ON IMPROVING LINEAR SOLVER PERFORMANCE: A BLOCK VARIANT OF GMRES

A. H. BAKER*, J. M. DENNIS[†], AND E. R. JESSUP[‡]

Abstract. The increasing gap between processor performance and memory access time warrants the re-examination of data movement in iterative linear solver algorithms. For this reason, we explore and establish the feasibility of modifying a standard iterative linear solver algorithm in a manner that reduces the movement of data through memory. In particular, we present an alternative to the restarted GMRES algorithm for solving a single right-hand side linear system $Ax = b$ based on solving the block linear system $AX = B$. Algorithm performance, i.e. time to solution, is improved by using the matrix A in operations on groups of vectors. Experimental results demonstrate the importance of implementation choices on data movement as well as the effectiveness of the new method on a variety of problems from different application areas.

1. Introduction. We consider the solution of a large sparse system of linear equations:

$$(1) \quad Ax = b,$$

where $A \in \mathbb{R}^{n \times n}$, and $x, b \in \mathbb{R}^n$. Iterative methods are often chosen to solve such linear systems, and, when A is nonsymmetric, the GMRES (generalized minimum residual) [43] method is a common choice. Because linear systems are ubiquitous in science and engineering applications, improving the robustness of linear solvers continues to be of interest.

The two main costs associated with an iterative linear solver algorithm are the floating-point operations and the cost of moving data through memory, and performance may be improved by reducing either of these costs. Our focus is on achieving a balance between improving the efficiency of an iterative linear solver from a memory-usage standpoint while maintaining favorable numerical properties. In particular, the goal of this work is to demonstrate the feasibility of improving the performance of a common iterative linear solver (restarted GMRES), and likewise other iterative solvers, via a combination of a memory-efficient implementation and algorithmic modifications that reduce data movement.

In this paper, we report on our investigation into a memory-efficient iterative linear solver and describe the resulting new block method. We emphasize the implementation of the new method, numerous numerical test results, and evaluation of

performance based on the tracking of data movement through parts of the memory hierarchy. In Section 2 we discuss related background information. We outline our approach for improving restarted GMRES performance in Section 3. Section 4 introduces our new block method. We present computational results for a variety of problems in Section 5 and discuss implications of implementation decisions on data movement in Section 6. Finally, we give concluding remarks in Section 7.

2. Background. Though the cost of a numerical linear algebra algorithm has traditionally been measured in terms of the floating-point operations required, a more memory-centric approach has long been advocated (e.g., see [21, 16, 27]). It is well-known that matrix algorithm performance continues to be limited by the gap between microprocessor performance and memory access time (e.g., see [16, 50, 32, 30, 22, 1]). The discrepancy between DRAM (dynamic random access memory) access time and microprocessor speeds has increased by nearly 50% per year [40]. As a result, the percentage of overall application time spent waiting for data from main memory has increased [40]. The situation is compounded by advances in algorithm development that have decreased the total number of floating-point operations required by many algorithms [22]. Therefore, the number of floating-point operations required by an algorithm is not necessarily an accurate predictor of algorithm performance for a large matrix algebra problem [22]. In fact, performance bounds based on sustainable memory bandwidth (such as the STREAM [31] benchmark) are thought to predict algorithm performance most accurately [22, 1]. In particular, when solving a linear system, efficient data reuse (i.e., reducing data movement) is crucial to reducing an algorithm’s memory costs [27, 16, 21].

Krylov subspace methods such as GMRES are based on an iteration loop that accesses the coefficient matrix A once per loop and performs a matrix-vector multiply. Thus, a desirable modification in terms of reducing data movement is to perform more than one matrix-vector product for a single memory access of A . This optimization is natural when solving several linear systems with the same coefficient matrix A but different right-hand sides. Such linear systems can be written as a single block linear system

$$(2) \quad AX = B,$$

where $A \in \mathbb{R}^{n \times n}$, $X, B \in \mathbb{R}^{n \times s}$, and the columns of B are the different right-hand sides. By solving the block linear system (as opposed to solving s systems individually), A now operates on a group of vectors (*multivector*) instead of a single vector at each iteration. The matrix A is accessed from memory fewer times than it would be if each system were solved individually.

O’Leary first introduced block iterative solvers for block linear systems with symmetric A with the Block Conjugate Gradient (BCG) and other related algorithms in [39]. For nonsymmetric A , a block version of the GMRES algorithm (BGMRES) is first described in [48], and detailed descriptions can also be found in [44, 45, 42]. BGMRES is essentially identical to GMRES, except that operations are performed with multivectors instead of single vectors. As with GMRES, the resources required by BGMRES may be impractical since storage and computational requirements increase with each iteration. In this case, a restarted version of BGMRES (BGMRES(m)) is commonly used in practice.

Several variants of the BGMRES method have been developed for both multiple and single right-hand side systems. For multiple right-hand side systems, a hybrid block GMRES method is presented in [44] that often solves the block system faster

than solving each single system individually due in part to fewer memory accesses. In addition, block methods that augment the approximation space with eigenvector approximations are given in [24, 33]. These methods are particularly useful for matrices that are sufficiently close to normal and have a few particular eigenvalues that inhibit convergence.

Of primary interest to us is the use of a block method on a block linear system to solve a single right-hand side system. This strategy is briefly noted as a possibility in [39] for block conjugate gradient algorithms. To our knowledge, the first mention of using Block GMRES to solve a single right-hand side system occurs in [9]. In this work, Chapman and Saad suggest that convergence may be improved for $Ax = b$ by using a block method with approximate eigenvectors or random vectors for the additional right-hand side vectors, particularly when convergence is hampered by a few small eigenvalues.

Also of note is a block variant of GMRES for single right-hand sides systems in [29]. This method is mathematically equivalent to standard GMRES and is implemented as an s -step method (matrix A performs s consecutive matrix-vector multiplies at each iteration). The primary drawback is loss of accuracy with increasing block size (s). As with most blocked algorithms, the implementation allows for the use of level 3 BLAS (Basic Linear Algebra Subprograms) [14], and codes based on these routines often achieve good performance because they minimize data movement (e.g., see [13, 14, 22]).

3. Approach. Our approach to reducing data movement in restarted GMRES (GMRES(m)) is to modify the algorithm such that more than one matrix-vector product occurs for a single memory access of A . To this end, we investigate an alternative for solving a single right-hand side system as in (1) based on solving a corresponding block linear system as in (2). This algorithmic change requires the selection of additional starting vectors and right-hand sides.

Algorithmic changes that reduce memory access costs should not degrade the numerical properties of the original algorithm. Therefore, our goal in choosing appropriate families of additional right-hand sides and starting vectors was to select vectors that would accelerate convergence to the single right-hand side solution. For this reason, we looked to existing Krylov subspace method acceleration techniques.

It is well-known that subspace information is lost in GMRES(m) due to restarting, and a number of acceleration methods attempt to in some sense compensate for this loss (e.g., see [34, 35, 47, 12, 9, 4]). Our block method derives from the LGMRES method [4], an augmented Krylov subspace method with appealing convergence properties. In particular, the extra right-hand sides used in the block method are the same as used to augment the standard GMRES approximation space in LGMRES.

In addition, beyond the algorithmic modifications required for a block formulation of GMRES(m), close attention to implementation techniques is essential for a memory-efficient, sparse linear solver. Therefore, in our new block method, we reduce the cost of the additional matrix-vector operations in each iteration loop via an efficient matrix-multivector multiply and associated routines which we discuss in detail in Section 6.

4. A new block algorithm. In this section, we first briefly review the LGMRES method, of which the new algorithm is a theoretical extension. We then describe the new algorithm and its implementation and discuss additional considerations.

4.1. The LGMRES method. Consider GMRES(m) when solving (1). Restart parameter m denotes a fixed maximum dimension for the Krylov subspace. If convergence has not occurred at the end of m iterations, the algorithm restarts. We refer to the group of m iterations between successive restarts as a cycle. We denote the restart number with a subscript: x_i is the approximate solution after i cycles or $m \cdot i$ total iterations, and r_i is the corresponding residual ($r_i = b - Ax_i$). The minimum residual property requires that GMRES(m) find $x_{i+1} \in x_i + K_m(A, r_i)$ such that $r_{i+1} \perp AK_m(A, r_i)$ (e.g., see [42]), where $K_i(A, r_i) \equiv \text{span}\{r_i, Ar_i, \dots, A^{i-1}r_i\}$ denotes an i -dimensional Krylov subspace.

Let $\hat{x}$ be the true solution to (1). We denote the true error after the i -th restart cycle by e_i , where $e_i \equiv \hat{x} - x_i$. Then the vector

$$(3) \quad z_i \equiv x_i - x_{i-1}$$

is an approximation to that error after i restart cycles, where $z_i \equiv 0$ for $i < 1$.

An error approximation is a natural choice of vector with which to augment the next approximation space $\mathcal{K}_m(A, r_i)$ since augmenting with the true error would solve the problem exactly (e.g., see [18]). Furthermore, because $z_i \in \mathcal{K}_m(A, r_{i-1})$, it in some sense represents the space $\mathcal{K}_m(A, r_{i-1})$ generated and discarded in the previous cycle. Therefore, the LGMRES method accelerates convergence by appending k vectors that approximate the error from previous restart cycles to the standard Krylov approximation space at the end of each restart cycle. In particular, after $i + 1$ restart cycles, LGMRES(m, k) finds an approximate solution to (1) in the following way:

$$x_{i+1} = x_i + q_{i+1}^{m-1}(A)r_i + \sum_{j=i-k+1}^i \alpha_{ij} z_j,$$

where polynomial q_{i+1}^{m-1} and α_{ij} are chosen such that $\|r_{i+1}\|_2$ is minimized.

4.2. The new algorithm: B-LGMRES. The augmentation scheme used by LGMRES(m, k) is easily extended to a block method by using the k previous error approximations z_j to build additional Krylov subspaces. We refer to this block extension as B-LGMRES(m, k), for “Block” LGMRES. Conceptually, we view one restart cycle (i) of B-LGMRES(m, k) as a cycle of Block GMRES on the system $AX_{i+1} = B$, where B contains the right-hand side of (1) and the k most recent error approximations z_j , $j = (i - k + 1) : i$. In other words, $B = [b, z_i, \dots, z_{i-k+1}]$. The initial guess at restart cycle i , X_i , is then written as $X_i = [x_i, 0, \dots, 0]$, where the approximate solution to our single right-hand side system, x_i , is placed in the first column and the remaining columns are set to zero. X and B are size $n \times (k + 1)$ or $n \times s$, where $s \equiv k + 1$ indicates the block size.

After $i + 1$ restart cycles, the B-LGMRES(m, k) approximation space consists of the traditional Krylov portion built by repeated application of A to the current residual r_i together with Krylov spaces resulting from the application of A to previous error approximations. Therefore, we write the B-LGMRES(m, k) approximation as

$$(4) \quad x_{i+1} = x_i + q_{i+1}^{m-1}(A)r_i + \sum_{j=i-k+1}^i \alpha_{ij}^{m-1}(A)z_j,$$

where the degree $m - 1$ polynomials α_{ij}^{m-1} and q_{i+1}^{m-1} are chosen such that $\|r_{i+1}\|_2$ is minimized.

Using (3), we now re-write B-LGMRES(m, k) in (4) in the following way:

$$z_{i+1} = q_{i+1}^{m-1}(A)r_i + \sum_{j=i-k+1}^i \alpha_{ij}^{m-1}(A)z_j.$$

In the above form, as shown for the LGMRES method in [4], this block method resembles a truncated polynomial-preconditioned full conjugate gradient method with variable preconditioning. In this analogy, the polynomial preconditioner is q_{i+1}^{m-1} , and it changes at each iteration (i). In addition, the error approximation vectors z_j are analogous to conjugate gradient direction vectors (e.g., see [2]), and now these direction vectors are weighted by polynomials in A (α_{ij}) instead of scalars. Furthermore, as in [4], it is easily shown that these direction vectors z_j are $A^T A$ -orthogonal.

THEOREM 1 (Orthogonality of the error approximations). *The error approximation vectors $z_j \equiv x_j - x_{j-1}$ in B-LGMRES are $A^T A$ -orthogonal.*

Proof.

We define subspaces $\mathcal{M}_{i+1}$ and $\mathcal{M}_i$ as

$$\begin{aligned} \mathcal{M}_{i+1} &\equiv \mathcal{K}_m(A, r_i) + \sum_{j=i-k+1}^i \mathcal{K}_m(A, z_j) \\ \mathcal{M}_i &\equiv \mathcal{K}_m(A, r_{i-1}) + \sum_{j=i-k}^{i-1} \mathcal{K}_m(A, z_j). \end{aligned}$$

By construction, $r_i \perp A\mathcal{M}_i$ and $r_{i+1} \perp A\mathcal{M}_{i+1}$.

From (3), $r_i - r_{i+1} = Az_{i+1} \Rightarrow Az_{i+1} \perp A(\mathcal{M}_i \cap \mathcal{M}_{i+1})$.

Because $\{z_j\}_{j=(i-k+1):i} \subset \mathcal{M}_i \cap \mathcal{M}_{i+1}$, $z_{i+1} \perp_{A^T A} \{z_j\}_{j=(i-k+1):i}$. $\square$

To provide additional insight into the B-LGMRES augmentation scheme, we briefly describe the B-LGMRES method in the framework presented in [9]. In [9], Chapman and Saad consider the addition of an arbitrary subspace, $\mathcal{W}$, to the standard Krylov approximation space of a minimum-residual method, such as GMRES. This addition results in the augmented approximation space

$$(5) \quad \mathcal{M} = \mathcal{K} + \mathcal{W},$$

where $\mathcal{K}$ is the standard Krylov subspace. A minimal residual method finds an approximate solution $\tilde{x} \in x_0 + \mathcal{M}$ such that the residual $\tilde{r}$ satisfies $\tilde{r} \perp A\mathcal{M}$, removing components of the initial residual r_0 in subspace $A\mathcal{M}$ via an orthogonal projection process. Following the discussion in [9], the minimization process over the augmented approximation space (5) is

$$\|\tilde{r}\|_2 = \min_{d,w} \|b - Ad - Aw\|_2,$$

where $d \in x_0 + \mathcal{K}$ and $w \in \mathcal{W}$. Chapman and Saad then show that if r_d results from minimizing $\|b - Ad\|_2$, where again $d \in x_0 + \mathcal{K}$, then

$$(6) \quad \|\tilde{r}\|_2 \leq \|(I - P_{AW})r_d\|_2,$$

where P_{AW} is an orthogonal projector onto subspace $A\mathcal{W}$. In particular, for a cycle of B-LGMRES(m, k) with $k = 1$, we have that $\mathcal{K} = \mathcal{K}_m(A, r_i)$ and $\mathcal{W} = \mathcal{K}_m(A, z_i) =$

1. $r_i = b - Ax_i$, $\beta = \|r_i\|_2$, $r_i = r_i/\beta$
2. $R_i = [r_i, z_i, \dots, z_{i-k+1}]$
3. $R_i = V_1 \hat{R}$ (QR factorization)
4. for $j = 1 : m$
5. $U_j = AV_j$
6. for $l = 1 : j$
7. $H_{l,j} = V_l^T U_j$
8. $U_j = U_j - V_l H_{l,j}$
9. end
10. $U_j = V_{j+1} H_{j+1,j}$
11. end
12. $W_m = [V_1, V_2, \dots, V_m]$, $H_m = \{H_{l,j}\}_{1 \leq l \leq j+1; 1 \leq j \leq m}$
13. find y_m s.t. $\|\beta e_1 - H_m y_m\|_2$ is minimized
14. $z_{i+1} = W_m y_m$
15. $x_{i+1} = x_i + z_{i+1}$

FIG. 1. $B\text{-LGMRES}(m, k)$ for restart cycle i .

$\mathcal{K}_m(A, e_i - e_{i-1})$. Therefore, from (6) we see that the addition of $\mathcal{W}$ in the B-LGMRES method results in the removal of components of r_d (the residual from the standard Krylov approximation space) from the subspace $A\mathcal{K}_m(A, e_i - e_{i-1})$ or, equivalently, the removal of components of the error from subspace $\mathcal{K}_m(A, e_i - e_{i-1})$.

4.3. Implementation. The implementation of $B\text{-LGMRES}(m, k)$ is similar to that of BGMRES. For reference, one restart cycle (i) of $B\text{-LGMRES}(m, k)$ is given in Figure 1. As with BGMRES, $B\text{-LGMRES}(m, k)$ requires the application of s^2 rotations at each iteration to transform H_m into an upper triangular matrix (e.g., see [42]). Because $B\text{-LGMRES}(m, k)$ solves $Ax = b$, as opposed to a block system, the least squares solution step (line 13) varies from that of standard BGMRES; the triangular matrix $\hat{R}$ from the QR decomposition in line 3 does not need to be saved since only $\beta = \|r_i\|_2$ is needed, and only s rotations must be applied to the least-squares problem's right-hand side (βe_1) at each step.

Though we think of the error approximations z_j , $j = (i - k + 1) : i$ as additional right-hand side vectors, we do not form the block approximate solutions X_i . Instead we append the k most recent error approximations to the initial residual to form a block residual R_i , as seen in line 2 of Figure 1. We normalize the error approximations ($z_j/\|z_j\|_2$) so that each column of the initial residual block R_i is of unit length. The m size $n \times s$ orthogonal block matrices V_j form the orthogonal $n \times m \cdot s$ matrix W_m , where $W_m = [V_1, V_2, \dots, V_m]$. H_m is a size $(m+1)s \times m \cdot s$ band-Hessenberg matrix with s sub-diagonals, and the following standard relationship holds:

$$AW_m = W_{m+1}H_m.$$

As with LGMRES, only i error approximations are available at the beginning of restart cycles with $i < k$. As a result, the creation of the initial residual block in line 2 of the $B\text{-LGMRES}(m, k)$ algorithm must be modified for the first k cycles where $i < k$. (The first cycle is $i = 0$.) Recall that $z_j \equiv 0$ for $j < 1$, and when $z_j \equiv 0$, we say that z_j is an error approximation that is not available. In our implementation, we replace any $z_i, \dots, z_{i-k+1}$ that is not available with a randomly generated vector of length n . This choice is justified in Section 4.4.

For the $B\text{-LGMRES}(m, k)$ implementation given in Figure 1, the multivectors

are of size s , where $s = k + 1$. For example, the orthogonal block matrices V_j in lines 3, 5, 8, 10, and 12 of Figure 1 are size s multivectors consisting of s vectors of length n . In addition, R_i in lines 2 and 3 and U_j in lines 5, 7, 8 and 10 are also multivectors. The matrix-multivector multiply occurs in line 5, and the importance of this aspect of the implementation is demonstrated in Section 6.

One restart cycle, or m iterations, of B-LGMRES(m, k) requires m matrix-multivector multiplies, irrespective of the value of k . Therefore, matrix A is accessed from memory m times per cycle. For comparison, we list the approximation space size, the number of vectors of length n stored, and the number of matrix accesses per restart cycle in terms of parameters m and k for GMRES(m), LGMRES(m, k), and B-LGMRES(m, k) in Table 1.

TABLE 1
Algorithm specifications per restart cycle.

Method	Approx. Space Size	Length n Vector Storage	Accesses of A
GMRES(m)	m	$m + 3$	m
LGMRES(m, k)	$m + k$	$m + 3k + 3$	m
B-LGMRES(m, k)	$m(k + 1)$	$(m + 2)k + m + 3$	m

B-LGMRES(m, k) is compatible with both left and right preconditioning. We denote the preconditioner by M^{-1} . For left preconditioning, the initial residual in line 1 of Figure 1 must be preconditioned as usual: $r_i = M^{-1}(b - Ax_i)$. Then we replace A with $M^{-1}A$ in line 5. To incorporate right preconditioning, we replace A with AM^{-1} in line 5. We define $\hat{z}_j \equiv M(x_j - x_{j-1}) = Mz_j$ and replace z with $\hat{z}$ everywhere in lines 2 and 14. While no explicit change is required for line 15 as given in Figure 1, note that, with right preconditioning, line 15 is equivalent to $x_{i+1} = x_i + M^{-1}\hat{z}_{i+1}$.

We note that in our implementation, no re-orthogonalization was performed, and residual norms are computed recursively at each step within a restart cycle.

4.4. Additional algorithmic considerations. Deflation is often an important issue for block methods and has been addressed in various ways (e.g., see [39, 38, 20]). For the B-LGMRES method, deflation is not required because we are not solving a block linear system. However, we now discuss the possibility of rank deficiency for the initial residual block.

Consider the initial block residual for restart cycle i : $R_i = [r_i, z_i, \dots, z_{i-k+1}]$. The initial residual block is rank deficient only if the vectors $\{r_i, z_i, \dots, z_{i-k+1}\}$ are linearly dependent. Recall that random vectors are used in place of unavailable error approximation vectors in cycles $i < k$. Therefore, all z_j are random for the initial cycle. Statistically these random vectors are linearly independent of the other vectors in the initial residual block (cf. [17, 26]).

For simplicity, consider the $k = 1$ case for restart cycle $i > 1$. The initial residual block is $R_i = [r_i, z_i]$. If r_i is the zero vector, then the solution has been found. If $z_i = 0$, stalling has occurred. Now assume that both r_i and z_i are not zero, and R_i is rank deficient. Then r_i and z_i are linearly dependent and $r_i = \alpha z_i$ for some $\alpha \neq 0$. Using the notation in Theorem 1, we have that $z_i \in \mathcal{M}_i$ and $r_i \perp AM_i$. Therefore, $\langle r_i, Az_i \rangle = 0$, where $\langle \cdot, \cdot \rangle$ denotes the Euclidean inner product. So for linearly dependent r_i and z_i we have

$$(7) \quad \langle z_i, Az_i \rangle = 0.$$

Because $z_i \neq 0$ implies stalling has not occurred, then $r_i \neq r_{i-1}$. By definition $r_i = r_{i-1} - Az_i$, and, as a result, $Az_i \neq 0$. Therefore since r_i , z_i , Az_i and α are all nonzero, (7) can only hold if A is not positive definite and $z_i \perp Az_i$.

Consequently, the initial residual block is rank deficient if any of the following three cases is true: $r_i = 0$, $z_i = 0$, or A is not positive definite and $z_i \perp Az_i$. The first case is not an issue since $r_i = 0$ indicates that a solution has been found. In the second case, stalling has occurred, and including z_i in the initial residual block at the start of the cycle does not make sense. However, at worst $z_i \approx 0$ in practice since this is a finite precision computation. Similarly, the third case is unlikely, particularly in finite precision, and in this case (and the previous) a random vector may be substituted for z_i if a breakdown is detected. In fact, we have not had any breakdowns due to rank deficiency in R_i in practice.

5. Numerical Experiments. In this section, we present promising experimental results from our implementation of B-LGMRES. We implemented the B-LGMRES algorithm in C using a locally modified version of PETSc 2.1.5 (Argonne National Laboratory's Portable, Extensible Toolkit for Scientific Computation) [6, 5]. We thoroughly discuss the specific details of this implementation in the next section.

We demonstrate the potential of the B-LGMRES method both with and without preconditioning by presenting experimental results for multiple test problems from the University of Florida Sparse Matrix Collection [11], the Matrix Market Collection [37], and the PETSc test collection. For reference, all test problems used in this section are listed in Table 2. If a right-hand side was not provided, we generated a random right-hand side. For all problems, the initial guess was a zero vector. All results provided were run on a single processor of a 16-processor Sun Enterprise-6500 server with 16 Gbytes RAM. This system consists of 400 Mhz Sun Ultra II processors, each with a 16 Kbyte L1 cache and a 4 Mbyte L2 cache.

For each problem we report wall clock time for the linear solve only; we do not time any I/O or the setup of the preconditioner. For the preconditioned problems, we use either ILU(p) or ILUTP(*droptol*, *permtol*, *lfil*) (e.g., see [42]). The timings reported are averages from five runs and have standard deviations of at most two percent. All tests are run until the relative residual norm is less than the convergence tolerance $\zeta = 10^{-9}$, i.e., when $\|r_i\|_2/\|r_0\|_2 \leq \zeta$. However, if a method does not converge in 1000 restart cycles, then the execution time reported reflects the time for 1000 cycles and we say that the method does not converge.

We evaluate the performance of B-LGMRES(m , k) for a particular problem by comparing its time to converge to that of GMRES(m) and LGMRES(m , k) with equal-sized approximation spaces. We use the GMRES(m) implementation available in PETSc 2.1.5 and the LGMRES(m , k) implementation in PETSc described in [4]. For GMRES(m), we chose restart parameter $m = 30$ because it is a common choice for GMRES(m) and is the default in PETSc. We required that the approximation spaces for both LGMRES(m , k) and B-LGMRES(m , k) be of size 30 as well. Furthermore, we wanted to evaluate the performance of LGMRES(m , k) and B-LGMRES(m , k) using the same number of error approximation vectors, i.e., the same k , for each. In choosing a value of k , we note that for LGMRES(m , k), $k \leq 3$ is typically optimal, and variations in algorithm performance are small for $k \leq 3$ (see [4]). Note that for a fixed approximation space size, increasing k for B-LGMRES(m , k) decreases the powers of A represented in the approximating subspace. For this set of test problems, preliminary testing showed that using $k > 2$ was typically not beneficial, and $k = 1$ was generally optimal. (For an approximation space larger than 30, we expect that

using $k > 1$ would be an advantage more often.) As a result, we chose $k = 1$ for the experiments presented here, and this choice together with the constraint of a size 30 approximation space determined parameter m for each method as in Table 1. Note the approximation space for B-LGMRES(15, 1) at restart cycle $i + 1$ is given by $\mathcal{K}_{15}(A, r_i) + \mathcal{K}_{15}(A, z_i)$ and that for LGMRES(29, 1) is given by $\mathcal{K}_{29}(A, r_i) + \text{span}\{z_i\}$.

We first present results for the non-preconditioned test problems. Figure 2 compares the time required for convergence for B-LGMRES(15, 1) to both LGMRES(29, 1) and GMRES(30). The x-axis corresponds to the numbered test problems given in Table 2 which are listed in order of increasing number of nonzeros. The y-axis is the time required for convergence for either LGMRES(29, 1) or GMRES(30) divided by the time required for convergence for B-LGMRES(15, 1). Therefore, bars extending above one indicate faster convergence for B-LGMRES(15, 1). For all of these problems, B-LGMRES(15, 1) converges. However, arrows above the bars in Figure 2 indicate that GMRES(30) did not converge in 1000 restart cycles for problem 1 and both LGMRES(29, 1) and GMRES(30) did not converge for problem 4. Again, the time for 1000 restart cycles is reported for methods that do not converge, resulting in an understated ratio of improvement for B-LGMRES(15, 1) for the bars with arrows. B-LGMRES(15, 1) converges in less time than GMRES(30) for all problems, and improvements over LGMRES(29, 1) are more modest since LGMRES is typically also an improvement over GMRES(m) [4].

We now do the same performance evaluation for B-LGMRES(m, k) on preconditioned problems, problems 7-17, in Figure 3. We use left preconditioning, and determination of convergence is based on the preconditioned residual norm as usual. As in Figure 2, the bars extending above one favor B-LGMRES(15, 1). The time required for convergence for B-LGMRES(15, 1) is less than that for GMRES(30) for problems 7-15 and about the same as GMRES(30) for problems 16 and 17. However, performance gains are not as dramatic as those without preconditioning due to lower iteration counts. For large problems, though, even a small improvement in iteration count translates into a non-trivial time savings. The comparison of B-LGMRES(15, 1) to LGMRES(29, 1) is not as straightforward. The LGMRES method is quite effec-

FIG. 2. A comparison of the time required for convergence for non-preconditioned test problems 1-6 with GMRES(30) and LGMRES(29, 1) versus B-LGMRES(15, 1).

FIG. 3. A comparison of the time required for convergence for preconditioned test problems 7-17 with GMRES(30) and LGMRES(29, 1) versus B-LGMRES(15, 1).

tive for these test problems, and, as a result, predicting which algorithm will “win” for a particular test problem is an open question. As an example, we tested problem memplus both without and with preconditioning, problems 3 and 8, respectively. For this problem, B-LGMRES(15, 1) converges in slightly less time than LGMRES(29, 1) when no preconditioner is used, but LGMRES(29, 1) is faster with preconditioning.

For all of the test problems in Table 2, we found that the time to solution of the restarted methods correlates well with the number of accesses of A , as opposed to the number of matrix-vector multiplies. In Figure 4, in the top panel, the y-axis indicates the ratio of time required for convergence to matrix accesses for the three algorithms: GMRES (30), LGMRES(29, 1), and B-LGMRES(15, 1). In the bottom panel, the y-axis indicates the ratio of the time required for convergence to matrix-vector multiplies. The near constant ratio for all three methods for each problem in the top panel shows that the number accesses of A largely determines execution time. However, the ratios in the bottom panel are not constant for each problem, indicating that the number of matrix-vector multiplies does not correlate well with execution time for B-LGMRES(15, 1). In the next section, the relationship between

FIG. 4. The upper panel shows the ratios of time required for convergence to number of accesses of A for GMRES (30), LGMRES(29, 1), and B-LGMRES(15, 1) on the 17 test problems. The lower panel shows the ratios of time required for convergence to number of matrix-vector multiplies.

data movement and execution time is discussed in detail.

Because our machine has sufficient resources, full GMRES is a viable option. Therefore, we also compared the time to solution of B-LGMRES(15, 1) to full GMRES for each of the 17 test problems. B-LGMRES converges in significantly less time than GMRES on all but four problems: problems 7, 10, 13, and 15. There was no correlation between problem size and method in terms of time required for convergence for these test problems. See [3] for more details.

For the problems presented here, the time to solution of B-LGMRES(m , k) is typically an improvement over that of GMRES(m), as shown in Figures 2 and 3. The additional right-hand side vector(s) in B-LGMRES inhibit the tendency of restarted GMRES to form similar polynomials at every other restart cycle (see [4]), thus improving convergence. As with the LGMRES method, B-LGMRES acts as an accelerator, but in general does not help with stalling. In other words, B-LGMRES(m , k) has a total approximation space size of $m \cdot (k + 1)$ and typically does not help problems that stall for GMRES($m \cdot (k + 1)$), though we have found a few exceptions. For problems that stall, full GMRES or Morgan's GMRES-DR method [35] can be good options. Although a thorough understanding of the convergence behavior of B-LGMRES is an open question that warrants further investigation, the experimental results presented in this section demonstrate that solving a single right-hand side system via a block system is a viable means of improving the time to solution of an iterative method such as GMRES(m). In particular, achieving a balance between maintaining or improving an iterative linear solver algorithm's numerical properties and reducing data movement is possible.

6. An efficient implementation. In this section, we give the specific details of our implementation and further quantify how B-LGMRES performance gains occur from the reduction of data movement. In addition, we demonstrate the importance of using performance programming techniques to achieve an efficient implementation. Following the experimental results in the previous section, we concentrate on a multivector of size $s = 2$ which corresponds to B-LGMRES(m, k) with $k = 1$. However, because the results in this section are applicable to improving the performance of general block linear solvers as well, we also discuss the advantages of a larger block size.

6.1. Background. Algorithmic changes in a numerical code affect the manner in which data are moved through a memory hierarchy. Floating-point operations typically occur after data are moved from the slower part of the memory hierarchy (main memory) to the faster and more limited caches to the registers. Two levels of cache are typical for current microprocessor designs, and three levels are increasingly common. We are most interested in data movement between main memory and cache and between levels of cache as this movement is most affected by our algorithmic changes. L1 caches typically have access times of two to three clock cycles. Access times are generally 5-15 times slower for L2 caches and 20-30 times slower for L3 caches. Accessing data from main memory typically requires at least 100 times more cycles than does accessing data from L1 cache (e.g., see [49, 36, 7]).

Unlike a dense matrix-vector multiply routine, a sparse matrix-vector multiply typically does not access data items in close succession. In particular, the compressed storage formats used for sparse matrices generally result in irregular patterns of memory referencing (e.g., see [19, 15]). Approaches to improving the performance of the sparse matrix-vector multiply for a given matrix problem include reordering the matrix and choosing matrix-specific data structures (e.g., see [46]). For example, one approach is to optimize the sparse matrix-vector multiplication by representing the sparse matrix as a collection of small dense blocks (e.g., see [25, 41, 49]). Another well-known technique referred to as loop blocking involves writing matrix operations that divide the matrix into submatrices or blocks that are better suited for reuse in cache than a matrix row or column array (e.g., see [21, 8, 27]).

Of particular interest to us is an approach in [22, 23] that improves the performance of *multiple* sparse matrix-vector multiplies. This approach allows the multiplication of a *multivector* of size four (i.e., a group of four vectors) by a matrix at about 1.5 times the cost of calculating a single matrix-vector product. The key to this approach is to group computations on the same data thus allowing more floating-point operations per byte of data moved through memory. Consider the size s multivector V , where $V \equiv [v_1, v_2, \dots, v_s]$ for vectors $v_1, v_2, \dots, v_s \in \mathbb{R}^{n \times 1}$. We chose a row-wise storage format for the multivectors in that V is stored as a vector of length $n \cdot s$ in which the components of the s vectors are *interlaced*. In other words, multivector elements separated by stride s belong to a single vector: $v_1 = [V(0); V(s); V(2s); \dots; V(ns-s)]$. A column-wise format also stores V as a length $n \cdot s$ vector, but each single vector ($v_1, v_2, \dots$) is stored contiguously in memory. We discuss the implications of row-wise versus column-wise storage in Section 6.2. In either case, by processing the s individual vectors as a group, the matrix-multivector multiply routine, for example, performs a greater number of floating-point operations for each access of a nonzero element of the coefficient matrix A and has the potential to reduce the amount of data moved through parts of the memory subsystem by a factor of s .

6.2. Implementation. The PETSc 2.1.5 libraries contain the tools for storing a multivector in an interlaced format, referred to as *multi-component vectors* in the PETSc manual [5]. We use the PETSc matrix-vector multiply routine for multiplying a matrix by a multi-component vector in B-LGMRES. Additionally, we modified our local installation of PETSc to include multivector versions of the PETSc routines *VecDot*, *VecAXPY*, *VecMAXPY*, and *MatSolve*. *VecDot* and *VecAXPY* are the vector dot product and axpy routines, respectively, required in the modified Gram-Schmidt steps. *VecMAXPY* adds a scaled sum of vectors to a vector, which is used when solving the least-squares problem. *MatSolve* performs a forward and back solve for use with the ILU preconditioner.

To demonstrate the benefit of the multivector optimization specifically, we implemented B-LGMRES in PETSc 2.1.5 both with and without multivectors. We refer to our implementation of B-LGMRES with multivectors as the *MV* implementation. This implementation produced the results given in the previous section. The B-LGMRES implementation without multivectors, referred to as *non-MV*, represents the best non-multivector implementation possible with the tools available in PETSc. Both implementations were written so as to eliminate any copying of data from one data structure to another and represent best coding efforts. For the problems in our test set in Table 2, the execution time of the MV implementation is close to twice as fast on average as the non-MV implementation with multivectors of size $s = 2$, independent of problem size (n) and number of nonzeros (nnz).

The multivector optimization impacts more than just the matrix multiply routine but rather pervades the implementation of the entire B-LGMRES algorithm. For example, because U and V in the B-LGMRES algorithm as given in Figure 1 are stored as multivectors, the orthogonalization routines in lines 6 - 9 require modification as well. Three primary sections of the B-LGMRES code are impacted by the multivector optimization: the matrix-vector multiply (*MatMult*), the modified Gram-Schmidt orthogonalization (*MGS*), and the application of the preconditioner (*Prec*), if required. Because the *Prec* section of code shows similar characteristics to the *MatMult* section, we only discuss the *MatMult* and *MGS* sections of code. We note that the execution time for the MV implementation for our set of test problems is not consistently dominated by a single section of the B-LGMRES code. In particular, the percentage of time spent in each of the three primary sections varies from 18% to 83% for *MatMult*, 6% to 55% for *MatMult*, and 31% to 53% for *Prec*.

The *MatMult* section of the code corresponds to the matrix-vector multiply in line 5 of Figure 1. For the non-MV implementation, successive calls are made to a matrix-vector multiply routine for each individual vector in V_j . In contrast, the MV implementation utilizes a single call to the PETSc matrix-multivector multiply routine, as described earlier in this section. The size of the data structures determines the part of the memory most affected by the multivector optimizations for the *MatMult* section. In particular, we denote the size of the data structures accessed by the *MatMult* section by $WS_{MatMult}$ which is the *working set size* or the size in Mbytes of data loaded through the memory hierarchy while computing the matrix-vector multiplication. $WS_{MatMult}$ is approximately equal to the storage required for matrix A , which is stored in PETSc AIJ format (equivalent to compressed sparse row). Therefore,

$$(8) \quad WS_{MatMult} \approx \text{sizeof}(A) = \text{sizeof}(\text{double}) * nnz + \text{sizeof}(\text{int}) * (n + nnz),$$

where *double* is a double precision value, *int* is an integer value, and function *sizeof*() returns the size of its argument in bytes. If $WS_{MatMult}$ is significantly larger than

the L2 cache size, then successive calls to a matrix-vector multiply routine repeatedly read matrix A from main memory through both levels of cache. For $WS_{MatMult}$ smaller than the L2 cache size but larger than L1, portions of matrix A may remain in L2 cache and allow some L2 cache reuse for the successive calls to matrix-vector multiply in the non-MV implementation.

The MGS section of code (lines 6-10 in Figure 1) often contributes significantly to the overall cost of the B-LGMRES algorithm. This section of code required the creation of multivector versions of the PETSc routines *VecDot* and *VecAXPY*. Following the PETSc use of *Stride* to denote multivector versions of common functions, we refer to the new versions of these routines as *VecStrideDot* and *VecStrideAXPY*, respectively. These routines represent the majority of the total time for the MGS section. Therefore, we wrote the routines in a manner that limits movement of data by fusing together computations on related data. For example, the functionality provided by *VecStrideDot* for a multivector of size s is equivalent to s^2 successive calls to *VecDot* (the approach used in the non-MV implementation). With successive calls to *VecDot*, $2 \cdot n \cdot s^2$ data values must be read from the memory hierarchy. *VecStrideDot* reduces the number of data values read to $2 \cdot n \cdot s$. Therefore if $WS_{MGS} \equiv \text{sizeof}(\text{double}) \cdot 2 \cdot n \cdot s$ is greater than either the L1 or L2 cache size, use of the multivectors impacts data movement in the MGS section of code.

Both *VecStrideDot* and *VecStrideAXPY* were written using loop temporaries and loop unrolling to aid compiler optimization. The use of loop temporaries allows a compiler to identify data reuse more easily at the register level. Loop unrolling further helps register reuse and allows different iterations of the loop to occur simultaneously. In our MV implementation we unroll the inner loop s times, where s is the block size. We chose to write our own *VecStrideDot* and *VecStrideAXPY* routines instead of using the level 3 BLAS DGEMM routine [14] due to the performance advantage of a hand-coded implementation. In Table 3, the timings to perform a multivector AXPY with $s = 4$ are given for the non-MV and MV implementations of our code as well as for two DGEMM kernels. The version of DGEMM labeled “src” is compiled from source code and the version labeled “opt” is the vendor supplied optimized library. Timings are given in μsec for a subset of the test problems with a range of matrix orders. The hand-tuned MV implementation of *VecStrideAXPY* is the clear winner for these problems. Because the MGS section can consume a large percentage of total execution time, simple optimizations such as those in *VecStrideAXPY* have as significant an impact on overall execution time of the solver as the use of the matrix-multivector multiply routine.

TABLE 3
Execution times in μsec for a single call to AXPY for the non-MV and MV implementations as well as for the standard and optimized BLAS 3 DGEMM routines with a block size of $s = 4$.

	Problem	n	non-MV	MV	DGEMM (src)	DGEMM (opt)
13	ex40	7740	2.00	1.25	3.96	2.96
3	memplus	17758	4.55	2.85	9.18	6.73

14	epb3	84617	19.54	12.58	43.49	31.88

In Table 4, we perform a similar comparison for the block dot product routine. The improvement here is more modest for the MV implementation, though both the MV and non-MV implementations are superior to both versions of DGEMM. Our implementations outperform DGEMM because the loops are unrolled to the specific

block sizes $s=2$ and $s=4$.

TABLE 4

Execution times in μsec for a single call to a dot product routine for the non-MV and MV implementations as well as for the standard and optimized DGEMM routines with a block size of $s = 4$.

	Problem	n	non-MV	MV	DGEMM (src)	DGEMM (opt)
13	ex40	7740	1.26	1.16	3.98	2.98
3	memplus	17758	2.56	2.27	9.32	6.83

14	epb3	84617	12.65	12.07	44.03	30.57

As explained previously, we store the multivectors row-wise (interlaced). Alternatively, one might wonder whether column-wise ordering is a viable option as column-wise ordering better facilitates algorithmic needs such as deflation and requires less reorganization of data. Therefore, in Table 5, we give results for the MatMult routine on block sizes $s = 2$ and $s = 4$. MV-row and MV-col indicate row-wise and column-wise implementations of the multivector implementation. Note that in addition to four problems from our test set, Table 5 includes an additional problem, poisson3Db, from the UF collection ($n = 85623$ and $\text{nnz} = 2374949$). This problem has a large bandwidth and highlights the potential performance difference between row-wise and column-wise storage as seen in row 5 of Table 5. Our experiments seem to indicate that the use of the column-wise storage format for multivectors on large problems with a large matrix bandwidth causes TLB thrashing, as suggested in [28]. To illustrate this, line 6 of Table 5 lists the results for the poisson3Db problem with Reverse Cuthill-McKee (RCM) [10] reordering. The RCM reordering reduces the matrix bandwidth and significantly decreases execution time for the column-wise multivector storage format. Note that a large bandwidth does not impact the row-wise storage as much because consecutive accesses of the multivector elements correspond to data items that are stored contiguously.

TABLE 5

Execution times in μsec for the non-MV and MV implementations of the MatMult routine for block sizes $s = 2$ and $s = 4$.

		block size = 2 (μsec)			block size = 4 (μsec)

Having described the multivector modifications to the MatMult and MGS sections, we now determine the effects of these changes by comparing the execution times for both sections of code in the non-MV and MV implementations. In Figure 5, the y-axis indicates the execution time for the non-MV implementation divided by the execution time for the MV implementation for both the MatMult and MGS sections of code for the 17 test problems. A value greater than one indicates that the execution time for MV is less than that for non-MV. The MV implementation reduces the execution time of the MatMult section by a factor 1.4 to 2.7 over the non-MV

FIG. 5. A comparison of execution time for the MatMult and MGS sections with the non-MV implementation of B -LGMRES(15,1) versus the MV implementation for ten restart cycles for the 17 test problems.

implementation. The least improvement in execution time for the MatMult section occurs for problems 4 and 9. These problems have neither the largest nor smallest n or nnz , but they do have the lowest average number of nonzeros per row: 4.9 and 4.3, respectively. However, problems 6 and 13 have the highest average number of nonzeros per row at 178.9 and 59.2, respectively, and do not show the most improvement in execution time. It is an open question what impact matrix density (or even nonzero structure) has on the effectiveness of the multivector optimizations in general. The execution time for the MGS section shows an even greater improvement on average: the MV implementation of MGS reduces execution time by a factor 2.3 to 2.7 over the non-MV implementation.

6.3. Impact of data movement on execution time. We now explain reductions in execution time due to the multivector optimization using data from hardware performance counters that monitor data movement through the memory hierarchy. We focus on two counters that measure the number of cache lines read from main memory to the L2 cache and the number of cache lines read from the L2 to the L1 cache because their measurements correlate strongly with execution time. We refer to the megabytes of data moved between main memory and L2 cache as $Mbytes_{L2}$ and between L2 and the L1 caches as $Mbytes_{L1}$.

To determine the specific source of performance gains for the MV implementation, we first examine data movement between main memory and the L2 cache for the non-MV and MV implementations. In Figure 6, the y-axis indicates the ratio of $Mbytes_{L2}$ for non-MV to MV for both the MatMult and MGS sections. Bars extending above one indicate that the non-MV implementation requires greater data movement for all test problems than does the MV implementation for both sections of code.

As $s = 2$, we expected a factor of two reduction in $Mbytes_{L2}$ for both MV implementations (MatMult and MGS) for test problems with a working set size significantly larger than the L2 cache. Using (8), we determined that eight test problems have $WS_{MatMult}$ larger than the 4 Mbytes L2 cache on our test system, and these problems (6 and 11-17) all have ratios from 1.75 to 2.0 in Figure 6. These ratios correlate well with factor of two reductions in execution time for those problems seen in Figure 5. For the MGS section of code, only problem 16 has WS_{MGS} greater than the

FIG. 6. A comparison of data movement from main memory to L2 cache in the MatMult and MGS sections for the non-MV implementation of B-LGMRES(15,1) versus the MV implementation for ten restart cycles for the 17 test problems.

4 Mbyte L2 cache size. However, problem 16 shows a ratio of $Mbytes_{L2}$ for non-MV to MV of 1.4 which does not correlate well with the factor of 2.4 improvement in execution time shown in Figure 5. The results in Figure 6 are also inconsistent with those in Figure 5 in other ways: several problems appear to show an increase in $Mbytes_{L2}$ for the MGS and MatMult sections for the MV implementation. In fact, for these problems the amounts of data moved are quite small for both implementations and the apparent increases are likely the result of measurement error. Nonetheless, the MV implementation is faster than the non-MV one. These inconsistencies indicate that a reduction in $Mbytes_{L2}$ does not accurately predict a reduction in execution time for MGS for most of the test problems. We show subsequently that the multivector optimization impacts a different part of the memory hierarchy for those problems.

We now consider data movement between the L1 and L2 caches. Analogously to Figure 6, Figure 7 shows the ratio of $Mbytes_{L1}$ for the non-MV to MV implementations for both the MatMult and MGS sections of code. For the MatMult section of code, we expected test problems with $WS_{MatMult} \gg \text{sizeof}(L1 \text{ cache})$ to show a reduction in $Mbytes_{L1}$. Test problem 1 has the smallest $WS_{MatMult}$ at 978 Kbytes, which is significantly larger than the 16 Kbyte L1 cache. Thus, all of the test problems have a $WS_{MatMult}$ larger than the L1 cache size. Figure 7 shows that the ratios of data moved do in fact range from 1.5 to 1.9. Similarly for the MGS section of code, problem 12 has the smallest WS_{MGS} at 241 Kbytes, which is also significantly larger than the L1 cache. Consequently, all of the test problems have ratios of non-MV to MV that range from 1.6 to 2.0. The reduction in $Mbytes_{L1}$ is thus consistent with the reduction in execution time seen in Figure 5 for both sections of code.

Therefore, from Figures 6 and 7, one can infer that the reduction in *total* execution time due to the MV implementation correlates to the reduction in $Mbytes_{L1}$ for our test problems (see [3] for more details). The importance of optimizations that reduce movement of data between levels of cache was unexpected in that emphasis is traditionally placed on reducing data movement between cache and main memory, which is of most concern to large problems. For much larger test problems, where both $WS_{MatMult}$ and WS_{MGS} are much larger than the L2 cache size, for example, we expect that the reduction $Mbytes_{L2}$ would more strongly correlate to execution time. However, our results indicate that data movement is not just an issue for very

FIG. 7. A comparison of data movement from L2 cache to L1 cache in the MatMult and MGS sections for the non-MV implementation of B-LGMRES(15,1) versus the MV implementation for ten restart cycles for the 17 test problems.

large problems.

In fact, the results presented in this section demonstrate that reformulating an iterative solver to use multivectors enables an efficient implementation that can reduce data movement for problems of any size. The key advantage of the multivector implementation is processing the group of vectors together, which enables the re-use of matrix data, for example, when performing a matrix-vector multiply. An efficient implementation of a block version of an iterative method may be only marginally more expensive per access of coefficient matrix A than a non-block version. While we focused on the B-LGMRES algorithm which performs best for a block size of $s = 2$, clearly these multivector optimizations would benefit larger block sizes and other types of block methods, including those that solve systems with multiple right-hand sides.

7. Concluding remarks. In this paper, we explore the feasibility of modifying restarted GMRES to reduce data movement. We show that for iterative linear solvers, the time to solution is largely dependent on the number of accesses of A from memory as opposed to the total number of matrix-vector multiplies. Therefore, modifications that reduce data movement are a particularly effective means of improving performance. Furthermore, our results indicate that careful attention to implementation details can be quite beneficial and using available performance programming techniques to drive algorithm development can be effective. A unique aspect of this study is the thorough investigation of data movement through the memory hierarchy. Typically the impact of memory performance on an iterative linear solver is not studied in this detail.

Our investigation led to a block variant of the GMRES method that solves a linear system with a single right-hand side. This new method, B-LGMRES, results from choosing error approximation vectors and additional right-hand side vectors. This choice mimics a truncated polynomial-preconditioned conjugate gradient method. In our experiments, B-LGMRES performed best with a block size of two for an approximation space of dimension 30. For larger approximation space sizes and larger problems, a larger block size may prove more beneficial. We find that predicting the algorithm's performance is non-trivial due to its dependence on many factors: problem size (number of nonzeros and matrix order), restart parameter, block size,

matrix properties, preconditioner choices, and machine characteristics. Furthermore, other right-hand side vectors may be more appropriate for particular problem classes. Given the potential performance gains from larger block sizes described in Section 6, our implementation of B-LGMRES can serve as a template for other block methods.

Nevertheless, the substantial improvement in performance due to reduced data movement is sufficient enticement toward pursuing block methods for single right-hand side problems. Given the increasing gap between processor performance and memory access time, re-examining popular linear solver algorithms is particularly important to achieving respectable performance on modern architectures.
