--Dose rates associated with this system range from nondetectable to ~150 mrem/h (exposure rate of ~100 to 105 mR/h gamma and 45 to 50 mrem/h neutrons) at contact depending on the plant operating status, hood and glovebox use, and length of filter accumulation time. The higher E-4 system dose rates are associated with the process line filterboxes and their upstream lines. Dose rates of E-4 system lines downstream of the filterboxes decrease with distance from the filterbox.

- 26-in.-Hg process vacuum--Dose rates associated with this system range from nondetectable to approximately 110 mrem/h (exposure rate of ~80 mR/h gamma and ~30 mrem/h neutrons). The highest dose rates are associated with the pump-protecting (upstream) HEPA filters and vacuum lines servicing processes involving plutonium-bearing liquids.

- Exhaust manifold system--Dose rates associated with this system are as high as 100 mrem/h (exposure rate of 65 to 75 mR/h gamma and 25 to 35 mrem/h neutrons) depending on what component parts of the E-4 system are present.

During the years of plant operation, process upsets have caused plutonium to be deposited in piping identified in the systems mentioned. A total of 6 kg of plutonium was contained in the 234-5Z Building E-4 exhaust system ducting as of 1995. This plutonium holdup value is based on a series of in situ nondestructive assay (NDA) measurements using gamma ray spectroscopy. Approximately 1.9 kg has been removed during the remediation process leaving approximately 4.1 kg in the E-4 exhaust system (see Appendix A, Westsik 1999 and Westsik 1998). All of the holdup is isolated from the environment by at least two independent and testable stages of HEPA filtration. There was approximately 20 g of plutonium contained in a single portion of ventilation ducting roughly 140 ft long, but this section was removed as part of the remediation project. There is less than 1 kg plutonium spread across approximately 40 primary filterboxes in the 234-5Z Building. This material is also isolated from the environment by two stages of testable HEPA filtration. The plutonium holdup in ventilation ducting is contained in a slightly moist atmosphere and is potentially airborne dispersible, although no movement has been observed to date.

The plutonium holdup in the 234-5Z Building ventilation system comes from a variety of process sources and is located primarily in ventilation systems servicing solid-form plutonium processing areas. The plutonium chemical composition is characteristic of the processing area of origin (i.e., primarily solid-form material). The material form ranges from condensate to powder as one of the following chemical forms of plutonium: oxide, oxalate, fluoride, or crystalline nitrate. The chemical form of the plutonium would tend to change towards PuO_2 interspersed within a matrix of nonradioactive material over the years. It is likely that any plutonium compound in the condensate in the ventilation ducting would have dried to a crystalline form.

A total of about 8.4 kg of plutonium is contained in the 234-5Z Building 26-in. mercury process vacuum system (Westsik 1989). This plutonium holdup value is based on nuclear material accountability measurements with confirmation from in situ NDA measurements using gamma ray spectroscopy. This plutonium holdup is isolated from the environment by at least two independent

stages of testable HEPA filtration. This material is contained in a moist atmosphere, is nondispersible by air, and exists primarily in a crystalline form in the main vacuum system headers in rooms 262, 263, 264, and 265.

A total of 175 g of plutonium (with an uncertainty range of 23 to 584 g) is contained in the inactive process equipment of the 232-Z Building (Westsik 1996). This material is isolated from the environment by two stages of testable HEPA filtration. Potential plutonium holdup in the abandoned 232-Z to 291-Z underground ductwork has not been determined because of inaccessibility.

A radiation and NDA survey program is in operation to verify that these deposits are in a static condition.

No significant plutonium holdup is observed, using in situ NDA measurements, in ventilation systems servicing the 236-Z and 2736-ZB facilities. The 236-Z facility was a plutonium solution processing facility and, as such, did not generate significant quantities of solid form plutonium materials. The 2736-ZB facility contains one plutonium repackaging glovebox.

More detailed information on this subject, including a description, schedule, and cost estimate of remedial actions, can be obtained in WHC-SD-CP-PMP-003, *Plutonium Finishing Plant (PFP) Remediation Project Management Plan* (WHC 1989).

The estimated quantities of plutonium and other radioisotopes that are the source of radiation in these process systems are listed in Table 8-9 and Appendix A.

8.2.2 Airborne Radioactive Material Sources

The ventilation areas are defined in Chapter 5.0. The current designation of ventilation zones are contained in DOE Order 6430.1A (DOE 1989), U.S. Energy Research and Development Administration (ERDA) 76-21 (ERDA 1976), *Nuclear Air Cleaning Handbook*, and Van Tuil (1970).

During normal operations in the PFP, sources of gaseous and airborne radioactive materials are confined inside of enclosures such as open-face hoods, gloveboxes, filterboxes, and process cells. Gaseous and airborne materials generated within these enclosures are handled by the exhaust system. The air is filtered through two or three stages of HEPA filters before being discharged to the atmosphere from one of the exhaust stacks. Air pressure in the enclosures is negative with respect to ambient air, thus helping to minimize the spread of contamination in the event that a breach of confinement occurs.

Tables 8-3, 8-5 and 8-8 list the process enclosures, gloveboxes, hoods and filterboxes containing radioactive materials with the potential for becoming an airborne hazard. The materials in the gloveboxes, filterboxes, and other process enclosures are not easily accessible. The materials in the hoods are accessible and are a potential airborne radioactivity exposure hazard. This potential exposure is averted by the use of ported sashes, a hood airflow testing and verification program, quantity limitations imposed by process and criticality control requirements, and personnel training.

Personnel training includes the fundamentals of radiation and criticality safety, use of radiation detection instruments, regulatory requirements, facility operating and emergency procedures, and training and familiarization with the processes performed and equipment to be used in the hoods. Materials in transport or storage are packaged to ensure that multiple barriers must be breached before the material would become an airborne hazard. See Chapter 6.0, Sections 6.2.8, 6.3.8, 6.4.1.8, and 6.5.8, for additional information on product handling.

The PFP HVAC exhaust system for the 234-5Z Building is described in Chapter 5.0, Section 5.4.1.

In the event of a contamination incident, airborne contamination may spread along with the airflow towards the exhaust vents. Most rooms have more than one exhaust vent to the E-3 system. In case of a contamination spread, CAM alarms are used to alert personnel to evacuate a contaminated area.

During normal operations, the CAM and fixed head sampler (FHS) filters are collected by radiological control technicians (RCTs) for counting. Any activity from the sample filter that exceeds the operational plant limit of 2×10^{-13} μCi/mL of gross alpha prompts the room containing the sampler or CAM to be posted as an airborne radioactivity area. An investigation to find the source of the release is performed. Gross alpha activity is assumed to be ^{239}Pu until proved otherwise. The DAC for ^{239}Pu is 2×10^{-12} μCi/mL, the most restrictive value listed for alpha emitters.

Descriptions of anticipated off-normal occurrences are provided in Section 9.1. The plant operational limit under which respiratory protection is not required is 2×10^{-13} μCi/mL. Personnel involved with plant or process operations that may result in airborne radioactivity are routinely required to wear respiratory protection during these evolutions as specified in plant and RCT operating procedures.

8.3 RADIATION PROTECTION DESIGN FEATURES

The PFP location was selected based on the same criteria that were used to locate the Hanford Site. It was remote, barren, had a small local and peripheral population, was close to transportation, had an abundant energy supply, had an adequate water supply, and had enough area to ensure that hazardous operations could be isolated from each other such that a problem at one location would not affect other installations. All these factors mitigate the potential for an offsite radiological consequence and were undoubtedly considered in the 1946 PFP site selection process. The evaluation of potential consequences of accidents involving radioactive materials was included as part of the siting criteria, but the methods used were not as sophisticated as those in current use. Calculations show that the location selected meets the current criteria given in 10 CFR 100, *Reactor Site Criteria* (NRC 1995) or DOE Order 6430.1A, Section 200 criteria (DOE 1989), as shown in Chapter 9.0.

Radiation protection features were built into the PFP. These features include a zoned HVAC system, compartmentalized process and analytical facilities, gloveboxes and hoods for hazardous operations, geometrically favorable plutonium material process and storage facilities, shielded storage, remote

location of liquid lines for process and waste materials systems, shielded storage vaults and remote areas for surge and accumulation tanks. The building layout is such that access to potentially hazardous areas is controlled via engineered features such as airlocks or administrative controls. Almost all of these features were built into the original design many years before the development of DOE Order 6430.1 (DOE 1983). The facility meets the intent of applicable DOE Order 6430.1A, Division 13, Section 1300 (DOE 1989), requirements for special facilities and Section 1304 for plutonium processing and handling facilities through the use of engineered features or administrative controls. The glovebox and other specialty viewing windows were selected using the appropriate standards. Additional information on the PFP compliance with DOE Order 6430.1A is in Chapters 5.0, 6.0, and 7.0 and WHC-SD-CP-ES-128 (WHC 1995a). The policy of confinement of plutonium materials was made a part of the facility design and was ultimately built into the facility.

8.3.1 Plant Design Features

The building layout is such that there is a radiological side and a nonradiological side of the facility. The radiological side contains the process facilities; process feed and product materials storage; PFP AL, radiochemistry laboratory, and PPSL; decontamination facilities for equipment and personnel; contaminated equipment repair facilities; and other similar facilities that need to be in a controlled access area for radiological control purposes. The nonradiological side contains offices, changerooms and restrooms, repair shops (mechanical, electrical, electronic, etc.), cold chemical and other storage areas, and other areas that do not need to be under stringent radiological controls.

The design of the PFP ventilation system incorporates features that enhance confinement of radioactive materials. Some of the unique features are identified below.

- Radioactive materials are removed from a contaminated effluent stream as close to the point of origin as practicable. HEPA filters are installed on the hoods and gloveboxes upstream from effluent's entry into the exhaust system. Credit is not taken for this filter, and there are two separate testable stages of HEPA filters before release to the environment.

- The 234-5Z, 242-Z, and 236-Z Buildings are a part of a single large supply-exhaust, once-through ventilation system. The 232-Z, 241-Z/ZA, and 243-Z Buildings have their own supply and exhaust systems. The 2736-ZB Building has its own supply and exhaust system. Supply air for the 2736-Z Building is provided by the 2736-ZB Building and exhaust ventilation is supplied by the 2736-ZA Building.

- Two of the exhaust fans for the 234-5Z, 236-Z, and 242-Z exhaust system are provided with backup power. One of these fans runs continuously under all conditions. If failure in the operating fan is detected, the alternate backup fan automatically starts. In the event of failure of the normal electric supply, one of the two exhaust fans restarts with power supplied from diesel-generators located in Building 2721-Z.

- Exhaust air from the PFP Complex is discharged through different stacks. Chapter 5.0, Section 5.4.1, identifies the location of stacks and the buildings they service.

- The PRF process cell is equipped with a large airlock for providing containment when introducing larger pieces of process equipment to the cell.

- Air is normally supplied to rooms and areas near the ceiling and exhausted near the floor.

- All contaminated or potentially contaminated zones are designed and operated to maintain a negative pressure referenced to ambient or to the adjacent lower contamination potential ventilation zone.

- Inward airflow through open-face fume hoods is maintained between 125-150 linear ft/min. Inward air flow through arm-port fume hoods is maintained between 125-180 linear ft/min. Glovebox exhaust systems are sized based on heat loading and assumed breached gloveports.

- Gloveboxes that are supplied air from the room around the gloveboxes are equipped with HEPA filters on the inlet to the glovebox to minimize the amount of particulate matter that would be carried out of the glovebox to the room in case of a pressure reversal.

Some examples of plant design features for systems or components within the PFP are provided in the following paragraphs.

8.3.1.1 Feed Material Receiving Preparation. Material received from onsite or offsite is packaged in DOT- or DOE-approved shipping containers. Plutonium oxide, recoverable material, and metal are primarily shipped (onsite) in DOT-6M containers. The packaging configuration for shipping radioactive materials is shown in Figure 8-2. The design of the DOT-6M provides for confinement of radioactive materials by use of multiple barriers as required for packaging alpha-emitting radioactive materials for shipment (WHC 1994c). The use of the DOT-6M container complies with the Users Guide for Shipping Type B Quantities of Radioactive and Fissile Materials, including Plutonium, in DOT-6M Specification Packaging Configurations (DOE-RL 1994) so that this container may continue to be used for offsite shipping.

8.3.1.2 Plutonium Nitrate Storage. Plutonium nitrate solutions are stored onsite in PR cans (information in Appendix B indicates that these cans will last a minimum of 50 yr with solution in them). Several different types of PR cans are in use. A typical packaging configuration of one of several types of PR cans used onsite is shown in Figure 8-3. This particular PR can consists of 6-in. Schedule 80S stainless steel pipe 27 in. long. It is sealed with a vented polyethylene closure that is packed with glass wool (for deentrainment of liquids and solids from the gaseous discharge). This PR can is capped with an impact-limiting hood when placed in a 55-gal stainless steel 18-gauge drum with a bolt-on lock ring. Plutonium nitrate solutions are also stored in polyethylene containers (e.g., FL-10, L-10, etc.).

8.3.1.3 Chemical Processing Areas. In the chemical processing areas, the PRF (236-Z Building) provides unique plant design features. One of the single

most important features is that approximately 70% of process equipment operation was done remotely. Also, remote operations were used in much of the valving and solution transfers. The operation of the canyon hoist can be done entirely in a remote mode. The PRF was also designed for conducting the majority of maintenance work in a designated maintenance cell or glovebox, thus minimizing manned entries required for maintenance of process equipment. Maintenance required on process vessels is conducted through lead-lined gloves in gloveboxes that are shielded with lead for reduction of exposure to maintenance personnel. Some of the design features of PRF are shown in Figure 8-4.

8.3.1.4 Product Load-out and Storage. Plutonium metal is placed in a 3 3/8-in. by 2-in. food pack (tuna size) can that is purged with argon gas. The food pack can is then mechanically sealed and subsequently bagged out of the glovebox. This package is then placed into a 4-in. by 4.5-in. food pack (tomato size) can that is mechanically sealed. The food pack can is then placed into a 4 1/4-in. by 7-in. food pack can that is mechanically sealed. This is the final configuration for placement into vault storage. Figure 8-1 identifies containers typically used for packaging plutonium metal, oxide, and recoverable items.

8.3.1.5 Product Handling. Product or recoverable plutonium-bearing materials are repackaged or packaged in gloveboxes. An illustrative example of one of the types of gloveboxes used for this work is the repackaging glovebox in the 2736-ZB Building. The unique design of the glovebox, which has a smooth inner and outer surface with lead shielding enclosed between the stainless steel exterior and interior skin, is described in Figure 8-5. Also 1/4-in. clear lead glass shielding is in place over the glovebox viewing windows.

8.3.1.6 General Operations. Radiological areas of the PFP are posted in accordance with 10CFR835 and PHRCM requirements. The process equipment, gloveboxes, and tanks that contain radioactive sources are described in Section 8.2.1. Routine access to operating areas is through a limited number of airlocks. Additional doorways are shown that are used for emergency egress only, rather than routine access.

An additional interface to control zone pressures for maintaining proper ventilation is airlocks. The airlocks are normally provided between zone 1 and zones 3, 3A, or 3B and between the building zones and outside wherever there is routine personnel traffic. All exterior doors, other than those provided with airlocks, are sealed to the greatest degree possible, while still allowing their use for emergency purposes. Most Airlocks are equipped with audible and visual alarms that will sound locally when both doors are open. Airlock doors are well fitted and gasketed to reduce in-leakage to a minimum. Additional information pertaining to the zones and airlocks at the PFP is located in Section 5.4.1 of Chapter 5.0.

The various process areas and gloveboxes within the PFP where radioactive materials are handled, processed, or stored have different types of shielding provided to reduce radiation exposure to personnel. The typical types and shield wall thicknesses of materials used for shielding are identified in Figure 8-7.

Piping runs containing radioactive liquids are routed through spaces not routinely occupied by plant personnel. Process-associated lines are routed

through the duct level of the facility, while waste streams are routed through the tunnel level prior to exiting the building.

Within the PFP, areas are posted to identify radiological hazards to prevent personnel from being exposed to high levels of radiation and/or radioactive contamination. These areas are administratively controlled through requirements established in Chapter 2.0 of PHRCM (FH 2000). These areas are classified based on the radiation or radioactive contamination levels posted. The criteria given in Table 8-10 identify requirements for posting controlled areas. High radiation areas have locked entrances or entrances that are controlled by the PFP Operations Management to prevent unauthorized entry.

The PFP has one personnel decontamination and one equipment decontamination area. The personnel decontamination area is located in room 126 of the 234-5Z Building. The equipment decontamination area is located in room 159 of the 234-5Z Building.

Room 221-A of the 234-5Z Building is the location of the main PFP RCT office. Room 631 of the 2736-ZB Building houses the other RCT office. Section 8.5.2 provides a description of the RCT facilities.

8.3.1.7 Monitoring Systems. Other PFP design features include the monitoring systems that are in place at strategic locations to detect and evaluate airborne contamination at work locations. The FHS systems are positioned to measure air concentrations to which persons are exposed. CAMs are required for sampling airborne contamination levels that may exceed 40 DAC-hours in one week.

The guidelines for placement of FHSs and CAMs were determined based on the type of operations, nuclides involved, ventilation patterns, potential release type, and magnitude and area/equipment configuration (HNF-PRO-331). The HVAC exhaust effluents from the PFP Complex are monitored by CAMs with local and remote alarm capability and fixed-head record samplers. Representative locations of the PFP CAMs are shown in Figure 8-13. Current locations are shown on the most recent revision of the CAM Station Locations drawing, H-2-80107. Section 8.3.4 provides a description of FHSs and CAMs.

Portal monitors are located at exits to plutonium material handling areas for detection of possible diversion of plutonium materials and are not considered for personnel protection purposes.

The PFP also uses portable instruments designed to survey personnel, equipment, and process areas for radioactive contamination and to provide an indication when contamination is detected. These instruments play an important role in contamination control and personnel safety. Some of the survey instrumentation used in the PFP consists of semiportable and fixed poppy alpha meters. These instruments are located throughout radiological areas within the PFP Complex where radioactive materials are processed, handled, transported, or stored. Representative locations of other types of survey instrumentation used within the PFP are shown in Figure 8-14.

8.3.1.8 Physical Considerations. Space has been provided in various areas so that temporary radiological containment (greenhouses) may be constructed. These structures ensure that the confinement function is maintained when

normal process confinement is breached for maintenance, repair, or modification outages.

Tanks and piping systems handling process or waste fluids use welded construction where possible to minimize the potential for leakage.

8.3.2 Shielding

The PFP was designed before the 1 rem/yr total whole-body dose criterion identified in DOE Order 6430.1A (DOE 1989). The PFP maintains occupational dose requirements, as given in 10 CFR 835, Subpart C, "Standards for Internal and External Exposure," (DOE 1993a) consistent with ALARA and the *Project Hanford Radiological Control Manual*, PHRCM (FH 2000). These guidelines limiting facility worker annual and quarterly whole-body and extremity exposures are applicable to the PFP. Radiological administrative control levels are shown in Table 8-11.

These Project Hanford Radiological Control Manual Administrative Control Levels are more restrictive than the requirements identified in 10 CFR 835, Subpart C (DOE 1993a). The DOE radiation exposure limits are listed in Table 8-12.

8.3.2.1 Radiation Shielding for Plutonium Materials Vault/Room Storage. The 2736-Z Building is the primary storage area for plutonium material in the PFP. This building consists of four rooms that are used for storage. The building is constructed of 14-in. reinforced concrete walls for shielding and safeguards protection. Three of the rooms have cubicles that are constructed of 8-in. thick precast concrete panels designed for shielding. Each cubicle has a cross-sectional area 1 by 2 ft and is approximately 8 ft tall with two doors constructed of 8-in. thick precast concrete.

The following is a summary of the storage vaults and rooms located within the PFP. This information provides a brief description of the vaults, rooms, and wall thickness where plutonium materials are stored. The movement of materials into, out of, and within the storage areas results in changes in dose rates. An example of dose rate values is given below for one vault. These dose rate values represent a single point in time but are representative of rates normally observed.

8.3.2.1.1 2736-Z Building. Storage vault 1 contains 68 cubicles (66 of the cubicles house 45 storage pedestals each, 2 cubicles consist of shelf storage). Vaults 3 and 4 contain 68 cubicles each (each cubicle has 28 storage pedestals). The cubicles are provided with 8-in. thick concrete doors that were designed for shielding. Vault 2 in 2736-Z is used for storage of 7-in. cans and lard cans (7.5 gal size). An overview of the 2736-Z Building and its layout is provided in Figure 8-15. An example of radiation field dose rate readings is provided for Vault 1 in Figure 8-16. These readings were made in August 1994. The dose rates have been normalized to 100% to correct for partial inventories existing at the time of the survey. Both neutron and gamma total dose readings are shown for the cubicles and the rooms adjacent to the cubicles.

8.3.2.1.2 Vaults 1, 3, and 4. The dose rate readings for each of the cubicles in the vault storage area were made with the cubicle doors open. The

readings in the rooms were made at 18 different locations with the cubicle and room doors in various open and shut configurations. This information provides approximate reductions of exposure with the cubicle concrete shielding doors in place. Example dose rate readings for vault 1 are given in Figure 8-16. Dose rates in Vaults 3 and 4 are similar to Vault 1.

8.3.2.1.3 Vault 2. This vault does not have shielding in place inside the room. The exterior walls are 14 in. thick, providing shielding from the room contents. This vault has the highest exterior dose rate. This exterior dose rate is routinely monitored, and high-dose-rate materials are not stored or concentrated near walls adjacent to routinely occupied areas.

The walls and cubicles that provide shielding for the radiation sources in the 2736-Z Building are shown in Figure 8-15.

8.3.2.1.4 Vault 174. This storage area consists of interim plutonium material storage in cubicle-type cabinets. The 1-ft thick reinforced concrete walls reduce the radiation levels outside the vault.

8.3.2.1.5 Vault 175. This storage area consists of interim plutonium material pedestal storage. The 1-ft thick reinforced concrete walls reduce radiation levels outside the vault.

8.3.2.1.6 Room 192-A. This area is used for storage of unirradiated Fast Flux Test Facility (FFTF) fuel assemblies and fuel rods. The 4-ft thick concrete walls reduce the radiation levels on the outside walls.

8.3.2.1.7 Rooms 192-B and 192-C. These rooms consist of plutonium material pedestal and lard can rack storage. The 2 ft 6 in. thick reinforced concrete walls reduce the radiation levels outside the rooms.

8.3.2.1.8 Vault 225. This room contains cubicle type plutonium-bearing material storage. The 1-ft thick reinforced concrete walls provide reduction of radiation levels outside the vault.

8.3.2.1.9 Vault 190. This storage area consists of plutonium material pedestal storage. The 1-ft thick reinforced concrete walls provide reduction of radiation levels outside the vault. Waste drums in the process of being filled are currently staged in this room.

8.3.2.1.10 Vault 166. This storage area contains inactive gloveboxes previously used for staging $Pu(NO_3)_4$ solutions. The 1-ft thick reinforced concrete walls reduce the radiation levels outside the vaults.

The shielding configuration is complex in that individual sources are stored in a shielded vault that has a variety of storage locations, internal shielding units, and storage arrangements.

It was determined that the total effective shielding may be more practically described by comparison of the dose rates of the occupied areas within the vaults with the dose rates at the nearest occupied area outside the vaults.

8.3.2.1.11 2736-ZD Vault. This facility is a reinforced concrete cylindrical vault 8 ft tall and 9 ft in diameter, with 1-ft thick interlocking

cover and base plate. The vault wall is about 10-in. thick. The cover and base are gasketed and bolted into place by stainless steel bolts. This facility is used to store EBR-II casks (maximum number of casks permitted in the vault is 7). The vault currently contains three EBR-II casks. According to the Criticality Prevention Specification "EBRII Shielded Cask Storage/Transfer, CPS-Z-165-83070 (BWHC 1997), the EBR-II cask is a 60 in. tall, 17 in. diameter steel casing with a 38 in. high, 6 in. diameter central payload cavity. Irradiated metallic fuel is contained inside a primary containment consisting of a 4 in. diameter (schedule 40) stainless steel pipe. This vessel is then enclosed inside another 6 in. diameter stainless steel container. Both vessels are weld-sealed and placed inside the cavity of the cask.

The casks contain Los Alamos Molten Plutonium Reactor Experiment (LAMPRE) fuel. This fuel is in the form of metallic fuel rods which consist of six percent ^{240}Pu. The total plutonium content of the fuel comes to 7.8 kg.

8.3.2.2 Radiation Shielding for Special Nuclear Material Handling. Certain locations within the PFP use particular types of shielding to minimize radiation dose to personnel who handle or transport radioactive materials. Some examples of the shielding provided and equipment used to enhance reduction of radiation exposure follow.

8.3.2.2.1 Fixed-Array Wagons. These carriers are four-wheel wagons with five fixed positions designed with 1/4-in. lead shielding. These carriers are used for transporting various plutonium items contained in cans within the PFP Complex. These wagons are a method of remote handling for transporting plutonium materials. A typical fixed-array wagon is shown in Figure 8-20.

8.3.2.2.2 Mettler Balance Shielding. The 1-in. thick lead X-ray glass is used for shielding personnel while performing weight checks of plutonium materials on Mettler-type balances (see Figure 8-21 for this shielding configuration).

8.3.2.3 Radiation Shielding For Processing Areas. The processing areas within the PFP are provided with various types of shielding to minimize exposure to personnel. Concrete, lead, leaded glass, masonite, Lexan™, and water are the principal shield materials used. Water levels are verified by procedure and visual inspection. Table 8-13 lists the specific areas or gloveboxes, rooms, and types of shielding that are located there.

8.3.3 Ventilation

This section provides a description of the personnel protection features of the PFP ventilation system and the general design features. The specific details that address the PFP ventilation and offgas treatment systems are addressed in Chapter 5.0, Section 5.4.1.

See Section 5.4.1 of Chapter 5.0 for a complete description of the PFP exhaust systems; Chapters 5.0 and 9.0 contain an evaluation of the natural forces acting upon these and other PFP systems.

8.3.3.1 Personnel Protection Features of the Ventilation System.

8.3.3.1.1 Maintaining Internal Exposure to ALARA.

- Inward airflow through open-face and arm-ported hoods is required to be maintained to 150 ± 25 lin ft/min and 180 ± 25 lin ft/min, respectively. The inward airflow prevents suspendable material from inadvertently migrating into the room around the worker at an open-face hood or through the penetrations of a ported hood while the penetrations are in use. Within the laboratory, limits have been established that minimize the quantities of radioactive material allowed in open-face hoods based on the potential for internal deposition.

- The radiological areas are maintained at a negative pressure referenced to ambient. This design feature provides airflow from zones of lowest to highest contamination potential and from outside to inside the building.

- In the case of a loss of ventilation, the process areas are immediately evacuated. The RCTs, in respiratory protection, reenter to assess the exposure potential. Reentry is not allowed until directed by management.

8.3.3.1.2 Preventing Spread of Radioactive Materials in Normal Plant Operations.

- The exhaust system for the 234-5Z, 242-Z, and 236-Z buildings is designed to operate continuously during most off-normal conditions (see Chapters 5.0 and 9.0 for the exceptions). Following loss of normal power or if the exhaust plenum pressure increases to -3.5 in. w.g., the electric supply and exhaust fans automatically shut down and one of the two emergency exhaust fans restart with backup power supplied by diesel-generators in Building 2721-Z to maintain some ventilation and a slight negative pressure in the facility. The diesel generators in Building 2721-Z also provide power for the HVAC control system and exhaust fans in the 2736-ZA Building in case of a loss of normal power. The continued operation of the ventilation system ensures that facility confinement is maintained.

- Most of the PFP buildings are part of a single supply-exhaust once-through ventilation system. The purpose of the once-through ventilation system is to prevent air that potentially could be contaminated from being recirculated back into the building or clean areas of the facility.

- The E-4 exhaust system maintains a negative pressure (with respect to zone 3) in process enclosures (zone 4) such that, during normal operation, air flows from the zone 3 areas through zone 4 and subsequently is filtered by E-4 HEPA filters before being discharged to the common exhaust plenum. The PFP ventilation exhaust system is detailed in Chapter 5.0, Section 5.4.1.

8.3.3.1.3 Minimizing Spread of Radioactivity During Abnormal Operations or Under Accident Conditions.

- Air is supplied to gloveboxes from the room where the glovebox is located through inlet HEPA filters [with the exception of dry air gloveboxes, which are supplied by the dry air system (see Chapter 5.0, Section 5.4.3, for details of the dry air supply system used in the 234-5Z and 2736-ZB Buildings)]. These filters would reduce the quantity of particulate matter that might be carried out of the glovebox to the room in the event of an air reversal. Supply air to dry air gloveboxes is filtered through a single HEPA located in the common supply duct.

- Dampers are in place in the supply-exhaust air ducts, which provides a means of reducing or increasing airflow during hazardous tasks where there is a high potential for a release of contamination (i.e., during a panel change).

- The E-3 exhaust system provides exhaust ventilation for all rooms within radiological areas. The individual room pressure and airflow can be altered by changing the position of the dampers in the E-3 exhaust vent ducts.

8.3.3.1.4 Controlling Contamination Between Areas.

- Airlocks are used throughout the PFP as a means to control zone pressures for maintaining proper ventilation. Airlocks are provided between zone 1 and zones 3, 3A, or 3B and between the building zones and the outside wherever there is routine traffic.

- The zone pressures are established as a means to ensure confinement of radioactive materials. A differential pressure exists even between rooms within zones where there is a potential for contamination so that the airflow is desinged to move toward the area that has the greatest contamination potential.

8.3.3.1.5 Controlling Air Contamination When Personnel Access Doors or Cell Hatches are Opened or Windows, Bags, or Gloves are Breached.

- Ventilation and balance personnel are required to adjust the ventilation airflow for tasks involving the opening of process cell doors, glovebox panel changes, etc., to ensure that confinement of radioactive materials can be maintained.

- The glovebox negative pressure is maintained between -0.5 in. w.g. to -2.0 in. w.g. relative to room atmosphere to provide confinement of radioactive material if a glove or bag is breached.

8.3.3.1.6 Interfacing with Process Offgases.

- The E-4 system provides offgas ventilation for tanks and process components that are ventilated directly or indirectly to the process or access gloveboxes.

- The E-4 system is a component of the offgas ventilation train for several components (calciner, evaporators, concentrators, etc.) that are provided with specific offgas treatments as described in Chapter 6.0.

8.3.3.1.7 Limiting the Spread of Radioactivity Within the Ventilation System.

- Radioactive materials within gloveboxes are confined close to the point of origin through the use of HEPA filters installed at the entrance to exhaust ducts.

8.3.3.1.8 Providing for Ventilation Exhaust in the Event of a Stack Failure.

- Natural forces studies, which are addressed in Chapters 5.0 and 9.0, show that the 291-Z-1 stack will not fail.

8.3.3.1.9 Providing for Power Outages.

- The PFP gloveboxes are designed with inlet and exhaust HEPA filters that provide for confinement of radioactive materials if there is a loss of ventilation.

- The quantities of radioactive materials in the laboratory hoods are limited and contamination in these hoods is maintained ALARA to minimize a potential spread of contamination during a power outage.

- In the event of a power outage, diesel-generators located in the 2721-Z Building provide backup power to two of the exhaust fans ventilating the 234-5Z, 236-Z, and 242-Z buildings. One of these exhaust fans runs continuously under all conditions. If a failure of normal power occurs or if a failure in the operating backup fan occurs, the alternate backup fan automatically starts. Only one of the two emergency exhaust fans operates on loss of normal power. The HVAC control system, also connected to backup power, actuates the second fan and switches dampers in the event the online fan fails during backup power operation. The diesel-generators in Building 2721-Z provide backup power to the exhaust fans for Building 2736-Z. See Section 5.4.2 of Chapter 5.0 for additional information on the backup power system.

8.3.3.1.10 Limiting Radioactivity in the Stack Effluent.

- The exhaust from the E-3 areas of the 234-5Z Building is filtered through a single stage of testable HEPA filters before discharge to the 291-Z-1 stack. If the filters in the E-3 filter room fail, the airflow is diverted to another E-3 filter room for filtration.

- The exhaust from the E-4 areas of the 234-5Z Building is filtered through a minimum of two stages of testable HEPA filters before discharge to the 291-Z-1 stack. The E-4 filter rooms 309 and 310 are the final exhaust HEPA filters for the 234-5Z Building ventilation exhaust. Only one of these filter rooms is in use at a time. If the filters in the filter room in service fail, the spare filter room is placed in service. See Chapter 5.0, Section 5.4.1 for additional details of the HVAC system.

- There are three stages of testable HEPA filters that filter the room and glovebox exhaust in the 2736-ZB Building. Within the 2736-ZA Building there are two stages of testable HEPA filters that filter the room exhaust. The 2736-Z Building consists only of storage rooms and exhausts through the 2736-ZA Building.

- The 236-Z Building room exhaust is filtered through a single stage of testable HEPA filters. The process cell and glovebox exhaust is filtered through two stages of HEPA filtration.

- The exhausts from the 241-ZA glovebox, 241-Z vaults/tanks and the 242-Z Building are filtered through two stages of testable HEPA filters. The 232-Z Building glovebox exhaust (E-4) is filtered through two stages of HEPA filters (untestable). Glovebox exhaust (E-4) then combines with the room exhaust (E-3) and is filtered through two stages of testable HEPA filters before discharging to atmosphere.

The gloveboxes and filterboxes are equipped with Magnahelic instruments that read the differential pressure across the filters. The power operators are required to conduct readings of all gloveboxes and filterboxes on a routine frequency (at least biweekly for filters related to current processing procedures) to ensure the Magnahelic readings are in the acceptable range. Any readings outside the acceptable range require that the filters be replaced. The testable HEPA filters are required to be tested periodically using a challenge aerosol to ensure filter integrity.

8.3.3.2 234-5Z, 236-Z, 242-Z, 2736-Z, and 2736-ZB Buildings and the 241-Z Complex.

8.3.3.2.1 Steam Supply Systems. Supply systems for these buildings are described in detail in Chapter 5.0, Section 5.4.6.

8.3.3.2.2 Dry Air Supply. Portions of the plutonium conversion lines in the 234-5Z Building received dry air to maintain low moisture content for the oxide or metal product. The dry air system currently supplies normal air to these lines. The 2736-ZB Building dry air system continues to supply dry air to the repackaging glovebox in room 636. See Chapter 5.0, 5.4.3 for a description of this system.

8.3.3.2.3 Instrument Air Supply. The instrument air supply system to these buildings is described in detail in Chapter 5.0, Section 5.4.3.

8.3.3.2.4 Vacuum Systems.

26-in.-Hg Process Vacuum Exhaust System. Process solutions can be transferred between gloveboxes within the PFP using the solution transfer vacuum system. The exhaust system for the 26-in. mercury process vacuum system is described in Chapter 5.0, Section 5.4.5.

17-in.-Hg Air Sampling Vacuum Exhaust System. Air is drawn through CAMs and FHSs located in the PFP buildings by two liquid-seal-type vacuum pumps. This system is described in detail in Chapter 5.0, Section 5.4.5.

5-in.-Hg Vacuum Exhaust System. This system is used to draw off gases from the furnaces in the HA-21I glovebox. This exhaust system is described in detail in Chapter 5.0, Section 5.4.5.

The vacuum systems supplied to these buildings are described in detail in Chapter 5.0, Section 5.4.5.

8.3.3.2.5 Exhaust System General Description. The PFP main stack (291-Z-1) exhausts filtered process air from gloveboxes, hoods, and process cells in the 234-5Z, 236-Z, and 242-Z Buildings and from those rooms that may have a potential for contamination. See Chapter 5.0, Section 5.4 for a detailed description of the exhaust system for the 234-5Z, 236-Z, and 242-Z Building. Exhaust ventilation for the 2736-Z and 2736-ZB Buildings is described in Chapter 5.0, Section 5.4.1. See Chapter 5.0, Section 5.4.1 for details of the ventilation system for the 241-Z Complex.

The exhaust monitoring and sampling system provides an alarm indication if radioactive materials are being discharged to the environs. The sampling part of the system obtains a record sample for laboratory analysis of what has been discharged. The range of the exhaust monitor is such that it can respond to the accidents categorized in Section 9.2.

E-1 Exhaust System. A description of this system for each building in the PFP can be found in Chapter 5.0, Section 5.4.1.

E-3 Exhaust System. A description of this system for each building in the PFP can be found in Chapter 5.0, Section 5.4.1.

E-4 Exhaust System. A description of this system for each building in the PFP can be found in Chapter 5.0, Section 5.4.1.

8.3.4 Criticality Alarm System

This section describes the criticality monitors and continuous airborne radioactivity monitoring instrumentation including calibration requirements; criteria for placement of instruments, detectors, recording devices; auxiliary and/or backup power supply; and alarms for monitoring instrumentation.

8.3.4.1 Criticality Alarm System.

8.3.4.1.1 General Description. The CAS uses gamma and neutron detectors located in areas (detector selection is dependent on the background radiation field encountered in the detector location) in which fissionable material may

be processed, stored, or transported. The number of detectors covering an area depends on area size, intervening shielding, and other factors, as identified in the following: DOE Order 5480.24, *Facility Safety* (DOE 1995a); HNF-SD-CP-SDD-003, *Definition and Means of Maintaining the Criticality Detectors and Alarms Portion of the PFP Safety Envelope*; *Criticality Alarm System*, HNF-PRO-546; and, ANSI/ANS 8.3, *Criticality Accident Alarm Systems*. An operable criticality alarm system is required by Operational Safety Requirements. Additional descriptive information is contained in HNF-IP-1115, *Nuclear Criticality Alarm Manual for the Plutonium Finishing Plant* (BWHC 1998a) and HNF-PRO-334, *Criticality Safety General, Requirements*, and HNF-PRO-546, *Criticality Alarm System*. Because the system is modular with spare modules and components readily available, unit replacement may be used to minimize system down time. All work involving fissionable materials is suspended or terminated in an affected area if the area's CAS is out of service. Alarm set points are based on the "minimum criticality event" (an absorbed dose of 20 rads at 2 m in 1 min) and area background radiation levels. The system alarms when 2 detectors in an area reach alarm threshold settings.

An alarm energizes a system of evacuation alarms. Personnel have been trained to make a safe rapid exit to at least 100 ft from the occupied facilities when the alarm sounds. Blue flashing lights are used to supplement the audible alarms in some areas.

A preventive maintenance and surveillance (PMS) procedure is used to perform verification of alarm audibility.

Individual detector coverage was established during the design phase of the system. The IRON 19 computer code was used. The information was used to establish detector overlap for verification of "2 out of n" logic coverage of potential criticality locations.

The CAS has the incidental collateral function of area radiation monitoring. Mobile criticality detection and alarm units [transportable criticality alarm system (TCAS)] are used as temporary criticality monitors for entries into areas not routinely protected by the CAS.

8.3.4.1.2 Gamma Detection Instrumentation. The gamma detection system is used with an audible signal generator (ASG), horn, power supply, intertie circuitry, and alarm monitoring equipment to form a complete CAS. Most of the components (except the detectors, horns, and power supply) are mounted in a criticality alarm panel. A typical criticality alarm panel is shown in Figure 8-22. A large facility like the PFP has the CAS grouped into a total of nine criticality alarm panels.

The criticality alarm detector (CAD) uses a plastic, NE 102 scintillator to detect gamma radiation. The scintillator produces a light output proportional to the gamma ray exposure rate. This light falls on the cathode of a photomultiplier tube providing an electrical signal proportional to the gamma ray exposure rate. A photomultiplier tube has an inherent logarithmic function relating amplification to voltage, which results in a logarithmic scale on the panel meter on the criticality alarm detector module (CADM).

Although the photomultiplier tube current originates as pulses, the CAD circuit response is to the integrated value of the pulses (i.e., the resultant current).

The CAD assembly is approximately 2.5 in. in diameter and 13 in. long. Figure 8-23 shows the CAD mounted on an assembly with brackets for positioning a calibration source.

Each CAD has an associated CADM that provides gamma indication and alarm functions. Calibration adjustments of the CAD-CADM combination are on the CADM. The CADMs are plug-in-type modules that plug into a criticality alarm panel.

The CADMs have an adjustable trip range. The practical gamma dose rate range is from a nominal 100 to 500 mrem/h. The choice for a particular location is determined by the postulated criticality event and two other considerations: the desired range of detection and the possible background levels. The background radiation may be either constant or transitory due to movement or storage of material near a CAD.

A key-lock switch is associated with each CADM. Turning the switch from "operate" position to "inhibit" position prevents a high-alarm output signal from the CADM to the logic and alarm circuitry. This switch is used during test, calibration, and replacement of CADs and CADMs. The key may be removed from the switch only in the operate position. Figure 8-24 identifies and lists the various components that are a part of the CADM.

Criticality alarm logic modules (CALM) and criticality alarm relay modules (CARM) are shown in Figure 8-25. The CALM provides the logic circuitry that causes the criticality alarm horns to sound if two or more CADMs on the same criticality alarm panel (CAP) are in the high-alarm state. One CALM accepts the inputs of up to six CADMs. Additional CALMs may be connected as required to accept outputs from all of the CADMs in a criticality alarm panel. Any two of the CADMs in an individual CAP will cause the alarm.

If one CADM goes into the high-alarm state, the CALM causes the CARM to go into "alert" condition. The signal would call for operations/maintenance response to determine the cause of the alert. If two or more CADMs on the same CAP go into the high-alarm condition, the CALM causes the associated CARM to go into "alarm" condition. (This 2-out-of-N logic alarm system ensures that a false alarm is not initiated by one CADM failing in alarm condition.) Relay contacts close, turning on an audible signal generator. An alarm monitor signal is also provided. The CADMs go into the failure trip state if the reading falls below the low set point, which can be caused by several different failures (e.g., a loss of power to the detector, a broken cable to the detector, a burned out artificial background light bulb, etc.) or by loss of power to the CADM. The failure trip state does not cause the CALM to put the CARM into the "alert" condition. That is, the failure trip state is not treated as an alarm and does not satisfy any of the "2-out-of-3 logic" for alarming. The CALMs and CARMs plug into a bin, which is mounted in CAP instrument rack.

The gamma detection instrumentation (as well as the rest of the system) operates from a float battery charger, with a battery backup. Backup power is

thereby provided if main power is lost. An alarm monitor signal is provided to warn of reduced voltage or loss of power to the system.

A gamma radiation source in a source holder is used to calibrate and routinely test the gamma detection instrumentation of the CAS. The design of the CAD mounting bracket enables the source to be placed in repeatable geometric positions with respect to the scintillation crystal in the CAD. This holder was designed to permit alarm trip calibration from a nominal value of 2 mrem/h to 100 mrem/h. The source holder can be adjusted to provide a radiation field intensity traceable to the National Institute of Standards and Technology (NIST). The gamma calibration source holder is adjusted annually using a transfer instrument calibrated by the PNNL calibrations section. A typical criticality alarm source holder is shown in Figure 8-26.

Each gamma detector and detector module within the PFP is calibrated at least annually and functionally tested at least monthly.

8.3.4.1.3 Neutron Detection Instrumentation. The neutron detectors are used exclusively in the 2736-Z Building. The neutron detectors are used where gamma ray shielding of storage arrays would require a large number of gamma detectors to provide adequate detection coverage (WHC 1993c).

The neutron detection instrumentation consists of two principal components: the detector (including associated electronic circuitry) and the comparator panel (located in 2736-ZA). This instrumentation is used with an audible signal generator, horns, power supply with battery backup, and alarm monitoring equipment to form a complete CAS. Detectors are located so that at least three are within detection range of a possible criticality.

Neutron detectors are periodically removed from service and calibrated to a uniform neutron flux at the PNNL calibration facility. When in service, neutron detectors are functionally tested for alarm trip monthly using an americium/beryllium neutron check source with a strength of approximately 1.0 E+07 neutrons/second. The source is contained within an outer source holder container and, when being used, is affixed to a 60 in. extension handle to provide distance between the source and source handler. When not being used for neutron detector testing, the source is stored in a heavily shielded 30 gal drum in the 2736-ZB Building. Drawing H-2-28814 documents construction of the neutron source holder, extension handle, and storage drum.

The audibility testing of all criticality alarm horns is conducted quarterly. Sufficient alarm audio sound generators are installed to achieve a sound level of at least 10 dB above the maximum background noise and not less than 75 dB in all occupied locations within the 25 rem/1 h boundary (except for areas with very high background noise) but does not subject any personnel to sound intensities greater than 115 dB. In areas with high background sound, the alarm sound is supplemented by local blue rotating beacons or flashing blue strobe lights. The alarms are present at every location from which prompt evacuation is essential, as specified in *Nuclear Criticality Alarm Manual for the Plutonium Finishing Plant*, HNF-IP-1115 (BWHC 1998a). The alarm system is designed to meet the criteria of ANSI/ANS 8.3 for evacuation signals.

8.3.4.1.4 Criticality Detector, Alarm Panel, and Horn Locations Within the PFP Complex. The 234-5Z Building has an installation of gamma ray

detection instrumentation. There are four criticality alarm panels located at intervals along corridors 2 and 13. The detectors are located in groups of three. The detector groups are divided among the four criticality alarm panels, although not necessarily in equal numbers per criticality alarm panel. Each criticality alarm panel has an associated 24-V storage battery and battery charger. The horn connections likewise are divided among the four criticality alarm panels. The audible alarm circuitry is intertied so that all of the horns in the PFP Complex will sound for an alarm originating at any one of the criticality alarm panels (except CAP 8). The horns are also intertied to sound with those in the 236-Z, 2721-Z, 2736-Z, 2736-ZA, and 2736-ZB Buildings.

The 236-Z Building has an installation of gamma detection instrumentation. The detectors are located in groups of three, divided between two CAPs. The two CAPs are located in the control room on the fourth floor. Each CAP has an associated storage battery and battery charger. The horn connections are divided between the two CAPs. The audible alarm circuitry in the two CAPs is intertied so that all the horns in the 236-Z Building will sound for an alarm originating at either CAP. The horns are also intertied to sound with those in the 234-5Z, 2721-Z, 2736-Z, 2736-ZA, and 2736-ZB Buildings.

The 2736-Z Building has an installation of neutron detection instrumentation to provide coverage of the plutonium storage vaults. In addition, a gamma-sensitive detector station is installed in the hallway of the 2736-Z Building as a backup detection system. The criticality alarm horns in the adjacent 2736-ZA Building are supplemented with four blue flashing lights in the exhaust fan and generator room because this building has a high noise background.

Three neutron detectors are installed in each of the four storage vaults of 2736-Z. These detectors are grouped near the ceiling at the center of each room. There are 12 neutron detectors in the building. Two comparator panels, required to interconnect the detectors, are located in the 2736-ZA Building. Three gamma detectors are installed in the hallway. The audible signal generator, the power supply equipment, and the gamma monitor logic and relay modules are in the 2736-ZA Building. The horns are intertied to sound with those in the 234-5Z, 236-Z, 2721-Z, 2736-ZA, and 2736-ZB Buildings.

The 2736-ZB Building has an installation of gamma detection instrumentation. There are five criticality detector stations with three detectors each. The CAP, battery, and battery charger are located in room 638. The alarm horns are intertied to sound with those in the 234-5Z, 236-Z, and 2736-Z Buildings. The criticality horns in the adjacent 2721-Z (generator) Building are supplemented with a blue flashing light because this building has a very high noise background.

The 241-Z Building has an installation of gamma detection instrumentation, CAP-Z8. There are two CAD stations that have three detectors each. The CAP, battery, and battery charger are in the 241-ZG Building. No alarm horn intertie is provided with any of the other buildings. This building is not continuously occupied and is located such that a criticality in the below-ground-level tanks will not have a significant effect on other buildings of the PFP Complex. Personnel hearing an alarm in or associated with the 241-Z Building are trained to report the fact to the PFP shift manager.

The 232-Z Building does not have the new CAS installed in the facility. The 232-Z building is awaiting D&D and is classified as a limited control facility.

Representative locations of the CAS within the PFP Complex (234-5Z, 236-Z, 2736-Z, 2736-ZA, 2736-ZB, 2721-Z, 241-Z, and 232-Z Buildings) are shown in Figure 8-27. Current locations of CAS detectors are in the most recent revision of the CAS drawings H-2-28885, H-2-80143, H-2-28888, and H-2-91823.

In all instances of outages of the CAS or components of the system, the Plutonium Operations management is notified in accordance with Limiting Conditions for Operation and Surveillance Requirements 3.1 "Criticality Safety Systems" of WHC-SD-CP-OSR-010 (WHC 1994c) and fissile movement is prohibited in the affected area. Notification of a "No Fissile Movement" restriction is required before the outage action starts or, if the outage is unplanned, notification is made within the compensatory action completion time specified in OSR LCO 3.1.2. All planned outages must have the approval of the Manager of PFP Safety and plant management of the PFP. In addition to outage approval, these managers will issue any special instructions for fissile material control during the outage. For further discussion, see FSP-PFP-5-8, Chapter 1.0 Conduct of Operations and Chapter 3.0, Safety.

8.3.5 Airborne Radioactivity Sampling and Monitoring.

Each year PFP RC reviews work space air sampling and monitoring to ensure compliance with 10CFR835, the Project Hanford Radiological Control Manual (DOE 1994), and Site procedures. Routine evaluations of air monitoring results ensure that airborne plutonium concentrations in the PFP are compliant with DOE limits (BWHC 1997a).

8.3.5.1 General Description. The purpose of the air sampling and monitoring program is to warn personnel of the unexpected release of airborne radioactive materials, provide data regarding potential personnel doses and the effectiveness of containment systems, to provide a legal record of personnel dose, and to determine if doses are maintained ALARA. In all applications, the intent is to restrict airborne radioactive materials to ALARA levels and not to exceed levels in the applicable DOE orders. This statement is applicable to the effluent monitors, also.

8.3.5.2 Sampling and Monitoring Systems.

8.3.5.2.1 Fixed-Head Samplers. The FHSs have been placed in strategic locations in the PFP to evaluate average airborne concentrations of contamination at work locations. As a minimum, FHSs are located where there is a potential for airborne radioactive contamination intakes greater than 2% of the ALI as contained in 10 CFR 835, Appendix A (DOE 1993a). The FHSs are used to sample room air for evaluation of potential inhalation hazards to personnel. Because of space or mounting limitations or airflow direction, not all FHSs installed for this latter purpose have been located in the breathing zone. Portable air samplers (goosenecks), and portable CAM units are used as required by radiation work permits to augment the FHS system. In areas where there are no FHSs and temporary sampling is required, CAMs or other types of portable samplers are provided.

The FHSs in the PFP are the open-face-type nominal 47-mm filter heads with filters that are supported by a screen. All FHSs are equipped with a calibrated flow-indicating device (rotameter) and pressure regulating device (to keep flow constant as the filter loads). The FHS particulate air samples are drawn at a 1.0 ft^3/min or 2.0 ft^3/min flowrate depending upon the building.

The FHS filters are exchanged by the PFP RCT personnel weekly. These filters may be exchanged at the discretion of RCT supervision to help evaluate an airborne contamination event. Data from filters also may be used to support the concentrations recorded by a CAM alarm. The sample filter is sent to the PFP A-Labs for analysis. The fixed-head stack environmental sample filters (record samplers) are sent to the Waste Sampling and Characterization Facilities (WSCF) for alpha and beta particle analysis.

The vacuum sources for FHS consist of the 17-in. mercury vacuum system (also referred to as the air sample vacuum system) or portable rotary pumps. The 291-Z and 236-Z air sample vacuum systems are not provided with backup power. Loss of plant vacuum does not present an immediate safety concern for those plant areas sampled by FHS units only. The 291-Z-1, 296-Z-3, 296-Z-5, and 296-Z-14 stack portable rotary vacuum pumps and the 2736-ZB air sample vacuum system are provided backup power from diesel generators in the 2721-Z Building.

Operability checks of the FHSs are conducted by the RCT organization weekly. The calibration frequency for FHSs is yearly.

8.3.5.2.2 Continuous Air Monitors. Within the PFP, CAMs are installed where there is potential for airborne concentrations exceeding the applicable DAC. The CAMs are used for sampling and monitoring areas where equipment, containment, or confinement failure could cause a rapid increase of airborne contaminant levels exceeding occupational DAC or ALARA concentrations. Because of the necessity of frequent changes of their sample filters, CAMs are not normally used to establish breathing zone air concentrations or to quantify chronic low-level airborne exposures.

In situations where the CAM sample is the only air sample being drawn in the workplace, care is taken to ensure that it is run as long as possible, up to a one week period between filter changeouts.

Room CAMs are located in areas recommended in PNNL air sampling evaluations for the PFP. Representative CAM locations at the PFP Complex are shown in Figure 8-13. Current locations are shown on the most recent revision of the CAM Station Locations drawing, H-2-80107.

The CAMs located within, and used as effluent monitors at, the PFP are primarily alpha sensitive (Eberline ALPHA-4A, -5A and 6, and Canberra type). They measure the alpha emission of airborne radionuclides that have been trapped on a filter media by detecting alpha particles having specific energies. This allows discrimination between ^{239}Pu and alpha emitting airborne radioactive materials. A typical alpha CAM used in the PFP is shown in Figure 8-28.

The sample filter holder for these units is designed with the radiation detector in close proximity to the surface of the filter. As sample air is

drawn through the filter, the detector measures the radioactivity accumulated on it. Filter media used for particulate CAMs and effluent exhaust record samplers in the PFP are of the membrane type, depending on the application of the CAM. Membrane filters are normally used in the alpha CAMs as the particulates collect on the surface of the media rather than being embedded in it. This significantly reduces degradation of alpha particle energies thus improving resolution and discrimination between radioisotopes and reduces the possibility of false alarms. Both filter types used are nominally 47 mm in diameter.

Most Eberline CAMs in the PFP have the conventional level rate meter and chart recorder configuration. The CAM amplifier electronics output the background-subtracted signal to the count-rate meter and chart recorder devices. When it is necessary to determine approximate air contamination concentrations after a valid CAM alarm, the chart can be used to estimate the total volume of sample collected during the off-normal condition. This is accomplished by examining the chart record and tracing the recorded count-rate data back to the sample's equilibrium point (i.e., the point of constant background). The time increment between the beginning of the count-rate increase and the time the sample is removed can then be estimated. Multiplying the estimated time duration of the event by the sample flowrate provides an estimate for total flow volume data. Chart records are normally retained in the individual RCT field office for 30 days and are disposed of after that time.

Most Eberline CAM electronic assemblies include an adjustable high-alarm set point. The CAM systems are equipped with a set of high-alarm-point external contacts that may be used to initiate automatic actions (equipment trips, remote alarms, etc.). All CAMs within the PFP have audible and visual alarms. Operator control stations (OCSs) in the MICON™ control station (room 714 of the 234-5ZA Building) provide remote annunciation capability for all stack CAM/loss of vacuum service alarms. The Building 2736-ZB and Building 2736-Z room CAM alarms annunciate to annunciator panels in room 631 of the 2736-ZB Building and room 221A of the 234-5Z Building.

The adjustable high-alarms set point is called the Alpha Set Point (ASP), and is established in accordance with HNF-PRO-5675, *Radiation Protection Real-time Monitoring*, using facility specific procedures, it is typically 25-35 cpm.

When an alarm situation does occur, the affected area is treated as if the unknown activity on the CAM sampling filter is the most restrictive dispersible contaminate in the facility. Analysis of sample filters from the affected area is then performed. If the analysis determines that the activity on the sample filter is radon and radon daughters, and an inspection of the area reveals no other circumstances requiring the area to remain on respiratory protection status, the CAM alarm set point can be raised to the normally used count value, above the current equilibrium point of the sample filter, in accordance with PHRCM.

CAMs rely on the same vacuum sources as the FHSs described in Section 8.3.5.2.1. The 291-Z-1, 296-Z-3, 296-Z-5, and 296-Z-14 stack CAMs and record samplers are provided backup power from the diesel generators in the 2721-Z Building. The 296-Z-6 stack CAMs are provided backup power from a diesel generator installed in the 2736-ZA Building. Portable pumps may be

installed upon loss of 17-in. mercury vacuum service. Loss of plant vacuum results in ceasing work activities in all contamination potential areas that use air monitors (CAMs). Personnel are not allowed to restart work activities in areas with CAMs until monitoring capability is restored. Vacuum supply for portable CAM units is by ac-powered rotary vacuum pumps with backup power provided to any portable CAMs used for stack monitoring. Sample airflow is indicated by flow indication devices (rotameters) on the CAMs. Large volumes of air must be drawn through the filter media to accurately determine small concentrations of airborne contaminants. Stack effluent monitoring probes are designed to be near isokinetic at the designed flowrate of the exhaust stack and CAM.

Sample probe pickup line inlet points for most CAMs in the PFP are located in exhaust ducts, stacks, or directly in the airflow path in front of room exhaust in work areas. A typical room exhaust filter located in the 2736-ZB Building is shown in Figure 8-29. How the sample pickup line is installed directly in the path of room airflow is also shown in Figure 8-29. The pickup probes are as short as possible with any required elbows or bends having as large a radius as is practical. Sample activity line loss is incorporated into air sample calculations where necessary. Sample line transmission fractions are specified in the procedures governing the calculations.

Most of the PFP CAMs are examined for proper operation each day by RCT personnel. Additional inspections and operational performance tests are completed weekly, along with the exchange of sample filters. CAMs are removed from service at 12 month intervals (normally several at a time) and replaced with units that have just been calibrated. All alpha CAMs are calibrated by the instrumentation contractor.

CAMs and their associated alarm function mitigate some potential facility worker hazards at PFP. In general, during stabilization activities, the primary boundary to release of radionuclides to occupied rooms are gloveboxes, process systems, or sealed plutonium storage containers. The primary boundaries to plutonium release inside PFP can fail through several potential mechanisms, such as improper maintenance, equipment degradation, or abnormal glovebox pressurizing events. In many cases, there is no obvious indication that a plutonium release has occurred. The CAMs serve to validate the satisfactory performance of the barriers to plutonium release. If one of these primary barriers fail and plutonium is released inside PFP, then alarms are actuated when the alarm setpoint is reached. Upon activation of the alarm, facility workers are trained to promptly evacuate the affected airspace. These actions in combination serve to reduce the potential plutonium inhalation dose received by the affected facility workers. The public and onsite non-facility workers are not significantly affected by these potential plutonium releases inside PFP because the exhaust air flow is filtered by the applicable exhaust ventilation system prior to release outside of PFP.

8.3.5.3 Miscellaneous Monitoring Devices.

8.3.5.3.1 Workstation Monitors. The CAMs and semi-portable alpha survey instruments (Poppies) are located at or near workstations and room exits because of the potential for personnel or equipment to become contaminated at the workstation. Cart-mounted units are available for use in the laboratory

and glovebox areas so that personnel may survey immediately after exiting a hood or glovebox. Cart-mounted CAMs are used to monitor as near as possible to operations that may produce airborne activity.

8.3.5.3.2 Effluent Monitors. The criteria for obtaining representative samples of effluents and the features of the sampling systems are identified in Sections 8.6.1.1 and 8.6.1.2.

8.4 ESTIMATED PERSON-REM FOR PLUTONIUM FINISHING PLANT OPERATING PERSONNEL (DOSE ASSESSMENT)

The estimated occupancy factor of the PFP radiological areas during normal operation is identified in "First Quarter ALARA Goal Status" (McQuinn 2000). The high exposure rate values are associated with the principal work station(s) in the designated rooms. The exposure rates provided are the summations of the neutron and gamma exposure rates. Workstation occupancy in high exposure areas is usually one-third or less of the indicated occupancy rate. An estimate of plant occupants in radiological areas during an anomaly is the same as during normal operation. The actual operating history of the plant shows that functional conformance to the 1 rem/yr shielding performance criteria of DOE Order 6430.1A (DOE 1989) is being achieved.

In the PFP, there are no areas with known airborne radioactivity concentrations that are easily accessible to, or normally occupied by, operating personnel. Areas with a high potential for airborne radioactivity are posted and locked. Entrance to these areas requires special authorization as well as respiratory protection. Where only a single engineered barrier exists between the process materials and the worker, multiple administrative controls and safety monitoring are provided, including air sampling and monitoring equipment, self-survey devices [Poppies and portable alpha meters (PAMs)], respiratory protection, and RCT coverage.

Many PFP personnel are provided with the Hanford Combination Neutron Dosimeter (HCND). These HCNDs are processed monthly, quarterly, or annually based on expected radiation exposure. The data from 386 personnel shows that the total exposure (beta-gamma plus neutron) for CY 1995 was 30.89 person-rem, which averages to 0.08 rem each.

A normalization to 100% vault contents was performed. The dose rates derived from this approach, when compared to current limits for occupational exposure, verify that the shielding in place is adequate. The CP and Snoopy (described in Section 8.5.2.1) are the principal instruments used for dose rate determination in the PFP facilities.

Gamma-to-neutron exposure-rate ratios are highly variable in these facilities. The observed ratios range from greater than 100:1 (gamma/neutron) to less than 1:100 with the average ratio in the 3:1 to 3:2 range. These ratios are principally dependent on shielding material used but do change with the chemical form of the source material and its specific activity and moisture content.

See Sections 5.2 and 10.5 for further information relating to physical and administrative protection of the onsite individual. Chapters 6.0 and 9.0

discuss facility capabilities for providing nuclear criticality safety for the process, the building, and the onsite individual.

8.5 RADIOLOGICAL CONTROL PROGRAM

This section addresses the Radiological Control (RC) program organization, training, equipment, instrumentation, facilities, and procedures. Where applicable, particular emphasis is placed on those aspects of the RC program directly related to the PFP operations. The radiation protection program implements the requirements of the DOE orders and regulations via the use of controlled procedures. These procedures reiterate the DOE policies and requirements, assign authorities, and provide the framework for the supporting and implementing documents. These documents are used to establish compliance with 10 CFR 835 (DOE 1993a), PHRCM (FH 2000) and DOE Order 5480.4, *Environmental Protection, Safety and Health Protection Standards* (DOE 1984) requirements. The basic program guidance is provided by 10 CFR 835, and the PHRCM, while various DOE 5480.4 documents establish the mandatory and recommended standards to be used in various components of the radiation protection program. The reference section of PHRCM lists documents or other DOE orders that are pertinent to, or provide a basis for, the implementation of the primary radiation protection regulation. Implementation of radiation protection requirements is through a series of procedures developed by the Hanford Site contractor including HNF-SP-1145, *Fluor Daniel Hanford Radiation Protection Program, Implementation of Title 10, Code of Federal Regulations, Part 835*. Hanford Site contractor documents are written so that compliance with them also means compliance with the applicable DOE regulations and orders.

DOE Order 5480.4 (DOE 1984) also lists reference standards as guidance for good work practices. These reference standards include Federal Radiation Council, ICRP, International Commission on Radiological Units and Measurements, National Council on Radiation Protection, and International Atomic Energy Agency reports; additional ANSI standards; specialty reports by the DOE, PNNL, and the Nuclear Regulatory Commission (NRC); and other documents that would contribute to the improved performance of a radiation protection program. The reference standards are used to keep the radiation protection program up to date. Modifications or additions to the PFP facilities are required to address the appropriate criteria of DOE Order 6430.1A (DOE 1989).

8.5.1 Equipment, Instrumentation, and Facilities

This section provides information on the various RC-related portable equipment, instrumentation, and facilities available to support the radiation protection program for the PFP [see PNL-MA-562, *Portable Radiation Survey Instrument Manual*, (PNL 1988c)]. The DOE has listed NRC documents as reference standards to be used when the subject area is not fully addressed in DOE documents. The guidance provided by NRC Regulatory Guides 8.4, *Direct Reading and Indirect Reading Pocket Dosimeters*, and 8.9, *Acceptable Concepts, Models, Equations, and Assumptions for a Bioassay Program* (NRC 1973b and NRC 1973a, respectively) and applicable ANSI standards has been followed, with exception of the criteria for film badge performance. Thermoluminescent dosimeters (TLDs) are used for monitoring personnel dose rather than film

badges. Specific performance criteria are applied to the TLD program that meet or exceed the intent of ANSI N13.15, *Performance of Personnel Thermoluminescence Dosimetry Systems*. The TLD program participates in the DOE Laboratory Accreditation Program (DOELAP). The Hanford standard dosimeter and Hanford combination neutron dosimeter are DOELAP accredited. The present practice of DOE-RL is to contract the selection and calibration of instrumentation separately from the management and operations (M&O) contract.

The instrumentation contractor currently provides the following services for the Hanford Site:

- Operation of the portable radiation detection instrument pool
- Radiation detection instrument calibration services
- The TLD services for personnel monitoring
- Environmental monitoring and sampling services
- Compilation and issuance of the annual Hanford Site environmental report
- Consulting services related to radiation and environmental protection.

A matrix relating the PFP radiation detection instrumentation to ANSI criteria documents is shown in Table 8-17. These standards are used by the PFP and its supporting organizations to provide a quality radiation protection program. Standards applicable to radiation protection design and confinement features are identified in Chapters 4.0, 5.0, and 6.0.

The function of the instrumentation calibration contractor is to aid the facilities in obtaining the best possible instrument for the designated purpose.

8.5.1.1 Portable Survey Instruments. Most of the portable instruments used by the PFP radiation protection program are from the Hanford Site instrument pool operated by the instrumentation contractor. Instrumentation is purchased by the various Hanford Site facilities and then placed into the pool for calibration, maintenance and repair. This allows the various facilities to have calibrated specialty instruments available on an as-needed basis. The Poppy alpha-sensitive semi-portable unit is one exception. The Poppy is unique to the PFP facility and is calibrated and maintained within the facility. Instrumentation available from the Hanford Site instrument pool is described in PNL-MA-562 (PNL 1988c). This manual also contains various correction factors and other data pertinent to the physical and environmental use of the instruments. The instrument characteristics are summarized in Table 8-18. The principal routinely used instruments at PFP are the CP, PAM, Eberline Model E-140 with pancake Geiger-Mueller (GM) detectors, Snoopy, and Poppy.

8.5.1.2 Portable Airborne Radioactivity Monitoring. The use of portable CAMs for airborne radioactivity monitoring is addressed in Section 8.3.4.2.

8.5.1.3 Criteria for Selection of Portable Laboratory Equipment and Instrumentation. Portable and laboratory technical equipment and instrumentation for performing airborne radioactivity sampling, area dose rate surveys, and personnel monitoring during normal operations or anomalies are selected using criteria from the Technical Assessment of Compliance with *Workplace Air Monitoring Program* (BWHC 1997a). Additional criteria for selection of portable survey instrumentation for performing contamination surveys is provided by the HIEC.

8.5.1.4 Instrument Storage, Calibration, and Maintenance Facilities. The portable radiological monitoring instruments, with the exception of Poppies, are provided to the PFP from the instrumentation contractor. Instruments are calibrated on a rotational basis by the instrumentation contractor or the PFP Instrument Shop on a fixed calibration schedule or when operational checks indicate problems. Calibration sources used are traceable to NIST (formerly NBS) standards. Appropriate ANSI standards are used as required by DOE orders and PHRCM (FH 2000) for calibrations and record keeping.

Spare and operational instruments are stored in various locations throughout the PFP facility. The principal storage locations are in the RC office in the 234-5Z Building, room 221B and the 2736-ZB Building, room 631. Instruments are also maintained in the emergency response supply lockers, which are inventoried and sealed to prevent unauthorized use.

Portable instruments that have malfunctioned or are due for calibration are tagged, segregated, and transported to the instrumentation contractor weekly. See Table 8-18 for calibration frequencies.

The Poppy alpha contamination survey instrument is maintained and calibrated by the PFP instrument technicians. A number of Poppies are kept in a storage rack in room 158; they are connected to ac power to maintain the batteries fully charged until they are needed to replace Poppies requiring calibration.

8.5.1.5 Radiological Control Offices. The RC facilities within the PFP are located in the 234-5Z and 2736-ZB Buildings.

The office in room 221-A of the 234-5Z Building is used by the RCT supervisory personnel and RCTs who support operations. This office also serves as the central RC facility for the PFP and contains records of survey and personnel dose data. It has a computer terminal located at the access control enrollment station (ACES) that is used for tracking doses obtained from gamma pencil readings. There is also a source for checking CPs. The RC facility in the 2736-ZB Building is located in room 631. These rooms are equipped with storage cabinets for portable survey instrumentation and equipment.

A console in room 221-A provides indication of room CAM alarms for high alpha, room CAM failure, or loss of instrument vacuum for the 2736-ZA Building west and east filterbanks and the 2736-ZB Building repackaging, shipping, staging, NDA, and receiving rooms. After receiving an alarm, the operator notifies RC and PFP Facility Operations, initiating the appropriate alarm response.

The office in room 631 is used by the RCTs who support operations in the 2736-ZB Building. This office houses the survey records and other applicable radiological data and has storage for portable survey instrumentation, a source for checking CP instruments, and a counter for air samples. Room 631 also houses a control panel console for remote alarm annunciation of CAMs that monitor the room air for the repackaging, shipping, staging, NDA, receiving rooms, and corridor 625. This console also provides visual and audible alarm notification for high alpha, room CAM failure, or loss of instrument vacuum.

Instrumentation and other RCT supplies are also available at satellite locations throughout the PFP. These satellite locations contain such things as instruments, rope, labels, signs, tags, writing materials, and other items necessary for routine RCT support of plant operations in the area. Specialty items to support nonroutine operations would be obtained from the RC office/ready room area.

The PFP RCT personnel operate the mini-scaler system that is located in room 221A of the 234-5Z Building. These systems are ZnS scintillation detectors used for air sample, nasal smear, and other gross alpha contamination counting.

Air samples are normally collected by the RCTs once a week. These samples are delivered to the laboratory counting area in room 221-A of the PFP AL, 222-S Laboratory, or WSCF Laboratory. Stack samples are collected at approximately 2 week intervals. If a CAM alarm occurs (with the exception of a stack alarm), the RCTs will collect the CAM filter immediately for counting in room 221-A. Air samples collected due to a stack CAM alarm are also counted in this facility. Stack record (fixed head) environmental release samples are transported to the WSCF Laboratory for immediate analysis.

8.5.1.6 Analytical Laboratory. A Tennelec™ air sample counting system modified to perform automatic alpha spectroscopy is located in room 221-G. It is equipped with an automatic sample changer. All samples are disposed of as TRU room waste after all counting procedures have been completed. Some high-activity samples are temporarily set aside for decay and recounting to verify presence or absence of radon/thoron daughters. The laboratories provide a report to the RC personnel and retain a copy for their records. If guideline values are exceeded, the laboratories reports this information to the Duty Rad Con Manager for a following investigation by the Rad Con Organization.

8.5.1.7 Protective Clothing. Protective clothing is required in any area within the PFP where personnel can come in contact with loose surface contamination. Changerooms are provided so that personnel can change from personal clothing into protective clothing. The RC organization specifies the amount and type of protective clothing based on the level and type (e.g., particulate, liquid) of contamination. The protective clothing requirements for areas within the PFP are identified in various radiation work permits (RWPs). The requirements are determined and maintained current by a periodic review of documented survey and surveillance information.

Protective apparel includes coveralls, caps, hoods, and booties made from a paper type material or cotton cloth. Gloves may be made of latex or other materials as required by the RWP. Garments made of other materials such as plastic wear and Goretex™ are used in special applications. Items are predominantly yellow in color or are conspicuously marked.

Required protective clothing is provided for the PFP personnel in all change areas. Clean clothing is stocked in cabinets and drawers according to size and type.

Cloth protective clothing is collected after use and sent to the laundry contractor for laundering. Used paper protective clothing is discarded as radioactive waste (RW) at the step-off pad (the exit point of the contamination area). A personnel survey is performed after removing protective clothing.

8.5.1.8 Respiratory Protection. Respiratory protection is used within the PFP when entering an area with high potential for airborne contamination or having known airborne contamination, and during operations that could or would cause airborne contamination. Respiratory protection types that may be prescribed include: full-face piece air-purifying respirator, PAPR, supplied airline respirators with escape provisions, and self-contained breathing apparatus (SCBA).

The RC organization is responsible for determining respiratory protection requirements based on real or potential hazards from airborne contamination. The respirator protection factor selected is based on actual or potential expected levels of airborne contamination and the type of work to be performed. Respiratory protection factors used in selecting respiratory protection equipment are given in *Radiological Work Permits*, HNF-PRO-423, and listed in Table 8-19.

Respiratory Protection Program, HNF-PRO-120, specifies the respiratory protection requirements for hazards including radiological, chemical, particulate, and biological agents.

8.5.1.9 Decontamination Facilities.

8.5.1.9.1 Equipment Decontamination. There is one radiation detection equipment decontamination area in the 234-5Z Building, room 159. Radiation detection equipment contaminated through normal operations are transported to this area for decontamination. Radiation detection equipment that cannot be decontaminated must be kept in a radiologically controlled area at all times and are discarded if, at a job completion, they still present a contamination-control or personnel-exposure problem. Decontamination techniques and agents used at the PFP for equipment are identified in Plant Operating Procedures *Decontaminate Surfaces Outside of Processing Gloveboxes*, ZO-170-311. Sinks and floor drains from this area drain to the 241-Z Complex.

8.5.1.9.2 Personnel Decontamination. Within the PFP there is one personnel decontamination station, room 126, located in the 234-5Z Building. This room is equipped with a sink, showers, decontamination supplies, an emergency supply cabinet, and a medical supply cabinet. The sink and showers drain to the 241-Z Complex. Solid wastes generated are segregated and disposed of based on anticipated or known radionuclides, total activity, and/or hazardous material content.

The PFP RC personnel are responsible for performing skin decontaminations and the final release survey after decontamination has been accomplished. The RC Organization is responsible for preparing the chemicals and reagents

necessary for performing personnel decontamination. The approved procedures for performing personnel skin decontaminations are identified in HNF-PRO-664, *Personnel Decontamination.*

8.5.1.10 Contamination Control Equipment. The primary contamination control method is confinement. The PFP uses engineered confinement barriers (hoods, gloveboxes, and ventilation) for all routine work or processes involving plutonium. These barriers are described in Chapters 5.0 and 6.0. Temporary contamination control is provided via use of bag-outs and temporary glovebags or temporary radiological containment. Bag-out is the routine method utilized to remove items from process gloveboxes. Temporary radiological containment and glovebags are used for work situations not provided with engineered contamination barriers or when an engineered barrier must be breached. Plant operating procedures cover the use of glovebags and temporary radiological containment (see *Install/Remove Temporary Radiological Containments*, ZO-170-300).

Requirements for temporary structures are found in WHC-EP-0749, *Radiological Containment Guide* (WHC 1994d). This checklist ensures that, when exhaust ventilation is needed, at least one HEPA filter is used. If a temporary radiological containment that requires exhaust ventilation is used outside of existing facility E-3 (or E-2 in the 2736-Z Complex) ventilation zones, the requirements of WHC-SD-CP-OSR-010, *Plutonium Finishing Plant Operational Safety Requirements*, Limiting Condition for Operation 3.2.1, "Filtered Exhaust from Zones 3 and 4," must also be met. The checklist requires signoff by the Operations Management and RC Management before any temporary radiological containment work commences. A typical temporary radiological containment and exhaust system is shown in Figure 8-41.

Heat-sealed plastic bags or plastic sleeving/tubing are normally used as the contamination control barrier for routine bag-out activities. Other materials, such as reinforced plastics, may be used depending on the material or items to be removed. Temporary glovebags or temporary radiological containment are used to provide confinement based on the amount of work area needed to perform the job. Glovebags are used for small-area jobs (e.g., valve repair, small glovebox window replacement). The temporary radiological containment is used for large-area work such as glovebox panel removal and vacuum pump repair.

Temporary radiological containments are normally installed with a second, smaller temporary radiological containment (anteroom) at the entrance to the primary temporary radiological containment. Its purpose is two-fold: it serves as a buffer zone between the room and the primary temporary radiological containment, and it serves as an area for personnel to remove their outer later of protective clothing when exiting the primary temporary radiological containment.

The primary temporary radiological containment has a portable exhauster installed with an aerosol-challenged HEPA filter that causes air to flow from the room into the temporary radiological containment. The temporary radiological containment air is then exhausted through the HEPA filter providing a means for removing any radioactive particulate before discharge to an HVAC system.

8.5.1.11 Personnel Dosimetry. It is Hanford policy that all employees, visitors, or vendors who are expected to receive >100 mrem/yr be issued and use record dosimeters. The TLD provides the legal record of the individual's radiation dose history. A supplementary program uses self-reading gamma pencil dosimeters to provide a real-time tracking system for the individual to note and control their exposure totals.

There are two types of TLDs used on the Hanford Site. These are the Hanford standard dosimeter and the Hanford combination neutron dosimeter. The Hanford standard dosimeter is used for personnel not expected to be exposed to neutron radiation. The Hanford combination neutron dosimeter has an added track etch detector for determining neutron doses. For further information on the operation of the various Hanford dosimeters see HNF-PRO-379, *External Dosimetry Program.*

8.5.1.11.1 Supplemental Dosimeter. In the supplemental dosimeter program, self-reading gamma pencil dosimeters must be worn for entry to any radiation area with a dose rate greater than 100 mrem/h. This supplemental dosimeter is available to plant personnel, as specified in RWPs, for work in high radiation areas within the plant. These devices are worn in addition to the TLDs to provide short-term information on an individual's radiation dose. Low-energy gamma ray pencils are used at the PFP and have a range of 0 to 200 mrem. These pencils are returned to RC personnel for reading, recording exposure information, and zeroing the pencil setting.

8.5.1.11.2 Personnel Nuclear Accident Dosimeters. The personnel nuclear accident dosimeters (PNADs) are issued by Dosimetry to personnel who work in or visit the PFP, because a nuclear criticality accident is possible. PNADs are required to be worn anywhere an active criticality alarm system is required. A PNAD is used to estimate the neutron dose to a person carrying the device only if a nuclear criticality accident occurs.

The PNAD components consist of bare indium foil, cadmium-covered indium foil, cadmium-covered copper foil, and a sulfur tablet. In the event of a criticality or high-level radiation event, the PNADs will be collected by RC personnel and transported to PNNL External Dosimetry for analysis. The components of the PNAD are shown in Figure 8-42. The shape of the unit has been modified to allow fastening to the Hanford Combination Dosimeter.

8.5.1.11.3 Quick-Sort Evaluation. The "quick-sort" is a field measurement of ^{24}Na activity in the human body after an exposure to neutron radiation. The quick-sort is a triage technique that is used immediately following a criticality event to identify personnel who may have received high neutron doses. Measurements are made quickly by placing a GM probe count rate meter against the abdomen of a subject who is bent over during the measurement. An alternative approach is to place the GM probe in the armpit and have the individual hold it tightly against his body by exerting pressure with his arm.

8.5.1.11.4 Metal Object Analysis. Samples of metallic objects (coins, rings, belt buckles, eyeglass frames, etc.) carried by a person involved in a criticality event may be analyzed to determine the activity of any radionuclides produced by exposure to neutron radiation. A complex evaluation of the activity of the different radionuclides produced, the mass of the original metallic elements, and consideration of the geometry of the exposure

conditions can all provide valuable information regarding the neutron spectrum and the dose received.

8.5.1.11.5 In Vivo Examination. A whole-body in vivo examination provides information regarding the activity of different radionuclides in the body and the spatial distribution of these nuclides. This information provides an evaluation of the dose received and, possibly, information regarding the orientation of the body during exposure.

8.5.1.11.6 Blood Analysis. Samples of blood can be analyzed by gamma-energy analysis to estimate the concentration of ^{24}Na resulting from neutron radiation. The DNA analysis of blood cells can provide the number of chromosomal aberrations that are correlated to the whole-body dose received.

8.5.1.11.7 Hair Analysis. Samples of hair can be used to estimate the dose and spatial profile of the exposure conditions to fast neutron radiation through analysis for ^{32}P.

8.5.1.12 Nuclear Accident Dosimeter. Several types of dosimeters and steps can be used to identify the dose that personnel may have received from significant exposure to a nuclear criticality event or from a very high-level radiation source (see *External Dosimetry Emergency*, HNF-PRO-383, and *External Dosimetry Program*, HNF-PRO-379). The Hanford Site nuclear accident dosimeter (NAD) is a stationary device used in the PFP for providing neutron and gamma dose information following a criticality or high-level radiation event. This information is used to determine the neutron dose in rad and the gamma dose in the presence of neutrons from 10 to 10^4 rad. The neutron fluence in each of five energy intervals is determined, which permits calculation of the neutron quality factor (QF) and in turn allows the calculation of the dose equivalent in rem.

The NAD, which is identified in Figure 8-43, is a paraffin-filled aluminum cylinder, 9 in. in diameter and 12 in. in height, containing a polyethylene candlestick (sometimes called a wand). The candlestick has an inner and outer dosimetry package and is 13 in. in length.

The inner dosimetry package, at the center of the paraffin moderator, provides for measuring the approximate tissue dose in rad from neutron and photon exposure. It is a plastic holder containing a gold foil to measure thermalized neutrons, a TLD chip (TLD-600) to measure neutrons, and a TLD-700 chip to measure photons. The outer dosimetry package is used to measure the gamma dose (TLD-700 chip) and to calculate the neutron spectrum from analysis of neutron activation products that are found in the cadmium-shielded and nonshielded indium, gold, and copper foils, a sulfur pellet, and a TLD-700 chip located outside of the cadmium shield.

The candlestick part of the NAD is exchanged annually by PNNL. The PFP staff is sent replacement candlesticks and instructed to pull and return the old ones. The candlesticks are surveyed by PNNL, who shortly thereafter send a report listing the accumulated neutron and gamma doses to the FH Site Technical Authority for Dosimetry and the PFP Technical Authority for Dosimetry.

8.5.2 Procedures

The DOE Order 5480.4 (DOE 1984) lists reference standards, including NRC Regulatory Guides, which are to be used as good work practice guidance. The guidance provided by NRC Regulatory Guides 8.7, *Occupational Radiation Exposure Records Systems* (NRC 1973d), 8.9 (NRC 1973a), and 8.10, *Operating Philosophy for Maintaining Occupational Radiation Exposures As Low as Reasonably Achievable* (NRC 1975), as well as by the associated ANSI standards, has been followed in the development of the Hanford Site procedures for implementing the radiation protection program. These procedures provide the authorization, guidance, and procedures for all aspects of the radiological control program. Fetal protection requirements are delineated in PHRCM (FH 2000) and 10 CFR 835 (DOE 1993a).

8.5.2.1 Methods, Frequencies, and Procedures for Conducting Radiation Surveys. The methods, frequencies, and procedures for conducting radiation surveys are described in *Required Radiological Surveillance*, HNF-PRO-435. Requirements for the procedures come from ANSI/American Society of Mechanical Engineers (ASME) NQA-1, *Quality Assurance Program Requirements for Nuclear Facilities*, PHRCM, Chapter 7 (FH 2000), and DOE Order 1324.5B, *Records Management Program* (DOE 1995b). The current radiological status (contamination levels and exposure rate), both inside and outside of radiological areas, are determined by radiation surveys. These surveys make it possible to recognize off-normal conditions, initiate corrective actions, and provide a method of determining long-range trends in radiological conditions. The surveys are conducted by trained and certified RCTs. Portable ion chamber instruments, principally the CPs, are used to measure dose rates for beta-gamma radiation. The GM counter would be used to measure beta and gamma contamination. The AN/PDR-70 Snoopy is the approved instrument for measuring neutron dose rates. Portable CRMs, principally the PAM, are used for alpha contamination surveys. The CRMs are source-response checked before each use and periodically during continuous use. Requirements have been established for instrument calibration. Scheduled (routine) surveys are conducted, as well as other surveys, in support of operations (e.g., surveys of high-risk operations) and include both workplace and personnel monitoring.

The referenced manuals provide guidance to the RCT on the preparations for the survey and the techniques to be employed. Standard methods for direct and smear surveys are employed and specific procedures have been developed. For example, "Scheduled Radiation Survey Task Description," describes an area that is to be a part of the repetitive survey program. This description is completed by the supervisor for each scheduled (routine) survey and provides information specific to each survey (e.g., special conditions and minimum survey equipment to be used) as well as action levels. The RCT performs the described required actions and logs the results on the appropriate forms.

The frequencies of routine surveys are based on frequencies presented in the PHRCM (FH 2000). Routine contamination surveys are conducted in radiological buffer areas established for the control of contamination and other areas with the potential for spread of contamination. The survey frequencies range from several times per shift to once per year. Some of these examples are: step-off pads at a control point may be surveyed several times a shift; change rooms are surveyed daily; radioactive workstations are surveyed weekly; potentially contaminated ducts, some shops and offices are surveyed monthly; uncontrolled areas next to controlled areas are surveyed

quarterly; some deactivated facilities are surveyed semiannually; and some buildings adjacent to nuclear facilities are surveyed annually. (See HNF-PRO-435 for additional information). Nonroutine surveys are performed as needed to support plant activities and to maintain cognizance of the plant's radiological status. The results of each routine or nonroutine survey are documented and the reports are retained in accordance with the requirements in DOE Order 1324.5B (DOE 1995b).

8.5.2.2 Plans to Ensure that Occupational Radiological Exposure will be As Low As Reasonably Achievable. The authorities, responsibilities, requirements, policies, procedures, and guidelines for implementing ALARA are delineated in FSP-PFP-5-8, Section 14, *Radiological Control.* Work practices and facility and equipment designs are reviewed to achieve ALARA goals; for example, the need to keep personnel exposures as low as possible is reviewed in each pre-job meeting.

The plan for implementing ALARA has been discussed in some detail in Sections 8.1.1 and 8.1.2.

8.5.2.3 Physical and Administrative Measures to Control Access and Stay Times for Radiological Areas. Both physical and administrative measures have been developed for controlling access to radiological areas in the PFP. The principal emphasis is on physical measures; administrative measures are developed as needed to ensure that the level of control is consistent with the degree of hazard. The primary physical measures include the following.

- **Controlled Facility Access**--Access to the facility is controlled by Hanford Patrol with entry restricted to those with proper security credentials.
- **Exterior Door Locks and/or Alarms**--Exterior doors to zone 3 areas are locked and/or alarmed with plant management control of keys.
- **Radiological Control Technician**--A RCT located at the ACES Station will restrict those individuals who have not met the access requirements for entering radiological areas.
- **Escorts**--Visitors are escorted while in radiological areas by plant personnel.

Additional information concerning existing physical measures for access control is given in Section 8.3.1.

Administrative access controls developed to supplement the physical measures include the following.

- **Radiological Work Permits**--These permits administratively control entrance to radiation areas and provide information such as radiological status of radiation areas, dosimetry, and personal protective equipment required. RWPs are described in PHRCM (FH 2000).
- **Posting and Labeling**--A uniform system has been established for identifying radioactive materials and radiological conditions within the plant. Procedures and practices pertaining to labeling and

posting are consistent with requirements described in PHRCM (FH 2000).

- **Training**--Formal programs with attendance requirements have been developed to ensure that all personnel are provided with adequate radiological safety and radiological worker training so work can be performed in a safe manner consistent with ALARA objectives.

Those who have not met the training requirements will be denied entry into radiological areas. Minimum requirements for entry into a RBA, RA, CA, HCA, HPA, or HRA is Certified plus a trained escort. Training is discussed in more detail in Section 8.5.2.5.

- **Alarms**--Audible alarms warn of abnormal radiological conditions, which initiates the evacuation of the area where the alarm is located and warns personnel not to enter the area.

- **Pre-Job Briefing**--Before the start of any non-routine work or work having potential to exceed a PHRCM (FH 2000) trigger level, a pre-job safety meeting is conducted to discuss or identify safety concerns, hold points, evacuation routes, criticality postings, etc. The RWP, procedures to be followed, and radiological conditions are discussed. The meeting is documented.

Physical and administrative measures for controlling safety and health are described in FSP-PFP-5-8, Procedure 1.1, "Safety Policy." These measures are part of the required radiological worker training.

Administrative measures for controlling exposure include the following:

- **Self-Estimation**--Plant personnel, before entering a radiological area, must review the dose rates posted at the room entrance, the general area dose rates, and their current dose data compiled by the Dose Tracking Program; then they must estimate a stay time that will result in a dose that does not exceed the guidelines and which is consistent with ALARA objectives.

- **Pre-Job Safety Meeting**--Stay times, based on radiation conditions such as dose rates, contamination levels, and potential airborne radioactivity, are reviewed and established in the pre-job safety meeting.

8.5.2.4 Bases and Methods for Monitoring and Controlling Personnel, Equipment, and Surface Contamination. Programs for monitoring and controlling personnel, equipment, and surface contamination have been developed and are described in PFP procedure *Personnel Decontamination*, ZRC-100-101 (BWHC 1998b) and in site procedures, principally HNF-PRO-379, HNF-PRO-380, HNF-PRO-328, and HNF-PRO-435. These programs are consistent with the requirements and guidelines of the PHRCM (FH 2000) and 10 CFR 835 (DOE 1993a). Smears are taken of the contaminated area or equipment and taken to a laboratory to be counted using a scaler. Laboratory counters are used to meet the sensitivity requirement for items being shipped or unconditionally released.

HNF-IP-0718, Section 6.1, "Release Surveys for Material and Equipment," provides the basis for the release survey methods and techniques currently in

use at the PFP. In extraordinary situations, this procedure is supplemented by a release survey plan developed by the PFP Radiological Control Organization. Release survey plans are kept at the RC Office in 234-5Z. Selection of the portable survey equipment to be used is based, in part, on recommendations from the instrumentation contractor.

10CFR835 and part 5 of PHRCM (551-554) (FH 2000) provide the basis for the requirements regarding methods of monitoring and controlling radioactive contamination and is the basis of the Hanford Site program.

Personnel are protected from contamination by use of engineered controls, protective clothing, detailed training, procedural controls, and periodic work area decontamination. Containments such as hoods, gloveboxes, enclosures, temporary radiological enclosures, and cells are used to confine contamination and to minimize the area of surface contamination. Even though primary radiological protection is provided by the engineered features, secondary protection, provided through the use of administrative controls, reduces challenges to the primary systems.

When exiting contamination areas personnel receive a whole body survey for contamination with portable or semiportable count rate instruments by an RCT or by self-survey, if they are qualified. All RBA exiting personnel must undergo hand and foot surveys with alpha-sensitive detectors. Personnel cannot be released from a controlled area with detectable contamination on skin, clothing, or personal effects as determined by standard survey instruments and techniques, and properly functioning personnel survey devices. If contamination is detected on skin or clothing, decontamination procedures, under the direction of an RCT, must be performed until there is no detectable contamination. Skin decontamination procedures (i.e., washing, scrubbing, and chemical reacting) are approved or performed by the Hanford Environmental Health Foundation (HEHF), the Hanford Site medical services contractor.

For unconditional release, equipment must be free of detectable contamination. A direct survey of the equipment is required using standard battery-operated portable instruments and approved techniques. A smear survey is used to detect removable radioactive contamination and to provide information regarding approaches for decontamination. These release surveys must be performed by an RCT.

A facility surface outside of contaminated areas is maintained free of detectable contamination as determined by both dry smears and direct surveys using standard survey techniques and instruments.

Facility surfaces in contamination areas are maintained as free of contamination as feasible using regular decontamination, pre-job planning, post-job cleanup (housekeeping), and timely decontamination. The areas near engineered barriers and other physical systems for contamination confinement are provided with instruments and systems for contamination control and detection located as near to the potential sources as feasible. Training, procedures, and job direction (pre-job meetings) are other components of the contamination control program. Off-normal contamination conditions are reported promptly to permit a timely cleanup, and action levels are assigned to ensure that proper recognition and importance are given to contamination control.

A routine surveillance program has been established to assess surface contamination conditions in both radiologically controlled and uncontrolled areas. The areas to be surveyed, the frequency of the surveys, and the bases for these have been documented on the survey form or in one of the Hanford Site approved procedures.

8.5.2.5 Radiological Protection Training Programs. The radiological protection training programs are described in PHRCM, Chapter 6, "Training and Qualification" (FH 2000). The training programs, designed to be consistent with DOE requirements and ALARA, cover five categories of personnel who may be exposed to radiation or radioactive materials at the PFP: (1) all employees, (2) radiological workers, (3) visitors, (4) RCTs, and (5) other personnel.

Personnel trained as radiological workers are taught the proper response to a CAM alarm, to respond to material spills, to respond to potentially contaminated wounds, to survey when exiting a hood or gloves and, if they find they are contaminated, to minimize their movement to that needed to obtain help. All training programs are fully documented and auditable.

The retention periods for radiological protection program records are identified in the Records Inventory and Disposition System (RIDS). The established retention periods meet or exceed the guidelines of ANSI N13.6, *Occupational Radiation Exposure Records System*. Generally, the organization producing the record maintains the record in the field in accordance with requirements and retires it to the records retention facility as applicable.

Regulatory Guide 8.7 (NRC 1973d) and ANSI N13.6 provide only general guidance for the physical protection of records. ANSI/ASME NQA-1, Supplement 175-128, and applicable procedures (e.g., *ALARA Program Records*, HNF-PRO-1633 and *Documentation of Radiological Surveys*, HNF-PRO-1892) provide some specific requirements for records storage. Field storage of RC-generated records is in accordance with procedural requirements. Many records are ultimately transferred to a Seattle facility operated by the General Services Administration (GSA). The records generated and maintained include personnel occupational exposure records, radiological status of work area records, radiological program records, radiological training records, medical records, and records of the ALARA program.

8.5.2.5.1 Radiological Training Records. Radiological safety training includes radiological safety orientation, radiological worker training, RCT training, and special training, (e.g., for use of SCBA). The RC Training group trains RCTs, and Technical Training provides the other training. Immediately following the completion of the training, evidence of the satisfactory completion, (completed forms, rosters, and examinations) is sent to Technical Training Support. These records are entered into a computerized Training Records Information System. An individual's training status is also entered into another computer database that is available to managers. Approximately every quarter the records (e.g., copies of examinations and checklists) are retired to a record retention facility for 10 yr. Records such as rosters and completed training forms are retired quarterly to a records retention facility for 75 yr.

8.5.2.5.2 Radiological Program Records. The radiological protection policies and standards, developed primarily by RC, are documented in various procedures. These manuals establish the scope and organization of the

radiological protection program and program requirements (e.g., training, frequency, and techniques used in the measurement of radiological exposures, radiological and contamination control procedures, plans for emergencies, and recording and reporting requirements). Document Control maintains the record copies of the manuals and significant revisions and retires them to a records retention facility for 75 yr.

Records of maintenance and calibration of portable and semiportable radiological detection instruments are generated and maintained by PNNL. The hard copies of the service performed are retained by PNNL and then retired to a record retention facility for 75 yr.

Records generated by plant calibration of Poppies are maintained in a computer database. These data are used to document and forecast plant-installed instrument and equipment calibrations and verifications. These records relative to the radiological protection program are generated and maintained in accordance with the guidance of ANSI N13.6 by appropriate organizations. Records of criticality alarm system calibration are maintained and dispositioned as part of the plant OSR compliance program.

8.5.2.5.3 Radiological Status of Work Area Records. Records of the radiological status of work areas generated by RC include documentation such as radiological and contamination survey reports, air sample counter logs that document the results of the analysis of air samples counted by the RCTs, RWPs, and radiation problems and incident reports (RPRs). These records are maintained in the PFP for a period not to exceed 1 yr, transferred to the RC Central File for a period not to exceed 3 yr, and then retired to a record retention facility for 75 yr. The reports of the air sample analyses performed by the analytical laboratories, including engineering procedures and equipment calibration, are not being maintained and used in accordance with the Regulatory Guide and DOE requirements. A plan has been developed for implementing corrective action.

8.5.2.5.4 As Low As Reasonably Achievable Records. The Hanford Site has a formal program to ensure that radiological exposures are reduced to ALARA. In addition to the program manual, several reports are generated and maintained. These include an annual report to DOE on the ALARA goals with quarterly status reports, reports of monthly meetings of ALARA committees and teams, ALARA Management Worksheets, and ALARA Checklists. The ALARA Management Worksheets and Checklists are completed by Operations or Maintenance for all jobs requiring a job specific RWP for tasks that exceed trigger levels found in PHRCM, Article 312.3 (FH 2000). The completed worksheets and checklists are attached to the RWP for pre-job meetings and work approvals and are retained for 75 yr as part of the radiological protection records. A retention period for other ALARA reports has not been established.

8.5.2.6 Occupational Radiological Exposure Records Systems. The occupational radiological exposure records system is operated in accordance with PHRCM (FH 2000), 10 CFR 835 (DOE 1993a), and ANSI N13.6 by PNNL and HEHF for all Hanford Site employees. The systematic generation and retention of records relating to occupational radiological exposures are described in FSP-PFP-5-8, Section 6.0, Records.

The guidance provided by NRC Regulatory Guide 8.7 (NRC 1973d) and ANSI N13.6 is being followed. The generation of records is adequate to evaluate program effectiveness and enable reconstruction, for legal or medical purposes, of the situations and conditions for analysis of the radiation dose received by individuals.

Personnel occupational exposure records, along with medical and related occupational exposure records, are maintained for the lifetime of a facility plus 75 yr. The PNNL generates and maintains the current and historical occupational exposure records (OER) files. The HEHF generates and maintains the current employees' medical records. Historical medical records are transferred to PNNL for inclusion in the employee's OER file. Hanford contractor-generated OER-related records such as skin contamination reports, lost dosimetry or other reports (unusual occurrence reports, etc.) related to personnel occupational exposures are forwarded to PNNL for inclusion in the appropriate OER files. The PNNL also collects and maintains a historical file of the Hanford Site health and safety-related documents that have been generated by the various Hanford Site operating contractors.

8.5.2.6.1 Individual Occupational Exposure Record. The personnel OERs are accumulated and maintained by PNNL under its contract to DOE. These records include a prior occupational radiological dose, internal and external occupational dose (including that received at other installations during current employment), special dose evaluations, reports of unusual doses or potential dose, and other data relative to the individual's dose status such as radiological incident reports provided to PNNL by RC. A nonrecord copy of these dose records is also maintained by RC. Process management receives a copy of the monthly, quarterly, and annual TLD doses as an aid in operational planning and for ALARA purposes.

The PNNL processes the personnel dosimeters and performs the in vivo examinations. A testing laboratory, under contract to PNNL, performs the bioassay analyses and reports its findings to PNNL. The dosimetry and bioassay results are immediately entered into a database computer system for use and retention. Hard copies of dose records are temporarily stored in a protected facility. The individual's complete history is microfilmed by PNNL for retention for 75 yr. One copy is stored in an offsite record retention facility, one copy is stored in a local record retention facility, and one copy is maintained by PNNL for immediate referral. Personnel dosimetry data are also entered into a computer program (ORE) to which site contractors have access and forwarded to the National Registry. Radiological dose data are summarized in an annual Radiological Exposure Information Record, which is prepared by RC and provided to DOE. Employees are provided reports of an occupational dose at least annually and following termination; if requested, reports can be made available on the day of termination.

8.5.2.6.2 Medical Records. All PFP hazardous material and routine radiation workers receive periodic medical examinations. The examinations are performed by the HEHF under its contract to DOE. These examinations ensure that each employee is medically capable of performing assigned tasks. The medical examination program is described in *Occupational Medical Qualification and Monitoring*, HNF-PRO-111.

All hazardous waste workers are examined annually. The examinations and laboratory tests are comprehensive. The HEHF provides a report of Medical

Clearance and other reports (such as Work Restrictions) to the Hanford Site contractors. The HEHF also staffs an onsite medical treatment facility with registered nurses to provide first-aid and emergency medical treatment. Information concerning first-aid treatment is reported on a Treatment Record form. These reports are included in the individual's complete medical file. This file is microfilmed, duplicated, and transferred to a record retention facility for 75 yr. One copy of the records is retained by HEHF for reference, one copy is retained at a separate local facility, and a third copy is transferred to an offsite record retention facility.

8.5.2.7 Neutron, Gamma, and X-Ray Personnel Monitoring for Normal Operations and Criticality Accidents. The methods and procedures for implementing the personnel external dosimetry program are described in PHRCM (FH 2000), 10 CFR 835 (DOE 1993a), and *External Dosimetry Program*, HNF-PRO-379. The Hanford Combination Dosimeters (HCD) is the principal device used for personnel dose measurements at PFP. Supplemental dosimeters, such as direct-reading gamma pencils and finger rings, are used when an HCD would not adequately measure an individual's external dose. The PNADs are used by PFP personnel. These dosimeters supplement the HCD by extending the range of the dosimetry system and allowing determination of neutron energies that personnel were exposed to under accident conditions. The characteristics and methods for using these dosimeters in normal operations are discussed in Section 8.5.1.11.

After each gamma pencil use, pertinent data, including user and pencil identification, location of use, date and time of use, and dosimeter reading, are recorded in a log. Each shift, these data are entered in a computerized dose tracking system that is used to manage personnel radiological doses and operations. The HCD is evaluated monthly, quarterly, or annually, depending on the anticipated rate of dose accumulation. Extremity dosimeters such as finger rings are normally evaluated on the same frequency as the individual HCD. The PNNL processes the TLDs, reviews the data, records the data in the individual's dose records, and reports the results. The RC organization prepares a Radiological Exposure Status Report and submits it to the PFP management. Each employee receives an annual statement of occupational dose status and is informed of any occupational dose as soon as possible after involvement in a radiological occurrence. The HCD systems meet DOELAP criteria for accreditation and are accredited. The PNNL Dosimetry organization has the responsibility for maintaining the accreditation.

The methods and procedures for monitoring criticality accidents as well as the methods for recording and reporting the results are discussed in Section 8.3.4.1.5.

Both RC and plant management regularly review the personnel dosimetry results per PHRCM (FH 2000). With counsel from RC, plant management uses the dosimetric results in operational planning. Principal uses include the following.

- The dose tracking system and monthly reports of personnel external dosimetry data are used by plant management to make employee assignments to avoid exceeding personnel dose guidelines. If necessary, an employee may be restricted from work or work areas to maintain that employee's dose below administrative guidelines.

- Dosimetric results are used to determine trends and identify locations, tasks, or operations where ALARA measures such as shielding, facility redesign, or work practice revisions are needed.

- Dosimetric results are used to determine when supplemental dosimeters are needed to adequately measure doses from radioactive materials.

- Dosimetric results are also considered in scheduling operations which involve potentially high external doses so that available employees do not exceed dose guidelines.

8.5.2.8 Internal Dosimetry. The criterion for performing in vivo examinations and bioassays is described in PHRCM, Section 522 (FH 2000).

In vivo counting, whole body or chest, is used to determine the quantity and types of radionuclides inhaled or ingested by personnel. The counting equipment is designed to measure the energy and number of gamma rays entering the detectors. Through calibration and comparison to known standards, an estimate of the type and quantity of radionuclides deposited within an individual can be determined. The deposited quantity is used to calculate the dose commitment that the individual will receive. This information becomes part of the individuals' permanent record and may be used to determine future dose limitations. Bioassays, urine and fecal, are also used to track and verify past and current doses accumulated by personnel. Usually, a chest count is performed and urine collection is initiated for those personnel involved in an airborne plutonium release, while blood and urine samples would be collected for a plutonium-contaminated wound situation.

New employees, rehires, and employees returning from leave-of-absence submit a Personal Radiological Exposure History Form to RC listing any contact with radioactive materials. Visitors and vendors may also be required to submit this form. Based on this information and work assignments, RC assesses the need for baseline in vivo and bioassay assessments.

The Radiological Control section reviews the work assignment of each radiological worker and establishes an appropriate type and frequency of routine surveillance for internally deposited radionuclides. Routine in vivo and in vitro bioassays are provided for radiological workers exposed to surface or airborne radioactive contamination where the worker could receive 100 mrem/yr committed effective dose equivalent (CEDE) from all intakes of all radionuclides from occupational sources or if any organ or tissue dose equivalent could exceed 5 rem committed dose equivalent (CDE). The routine in vivo examination and bioassay frequency for plutonium are as follows:

- For jobs with high exposure risk, a urinalysis must be done annually, a chest count must be done annually, and a whole-body count is not required.

- For jobs with low exposure risk, a urinalysis must be done annually and neither a chest count or a whole-body count is required.

Special examinations and evaluations for different radionuclides at different intervals are required when a radionuclide can potentially exceed 10% of the DOE standards but can be undetected by routine evaluations. For

example, routine fecal sampling may be required for personnel working in facilities with high potential for intake of insoluble material.

Based on field information, the Radiological Control section determines if any in vivo or bioassay analyses are required when a person is suspected of having received a significant intake of radioactive material. Any person is monitored who has a potential for having received a 100-mrem annual CEDE from any intake or 10% of the tissue dose equivalent for a particular organ. The initial determination and need for an in vivo examination is usually made by field indicators, (e.g., nasal smears, air samples, or personal contamination surveys). The Radiological Control section, with the advice of the PNNL dose evaluator, determines the need for specific bioassay analyses to confirm an uptake of radioactive material. Employees give their written approval for all medical tests. Doses from internally deposited radionuclides exceeding 2% (100-mrem annual CEDE) of the applicable ALI are investigated in consultation with the PNNL dose evaluator. Table 8-21 is from *Personnel Decontamination*, ZRC-100-001, Appendix 2 (BWHC 1998b). It identifies the internal dosimetry evaluations required and the urgency of these evaluations for a range of contamination levels determined by field indicators. The HEHF physicians may be called on for medical assistance.

Internal dosimetry evaluations may also be performed when an employee reports a recent medical administration of radionuclides, at the request of the employee, to aid in the development of new techniques or programs, and at termination.

The PNNL has been assigned the responsibility for providing the facilities and services required for performing in vivo and in vitro bioassays for the Hanford Site. The PNNL has received and is maintaining its internal dosimetry program accreditation by actively participating in the DOE Laboratory Accreditation Program (DOE LAP).

8.5.2.9 Methods and Procedures for Evaluating and Controlling Potential Airborne Radioactivity Concentrations. The methods and procedures for evaluating and controlling potential airborne radioactivity concentrations are described in *Work Place Air Monitoring*, HNF-PRO-331. Line management, Nuclear Safety (NS), Industrial Safety, and RC all have responsibilities for evaluating and controlling airborne radioactivity.

The prevention of internal deposition of radionuclides is accomplished by the use of engineered systems as required by PHRCM (FH 2000) and 10 CFR 835 (DOE 1993a). A total confinement policy is in effect at the PFP. That is, all radioactive material having a potential to become airborne must be totally confined in an engineered system. If a task would deviate or potentially deviate from the total containment criteria, temporary confinement such as a temporary radiological containment must be provided, or a deviation from the policy is required.

These engineered controls include confinement of radioactive contaminants by ventilation, piping systems, gloveboxes, hot cells, temporary radiological containment, and shipping containers. When establishing radiological controls for work involving the potential for airborne radioactive materials, the first consideration is using techniques that prevent a release to the work atmosphere. Even then, to be conservative, the RWP for an operation in many

cases requires that respiratory protection be worn by personnel in the area adjacent to the work location.

Loose surface contamination in contamination control areas is controlled to levels low enough to minimize the potential resuspension of radioactive aerosols by constant attention to housekeeping and post-job cleanup. In controlling airborne radioactivity, the PFP objective is to restrict airborne radioactivity concentrations to ALARA levels and not exceed the prescribed DAC limits of 10 CFR 835, Appendix A (DOE 1993a).

Ambient air sampling and monitoring systems are placed in strategic locations to detect and evaluate potential airborne contamination at work locations. Sampling is required where airborne concentrations may exceed 2% of the applicable DAC. Locations of FHSs and CAMs are determined, documented, and periodically reviewed using HNF-PRO-331, *Workplace Air Monitoring Program* and various standards and guides; resultant document is HNF-5242, *Technical Basis for Work Place Air Monitoring for the Plutonium Finishing Plant (PFP).* Air sampling equipment and techniques used can be divided into four categories: (1) breathing zone or room air samples, (2) CAM devices, (3) stack effluent samplers and monitoring systems, and (4) portable air samplers. Breathing zone or room air samplers are used to establish average breathing zone air concentrations or to quantify chronic low-level airborne exposures.

The CAMs are used in areas where dispersible radioactive material is handled and/or the potential for airborne radiological release is high, to provide an annunciation of a changing workplace environment. As a minimum, CAMs are located at workstations where potential concentrations of radioactive airborne materials may exceed 1 DAC during the occupancy period (DOE 1994). They provide early warning of a significant release (40 DAC-h of ^{239}Pu) of radioactive material. Facility exhaust stacks are monitored by CAMs to provide rapid indication of a detectable release of airborne radioactivity. Portable air samplers are used for special or supplemental air sampling (grab sampling) when a CAM indicates an increase in radioactivity, for special evaluations of radiological conditions, or for specific tasks.

Depending on the location of the CAM and susceptibility to interference from radon at particular locations, the alarm set points may be reduced from the maximum value based on RC assessment of false alarm frequency. One of the primary objectives when calculating the CAM alarm set point is to allow personnel sufficient warning of a significant release or potential environmental release of airborne radioactivity, while attempting to minimize spurious alarms. Alarm set points are determined by calculating the meter reading equivalent to a predetermined air concentration accumulation in a given amount of time. Normally this is calculated as a set number of DAC hours exposure.

Naturally occurring radon and thorium daughters interfere with the ^{239}Pu measurement. At CAM sample locations where wide fluctuations in the natural activity occur, the set point may be adjusted to compensate for the increased natural activity. For locations where the natural activity fluctuations are both frequent and severe, it may be necessary to calculate an average background value into the alarm set point. The background values for Radiological Control CAMs are derived in accordance with HNF-PRO-5675, *Radiaiton Protection Real-time Air Monitoring.*

The RCTs exchange the air sample filters and record all applicable sample data weekly. There are approximately 390 samples exchanged every week. Some environmental sample filters are exchanged monthly. Air sample filter (fixed head samplers) exchanges may be performed on a daily or shift basis where the potential for airborne contamination is high. In addition to the weekly schedule, the CAM filters are exchanged after an alarm occurs to allow identification and evaluation of the alarm-causing material. The criteria for sample filter exchange frequency include radiological history, nature of operations, and frequency and length of personnel occupation. The RCT submits the filter to the PFP AL for counting.

Approximately 390 filters per week are submitted to the PFP AL, room 221-G, for counting and inclusion in a computer program used for tracking/trending air sample data. Printouts are distributed to RC for review. If an abnormal condition occurs, such as a CAM alarm or a high concentration of radon, the RCT counts the filter on RC field equipment before submitting it to the counting laboratory. The PFP Lab logs the results of the analysis of the radioactivity on the filter. Results of the analysis of samples taken during an abnormal condition, or of samples indicating abnormal conditions, are immediately reported to Operations and RC for action. For normal conditions, the logged information is reported to RC quarterly unless guideline values are exceeded. Daily inspections and weekly sample exchanges performed by the RCTs are incorporated into the Scheduled Radiological Survey Program, and the results are recorded per approved procedure.

Calibrations of equipment and instruments or air sampling system components are performed by Plant Maintenance or PNNL. Calibration procedures follow the requirements of ANSI N323, *Radiological Protection Instrumentation Test and Calibration*. The RCTs perform scheduled efficiency and performance checks of counting equipment they operate.

Additional information on the air sampling equipment is provided in Section 8.3.4.2.2.

Areas subject to rapidly changing airborne contamination conditions or where airborne concentrations are (or are likely to be) greater than 0.1 DAC are posted as airborne radioactivity areas. Appropriate protecting clothing and respiratory protection are required for entry.

8.5.2.10 Use of Respiratory Protective Devices. The use of respiratory protective devices, including the respiratory protective equipment fitting programs and training of personnel, is discussed in Section 8.5.1.8. The respiratory protection program meets the requirements of *Respiratory Protection*, HNF-PRO-120.

8.5.2.11 Decontamination and Decommissioning. The radiological protection program at the PFP has the flexibility to provide the services necessary to support D&D activities.

8.6 ESTIMATED PERSON-REM OFFSITE DOSE ASSESSMENT

The effluent streams from the PFP are sampled and analyzed for radioactivity in accordance with the requirements of approved procedures including HNF-PRO-2364, *Radioactive Airborne Effluent Sampling*, HNF-PRO-455,

Solid Waste Management, and HNF-PRO-456, *Water Quality*. The Environmental Compliance Manual establishes limits on the quantities of radioactive material that can be released to the environment from airborne, liquid, and solid waste streams. These limits are set such that the requirements of federal, state, and local regulations are met and releases from facilities are maintained ALARA. For specific information regarding effluent sources and sampling refer to Chapter 7.0. This section addresses the estimated radiation dose to offsite individuals from activities at PFP, which produce gaseous and liquid effluents. The contribution to an offsite dose from solid waste will not be addressed since this waste form is not released to the public from the PFP.

The contribution of the PFP effluents as offsite dose to the public is assessed in the following manner:

- Identify the waste streams of concern
- Sample for specific radionuclides to determine routine releases
- Monitor for radioactivity to detect off-normal or transient levels of radioactivity that may exceed established limits
- Perform environmental monitoring of specific media (flora, fauna, soil, water, etc.) to evaluate pathways of specific radionuclides to man.

Chapter 7.0 of this safety analysis report (SAR) provides a detailed description of all waste streams. Chapters 5.0, 6.0, and 9.0 provide additional details of design features that provide attenuation of postulated accidents and off-normal situations. Offsite environmental monitoring is provided by PNNL under their DOE contract. Onsite environmental monitoring is performed by Hanford Site contractors. The onsite monitoring program is used to evaluate the long-term effect (if any) of the PFP (and other facilities) effluent on the adjacent environs.

The gaseous effluents of interest to offsite dose estimation are from the 291-Z-1 main stack, 296-Z-3 stack, 296-Z-5 stack, 296-Z-6 stack, and the 296-Z-14 stack. The PFP's main stack exhausts filtered process and ventilation air from gloveboxes and hoods (zone 4) in the 234-5Z, 236-Z, and 242-Z Buildings as well as zone 3 (personnel occupied) process areas. The 296-Z-3 stack exhausts filtered air from the sumps and vessels of the 241-Z and 241-ZA/ZB Buildings. The 296-Z-5 stack exhausts filtered process and ventilation air from the 2736-ZB Building. The 296-Z-6 stack services the 2736-Z storage vaults and the 2736-ZA. The 296-Z-14 stack services the process areas and glove boxes of the 232-Z Incinerator Building (which is now undergoing TCO).

The radionuclides of concern in gaseous PFP effluents are the various isotopes of plutonium. Radionuclide effluent sampling is conducted for gaseous effluent emission points in a manner that meets requirements defined in *Radioactive Airborne Effluent Sampling*, HNF-PRO-2364. Various federal [DOE/Environmental Protection Agency (EPA)], state, local, and Hanford procedures define the basis for the air quality requirements. The effluent sampling emission measurement system is designed to sample the effluent at near-isokinetic conditions to provide sample data that are representative of

the actual emissions. The data provide the basis for the PFP annual effluent environmental release reporting.

Effluent streams are monitored to detect off-normal transient conditions that could lead to a release in excess of applicable limits. The monitoring is adjusted to alarm at release concentrations as low as possible, without generating spurious alarms, but having the range capability to alarm at a minimum of 5,000 times the DCG over a 4-h release.

Environmental monitoring data are used to detect trends in quantities of radionuclides released to the environment. The sampling and monitoring methods are of sufficient sensitivity to allow corrective actions before applicable limits or guidelines are exceeded. Specific types of media are sampled to track the migration of radionuclides in the environment, especially in those pathways of exposure to man. The environmental monitoring program serves to assess the performance of the various effluent control mechanisms.

The following approach was used to estimate offsite doses as a result of routine operations of the PFP.

- **Collect Release Data**--Effluent monitoring and sampling data were assembled to evaluate annual routine releases from the facility.

- **Exposure Pathways**--The possible exposure pathways to man have been determined. These include inhalation of airborne contaminants, ingestion of waterborne contaminants or airborne contaminants that have been deposited on foodstuffs, and direct exposure from airborne or deposited radionuclides.

- **Assemble Parameters for Calculation**--Assemble values for the parameters necessary for calculating the dose to man from a given release, including meteorological, geological, and hydrological data; site characteristics; resource-use information; and population studies.

- **Calculate Offsite Dose**--The data and other parameters are used in a validated mathematical model for calculating the offsite dose. The calculation for this SAR employs the computer code GENII, as developed by PNNL (PNL 1988a).

Collective doses are calculated for the population surrounding the site, as well as those for the maximum exposed individual (MEI), based on the highest annual release data within the last five years. Radiation exposures to the public from anticipated off-normal and accident conditions are provided in Chapter 9.0.

Meteorological data for determining dispersion coefficient ($\bar{\chi}$/Q') values are obtained from the PNNL Atmospheric Sciences Department Hanford Meteorological Station (HMS) 622R. Joint frequency meteorological data from 33 ft and 200 ft elevations (1983 through 1991) were averaged to obtain $\bar{\chi}$/Q' values used in the onsite and offsite personnel and population exposure calculations.

8.6.1 Effluent and Environmental Monitoring

This section describes the basic effluent and environmental monitoring programs for estimating the PFP contribution to radioactivity in the environment. See Chapter 3.0 for details of the meteorological conditions of the Hanford Site from which the joint frequency meteorological data was obtained.

8.6.1.1 Gaseous Effluent Sampling and Monitoring. This section describes the basic effluent and environmental monitoring programs for estimating the PFP contribution to radioactivity in the environment. The PFP developed a monitoring program in accordance with the requirements of *Environmental Notification and Reporting*, HNF-PRO-453, to implement DOE Order 5400.1, *General Environmental Protection Program* (DOE 1988a), requirements. The monitoring program contains the rationale, design, and operational criteria for monitoring and sampling programs, the extent and frequency of monitoring and sampling, procedures for laboratory analysis, the Quality Assurance (QA) requirements, and the verification and direction for the preparation and disposition of reports.

The operational objective for the management of airborne effluents is to control the annual average concentrations of radionuclides released to the environment (under routine operating conditions) to ALARA levels. This objective is in conformance with the DOE Order 6430.1A, Section 1300-9 (DOE 1989) design requirements. See HNF-PRO-2364, *Radioactive Airborne Effluent Sampling*, for additional information relating to airborne effluents.

8.6.1.1.1 Record Sampling Capabilities. See Chapter 7.0, Section 7.1.2.1.1.

8.6.1.1.2 Monitoring Capabilities. See Chapter 7.0, Section 7.1.2.1.2.

8.6.1.1.3 Analysis Continuity and Integrity. See Chapter 7.0, Section 7.1.2.2.

8.6.1.1.4 Monitoring and Sampling Criteria. See Chapter 7.0, Section 7.1.2.1.

8.6.1.2 Liquid Effluent Sampling and Monitoring. Condensates, cooling water, and other "normally cold" streams from the PFP are routed to the 200 East Area TEDF. The streams that have a potential to be contaminated are routed through the LLWTF before discharging to TEDF. The "normally cold" streams historically were released to the 216-Z-20 Crib and 216-Z-21 Trench that are now inactive and blanked off. Both sampling and monitoring are conducted on this waste stream (see Chapters 5.0 and 7.0 for additional details).

Liquids discharged to the TEDF are sampled using an online grab sampling unit. A sample aliquot is removed from the sample collection container and sent to the WSCF for isotopic analysis, and other analyses, for verification of compliance with TEDF acceptance requirements.

The PFP and WSCF procedures delineate the sampling frequency, specific analyses to be performed, analytical methods to be used for specific contaminants, record keeping, action levels, and QA methods to be used for the samples removed from the PFP effluent streams.

Radioactive liquid waste streams discharged to the 241-Z Building collection tanks are ultimately transferred to the TK-D5 tank, which is sampled, analyzed, treated (neutralized), and subsequently transferred via 244-TX to underground tank storage.

8.6.1.2.1 Sampling and Monitoring Capabilities. The sampling equipment is located in 225-WC. Sampling is achieved by two composite samplers (see Figure 8-44 for a diagram of a composite sampler). The liquid is drawn into a 5-gal receiver container. A 2-L sample is removed from the receiver and sent to the WSCF for analytical processing. The MDL for plutonium using this sampling technique is 0.4 pCi/L.

8.6.1.2.2 Analysis Continuity and Integrity. Sample integrity is maintained through implementation of procedural requirements by the sample collecting and laboratory personnel involved. Sample data are noted on the sample container by the collector and via a hand-held bar code scanner. These data and the sample are logged in at an assembly point (RCT Office, Operations desk, Control Room, etc.) and then transferred to the appropriate analytical facility. At the analytical facility, the samples are logged in by the transporter and the analytical facility representative on an inventory sheet, at which time possession of the samples is transferred to the laboratory. The laboratory then implements its routine chain of custody procedures during sample analysis. The laboratory sends copies of the analytical results to the concerned parties and maintains a copy in its own files. The analytical results are used to evaluate compliance with DOE requirements and are usually summarized in monthly, quarterly, or annual reports. The concerned parties (PFP Operations, Environmental Protection, RC Operations, etc.) perform tracking and trending of the results based on their individual needs and requirements. The methods used meet the requirements of HNF-PRO-456, *Water Quality*.

8.6.1.2.3 Sampling and Monitoring Criteria. The requirements for liquid effluent sampling and monitoring used at PFP are defined in ANSI N42.18 and *Water Quality Program*, HNF-PRO-456, which implement DOE Orders 5400.5 (DOE 1993b) and 5480.11 (DOE 1988b).

The liquid effluent sampling and monitoring systems were designed and are operated to meet the above criteria. The flow proportional sampler is installed per the manufacturer's instructions.

8.6.1.3 Solid Waste Sampling and Monitoring. The solid waste generated at the PFP is packaged for storage and/or disposal at other Hanford Site or offsite facilities and therefore does not impact the offsite population. To ensure that the offsite population is not exposed to radiation or radioactive materials during transport, all solid waste packages are carefully monitored for external radiation levels and removable contamination using standard radiological survey techniques before being released from the PFP. All solid waste packages must conform to the shipping criteria established in *Radioactive Material/Waste Shipments*, HNF-PRO-157, and 49 CFR 173, Subpart I (DOT 1994) before release for shipment. See Chapter 7.0, Section 7.3 for further information relating to solid waste handling.

8.6.1.4 Environmental Monitoring. It is the goal of Hanford site contractors to manage and conduct site activities in an environmentally responsible and cost-effective manner that is in compliance with the applicable environmental

statutes, regulations, and standards of DOE, Washington State Department of Ecology (Ecology), and EPA. In addition, Hanford site contractor policies ensure that its activities are conducted to protect employees, government property, and the public.

The PFP participates in the onsite environmental monitoring by supplying power to nearby air monitoring stations and by supplying personnel for performance of surveys and sample collection. The PFP provides data to this program via quantification of its liquid and gaseous effluents as annually summarized in WHC-EP-0141-1 (WHC 1990).

8.6.1.4.1 Environmental Monitoring Plan for PFP Environs. Operational environmental monitoring for PFP consists of samples taken in or near the 200 West Area. Additional environmental samples are collected by PNNL to assess the total Hanford Site contribution to environmental radioactivity.

8.6.1.4.2 Special and Emergency Sampling. Special and emergency sampling is conducted in the operations areas to augment the routine sampling program, support construction projects, and verify near-field waste containment. Special sampling is undertaken to clarify results from the analysis of routine samples.

8.6.1.4.3 Annual Reports--An annual report of the environmental conditions in the 200 West Area is issued every calendar year (examples are WHC 1990 and WHC 1994a). The report includes the results from the analyses of all environmental media, as applicable, and fulfills the requirements of *Environmental Notification and Reporting*, HNF-PRO-453.

8.6.2 Estimated Exposures

The estimated exposures presented in this section are based on the routine operating releases from PFP. The gaseous effluent releases arise from stacks 291-Z-1, 296-Z-3, 296-Z-5, 296-Z-6, 296-Z-14, and 296-Z-15. Of the six stacks used to exhaust gaseous effluents from PFP, only the 291-Z-1 rises above roof level and is considered an elevated release. The other vents are treated as ground level releases.

To derive the source term from PFP, the release data for the years 1989 through June of 1995 were obtained from the laboratory to determine the year that would represent the greatest release. It was determined that 1993 had the highest concentration for elevated releases (291-Z-1 stack). The beta-emitting radionuclide ^{241}Pu was not included in the source term. This is because the concentrations of ^{241}Pu are several orders of magnitude less than the alpha emitters. Therefore, beta particle emitters do not contribute significantly to the total dose from plutonium when compared to alpha particle emitters.

The primary pathway of exposure to plutonium in gaseous effluents is by inhalation; however, ingestion of foodstuffs contaminated with radionuclides via deposition is also a credible, albeit minor, contributor to the total offsite dose. Also, the doses from inhalation and ingestion are cumulative, which means that the offsite individual continues to grow food and live off the land for an assumed 50 yr after the release.

The exposures to the MEI as well as the cumulative population are calculated. The MEI is assumed to live at the site boundary at the location of highest radionuclide concentration. For gaseous effluents following Gaussian dispersion kinetics, this location is the point where the dispersion coefficient, $\bar{\chi}/Q'$, is greatest. The worst case $\bar{\chi}/Q'$ for maximum individually chronic (annual average) ground and stack level releases at offsite locations are 5.02 E-08 s/m^3 and 1.03 E-08 s/m^3, respectively. The highest annual average $\bar{\chi}/Q'$ is at 17.7 miles in the west offsite boundary (Nguyen 1995).

To calculate exposure to the population, average annual $\bar{\chi}/Q'$ values were calculated for a series of rings at varying distances from PFP in 16 directional sectors. The rings corresponding to the transport distances evaluated are listed in Nguyen (1995). The effects of the PFP airborne effluents are calculated for the midpoints of each of 16 sectors, each 22.5° wide and at 10 specified distances representing the 0 - 50-mi radius area surrounding the facility. The directional sectors are defined by midpoint. The annual average $\bar{\chi}/Q'$ values are based on 1983 to 1991 meteorological data. The population-weighted worst case $\bar{\chi}/Q'$ for chronic (annual average) ground and stack level releases at offsite locations are 1.36 E-03 s/m^3 and 4.55 E-04 s/m^3, respectively. The highest annual average $\bar{\chi}/Q'$ is at 50 miin the southeast (Nguyen 1995).

8.6.2.1 Identification of Sources. The mission of the PFP Complex includes recovery and/or processing of various forms of plutonium-bearing materials, conversion of plutonium-bearing materials to a stable form, and storage of recoverable and/or processed plutonium-containing materials. The various ventilation systems serve as the source of radionuclide releases. Although several different TRU radionuclides can be detected in the waste streams, by far the most significant contributors to an offsite dose are the plutonium isotopes. See Chapter 7.0, Section 7.2 for source descriptions.

A detailed description of radioactive gaseous waste streams is presented in Chapter 7.0, Section 7.2.1. The short stacks are treated as ground-level releases, while the 291-Z-1 stack is treated as an elevated (200 ft) release.

8.6.2.2 Analysis of Effects and Consequences. The offsite doses to the MEI and the cumulative population are shown in Table 8-23. The effective dose equivalent (EDE) and maximum organ doses are also presented in the Table 8-23. The maximum organ dose in all cases is to the bone surface as a result of the modeled plutonium intake. The dose to the MEI and the population was calculated by GENII using the dispersion coefficients presented in Nguyen (1995). The MEI is assumed to reside at the site boundary location possessing the highest value of $\bar{\chi}/Q'$ (Nguyen 1995). In the case of the population dose calculation, the 1990 population within 50 mi of the PFP was considered, which is 375,860 persons. The average $\bar{\chi}/Q'$ values were calculated by GXQ 4.0 and used for the dose determination using GENII. Average consumption values for farm produce was assumed for determining the average population dose.

The dose to the MEI from PFP operations is several orders of magnitude less than either the EPA limit [40 CFR 61, *National Emission Standards for Hazardous Air Pollutants*, Subpart H (EPA 1995)] of 10 mrem/yr EDE or the DOE EDE limit of 100 mrem/yr.

The dose equivalents listed in Table 8-23 may be compared to the estimated per capita background EDE of 300 mrem/yr from natural background and

65 mrem/yr from manmade sources (medical X-rays, diagnostics, consumer products, etc.) for a total of 365 mrem/yr. It is unlikely that the release has any measurable impact on the population based on latent cancer fatality (LCF) to the exposed.

For example, the CEDE for offsite chronic ground level release is calculated to be 8.0×10^{-4} person-rem (Table 8-23). The ICRP has determined that the nominal cancer fatality coefficient for a population of all ages for a low dose (low dose-rate whole body irradiation) is approximately 5.0×10^{-4} LCF/person-rem EDE (ICRP 1991).

Assuming the chronic ground level release occurs during 99.5% meteorology, the health effect to the exposed offsite population is given by:

$$(8.0 \times 10^{-4} \text{ person-rem}) \ (5.0 \times 10^{-4} \text{ LCF/person-rem}) = 4.0 \times 10^{-7} \text{ LCF}.$$

To place this in perspective, the exposed offsite population of 114,734 persons within 50 mi and located to the SE of PFP (including the Tri-Cities) would normally be expected to have approximately 225 LCFs per year (NSC 1990) from causes other than chronic PFP emissions.

The difference is approximately a factor of 1.13×10^{10} higher from non-PFP causes. This indicates that the risk to the exposed offsite population of a cancer fatality from all causes is 11,300 million times greater than the risk of a cancer fatality resulting from routine PFP emissions. The population and health effect for chronic ground and stack level releases are shown in Table 8-23.

8.6.3 Liquid Effluents

The offsite MEI and population exposures resulting from PFP liquid effluent discharges were not calculated as there are no radioactive exposure pathways from PFP liquid effluents to the public.

Waste liquids containing radioactive materials are transferred to other Hanford Site facilities for volume reduction and/or other treatment prior to storage in underground tanks. Therefore, the general public is not exposed to liquid radioactive effluents from the PFP. Small quantities of specialty liquids not compatible with the liquid waste system are processed to achieve compatibility or are solidified for disposal. Most of the decontamination processes are based on the use of dampened material to minimize the generation of liquid wastes. Therefore, decontamination efforts usually produce a much larger volume of solid rather than liquid wastes.

8.6.4 Solid Effluents

Solid wastes from PFP operation and facilities are either transferred to the Hanford Site solid waste burial facilities or placed in retrievable storage (TRU only) areas for ultimate shipment to a geologic repository.

Since solid wastes are not released to the environment, there is no onsite or offsite impact within the scope of this document. Solid wastes that may contain TRU are assayed to determine the disposal category: geologic repository or low-level.

Table 8-1. Shield Design Criteria.

Area category	Access time allowed	Initial design level (mrem/h)	Maximum (mrem/h)
Uncontaminated area	Full time	0.05	0.1
Contaminated area 1	Full time	0.2	0.5
Contaminated area 2	Less than 1 h/day	2.0	5.0
Contaminated area 3	Less than 1 h/week	10.0	20.0
Contaminated area 4	Less than 10 h/yr	50.0	100.0
Contaminated area 5	No normal access permitted	>100	--

Note: Section 5.2 of Chapter 5.0 discusses natural phenomena hazard design criteria from U.S. Department of Energy Order 6430.1A (DOE 1989). This section describes the special features that were incorporated into the design and ultimately built into the facilities to make the facilities appropriate for processing and handling large quantities of special nuclear material. Chapter 4.0 discusses the principal design criteria used at the PFP.

Table 8-2. Potential Radiation Sources in Plutonium Reclamation Facility. (4 sheets)

Equipment number	Location	Function*	Description	Working volume (L)	Former process chemical form
TK-32 (CA column)	Process cell	Extracts plutonium from aqueous feed	4-in. x 45-ft stainless steel and Pyrex™	144	$Pu(NO_3)_4$[a]
TK-33 (CC column)	Process cell	Strips plutonium from organic feed	4-in. x 45-ft stainless steel and Pyrex™	144	$Pu(NO_3)_4$[a]
TK-WS-1 (CO column)	Process cell	Plutonium scrubbing	6-in. x 19-ft 10-in. stainless steel, Teflon™-lined	90	$Pu(NO_3)_4$[a]
TK-123 (CU column)	Process cell	Uranium stripping	4-in. x 23-ft stainless steel	65	$Pu(NO_3)_4$[a]
TK-69 (CX column)	Process cell	DBP scrubbing	6-in. x 12-ft 7-in. stainless steel, Teflon™ lined	70	Trace plutonium[a]
TK-48 (OA column)	2nd floor west section	Organic reacidification	5-in. x 4-ft 6-in. stainless steel, Teflon™-lined	18	Trace plutonium
TK-15	Process cell	S&C Product receiver	5-in. x 3-ft 9-in.[b] stainless steel	45	$Pu(NO_3)_4$
TK-16	Process cell	Miscellaneous storage	5-in. x 15-ft 4-in.[b] stainless steel	185	$Pu(NO_3)_4$[a]
TK-17	Process cell	Feed makeup tank	5-in. x 15-ft 4-in.[b] stainless steel	185	$Pu(NO^3)_4$
TK-18	Process cell	Feed transfer to CA column	5-in. x 15-ft 4 in.[b] stainless steel	185	$Pu(NO^3)_4$
TK-19	Process cell	CAW receiver cell	5-in. x 15-ft 4-in.[b] stainless steel	185	$Pu(NO^3)_4$
TK-126	Process cell	Miscellaneous storage	5-in. x 15-ft 4-in.[b] stainless steel	185	$Pu(NO^3)_4$
TK-127	Process cell	Miscellaneous storage	5-in. x 15-ft 4-in.[b] stainless steel	185	$Pu(NO_3)_4$[a]
TK-36	Process cell	CAIS pump tank to CA column	5-in. x 45-in.[b] stainless steel	45	$Pu(NO_3)_4$

Table 8-2. Potential Radiation Sources in Plutonium Reclamation Facility. (4 sheets)

Equipment number	Location	Function*	Description	Working volume (L)	Former process chemical form
TK-37	Process cell	CAX pump tank	5-in. x 15-ft 4-in. stainless steel[b]	185	TBP and CCl4
TK-38	Process cell	CAX pump tank	5-in. x 48-in. stainless steel[b]	185	TBP and CCl4
TK-39	Process cell	CAW receiver tank (waste)	5-in. x 15-ft 4-in. stainless steel[b]	185	$Pu(NO_3)_4$
TK-40	Process cell	CXP receiver tank (waste)	5-in. x 13-ft. 8-in. stainless steel[b]	185	$Pu(NO_3)_4$
TK-41	Process cell	CUU receiver tank (waste)	5-in. x 45-in. stainless steel[b]	45	$Pu(NO_3)_4$
TK-42	Process cell	Concentrator feed tank	5-in. x 45-in. stainless steel[b]	45	$Pu(NO_3)_4$
TK-43	Process cell	Product concentrator	4-in. x 10-ft 9-in. stainless steel with annular steam jacket	5	$Pu(NO_3)_4$
TK-44	Process cell	Condenser	6-in. x 3-ft 8-in. stainless steel	N/A	N/A
TK-45	Process cell	PR tank	5-in. x 45-in. stainless steel[b]	45	$Pu(NO_3)_4$
TK-46	Process cell	PR tank	5-in. x 45-in. stainless steel[b]	45	$Pu(NO_3)_4$
TK-20	Process cell	Evaporator	5-in. x 45-in. stainless steel[b]	45	$Pu(NO_3)_4$
TK-21	Process cell	Evaporator feed	6-in. x 72 in. stainless steel with shell & tube heat exchanger	25	$Pu(NO_3)_4$
TK-22	Process cell	Condenser for Evaporator TK-21	6-in. x 44-in. stainless steel	N/A	N/A
TK-23	Process cell	Evaporator receiver for TK-21	5-in. x 45-in. stainless steel[b]	45	$Pu(NO_3)_4$
TK-24	Process cell	Evaporator receiver for TK-21	5-in. x 45-in. stainless steel[b]	45	$Pu(NO_3)_4$
TK-25	Process cell	Mt receiver tank	5-in. x 45-in. stainless steel[b]	45	$Pu(NO_3)_4$

Table 8-2. Potential Radiation Sources in Plutonium Reclamation Facility. (4 sheets)

Equipment number	Location	Function*	Description	Working volume (L)	Former process chemical form
TK-26	Process cell	MT receiver tank	5-in. x 45-in.,[b] stainless steel	45	$Pu(NO_3)_4$
TK-27	Process cell	CAR supply to CA column	5-in. x 45-in.,[b] stainless steel	45	$Pu(NO_3)_4$
TK-29	Process cell	CAS pump tank to CA column	5-in. x 45-in.,[b] stainless steel	45	N/A
TK-30	Process cell	CCX pump tank to CC column	5-in. x 45-in.,[b] stainless steel	45	N/A
TK-128	Process cell	PR tank	5-in. x 45-in.,[b] stainless steel	45	$Pu(NO_3)_4$
TK-49	Process cell	Miscellaneous transfer tank	5-in. x 45-in.,[b] stainless steel	45	$Pu(NO_3)_4$
TK-52.1 & TK-52.2	East glovebox	East drain header receiver tanks	6-in. x 2-ft 6-in. glass pipe	20	$Pu(NO_3)_4$
TK-52.3 & TK-52.4	West glovebox	West drain header receiver tanks	6-in. x 2-ft. 6-in. glass pipe	20	$Pu(NO_3)_{4a}$
TK-70	Process cell	CXX pump tank	5-in. x 45-in.,[b] stainless steel	45	$Pu(NO_3)_4$[a]
TK-58	Room 50 glovebox	Organic deentrainment	4-in. x 2-ft. 6-in. glass pipe	10	$Pu(NO_3)_4$
TK-120	Process cell	CAP pump tank	5-in. x 45-in.,[b] stainless steel	45	a
TK-WM-1	Process cell	CAW receiver		185	$Pu(NO_3)_4$
D centrifuge	West glovebox	Solids removal from product	5.6-in. x 14-ft 4-in. stainless steel, 3 tubes	2.7	$Pu(NO_3)_4$
B1 & B2 centrifuges	MT-6 glovebox	Solids removal from waste stream (CAW)	Stainless steel	2.7	$Pu(NO_3)_4$
Filter 16.1	East glovebox	Solids removal from feed solution	Stainless steel	N/A	$Pu(NO_3)_4$[a]
Filter 16.2	East glovebox	Solids removal from feed solution	N/A	N/A	$Pu(NO_3)_4$
Filter 5.1	West glovebox	Filter for solids removal	N/A	N/A	$Pu(NO_3)_4$

Table 8-2. Potential Radiation Sources in Plutonium Reclamation Facility. (4 sheets)

Equipment number	Location	Function*	Description	Working volume (L)	Former process chemical form
TK-C1	MT-6 glovebox	Vacuum catch tank for TK-C2 and TK-C3	4-in. x 1-ft. 6-in. stainless steel	5.6	$Pu(NO_3)_4$
TK-C2	MT-6 glovebox	Receiver tank for MT solutions	Glass	13.9	$Pu(NO_3)_4$
TK-C3	MT-6 glovebox	Receiver tank for MT solutions	Glass	14.4	$Pu(NO_3)_4$
C centrifuge	MT-6 glovebox	Solids removal from liquid feed for solvent extraction	Stainless steel	2.7	$Pu(NO_3)_4$

[a] $Pu+4.2TBP.4NO_3$.
[b] Equals four tubes per tank.
[c] Solid.
*S&C = slag and crucible
DBP = dibutyl phosphate
•CA = first column of PRF solvent extraction process
CAW = column aqueous waste
•CAIS= plutonium rich reflux stream
•CAX = column organic extract
CXP = solvent cleanup waste
CUU = column uranium waste
PR = product receipt
•CCX = .04M hydroxylamine nitrate, .2 M nitric acid, & .05 M hydrazine
•CXX = dispersed aqueous solution ascending through downward flow of organic in CX column
•CAP = CA column product stream

Table 8-3. Potential Radiation Sources in Remote Mechanical C Line. (3 sheets)

Equipment type*	Location	Function	Description	Working volume (L)	Former process chemical form
VDF & Pan	HC-9B	Plutonium oxalate solids are separated from the filtrate	5-in. x 11-in.-dia 8-in. x 7-in. 8.25-in. x 10-in. 0.5-in.	222.2	$Pu(NO_3)_4$
Calciner	HC-9B	Discomposes plutonium oxalate solids to PuO_2	6-ft 9-in. stainless steel through x 4-in.-dia. screw	N/A	PuO_2 **
Fluorinator	HC-9B	Conversion of PuO_2 to PuF_4	5 ft 6 in. long x $\frac{1}{4}$ in. high made of inconel™ with platinum-iridium liner	N/A	PuF_4
Powder pans	HC-1* HC-11	Interim storage and transport of PuF_4 powder	7-in. x 6-in. high pans	1.7	PuF_4
Mixer/dumper (abandoned in place)	HC-13MD	Mixing calcium metal, iodine crystals with PuF_4 powder (abandoned in place) Glovebox is used for seal-in/seal-out of material to/from thermal stabilization processes	10-in.-diameter x 3-in. high Lexan™ mixer that tapers conically to 7 in.	6.5 N/A	PuF_4 PuO_2 (current process chemical form)
Induction furnaces (3)	HC-15	Firing of reduction charge	3/8-in. OD, 0.035-in. wall thickness copper tubing coiled around a heat-resistant type with an 8-in. OD and 1/8-in. wall thickness	N/A	PuF_4
PV	HC-1* HC-12S HC-13MD HC-15 HC-16CC HC-17DC	Contains PuF_4 charge along with chemicals for reduction, crucible, and MgO sand	7-in. x 12.7-in Hastelloy™ X	4.3	PuF_4, plutonium metal, plutonium S&C
Damper hammer mill	HC-17DC	Separate the plutonium metal and grind up the sand, S&C	N/A	N/A	Plutonium metal, plutonium S&C
B valve	HC-9B	Transfer PuO_2 from calciner to flourinator	N/A	N/A	PuO_2

Table 8-3. Potential Radiation Sources in Remote Mechanical C Line. (3 sheets)

Equipment type*	Location	Function	Description	Working volume (L)	Former process chemical form
Reactor	HC-9B	Formation of oxalate slurry	6-in. schedule-10 stainless steel	2.7	$Pu(NO_3)_4$
VRT	HC-9B	Supplies vacuum to the VDF	6-in. x 2-ft glass tank	11	$Pu(NO_3)_4$
CRT	HC-9B	Receives offgases from the calciner	6-in. x 1-ft glass tank	5.5	$Pu(NO_3)_4$
OT	HC-9B	Catch tank for overflow of VDF pan	6-in. x 1-ft glass tank	5.5	$Pu(NO_3)_4$
Batch tanks	HC-227S	Blending and sampling	6-in. x 8-ft. glass tank (3)	44.5	$Pu(NO_3)_4$
Vacuum trap	HC-227S	Prevent solutions from entering 26-in. vacuum system	6-in. x 1-ft 5-in. glass tank	8.3	$Pu(NO_3)_4$
Load-out tank	HC-227S cell	Product staged for loadout	6-in. x 2-ft glass tank	11	$Pu(NO_3)_4$
Storage tanks	HC-4	Interim product storage	6-in. x 4-ft glass tank	22	$Pu(NO_3)_4$
ACT	HC-7	Receiver tank for miscellaneous solutions	6-in. x 4-ft glass tank	22	$Pu(NO_3)_4$
Vacuum trap and E-4 vent trap	HC-7	Prevent solutions from entering 26-in. vacuum system	6-in. x 1-ft glass tank	5.5	$Pu(NO_3)_4$
Vacuum tank	HC-7	Prevent solutions from entering 26-in. vacuum system	6-in. x 1-ft glass tank	5.5	$Pu(NO_3)_4$
PMT	HC-7	Meter H_2O_2	3-in. x 1-ft 10-in. stainless steel tank	1.4	H_2O_2

Table 8-3. Potential Radiation Sources in Remote Mechanical C Line.
(3 sheets)

Equipment type*	Location	Function	Description	Working volume (L)	Former process chemical form
PRT	HC-7	Plutonium valence adjustment	6-in. x 3-ft glass tank	16.7	$Pu(NO_3)_4$ H_2O_2
THT	HC-7	Feed tank	6-in. x 3-ft glass tank	16	$Pu(NO_3)_4$
FKT/FCT	HC-7	$KMnO_4$ used to eliminate $C_2H_2O_4$	5-in. interconnected glass tank	22	$Pu(NO_3)_4$
FST	HC-7	Sampling and transfer of filtrate solution to PRF	6-in. x 6-ft glass tank	33-36	$Pu(NO_3)_4$

* The HC-1 conveyor glovebox is currently utilized in the thermal stabilization process.
** They may still exist in process vessel.

VDT = vacuum drum trap
*VDF = vacuum drum filter
PV = pressure vessel
VRT = vacuum receiver tank
CRT = condensate receiver tank
OT = overflow tank
ACT = aqueous catch tank
PMT = peroxide measuring tank
PRT = pre-reduction tank
THT = transfer head tank
FKT = filtrate kill tank
FCT = filtrate catch tank
FST = filtrate storage tank

Table 8-4. Liquid Effluent Waste Ranges.*

Activity (normal range)	Source	Collection point
<2 E-10 Ci/L	Cooling and seal water 234-5Z HVAC drains, steam condensate drains, roof drains (west end), cold chemical drains, 2736-ZB HVAC condensate drains	Manhole Z-1
<2 E-10 Ci/L	The 234-5Z storm drains, ventilation condensate, and Manhole 1 drain	Manhole Z-2
<2 E-10 Ci/L	The 234-5Z D-1, D-2 drain headers. Roof drains (east end), 242-Z D-1 drain header and 291-Z sump	Manhole Z-3
<2 E-10 Ci/L	The 236-Z condensate drains, drain headers D-1, D-3, and Manhole Z-3 drain	Manhole Z-4
<2 E-10 Ci/L	Manholes S-7 and C-1	Manhole C-2

*Liquid effluent waste system is discussed in Chapters 5.0 and 7.0.

Table 8-5. Potential Plutonium Sources Contained in Gloveboxes and Hoods. (3 sheets)

Glovebox /hood	Location	Description	Physical form	Nominal chemical form
HC-60	Room 230-C	Framed glovebox with Lexan™ panels and 40.8-in. gloveports	Liquid/solid (sludge)	$Pu(NO_3)_4$ Organic
HA-40F	Room 169	Stainless steel glovebox	Solid	Plutonium ash
HA-46F	Room 170	Stainless steel glovebox with Lucite™ panels and lead shielding	Solid	Plutonium ash
Glovebox 636	Room 636, 2736-2B	Stainless steel glovebox with Lucite™ panels impregnated with lead	Solid	PuO_2, plutonium metal, PuF_4
HA-20MB	Room 235-B	Stainless steel glovebox with Lucite™ panels	Solid	PuO_2, plutonium metal, PuF_4
HA-21I	Room 235-B	Stainless steel with Lucite™ panels and lead shielding	Liquid/solid (sludge)	Plutonium process residues, plutonium ash, non-organics
HA-22B	Room 235-B	Stainless steel with Lexan™ or Lucite™ panels and lead shielding	Liquid/solid (sludge)	Plutonium process residues
HA-23S	Room 235-B	Stainless steel glovebox with water walls for shielding	Liquid/solid (sludge)	Plutonium process residues
H-7A	Room 235-A1	Stainless steel glovebox with Lucite™ panels	Liquid	$Pu(NO_3)_4$

Table 8-9. Estimated Quantities of Radiation Sources Located in Plutonium Finishing Plant E-4, 26-in. Mercury Process Vacuum and Exhaust Manifold Systems.

System	Location	Description content	Estimated plutonium content	Plutonium form	Chemical
E-4 Exhaust	Rooms 262,263, 264, 308, and 302	Approximately 4,000 linear ft of 2-in. to 68-in. duct work	4.1 kg[a]	Solid	PuO_2 residues
26-in. vacuum	Room 265	The 0.75-in. piping drops from first floor to main heater. Approximately 825 ft of 2-,3-, and 4-in. schedule-40 stainless steel piping	4.3 kg[b]	Solid	PuO_2 residues
Exhaust manifold	Rooms 262, 308, and down to base of 291-Z stack	Approximately 42,000-ft^2 132-in.x 132-in. (nominal size duct work)	0.01 kg[c]	Adhered solid	PuO_2 residues

[a]Westsik 1999.
[b]Westsik 1989.
[c]Westsik 1989a.

Table 8-10. Criteria for Posting.

Radiation areas	
Area	Dose rate criteria
Radiation area	>0.005 rem/h and <0.1 rem/h at 30 cm
High radiation area	>0.1 rem/h at 30 cm and ≤500 rad/h at 100 cm
Very high radiation area	>500 rad/h at 100 cm
Hot Spot	5 times general area dose rate and >0.1 rem/h
Contamination areas	
Contamination	Contamination levels >1 time but ≤100 times 20 dpm/100 cm^2 (transuranic)
High contamination	Contamination levels >100 times 20 dpm/100 cm^2 (transuranic)
Fixed contamination	Removable contamination levels < 20 dpm/100 cm^2; total contamination levels > 500 dpm/100 cm^2 (transuranic)
Soil contamination	Contaminated soil not releasable in accordance with DOE Order 5400.5
Airborne radioactivity	Concentrations ($\mu Ci/cm^3$) >10% of any DAC value

Table 8-11. Hanford Site Radiological Administrative Control Levels.

Maximum dose equivalent (annual; mrem)				
TEDE	Skin and extremity[a]	Lens of eye[a]	Any organ[a]	Approval required to exceed this level[b]
500	15,000	4,500	15,000	Level 3 line manager and RCM[c]
1000	22,500	6,750	22,500	Level 2 line manager and RCM
1500	30,000	9,000	30,000	Contractor senior site executive
2000				DOE PSO
Age x 1,000 = lifetime TEDE				Level 1 line manager and RCM

Source: Project Hanford Radiological Manual (HNF-5173, Rev. 0, FH 2000).
[a] The values are based on the nonstochastic limit and are calculated as committed doses.
[b] Approvals are sequential.
[c] Approval may be delegated within the Radiological Control Organization.

DOE - U.S. Department of Energy.
PSO - Program Secretarial Officer.
RCM - Radiological Control Manager.
TEDE - total effective dose equivalent.

Table 8-12. U.S. Department of Energy Radiation Protection Standards Limiting Values for Assessed Dose from Exposure of Occupational Workers to Radiation.

Type of exposure	Dose (rem)
Stochastic effects	5.0 (annual TEDE*)
Nonstochastic effects	
Lens of eye	15.0
Extremity	50.0
Skin of the whole body	50.0
Organ or tissue	50.0
Unborn child Entire gestation period	0.5

Criticality alarm system	X					X					X		X	
Nuclear accident dosimeters			X			X								
Personal nuclear accident dosimeters			X			X								

[a] Previous designation.
[b] The units used as environ monitors are modified versions of the asic + HMTD units.
[c] Only parts applicable to nuclear facilities implemented.

Table 8-18. Plutonium Finishing Plant Portable Radiation Monitoring Instruments. (2 sheets)

Name (nominal)	Detection type	Range	Minimum detectable energy (without β shield)[a]	Calibration		Linearity	Accuracy (as calibrated)
				Frequency	Method		
CP	Air-filled ionization	0-5,000 mrem/h	β≥65 keV Y≥5 keV	Annual	Uniform field ^{137}Cs	±5	+10% -5
LPC	Air-filled ionization	0-5,000	β≥0.3 keV Y≥5 keV	Annual	Uniform field ^{137}Cs	+10 -5	+10% -5
EGM	Pancake GM	0-100,000 counts/min	β≥70 keV Y≥5 keV	Annual	^{14}C ^{90}Sr-^{36}Cl Y, ^{230}Th	±5	N/A
PAM	ZnS Scintillation	0-100,000 counts/min	α±4 Mev[a]	Annual	^{230}Th	±5	N/A
XCP	Air-filled ionization	0-5,000 mrem/h	β±70 keV Y≥5 keV	Annual	Uniform field ^{137}Cs	±5	+10 -5
Bumble bee	Air-filled ionization	0-5,000 mrem/h	β≥65 keV Y≥5 keV	Annual	Uniform field ^{137}Cs, ^{230}Th, U_{pat}	±5	+10% -5
Snoopy	BF^3 Proportional	0-2,000 mrem/h	Neutrons thermal to 15 Mev[a]	Quarterly	^{252}CF source ^{60}Co	±10	+10% -5
Ludlum 177-8	Pancake GM	0-500,000 counts/min	β≥70 keV Y≥5 keV	Annual	^{14}C ^{36}Cl, ^{90}Sr-^{36}Y, ^{230}Th	±2	N/A
Poppy	Air-filled proportional	0-500,000 counts/min	α≥4 Mev[a]	Annual	^{230}Th ^{239}Pu	±1.5	N/A
HRCP	Air-filled ionization	0-50,000 rem/h	β±44 keV Y≥5 keV	Annual	Uniform field ^{137}Cs and ^{60}Co	±10	+10% -5

Table 8-18. Plutonium Finishing Plant Portable Radiation Monitoring Instruments.
(2 sheets)

Name (nominal)	Detection type	Range	Minimum detectable energy (without β shield)[a]	Calibration		Linearity	Accuracy (as calibrated)
				Frequency	Method		
Alpha CAM (Eberline Alpha-5)	Silicon diffused junction	1-10,000 counts/min	α≥1.5 MeV	Annual	^{239}Pu	±10	±15%

Source: PNL-MA-562 (PNL 1988c).
[a]Where applicable.
[b]NIST (formerly NBS) traceable.
[c]Designed to 8 DAC-h for ^{239}Pu (achievable under laboratory conditions) but these are the practical field use values.
α = Alpha.
β = Beta.
γ = Gamma.

Table 8-19. Respiratory Protection Factors.

Respirator type	Protection factor
Full-face mask	100
Duo flow, air purifying	100
Powered air purifying	1,000
Duo flow, supplied air	1,000
Consistent flow without egress air	1,000
Pressure demand air line	1,000
Content flow hood	1,000
Pressure demand air line with egress air	10,000
SCBA	10,000

Table 8-20. Not Used

Table 8-21. Notification Criteria for PFP.

Criteria for Notifying Radiological Central Standards Group		
Indicator	Alpha Emitters (dpm)	Beta/Gamma Emitters (dpm)
Nasal or Mouth smears	>BKG	>BKG
Facial contamination[b]	>200	>4,000
Head/neck contamination	>2,000	>40,000
Contamination Inside Respirator	>DL	
Airborne contamination	Acute exposure >10 DAC-hours[b] (after incorporating respiratory protection factor)	
Hands, Forearms, clothing[a] (spotty, loose)	>10,000	>200,000

(a) Clothing contamination levels apply to exposure without respiratory protection, such as contamination levels on inner coveralls while undressing.

(b) DAC-hours = time-integrated exposure to airborne contamination.

Criteria for Notification to Medical (First Aid or HEHF Physician)		
Indicator	Alpha Emitters (dpm)	Beta/Gamma Emitters (dpm)
Nasal or Mouth Smears	>1,000	>100,000
Facial contamination	>25,000	>500,000
Head/neck contamination	>100	>20,000

NOTE; HEHF EMERGENCY CONTACT, FDH Radiation Protection Central Standards Group, PNNL Exposure Evaluator AND PATROL OPERATIONS CENTER.

Table 8-22. Not Used

Table 8-23. Offsite Doses for Ground and Stack Level Releases from PFP Based on Annual $\overline{\chi}/Q$'s (Chronic release).

Release type	EDE		Maximum Organ[a]
Maximum individual			
Ground level	3.0 E-08 rem		5.5 E-07 rem
Stack level	1.0 E-06 rem		1.9 E-05 rem
Population	Unit in person-rem	Health effect	Unit in person-rem
Ground level	8.0 E-04	4.0 E-07 LCF[b]	1.5 E-02
Stack level	4.4 E-02	2.2 E-05 LCF[b]	8.2 E-01

[a]The maximum organ for all cases is the bone surface.
[b]Latent cancer fatality.

Subj	Residual Plutonium In Remediation Project		Date: January 07, 1999

In early 1996 the PFP Remediation Project Segment 2, a 57 foot long segment of glovebox exhaust ventilation ductwork located in rooms 263 and 264 of 234-5Z, was removed. Prior to removal the segment of 6" diameter ductwork was assayed in about 1977 and then again in 1996. During the removal process the individual cut out pieces were assayed. These measurements were all performed using NaI-based detection systems. The sections of ductwork were scraped and the material assayed using segmented gamma scanning (SGS) technology. The waste from these processes was placed in waste drums and assayed again using SGS technology. Below is a summary of the assay results from the various measurements.

1.	~1977 assay *in situ*	1800 g Pu
2.	January 1996 assay *in situ*	1354 g Pu
3.	Removed ductwork sections assayed prior to scraping	1878 g Pu
4.	Assay of material scraped from ductwork plus waste drums	2183 g Pu

The results from assays after removal confirm the initial assay data. They also give an indication of the stability of plutonium holdup over time. The material does not appear to have moved in the nearly twenty years between assays. Based on this information the current accountability value of 4.1 kg Pu is confirmed also.

Please contact me on 373-1947 if you have any questions.

AES File/LB			

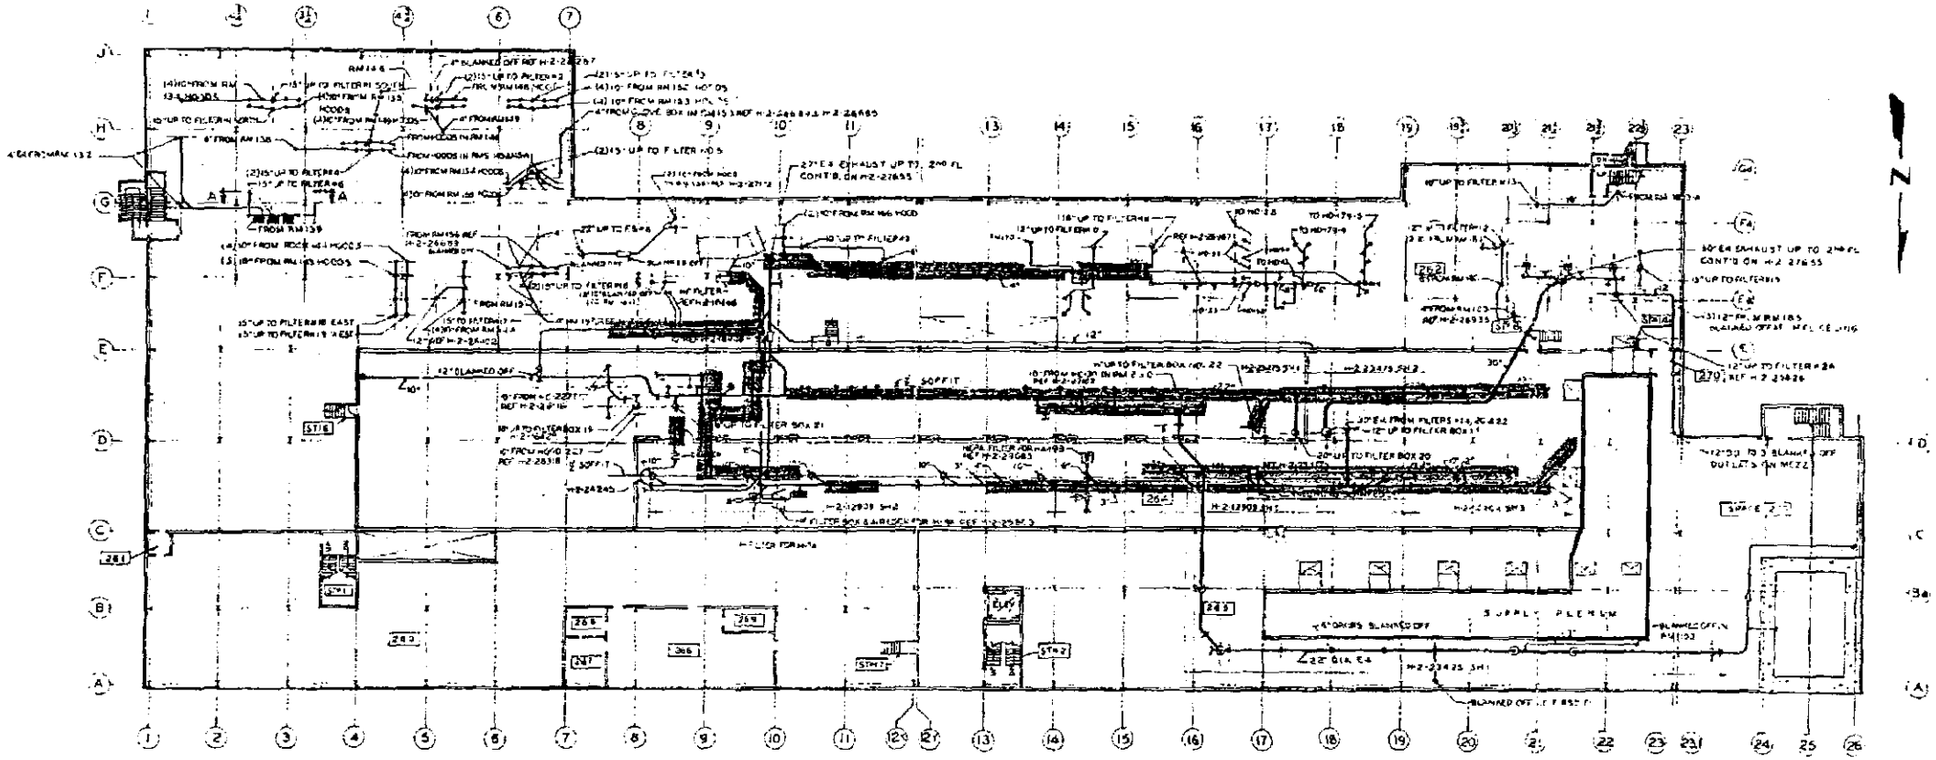
In support of Remote Mechanical C (RMC) Line Startup the Plutonium Finishing Plant (PFP) Analytical Laboratory has been requested to further evaluate, and summarize, the measured plutonium holdup in the E-4 ducting of the PFP. This compilation of nondestructive assay (NDA) and "radiation survey" data was made in cooperation with PFP Process Engineering, Process Chemistry & Engineering Laboratory and Analytical Chemistry Services Laboratory personnel.

Based on a process engineering estimate, the total length of E-4 ducting in the PFP is approximately 4,000 linear feet. During previous campaign and contractor turnover inventories, 960 linear feet of E-4 ducting was measured for plutonium holdup using standard portable NDA equipment. These NDA measurements, documented in Internal Memo Number 12243-88-081, revealed a measured plutonium holdup of 5 Kg with a range of 3.5 Kg to 7.1 Kg.

To satisfy concerns on the amount of plutonium holdup in unmeasured areas of the E-4 ducting, a "radiation survey", using a collimated CP meter, was made of the remaining 3,040 linear feet of E-4 ducting. This "radiation survey" was used to locate areas of E-4 ducting for additional NDA measurements. The results of these additional NDA measurements are documented in Internal Memos Number 12234-88-NMU-029 and Number 12221-88-088. This "radiation survey" revealed a plutonium holdup of 0.65 Kg over roughly 3,016 linear feet of E-4 ducting with an undetermined uncertainty. This same "radiation survey" revealed an additional 24 linear feet of ducting which contained a significantly higher plutonium holdup than the 3,016 linear feet. This portion of the E-4 ducting was also measured nondestructively using standard portable NDA equipment and revealed a measured plutonium holdup of 0.33 Kg with a range of 0.13 Kg to 0.49 Kg.

A. D. Danko
Page 2
May 11, 1988

The combined plutonium holdup in PFP E-4 ducting is estimated to be 6 Kg. Since the systematic error, or bias, for the combined assay data is not known, the total uncertainty cannot be evaluated.



The location of this material holdup is graphically presented in Attachment I, by type of assay, and Attachment II, by material loading in grams plutonium per foot of ducting. Any questions on this subject can be addressed to me or Mr. R. A. Jones on 373-2886.

Subject: CORROSION RATES FOR SOLUTIONS STORED AT PLUTONIUM FINISHING PLANT

TO: E. C. Vogt T5-50

cc: M. W. Gibson T5-55
L. H. Rodgers T5-53
WSL File/LB

There is a large quantity of plutonium bearing solutions stored at the Plutonium Finishing Plant (roughly 4100 liters). Of this quantity, the majority is in a nitric acid matrix and is stored in stainless steel PR cans. A small subset of these solutions are stored in 10-L containers and are in a HCl matrix. These items (27 items) represent a serious potential for leaking. The U.S. Department of Energy, Richland Operations Office, (DOE-RL) has requested information on the expected corrosion rates of these containers.

The FL-10 container is a 10 liter polyethylene bottle (polybottle) that is roughly 4 feet high and 4 inches in diameter. The bottle is set inside a 6 inch schedule 40 stainless steel pipe. This, in turn, is placed inside a set of two 55 gallon drums that are stacked on each other and welded together. The polyethylene becomes embrittled over time due to radiolysis and acid attack. The 10-Ls have been in storage for roughly 20 years and the integrity of the polybottles are suspect. Neither the stainless steel pipe or the carbon steel outer drums are designed to with stand HCl corrosion.

The corrosion rates for 304L stainless steel in HCL solutions are sketchy . The "Metals Handbook Ninth Edition", Volume 13, Page 1162 states:

> The commonly used austenitic stainless steels, such as 304 and 316, are nonresistant to HCl at any concentration and temperature. At ambient temperatures and above, corrosion rates are high.

High corrosion rates are rates that are over 20 mpy (0.02 inches/yr). The rates could be much higher. At a rate of 20 mpy a schedule 40 stainless steel wall (0.28 inches) would last about 13 years. Chances are the rates are much higher.

Some of the solutions contain low concentrations of HF. In a corrosion study performed at the Idaho Chemical Processing Plant by H.S. Cole in 1974 indicate that at room temperature corrosion rates of 0.1 M HF in a nitric acid matrix has corrosion rates around 10 mpy. Due to the low HF concentrations the HCl rates bound the corrosion rates.

In the absence of rate data x-ray photography using an Iridium source for assessing the integrity of the polybottles is planned. This is the same technology that is currently used to x-ray welds. The x-rays will show a shadow of the edge of the stainless steel pipe, the polybottle and the liquid level. Any solution that may have leaked out of broken polybottle into the annular space inside the pipe will also be visible. If any leaking polybottles are identified, the outer drum will be opened, the stainless steel pipe will be visually inspected for signs of corrosion, and an acid absorbent will be placed in the bottom of the drum to prevent corrosion of the drum as a precautionary measure. These items will be the first items to be transloaded and stabilized once the necessary modifications to glovebox 227 have been completed as identified in the plant integrated schedule.

The PR cans contain plutonium bearing solutions in a nitric acid matrix. The 304L containers have excellent corrosion resistance to nitric acids.

The reference above states that:

> The basic corrosion data for the austenitic stainless steels is plotted (see page 1155). The diagram shows the effect of the temperature and HNO3 concentration on the corrosion of type 304 stainless steel (304L will be a little better). Increasing either or both the temperature of the acid concentration increases the corrosion rate. At room temperature or the acid concentration needs to reach 100% to reach a rate of 0.13 mm/yr. Most of the PR containers are schedule 80 pipe (wall thickness 0.432 inches). A few (the Mark IV type) are schedule 40 (wall thickness of 0.28 inches). Regardless, it would take over 50 years for the acid to corrode through the schedule wall if the acid were 100%.

In conclusion the HCl based solution represent a major concern that should be addressed in the near term. Pu nitrate solution does not represent a significant corrosion hazard and allows safe storage well beyond the expected completion of the Environmental Impact Statement.

PLUTONIUM FINISHING PLANT
FINAL SAFETY ANALYSIS REPORT

CHAPTER 9.0

ACCIDENT SAFETY ANALYSIS

FEBRUARY 2001

This page intentionally left blank.

PREFACE

Revision 2 of Chapter 9.0 of the Plutonium Finishing Plant (PFP) Final Safety Analysis Report (FSAR) consists of modifications to incorporate additional thermal stabilization operations in Gloveboxes HC-21C and HA-21I and new operations involving solution stabilization using the Magnesium Hydroxide Precipitation Process and plutonium material packaging operations using the Bagless Transfer System. Engineering Change Notice 632069 appended the thermal stabilization of non-product quality oxide feed material addendum (HNF 1999b) to the PFP FSAR allowing non-product quality, reactive plutonium-bearing material to be thermally stabilized in Glovebox HC-21C. All reactive plutonium-bearing material suitable for stabilization in Glovebox HC-21C, except PRF sludges, can also be thermally stabilized in Glovebox HA-21I. The Magnesium Hydroxide Precipitation Process addendum (Carson 2000) to the PFP FSAR has been incorporated in Revision 2. In addition, the calculation notes for the Bagless Transfer System (FH 2000) have been incorporated in Revision 2 of the FSAR. The total facility dose from a seismic analysis was previously discussed only in the Laboratory Prototype Calciner addendum. In this revision (Rev 2), the total facility dose from a seismic analysis is discussed in Section 9.2.4.12 and only the Laboratory Prototype Calciner portions are discussed in the addendum. A few editorial changes have also been incorporated in this revision of the FSAR.

It is noted that various sections of Chapter 9.0 present information concerning plutonium-bearing solution stabilization operations using the Production Vertical Denitration Calciner located in the RMC Line and the Laboratory Prototype Calciner in the Plutonium Process Support Laboratories. Operation of either the production calciner or the laboratory calciner for solution stabilization is not authorized at this time and the related portions of Chapter 9.0 will be updated, if necessary, prior to initiation of operations. Portions of the Hazard Evaluation in Appendix 9A for thermal stabilization operations in Gloveboxes HC-21A, HC-21C, HC-18BS, and HC-18M have been superseded by the hazard evaluations in Appendices 9F and 9G.

The new packaged boilers operated by Johnson Controls, Inc. which provide steam to the PFP were previously incorporated in the FSAR. This included switching the emergency exhaust fans from those which are steam-driven to those which are connected to the backup power system. However, the conversion from using steam-driven fans to backup power driven fans has not been fully implemented. The emergency exhaust fans are currently run by the new steam supply system installed under the Hanford energy conservation program. Electrically-driven emergency exhaust fans are planned to be connected to the diesel-generator standby power supply during Fiscal Year 2000. A supplemental ECN has been written for the FSAR to reflect the continued use of the steam-driven emergency exhaust fans currently in operation. The emergency exhaust fan functions are unchanged from that described in the FSAR regardless of the type and source of power.

The significant areas of change in Revision 2 are indicated by vertical bars in the margin of each affected page.

This page intentionally left blank.

CONTENTS

9.0 ACCIDENT SAFETY ANALYSIS 9-1
9.0.1 Introduction 9-1
9.0.1.1 Summary Conclusion 9-1
9.0.1.2 General Observations 9-1
9.0.2 Preliminary Analysis 9-4
9.0.2.1 Discussion 9-4
9.0.2.1A Preliminary Hazards Analysis of Plutonium-Bearing Solution Stabilization Process Using the Production VDC Process 9-6
9.0.2.1B Preliminary Hazards Analysis of Thermal Stabilization of Plutonium Oxide Process . . 9-7
9.0.2.1C Preliminary Hazards Analysis of the Laboratory Prototype Calciner 9-8
9.0.2.1D Thermal Stabilization of Metal 9-8
9.0.2.1E Preliminary Hazards Analysis of Chemical Hazards 9-8
9.0.2.2 Screening Process, Plutonium Releases 9-9
9.0.2.3 Functions Excluded from Analysis 9-10

9.1 ABNORMAL OPERATIONS 9-11
9.1A ABNORMAL OPERATIONS FOR THE PLUTONIUM-BEARING SOLUTION STABILIZATION PROCESS USING THE PRODUCTION VERTICAL DENITRATION CALCINER 9-11
9.1B ABNORMAL OPERATIONS FOR THE THERMAL STABILIZATION OF PLUTONIUM OXIDE PROCESS 9-12

9.0 ACCIDENT SAFETY ANALYSIS

9.0.1 Introduction

Chapter 9.0 contains analyses of a number of potential accidental events that could have adverse radiological or chemical consequences. Abnormal events considered in Section 9.1 address scenarios that could result in radiological consequences to plant personnel but where plant confinement barriers are not significantly challenged and hence significant consequences outside the facility are not expected. The primary focus of the accidents addressed in Section 9.2 is on the consequences to offsite individuals and to workers onsite but in adjacent facilities. The analyses of events affecting onsite and offsite people combine probability and consequences to develop a risk level. The risk level is then compared to acceptability guidelines in order that Management can evaluate the safety status of the plant.

The chapter includes three sections in addition to the sections on abnormal operations and accidents. These are a description of the screening process through which the detailed analyses were chosen, a discussion of the methods used to calculate radiation dose, and a section presenting the risk guidelines.

9.0.1.1 Summary Conclusion. There were no events analyzed that had unacceptable consequences as defined by the guidelines presented in Section 9.4.

9.0.1.2 General Observations. During the process of developing Chapter 9.0 a number of general observations were made that may not be apparent when looking at individual events. These observations are presented below.

9.0.1.2.1 Site Impact on Offsite Safety. The site is described in detail in Chapter 3.0. However, it is appropriate to identify specific qualities of the site which reduce the impact of the Plutonium Finishing Plant (PFP) on the nearest offsite individuals. The PFP is on a 560-mi^2 government owned, U.S. Department of Energy (DOE) controlled site. The surrounding region has a low population density as demonstrated by 1990 data. The population density is 20 persons per square mile within a 20-mi radius and increases to 42 persons per square mile within a 50-mi radius. The density drops to 7 persons per square mile in the 22.5° sector identified in the worse case scenario. These features emphasize the isolation and low availability of population to exposure.

9.0.1.2.2 Site Impact on Onsite Safety. Processing plants in the Hanford 200 Areas were built with considerable separation from each other. Early site design criteria addressed the prospect of attack by Japanese carrier-based aircraft. Spacing and orientation of the buildings were intended to make them less vulnerable to attack and more easily defended. It is not clear how much consideration went into protection of adjoining onsite personnel from radiological harm, but the fact is that the protection is provided. The 234-5Z Building was built on the western side of the 200 West Area, as a result of considerations for safety, security, and convenience. Thus accidental releases of radioactive materials or chemicals

are considerably dispersed before they potentially impact the non-PFP or onsite person.

9.0.1.2.3 Plant Features Impacting Safety. Chapter 5.0 provides a detailed physical description of the plant. The plant contains approximately 220,000 ft^2 considering all levels. Ten percent of the space is active in plutonium processing. The major processing areas are surrounded by reinforced concrete walls. The remaining areas are used for laboratories, service areas, offices, utilities, ventilation, filter rooms, and small batch processes.

The main facility, 234-5Z, was designed based on criteria circa 1943 to 1949 and construction was completed in 1949. The 234-5Z Building has a structural steel framework with outer panels consisting of steel sheeting, insulation and aluminum sheeting. Eight-inch reinforced concrete internal walls separate major process and storage areas into compartments. These areas and the rest of the building are subdivided by metal or plaster on metal lath walls. The roof, which was upgraded in 1983, is a Factory Mutual Class 1 roof over a pre-existing metal deck. Considering the time period and the existing structure, the design likely leaned heavily on the primary operating contractor's experience with facilities used to process hazardous materials. Later buildings were also designed as isolated compartments. This separation of process lines and storage areas enhances the safety of the plant.

9.0.1.2.4 Process Operations Impacting Safety. Chapter 6.0 contains detailed descriptions of PFP process operations. These operations include the following:

- Special Nuclear Material (SNM) shipping/receiving
- SNM storage
- Remote Mechanical A (RMA) and Remote Mechanical C (RMC) Line operations, including reactive material stabilization and plutonium-bearing solution stabilization using the Production Vertical Denitration Calciner (VDC)
- Laboratory support
- Facility cleanout activities
- Radioactive waste handling.

A narrative description of SNM receiving/sorting/storing and shipping is provided in Section 6.2 and 6.3. Reactive material undergoes thermal stabilization conducted in gloveboxes HC-21C and HA-21I. Plutonium-bearing solutions are stabilized using the Production VDC in glovebox HC-230C-2. Narrative descriptions and detailed information are contained in Section 6.4.1.

The PFP contains three laboratories: the Plutonium Process Support Laboratories (PPSL), the PFP Analytical Laboratory (PFPAL), and the Standards Laboratory. Information regarding these laboratories is provided in Section 6.5. Radioactive and mixed waste handling operations are addressed primarily in Chapter 7.0, and facility cleanout activities are addressed in Section 6.7.

Any future operations involving plutonium recovery and conversion operations will have appropriate safety documentation prepared. Note that, although these processes are inactive, the seismic accident analysis contained in Section 9.2.4 assumes that Plutonium Reclamation Facility (PRF) and RMC

line gloveboxes and process equipment contain maximum allowable plutonium inventories. This was done to (1) account for residual quantities of plutonium remaining in the process equipment and gloveboxes following the cessation of operations, (2) allow flexibility in the use of gloveboxes for in-process storage of plutonium, and (3) provide an upper bound estimate of potential radiological consequences of a seismic event.

Note also, that the validity of the analyses found in Sections 9.1 and 9.2 are predicated on the assumption that the equipment in the plant will be well maintained and that modifications to the facilities and equipment will be made under stringent controls.
