WELL GW-289

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in November 1986, completed with a screened monitored interval from 28.9 to 40.8 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-288 and is located in Bear Creek Valley (BCV), along the western edge of the Bear Creek Burial Grounds (BCBG) waste management area. The BCBG includes numerous hazardous and nonhazardous waste disposal units that received a mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. Liquid wastes included oils, machine coolants, and borax waste water, all or most of which may have contained varying amounts of radioisotopes (primarily uranium isotopes). In 1989, most of the waste-disposal units in the BCBG waste management area were covered with multi-layer, low-permeability caps installed during RCRA closure of the site.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Seventeen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 11 samples between February 1988 and August 1995, and the low-flow sampling method used to obtain six samples between June 1998 and October 2005.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Maryville Limestone). The bulk of the groundwater flow in the Maryville Limestone occurs within this interval, which is a highly permeable zone that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek that traverse the Maryville Limestone and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow toward the Maynardville Limestone, a highly permeable (karst) formation that statigraphically overlies the Maryville Limestone (and Nolichucky Shale) and subcrops along the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 17 ft bgs and exhibits seasonal fluctuations of about 3 ft. Moreover, measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in well GW-289 are typically lower than evident in well GW-288, which is completed at a greater depth (60 ft bgs) in the Maryville Limestone. Based on the distance between the monitored interval midpoint (elevation) in each well (18.4 ft), the contemporaneous groundwater elevations indicate upward vertical hydraulic gradients (0.001 –0.03) from the shallow bedrock interval (GW-288) to the water table interval (GW-289).

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-289 indicate flow to the south and southwest toward the Maynardville Limestone and the main channel of Bear Creek. However, groundwater flow in the Maryville Limestone is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Consequently, the direction(s) of groundwater flow in the vicinity of well GW-289 may be primarily westward (parallel with geologic strike) toward discharge areas in NT-8.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 148 – 205 mg/L, excluding a suspected outlier (96 mg/L) in February 1990;
- pH of 6.2 – 6.81 (field measurements);
- low molar proportions of chloride, sulfate, potassium, and sodium (<10% of total anions/cations);
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Eleven groundwater samples had nitrate concentrations above the analytical reporting limit, with the highest value (0.8 mg/L in March 1989) being substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Four groundwater samples had uranium concentrations that exceeded the analytical reporting limit, with the highest value (0.005 mg/L in October 1988) being substantially less than the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results and detection of common laboratory reagents (e.g., acetone and MC) in samples collected from the well before February 1990, one or more of the following VOCs were detected in the groundwater samples: PCE, TCE, 12DCE, 11DCE, and VC (Table 1). The Walk-In Pits (WIP) are the likely the source of the dissolved VOCs in the shallow groundwater at this well. Groundwater near the WIP contains a distinct plume of dissolved VOCs dominated by PCE, with concentrations in some areas exceeding 2000 µg/L, which is about 1% of the maximum PCE solubility and possibly indicates DNAPLs in the subsurface (DOE 1997).

The primary contaminant in the groundwater near the well is PCE, which has been detected in all of the samples and has a historical maximum concentration of 1,300 µg/L (April 1988). Secondary VOCs are TCE, c12DCE, and VC which have historical maximum concentrations below 20 µg/L. Recent sampling results show that concentrations of PCE and TCE continue to exceed respective drinking water MCLs (Table 1).

As shown by the data summarized below, the PCE concentrations are higher in the groundwater flow/transport pathways intercepted by the monitored interval in well GW-289 than the PCE concentrations in the deeper groundwater flow/transport pathways intercepted by the monitored interval in well GW-288.

Well	PCE Concentration (µg/L)							
	Conventional Sampling				Low-Flow Sampling			
	May 1988	Oct. 1988	Feb. 1990	Aug. 1995	Mar. 2002	Aug. 2002	June 2005	Oct. 2005
GW-288	1,600	1,400	1,200	690	180	250	65	110
GW-289	800	880	590	930	670	690	590	940

These results may reflect the influence of the upward vertical hydraulic gradient from the shallow bedrock interval (GW-288) to the water table interval (GW-289) in the vicinity of these wells (see Section 3.0). The PCE concentrations in the shallower groundwater flow system are at least partially maintained by PCE-contaminated groundwater upwelling from deeper in the Maryville Limestone.

The preceding data summary also suggests a widely fluctuating, indeterminate trend in PCE concentrations at well GW-289, which is illustrated by a time-series plot (Figure 1). These sampling results suggest little if any long-term change in the relative flux of PCE via the groundwater flow/transport pathways intercepted by the monitored interval in the well. Moreover, the persistent low concentrations of TCE and other PCE degradation products in the samples suggest that there is minimal biotic or abiotic degradation of the PCE in the groundwater at this well. Some of the geochemical characteristics of the groundwater at this well (e.g., oxidation-reduction potential is greater than 150 millivolts) are not conducive to anaerobic biotic degradation of PCE.

5.4 GROSS ALPHA ACTIVITY

Two of the eight groundwater samples collected from the well since February 1990 had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (1.54 pCi/L in June 1998) being substantially below the MCL for gross alpha activity (15 pCi/L). Results obtained before January 1990 do not meet applicable data quality objectives because the sample specific MDA and/or CE are not available for these samples.

5.5 GROSS BETA ACTIVITY

Three of the eight groundwater samples collected from the well since February 1990 had gross beta activity above the applicable MDA and corresponding CE, with the highest value (8.6 pCi/L in June 1998) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). Results obtained before January 1990 do not meet applicable data quality objectives because the sample specific MDA and/or CE are not available for these samples.

WELL GW-291

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in November 1986, completed with a screened monitored interval from 6.7 to 14.2 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-290 and is located in Bear Creek Valley (BCV) on the southern flank of Pine Ridge, south of Burial Ground C-West in the Bear Creek Burial Grounds (BCBG) waste management area. The BCBG includes numerous hazardous and nonhazardous waste disposal units that received a mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. Liquid wastes included oils, machine coolants, and borax waste water, all or most of which may have contained varying amounts of radioisotopes (primarily uranium isotopes). In 1989, most of the waste-disposal units in the BCBG waste management area were covered with multi-layer, low-permeability caps installed during RCRA closure of the site.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Seventeen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 11 samples between February 1988 and August 1995, and the low-flow sampling method used to obtain six samples between June 1998 and October 2005.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Maryville Limestone). The bulk of the groundwater flow in the Maryville Limestone occurs within this interval, which is a highly permeable zone that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek that traverse the Maryville Limestone and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow toward the Maynardville Limestone, a highly permeable (karst) formation that statigraphically overlies the Maryville Limestone (and Nolichucky Shale) and subcrops along the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 9 ft bgs and exhibits seasonal fluctuations of about 3 ft. Moreover, measurements recorded during a contemporaneous sampling event (i.e., within 24 hours) showed that the presampling groundwater elevation in well GW-291 was lower than that evident in well GW-290, which is completed at a greater depth (32.5 ft bgs) in the Maryville Limestone. Based on the distance between the monitored interval midpoint (elevation) in each well (15.18), the contemporaneous groundwater elevations indicate an upward vertical hydraulic gradient (0.213) from the shallow bedrock interval (GW-290) to the water table interval (GW-291).

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-291 indicate flow to the south and southwest toward the Maynardville Limestone and the main channel of Bear Creek. However, groundwater flow in the Maryville Limestone is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Consequently, the direction(s) of groundwater flow in the vicinity of well GW-291 may be primarily westward (parallel with geologic strike) toward discharge areas in NT-8 (the well is located just south of NT-8-E).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 176 – 267 mg/L;
- pH of 6.4 – 7.1 (field measurements);
- low molar proportions of chloride, sulfate, potassium, and sodium (<10% of total anions/ cations);
- elevated boron concentrations (>2 mg/L), probably from borax waste water (see Section 1.0); and
- total concentrations of other trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Fourteen groundwater samples had nitrate concentrations above the analytical reporting limit, with the highest value (0.6 mg/L in February 1988) being substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Three groundwater samples had uranium concentrations that exceeded the analytical reporting limit, with the highest concentration (0.002 mg/L in August 1989) being substantially less than the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results and detection of common laboratory reagents (e.g., acetone) in samples collected from the well before February 1990, one or more of the following VOCs were detected in the groundwater samples: PCE, TCE, 12DCE, 111TCA, trichlorofluoromethane (TCFM), 11DCA, and 12DCA (Table 1). The Walk-In Pits (WIP) are the likely the source of the dissolved VOCs in the shallow groundwater at this well. Groundwater near the WIP contains a distinct plume of dissolved VOCs dominated by PCE, with concentrations in some areas exceeding 2000 µg/L, which is about 1% of the maximum PCE solubility and possibly indicates DNAPLs in the subsurface (DOE 1997).

The primary contaminants in the groundwater samples are PCE and TCE, which have been detected in all of the samples, have historical maximum concentrations that exceed 100 µg/L, and continue to exceed the applicable drinking water MCL (Table 1). The secondary contaminants in the samples are c12DCE and TCFM, which have been detected in all samples for which the compounds have been reported and have historical maximum concentrations less than 10 µg/L. The low concentration of c12DCE and lack of other degradation products in the samples (11DCE or VC) suggest that there is minimal biotic or abiotic degradation of the PCE and TCE in the groundwater at this well.

A time-series plot of the PCE concentrations shows a widely fluctuating, indeterminate long-term trend (Figure 1). The indeterminate trend, also evident in concentration trends of the individual VOCs (Table 1), suggests little long-term change in the relative flux of dissolved VOCs along the shallow groundwater flowpaths intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

Two of the 10 groundwater samples collected from the well since February 1990 had gross alpha activity above the applicable MDA and corresponding CE, with the highest values (2.25 pCi/L in March 1991) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Three of the 10 groundwater samples collected from the well since February 1990 had gross beta activity above the applicable MDA and corresponding CE, with the highest value (6.06 pCi/L in March 1991) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-300

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in July 1987, completed with a screened monitored interval from 132 to 147 ft bgs, and constructed nominal 4.5-inch diameter stainless steel (Type 304) and well screen (0.01 slot wire-wound). The well is located on the southern flank of Chestnut Ridge southeast of Y-12, just southwest of the Chestnut Ridge Borrow Area Waste Pile (CRBAWP). Before the CRBAWP was established (in 1984), the area served as as a borrow area (known as the East Borrow Area) for soil to be used in construction of multilayer caps. The CRBAWP contained low level mercury-contaminated soils from the Oak Ridge Civic Center/Sewer Line Beltway Project. These materials were excavated from the CRBAWP and transported to Industrial Landfill V during 2000 for final disposal.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-one groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 29 samples between February 1988 and April 1996, and the low-flow sampling method used to obtain samples in April and October 2004.

Unusually low levels of TDS (<150 mg/L) are a distinguishing characteristic of the groundwater samples from this well (see Section 4.0). The low TDS of the samples suggests relatively low residence time for the groundwater in the well, which indicates that the monitored interval for the well intercepts highly permeable groundwater flowpaths.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the lower Knox Group, which forms the steep northern flank of Chestnut Ridge. The Knox Group formations, along with the uppermost formation (Maynardville Limestone) of the underlying Conasauga Group, comprise an aquifer consisting of three vertically gradational subsystems distinguished by groundwater flux, which decreases with depth: (1) the stormflow zone, (2) the vadose zone, and (3) the groundwater zone (Solomon et al. 1992). The stormflow and vadose zones occur at shallow depths within the thick (>100 ft) residuum that has developed on Chestnut Ridge. In the bedrock zone, orthogonal sets of permeable, planar fractures form water-producing zones within an essentially impermeable matrix, and dissolution of carbonates has enlarged fractures and produced an interconnected conduit-flow system characteristic of karst aquifers. Because the occurrence of solution features and the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity of the groundwater zone is vertically gradational. Most groundwater flux occurs within the transitional horizon between residuum and unweathered bedrock (water table interval); lower flux (and longer solute residence times) occurs at successively greater depths in the bedrock (Solomon et al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 108 ft bgs and exhibits moderate (about 18 ft) seasonal fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-300 indicate flow to the south-southwest toward a drainage features that traverse the broad southern flank of the ridge.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date indicates that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 106 – 184 mg/L;
- pH of 7.1 – 7.8 (field measurements), excluding a suspected outlier (4.3 in September 1992);
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite);
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. Additionally, mercury is a contaminant of concern at the CRBAWP (see Section 1.0). As discussed in the following sections, which are based on the respective monitoring data reported for the groundwater samples collected from the well since January 1991, none of the principal contaminants are present at elevated concentrations in the groundwater at this well.

5.1 NITRATE

Six groundwater samples collected to date had nitrate concentrations at or above the applicable analytical reporting limit, with the highest concentration (0.5 mg/L in April 1995) being an order-of-magnitude below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Two of the groundwater samples collected to date had uranium concentrations above the applicable analytical reporting limit, and the highest result (0.001 mg/L in July 1994) is an order-of-magnitude lower than the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were not detected in any of the groundwater samples collected to date:

5.4 GROSS ALPHA ACTIVITY

Five groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (12.2 pCi/L in April 1996) being slightly below the MCL for gross alpha activity (15 pCi/L). However, this result appears to be an outlier because the other values area all less than 5 pCi/L.

5.5 GROSS BETA ACTIVITY

Three groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, with the highest value (24 pCi/L in February 1992) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

5.6 Mercury

None of the groundwater samples collected to date had mercury concentrations above the reporting limit.

WELL GW-301

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in July 1987, completed with a screened monitored interval from 148.5 to 163.5 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located on the crest of Chestnut Ridge south of Y-12 (unless noted otherwise, directions are in reference to the Y-12 grid system), about 200 ft northeast (hydraulically downgradient) of the Chestnut Ridge Borrow Area Waste Pile (CRBAWP). The CRBWAP was used from the mid-1980s as a storage site for soils contaminated with mercury and other metals; all soil was removed from the site in 2000.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-six groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 32 samples between February 1988 and July 1997, and the low-flow sampling method used to obtain 14 samples between January 1998 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the Knox Group (Copper Ridge Dolomite). Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 130 ft bgs and exhibit substantial (17 ft) water-level fluctuations, which is typical of many Knox Group wells on Chestnut Ridge.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 90 – 230 mg/L;
- pH (field measurements) of 6.5 – 8.7;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for 34 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Twenty-three groundwater samples (collected between February 1991 and January 1999) had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.64 mg/L in April 1995) being below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Three groundwater samples had uranium concentrations above the applicable analytical reporting limit, and each result (0.001 mg/L) is substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected in four groundwater samples: acetone in October 1991(13 µg/L) and July 1998 (1 µg/L), chloroform in July 1997 (1 µg/L), chloromethane in January 2000 (2 µg/L), and bromomethane January 2000 (2 µg/L). These results are considered to be outliers.

5.4 GROSS ALPHA ACTIVITY

Nine groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (5.62 pCi/L in January 2003) being below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Twelve groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (8.43 pCi/L in May 1992) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-302

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in November 1989, completed with a screened monitored interval from 121.5 to 134.8 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located on the crest of Chestnut Ridge south of Y-12 (unless noted otherwise, directions are in reference to the Y-12 administrative grid), about 200 ft northeast (hydraulically downgradient) of the United Nuclear Corporation Site (UNCS). The UNCS is a closed facility that was used for the disposal of cement-fixed sludge and radiologically-contaminated soils and demolition debris. A multilayer low-permeability cap was installed at the site in 1992 in accordance with the CERCLA ROD signed in 1991 (DOE 1991).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-eight groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 26 samples between May 1990 and April 1997, and the low-flow sampling method used to obtain 12 samples between November 1997 and August 2003.

Elevated concentrations of chromium and nickel attributable to chemical and/or microbiologically-induced corrosion of the stainless steel well casing and/or screen (see Section 5.6) are a distinguishing characteristic of the groundwater samples from this well. It may be necessary to extensively purge (or redevelop) the well before sampling to obtain representative monitoring results for these metals.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the Knox Group. The average static groundwater level in the well is 99 ft below ground surface. Presampling depth-to-water measurements for the well indicate substantial (10 - 25 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- moderate TDS (>150 mg/L<800 mg/L);
- pH (field measurements) of 6.7 – 7.7;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of potassium and sulfate (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals (except chromium and nickel) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Groundwater samples from this well typically contain chloride concentrations above 20 mg/L and sodium levels above 10 mg/L, which exceed the respective UTLs for groundwater in the Knox Group. Elevated concentrations of these ions may result from the recharge of surface water containing dissolved salt used to de-ice the South Patrol Road. Similarly elevated levels of chloride and sodium also are evident in other wells at the UNCS (1090 and GW-339) that are accessed via this paved road, whereas much lower chloride and sodium concentrations (less than respective UTLs) are evident in the wells at the site that are accessed via a gravel road (GW-203, GW-205, and GW-221). Alternatively, elevated chloride and sodium concentrations in the groundwater at these wells may reflect dissolution of locally disseminated evaporite minerals. In either case, the elevated chloride levels in the groundwater at the well may play a role in maintaining the elevated chromium and nickel concentrations in the samples from the well (see Section 5.6) because chloride may combine with available metal cations to form soluble complexes that do not readily partition to mineral surfaces in the monitored-interval filter pack materials and surrounding bedrock (McLean and Bledsoe 1992).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Also, as noted previously, chromium and nickel are contaminants in the groundwater samples from this well. The following discussion of contaminant concentrations in the well is based on the analytical results reported for groundwater samples collected from the well since January 1991.

5.1 NITRATE

Thirty-two groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (3.3 mg/L) being below the MCL for nitrate (10 mg/L).

5.2 URANIUM

One groundwater sample had a uranium concentration above the applicable analytical reporting limit and this result (0.002 mg/L) is substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for each groundwater sample show non-detect values or false positive results for all of the VOCs analyzed.

5.4 GROSS ALPHA ACTIVITY

Fourteen groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (10.77 pCi/L) being below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Eleven groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (19.6 pCi/L) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

5.6 OTHER

Almost all of the groundwater samples collected from the well since January 1991 contained total chromium and/or nickel concentrations above the respective analytical reporting limit. As shown below in Table 1, most of the chromium and nickel concentrations exceed respective background levels (UTLs) in the Knox Aquifer and 22 of the samples had chromium and/or nickel concentrations above respective MCLs of 0.1 mg/L.

Table. Chromium and nickel results for well GW-302

Sampling Method and Date	Total Concentration (mg/L)

08/12/03	0.0432	0.0469
Note: Bold typeface denotes results that exceed the MCL.		

The following considerations suggest that elevated concentrations of nickel and chromium in the groundwater samples from this well are most likely attributable to corrosion of the stainless steel (Type 304) riser casing and well screen: (1) mobile species of these metals are not typically present in groundwater with the neutral pH evident in the well; (2) Type 304 stainless steel contains 18-20% chromium and 8-12% nickel and is prone to crevice corrosion (Oakley and Korte 1996); (3) groundwater in the well exhibits geochemical conditions that may be corrosive to Type 304 stainless steel (e.g., dissolved oxygen >2 mg/L; Driscoll 1986); and (4) as noted in Section 4.0, elevated chloride levels in the groundwater may greatly limit the partitioning of nickel and chromium ions in the well.

In addition to the considerations listed above, results of microbiological sampling of selected Knox Group wells in February 2000 support the possibility of microbiologically induced corrosion (MIC) of the stainless steel riser casing and screen as a potential source of the elevated nickel and chromium concentrations in the groundwater from the well. The microbiological sampling targeted four wells with stainless steel riser casing and screen, including an upgradient/background well (GW-521) and three wells where corrosion is suspected (GW-302, GW-305, and GW-339), and one well with PVC riser casing and screen (GW-203). Qualitative bacterial counts, estimated from the appearance of each groundwater sample after an eight- to nine-day growth period, provided data regarding the relative degree of microbial activity in the groundwater at each well (AJA 2001). As shown below in Table 2, the microbiological sampling results indicate: (1) microbial activity in the groundwater samples from each well where corrosion is suspected; (2) negligible microbial activity in the groundwater sample from the upgradient background well; and (3) high bacterial counts for the sample from well GW-203, which has PVC well casing and screen and does not yield groundwater samples with elevated chromium or nickel concentrations.

Table 2. February 2000 Microbiological Sampling Results

Well	Riser/Screen Material	Indication of Corrosion?	Maximum Bacterial Count (colony forming units per milliliter)		
			Iron-Related	Slime-Forming	Sulfate-Reducing
GW-203	PVC	No	5,000	50,000	<100
GW-302	Stainless steel	Yes	<100,000	<50,000	<100
GW-305	Stainless Steel	Yes	5,000	500,000	100
GW-339	Stainless steel	Yes	5,000	50,000	<100
GW-521	Stainless steel	No	<100	<100	<100
Note: Modified from (AJA 2001).					

Iron-related bacteria and slime-forming bacteria have been documented to cause MIC of stainless steel (Sarouhan et al. 1998).

WELL GW-305

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1987, completed with a screened monitored interval from 165.3 to 179.6 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located on the crest of Chestnut Ridge southwest of the west end of Y-12, about 100 ft directly east (hydraulically downgradient) of Industrial Landfill IV. In operation since 1989, this landfill receives about 12,000 ft^3 per year of nonhazardous and nonradioactive industrial wastes, including cardboard, plastics, rubber, scrap metal, wood, paper, and special wastes generated from DOE operations on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Sixty-three groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 36 samples between February 1988 and July 1997, and the low-flow sampling method used to obtain 27 samples between January 1998 and October 2004.

Groundwater samples from this well are distinguished by elevated total (and dissolved) concentrations of nickel that are probably attributable to chemical and/or microbiologically-induced corrosion of the stainless steel riser casing and/or well screen (see Section 5.6).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from bedrock in the lower Knox Group (Copper Ridge Dolomite), which underlies the steep northern flank of Chestnut Ridge. The Knox Group formations, along with the uppermost formation (Maynardville Limestone) of the underlying Conasauga Group, comprise an aquifer consisting of three vertically gradational subsystems distinguished by groundwater flux, which decreases with depth: (1) the stormflow zone, (2) the vadose zone, and (3) the groundwater zone (Solomon et al. 1992). The stormflow and vadose zones occur at shallow depths within the thick (>100 ft) residuum that has developed on Chestnut Ridge. In the bedrock zone, orthogonal sets of permeable, planar fractures form water-producing zones within an essentially impermeable matrix, and dissolution of carbonates has enlarged fractures and produced an interconnected conduit-flow system characteristic of karst aquifers. Because the occurrence of solution features and the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity of the groundwater zone is vertically gradational. Most groundwater flux occurs within the transitional horizon between residuum and unweathered bedrock (water table interval); lower flux (and longer solute residence times) occurs at successively greater depths in the bedrock (Solomon et al. 1992).

The average result of several falling head permeability tests performed in well GW-305 (Jones 2004) shows that the average hydraulic conductivity of the bedrock near the well is about 8.7×10^{-6} cm/s (0.025 ft/day). This indicates that the monitored interval for the well intercepts low-permeability groundwater flow/transport pathways.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 120 ft bgs and exhibits substantial (>15 ft) seasonal fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-305 indicate radial flow directions, with components of flow to the north into BCV, to the east along the axis of the ridge (parallel with geologic strike), and south toward drainage features that traverse the broad southern flank of the ridge.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS 88 – 240 mg/L;
- pH of 7.1 – 8.6 (field measurements);
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total concentrations of trace metals (except nickel) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the respective monitoring data reported for the groundwater samples collected from the well since January 1991, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Thirty-five groundwater samples had nitrate above the applicable analytical reporting limit; all the results are less than 1 mg/L and are substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Uranium concentrations reported for the groundwater samples collected in July 2004 (0.004 mg/L) and November 1999 (0.00122 mg/L) exceed the applicable analytical reporting limit; both results are substantially below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs have been detected in Forty-one of the groundwater samples collected since January 1992 (Table 1): 11DCA, 11DCE, and 111TCA. The source of these VOCs has not been confirmed but is probably Industrial Landfill IV, which is the only potential contaminant source area that is hydraulically upgradient of the well. However, chlorinated hydrocarbons or other wastes containing VOCs are not noted in the waste disposal records for the landfill. Additionally, assuming rapid migration to the saturated zone and unimpeded advective transport in the groundwater, the average hydraulic conductivity value (0.025 ft/d) indicated by falling head permeability tests in well GW-305 (Jones 2004) do not support transport of dissolved VOCs to the well within the time period (825 days) between the initial disposal of waste at Industrial Landfill IV (October 1, 1989) and the first-time detection of 111TCA in the well (January 4, 1992). Thus, the repeated detection of 111TCA and other VOCs in the groundwater samples from the well, despite the apparently low permeability of the flowpaths intercepted by the monitored interval in the well, suggest that: (1) the VOCs are from an unknown source area located very close to the well; (3) the VOCs are from undocumented or misidentified wastes disposed in Industrial Landfill IV, and have migrated via a combination of mechanisms (e.g., vapor phase transport) that may greatly increase the rate of transport relative to the groundwater flow rate inferred from the falling head permeability tests; or (3) the VOCs are from undocumented or misidentified wastes disposed in Industrial Landfill IV that were present in the groundwater at the well before January 1992, but were not detected in the groundwater samples collected from the well, perhaps because purging the well for conventional sampling diluted the samples.

The VOC data summarized in Table 1 and time-series plots (Figure 1) show: (1) the initial detection of 111TCA in January 1992 (0.6 μg/L) and subsequent concentration increase through July 2000 (26 μg/L), followed by a more indeterminate trend through October 2004 (18 μg/L); (2) the initial detection of 11DCA in July 1996 (1 μg/L) and subsequent concentration increase July 2003 (17 μg/L), followed by a more indeterminate trend through October 2004 (17 μg/L); and (3) the initial detection of 11DCE in January 1997 (1 μg/L), a subsequent increase through July 2003 (6.4 μg/L), followed by a slightly decreasing trend through October 2004 (4.6 μg/L). The sequential detection of these VOCs potentially reflects the arrival of the parent compound (111TCA) followed by the arrival of related degradation products (11DCA and 11DCE).

5.4 GROSS ALPHA ACTIVITY

Eight groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (12.4 pCi/L in July 1994) being slightly below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Six groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (12.2 pCi/L in July 1994) being substantially less than the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

5.6 OTHER

As noted in Section 2.0, the groundwater samples from this well typically contain elevated nickel concentrations; 34 of the samples had nickel concentrations above the UTL, with 24 results exceeding the MCL, including nickel results reported for all but two of the samples collected since July 1999 (Table 2). Corrosion of the stainless steel well casing and screen in the well is the suspected source of the nickel (and chromium) in the samples because: (1) mobile species of nickel are not typically present in groundwater with the neutral pH evident in the well; (2) Type 304 stainless steel contains 18-20% chromium and 8-12% nickel and is prone to crevice corrosion (Oakley and Korte 1996); and (3) microbiological sampling results support the possibility of microbiologically induced corrosion (MIC). The microbiological sampling targeted four wells with stainless steel riser casing and screen, including an uncontaminated (upgradient/background) well (GW-521), three wells where corrosion of the riser casing/well screen is suspected (GW-302, GW-305, and GW-339), and one well with PVC riser casing and screen (GW-203) that does not yield samples with elevated chromium and/or nickel concentrations. Qualitative bacterial counts estimated from the appearance of each groundwater sample after an eight- to nine-day growth period, summarized in Table 3, indicate: (1) microbial activity, particularly iron-related and slime-forming bacteria, in the groundwater samples from each well where corrosion is suspected; (2) negligible microbial activity in the groundwater sample from the uncontaminated well; and (3) high bacterial counts for the sample from the well with PVC riser casing and screen (AJA 2001). Iron-related bacteria and slime-forming bacteria have been documented to cause MIC of stainless steel (Sarouhan et. al. 1998).

Two unidentified cylindrical objects were observed at the bottom of the well during a borehole camera survey performed in November 1999 (LMES 1999). The composition of the objects could not be determined from the camera survey, but if either object is metallic, then galvanic corrosion of the object(s) and the well end-cap also may be a source of the nickel in the groundwater samples from the well.

WELL GW-307

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in July 1987, completed with a screened monitored interval from 28.7 to 41.6 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley (BCV) west of Y-12, directly south of the main channel of Bear Creek and approximately 100 ft north of the western end of the Rust Spoil Area, which was used from 1975 to 1983 for disposal of construction debris generated at Y-12.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 11 samples between February 1988 and April 1991, and the low-flow sampling method used to obtain samples in March and August 2005. The sampling history includes a quarterly sampling frequency followed by a 14-year period (April 1991 – March 2005) when no samples were collected from the well, and semiannual sampling in 2005.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Maynardville Limestone (Conasauga Group), which exhibits the hydrologic characteristics typical of karst aquifers. Most groundwater flow in the Maynardville Limestone, which subcrops along the axis of BCV and underlies the main channel of Bear Creek, occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Hydrologic interaction between the creek and the shallow karst network provides the principal exit-pathway for contaminants released from source areas within the Bear Creek watershed west of Y-12. Below the shallow karst network, fractures provide the primary groundwater flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of approximately 26 ft bgs and exhibits seasonal fluctuations of approximately 10 ft. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV and on Chestnut Ridge, groundwater elevation isopleths in the vicinity of the Rust Spoil Area indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the unfiltered groundwater samples collected to date show that the well yields sulfate-enriched, calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 536 – 728 mg/L;
- pH of 6.33 – 6.7 (field measurements);
- low molar proportions of chloride, potassium, and sodium (<10% of total anions/cations);
- elevated sulfate concentrations (>80 mg/L); and

- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

It is not clear if the elevated sulfate concentrations typical of the groundwater samples reflect localized geochemical characteristics, such as dissolution of locally disseminated sulfide minerals, or if the elevated concentrations are the result of contamination from one or more sources located hydraulically upgradient of the well, including the Rust Spoil Area.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that nitrate and VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit (Table 1), including eleven samples with concentrations that exceed the drinking water MCL for nitrate (10 mg/L). Elevated nitrate concentrations in the samples indicate that the monitored interval for the well intercepts groundwater flow/transport pathways for nitrate (and other contaminants) released from the former S-3 Ponds, which are RCRA-regulated, unlined surface impoundments that were closed in 1988 and covered with a multilayer low-permeability cap in 1989. Located approximately 2,600 ft east-northeast (hydraulically upgradient) of the well, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984, which emplaced a heterogeneous plume of inorganic, organic, and radiological contaminants in the groundwater. Nitrate, a principal component of the plume, enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale, which underlies the former S 3-Ponds, and recharge of nitrate-contaminated surface water in Bear Creek (DOE 1997). Because nitrate is chemically stable and highly mobile in groundwater, the elevated concentrations of nitrate (>10 mg/L) effectively trace the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells, the extent of elevated nitrate concentrations in the Maynardville Limestone west of Y-12 reflects: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for approximately 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) and is significantly influenced by hydrologic communication with surface water in Bear Creek.

As shown by the groundwater sampling results summarized in Table 1, nitrate concentrations above the 10 mg/L drinking water MCL were reported for each sample collected between February 1988 and April 1991, with the historical maximum concentration of 40 mg/L in August 1988. In contrast, nitrate concentrations near 2.5 mg/L were detected in the samples collected most recently (March and August 2005). These results define a clearly decreasing long-term concentration trend, as illustrated by a time-series plot of the nitrate data (Figure 1), which undoubtedly corresponds with the substantially reduced flux of nitrate in the Maynardville Limestone that occurred in response to the closure/capping of the former S-3 Ponds. Note that the most recent nitrate results suggest that the rate of concentration decrease has slowed considerably. For example, the nitrate concentration evident in April 1991 (11 mg/L) reflects an approximately 75% decrease from the historical maximum evident only 19 months earlier (August 1988), but a further 75% decrease subsequently is evident 14 years later in March (2.24 mg/L) and August 2005 (2.67 mg/L). This suggests that the nitrate concentrations in the groundwater at this well may have reached asymptotic levels, which indicates that the most highly contaminated groundwater has been flushed from the shallow karst network in the Maynardville Limestone underlying the upper reaches of Bear Creek (DOE 1997). Thus, the nitrate concentrations may have reached asymptotic levels that reflect the relative rate of influx from less permeable intervals (matrix diffusion) and natural attenuation processes.

5.2 URANIUM

Ten groundwater samples collected to date had uranium concentrations above the applicable analytical reporting limit (Table 1), with the highest concentration (0.007 mg/L in May 1988) being substantially below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected since November 1989 (previous samples were not analyzed for VOCs): acetone, CTET, chloroform, PCE, TCE, 12DCE (isomers), 11DCA, 111TCA, and 4-methyl-2-pentaone (Table 2). The presence of VOCs in the samples indicates that the monitored interval in the well intercepts groundwater flow/transport pathways for VOCs released from one or more upgradient sources that contribute to an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. Available data for the network of wells completed in the Maynardville Limestone west of the flow divide indicate that VOC-contaminated groundwater, as defined by individual or summed VOC concentrations above 5 µg/L, appears to originate near Spoil Area I and to extend hydraulically downgradient for several thousand feet westward (parallel with geologic strike) down the axis of BCV. The apparent distribution of VOCs within the plume reflects the relative influx from multiple source areas, commingling during downgradient groundwater transport, and hydraulic communication with Bear Creek (DOE 1997). In the upper part of BCV, hydraulically upgradient (east) of the well, the primary VOCs are TCE, c12DCE, and PCE and the confirmed or suspected source areas include Spoil Area I, the contaminant plume emplaced during historical operation of the former S-3 Ponds, and the Rust Spoil Area (or nearby source within the Bear Creek floodplain), the latter site considered a primary source of TCE.

Based on frequency of detection and concentration magnitude, the primary VOC in the groundwater samples is TCE, which is the only VOC detected in all of the samples collected to date, with concentrations above 50 µg/L detected in most of the samples collected before the extended (14-year) gap in the sampling history. Also, the most recent sampling results (March and August 2005) show that the TCE concentrations remain above the drinking water MCL (Table 2). At least one of the other VOCs was detected in each sample collected to date, with 12DCE detected at the highest concentration (23 µg/L in May 1990) and all the other compounds except chloroform detected at concentrations below 5 µg/L. Also, the most recent sampling results (March and August 2005) show that the concentrations of CTET, PCE, and c12DCE are less than corresponding MCLs (Table 2). The Rust Spoil Area (or nearby undocumented source within the Bear Creek floodplain) is the suspected source of the TCE in the groundwater at this well (DOE 1997). Considering the elevated nitrate concentrations and presence of Tc-99 in the groundwater at this well, the contaminant plume emplaced during historical operation of the S-3 Ponds also is a potential source of VOCs in the well, as is Spoil Area I, which was used from 1980 to 1988 for the disposal of construction spoil and related debris generated at Y-12 and is the suspected source of the VOCs (primarily PCE, TCE, and 12DCE) in monitoring wells at the site (DOE 1997).

As shown on Figure 2, a time-series plot of TCE concentrations detected in the groundwater samples collected since November 1989 shows a variable but clearly decreasing long-term concentration trend spanning the prolonged gap in the sampling history for the well. This trend suggests a corresponding decrease in the relative flux of TCE via the groundwater flow/transport pathways intercepted by the monitored interval in the well. Interestingly, the concentrations of other VOCs detected in the samples do not show a similar long-term decrease, as illustrated by the equal PCE concentrations (2 µg/L) reported for the samples collected in January 1990 and March 2005. Assuming a heterogeneous mixture of dissolved VOCs in the groundwater from the shallow karst network in the Maynardville Limestone, it is unclear why the VOC concentrations exhibit such divergent trends. Perhaps the TCE is not well mixed with other VOCs in the groundwater system, but instead occurs within separate, discreet transport pathways intercepted by the monitored interval in the well. Separate transport from different source areas also may occur, with more temporally variable flux from the source of TCE but more consistent flux of PCE from a separate upgradient source area (e.g., Spoil Area I).

5.4 GROSS ALPHA ACTIVITY

Five groundwater samples collected since January 1990 (the sample-specific MDA and/or CE are not available for previous samples) had gross alpha activity above the applicable MDA and corresponding CE (Table 1), with the highest values (8.02 pCi/L in August and October 1990) being below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Seven groundwater samples collected since January 1990 (the sample-specific MDA and/or CE are not available for previous samples) had gross beta activity above the applicable MDA and corresponding CE (Table 1), including two values (51.3 pCi/L in January 1990 and 51.1 pCi/L in August 1990) that slightly exceed the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). The source of the gross beta activity in the groundwater at this well is Tc-99, which was detected (i.e., >MDA and CE) in the groundwater samples collected in March (16 pCi/L) and August 2005 (19 pCi/L), although both results are substantially below SDWA screening level (900 pCi/L) for a 4 mrem/yr dose equivalent from Tc-99. Nevertheless, Tc-99 is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, which is the only site at Y-12 that received wastes containing this radionuclide (DOE 1997). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the transport of Tc-99 in the Maynardville Limestone closely mirrors that of nitrate, which reflects their common source and their similar transport characteristics in the groundwater.

A time-series plot of gross beta activity reported for the groundwater samples collected since January 1990 shows a decreasing long-term concentration trend (Figure 3). This decreasing trend for gross beta activity is probably attributable to the closure/capping of the former S-3 Ponds, which substantially reduced relative flux of Tc-99 in the Maynardville Limestone downstream of the site. Additionally, as with the nitrate concentrations in the well, gross beta activity appears to be decreasing at a slower rate than indicated by historical data. For instance, gross beta activity evident in April 1991 (27 pCi/L) reflects an approximately 50% decrease from the level evident in August 1990 (51 pCi/L), with a further 75% decrease indicated by the nitrate concentrations nearly 15 years (171 months) later in August 2005 (14 pCi/L). These findings suggest that gross beta activity may have reached essentially asymptotic levels.

WELL GW-310

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in July 1987, completed with a screened monitored interval from 19.5 to 27.1 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley west of Y-12, directly south of the main channel of Bear Creek and approximately 50 ft east of the northeast corner of the Rust Spoil Area, which was used from 1975 to 1983 for disposal of construction debris generated at Y-12.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fifteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 13 samples between February 1988 and April 1991, and the low-flow sampling method used to obtain samples in March and August 2005. The sampling history includes a quarterly sampling frequency followed by a 14-year period (April 1991 – March 2005) when no samples were collected from the well, with semiannual sampling in 2005.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Maynardville Limestone (Conasauga Group), which exhibits the hydrologic characteristics typical of karst aquifers. Most groundwater flow in the Maynardville Limestone, which subcrops along the axis of BCV and underlies the main channel of Bear Creek, occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Hydrologic interaction between the creek and the shallow karst network provides the principal exit-pathway for contaminants released from source areas within the Bear Creek watershed west of Y-12. Below the shallow karst network, fractures provide the primary groundwater flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of approximately 18 ft bgs, and exhibits seasonal fluctuations of approximately 3 ft. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV and on Chestnut Ridge, groundwater elevation isopleths in the vicinity of the Rust Spoil Area indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the unfiltered groundwater samples collected to date show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 432 – 700 mg/L;
- pH of 6.1 – 6.59 (field measurements);
- low molar proportions of chloride, sulfate, potassium, and sodium (<15% of total anions/cations); and

- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that nitrate and VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit (Table 1), including eleven samples with concentrations that exceed the drinking water MCL for nitrate (10 mg/L). Elevated nitrate concentrations in the samples indicate that the monitored interval for the well intercepts groundwater flow/transport pathways for nitrate (and other contaminants) released from the former S-3 Ponds, which are RCRA-regulated, unlined surface impoundments that were closed in 1988 and covered with a multilayer low-permeability cap in 1989. Located approximately 1,700 ft east-northeast (hydraulically upgradient) of the well, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984, which emplaced a heterogeneous plume of inorganic, organic, and radiological contaminants in the groundwater. Nitrate, a principal component of the plume, enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale, which underlies the former S-3 Ponds, and recharge of nitrate-contaminated surface water in Bear Creek (DOE 1997). Because nitrate is chemically stable and highly mobile in groundwater, the elevated concentrations of nitrate (>10 mg/L) effectively trace the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells, the extent of elevated nitrate concentrations in the Maynardville Limestone west of Y-12 reflects: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for approximately 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) and is significantly influenced by hydrologic communication with surface water in Bear Creek.

As shown by the groundwater sampling results summarized in Table 1, nitrate concentrations reported for all but one of the samples collected between February 1988 (29.1 mg/L) and January 1991 (14 mg/L) exceed the 10 mg/L drinking water MCL, with the historical maximum concentration of 61 mg/L in August 1988. In contrast, nitrate concentrations near 5 mg/L were detected in the samples collected in April 1991 and in March and August 2005. These results define a clearly decreasing long-term concentration trend, as illustrated by a time-series plot of the nitrate data (Figure 1), but suggest that the rate of concentration decrease has slowed. For example, the nitrate concentration evident in April 1991 (5 mg/L) reflects an approximately 90% decrease from the historical maximum concentrations evident only 19 months earlier (August 1988), but indicates little significant change compared to the nitrate concentration evident 15 years later in March (3 mg/L). The overall decrease in nitrate concentrations primarily reflects the substantially reduced flux of nitrate in the Maynardville Limestone following the closure/capping of the former S-3 Ponds, and the slowing rate of decrease in nitrate concentrations indicates that the most highly contaminated groundwater has been flushed from the shallow karst network in the Maynardville Limestone. Thus, the nitrate concentrations may have reached asymptotic levels that reflect the relative rate of influx from less permeable intervals (matrix diffusion) and natural attenuation processes.

5.2 URANIUM

Eleven groundwater samples collected to date had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.007 mg/L in May 1988) being substantially below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected since May 1989 (previous samples were not analyzed for VOCs): chloroform, PCE, TCE, 12DCE, and 4-methyl-2-pentaone (4M2P) (Table 2). The presence of VOCs in the samples indicates that the monitored interval in the well intercepts groundwater flow/transport pathways for VOCs released from one or more upgradient sources that contribute to an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. Available data for the network of wells completed in the Maynardville Limestone west of the flow divide indicate that VOC-contaminated groundwater, as defined by individual or summed VOC concentrations above 5 µg/L, appears to originate near Spoil Area I and to extend hydraulically downgradient for several thousand feet westward (parallel with geologic strike) down the axis of BCV. The apparent distribution of VOCs within the plume reflects the relative influx from multiple source areas, commingling during downgradient groundwater transport, and hydraulic communication with Bear Creek (DOE 1997). In the upper part of BCV, hydraulically upgradient of the well, the primary VOCs are TCE, c12DCE, and PCE and the confirmed or suspected source areas include Spoil Area I, the contaminant plume emplaced during historical operation of the former S-3 Ponds, and the Rust Spoil Area (or nearby source within the Bear Creek floodplain), the latter site considered a primary source of TCE.

Based on frequency of detection and concentration magnitude, the primary VOCs in the groundwater samples are TCE and 12DCE, one or both of which were detected in each of the samples collected to date, with a historical maximum concentration above 100 µg/L for each compound (Table 2). Additionally, the most recent (March and August 2005) show that TCE concentrations remain at or slightly above the 5 µg/L drinking water MCL. Of the other VOCs detected in the samples, most of the results are less than 5 µg/L, and only PCE was detected in any of the samples collected after January 1990 (Table 2). Also, as noted above, the dominance of TCE in the samples is believed to indicate groundwater transport/migration from the Rust Spoil Area (or nearby source within the Bear Creek floodplain). Considering the elevated nitrate concentrations in the groundwater samples, the contaminant plume emplaced during historical operation of the S-3 Ponds also is a potential source of VOCs in the well, as is Spoil Area I, which was used from 1980 to 1988 for the disposal of construction spoil and related debris generated at Y-12 and is the suspected source of the VOCs (primarily PCE, TCE, and 12DCE) in monitoring wells at the site (DOE 1997).

A time-series plot of TCE concentrations detected in the groundwater samples collected since May 1989 shows a variable but clearly decreasing long-term concentration trend (Figure 2). The trend spans the prolonged gap in the sampling history for the well, but nonetheless suggests a corresponding decrease in the relative flux of TCE via the groundwater flow/transport pathways intercepted by the monitored interval in the well. Interestingly, the concentrations of 12DCE likewise show a decreasing concentration trend, but the PCE levels do not, as illustrated by the equal PCE concentrations (2 µg/L) evident in May 1989, August 1990, and March 2005. Assuming a heterogeneous mixture of dissolved VOCs in the groundwater from the shallow karst network in the Maynardville Limestone, it is unclear why the VOC concentrations exhibit such divergent trends. Perhaps the TCE is not well mixed with the other VOCs in the groundwater system, but instead occurs within separate, discreet transport pathways intercepted by the monitored interval in the well. Separate transport from different sources of VOCs also may occur, with more temporally variable flux from the source of TCE but more consistent flux of PCE from a separate upgradient source area (e.g., Spoil Area I).

5.4 GROSS ALPHA ACTIVITY

Five groundwater samples collected since January 1990 (the sample-specific MDA and/or CE are not available for previous samples) had gross alpha activity above the applicable MDA and corresponding CE (Table 1), with the highest values (6.76 pCi/L in October 1990) being below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

All of the groundwater samples collected since January 1990 (the sample-specific MDA and/or CE are not available for previous samples) had gross beta activity above the applicable MDA and corresponding CE (Table 1), including results for samples collected in August (71 pCi/L) and October 1990 (125 pCi/L) that exceed the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). The other results for gross beta activity are all less than 40 pCi/L with the most recent results (March and August 2005) being below 20 pCi/L. The source of the gross beta activity in the groundwater at this well is probably Tc-99, a beta-emitting radionuclide that is considered a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, which is the only site at Y-12 that received wastes containing this radionuclide (DOE 1997). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the transport of Tc-99 in the Maynardville Limestone closely mirrors that of nitrate, which reflects their common source and their similar transport characteristics in the groundwater.

WELL GW-311

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in July 1987, completed with a screened monitored interval from 25.6 to 40.3 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley west of Y-12, adjacent to Old Bear Creek Road on the south side of the Rust Spoil Area, which was used from 1975 to 1983 for disposal of construction debris.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-one groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 27 samples between February 1988 and September 1997, and the low-flow sampling method used to obtain 14 samples between March 1998 and August 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Maynardville Limestone). The average static groundwater level in the well is 33 ft bgs. Presampling depth-to-water measurements for the well indicate substantial (10 - 25 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 192 – 320 mg/L;
- pH of 6.4 – 7.7 (field measurements);
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion, which is based on the analytical results reported for 31 groundwater samples collected from the well since January 1991.

5.1 NITRATE

All of the groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.78 mg/L in March 1995) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Fifteen groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.003 mg/L in February 1994) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

TCE was detected in all 31 groundwater samples collected from the well since January 1991; CTET and/or chloroform were detected in 14 of the 19 samples collected between January 1991 and August 1998. The source of the VOCs in the well is believed to be the Rust Spoil Area. This site (or a nearby source in the Bear Creek floodplain) contributes primarily TCE to the discontinuous plume of dissolved VOCs in the Maynardville Limestone, which receives influx from multiple sources in the Bear Creek Regime via direct recharge, hydrologic communication with Bear Creek, and inflow of contaminated groundwater from the Nolichucky Shale (DOE 1997). Available data show that the concentration of TCE in the well decreased steadily from 30 μg/L in January 1991 to less than 10 μg/L after August 1998 and has remained at or below the MCL (5 μg/L) since September 2000 (Figure 1). Also, neither CTET nor chloroform was detected in the samples collected since March 1999.

5.4 GROSS ALPHA ACTIVITY

Eight groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (18 pCi/L in February 2000) being slightly above the MCL for gross alpha activity (15 pCi/L). None of the other gross alpha results exceed 5 pCi/L.

5.5 GROSS BETA ACTIVITY

Seven groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (10.1 pCi/L in February 1993) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-312

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in September 1987, completed with a screened monitored interval from 29.6 to 41 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley west of Y-12, adjacent to Old Bear Creek Road on the south side of the Rust Spoil Area, which was used from 1975 to 1983 for disposal of construction debris generated at Y-12.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-five groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 23 samples between February 1988 and August 1995, and the low-flow sampling method used to obtain samples in March and August 2005. The sampling history includes a quarterly sampling frequency followed by a 10-year period (August 1995 – March 2005) when no samples were collected from the well, with semiannual sampling in 2005.

Unusually low levels of TDS (<150 mg/L in recent samples) and high levels of pH are distinguishing characteristics of the groundwater samples from this well (see Section 4.0). The low TDS of the samples suggests relatively low residence time for the groundwater in the well, which indicates that the monitored interval for the well intercepts highly permeable groundwater flowpaths. Historic data (conventional sampling) showed that the groundwater had very high pH (>12), but recent (low-flow sampling) results show moderately lower pH values (9.5 – 10).

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Maynardville Limestone (Conasauga Group), which exhibits the hydrologic characteristics typical of karst aquifers. Most groundwater flow in the Maynardville Limestone, which subcrops along the axis of BCV and underlies the main channel of Bear Creek, occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Hydrologic interaction between the creek and the shallow karst network provides the principal exit-pathway for contaminants released from source areas within the Bear Creek watershed west of Y-12. Below the shallow karst network, fractures provide the primary groundwater flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of approximately 33 ft bgs, and exhibits seasonal fluctuations up to 13 ft. Note that the water level typically occurs within the screened interval of the well. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV and on Chestnut Ridge, groundwater elevation isopleths in the vicinity of the Rust Spoil Area indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the unfiltered groundwater samples collected to date show that the well yields slightly alkaline sodium-bicarbonate groundwater generally characterized by:

- TDS of 80 – 740 mg/L, recent results (low-flow sampling) are 80 – 123 mg/L;
- pH of 9.63 – 12.6 (field measurements), excluding an outlier (7) in June 1995;

- low molar proportions of chloride, potassium, and sulfate (<15% of total anions/cations);
- high molar proportion of sodium (>45% of total anions/cations);
- low concentrations of calcium (<20 mg/L) and magnesium (<5 mg/L); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The elevated pH and unusually high sodium concentrations in the groundwater at this well may reflect the influence from grout used to construct the well or from concrete debris disposed at the Rust Spoil Area.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

All but one of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (2 mg/L in April 1991) being substantially below the MCL for nitrate (10 mg/L). The lack of elevated nitrate concentrations in the samples indicates that the monitored interval for the well does not intercept groundwater flow/transport pathways that are extensively interconnected with the contaminant plume emplaced during historical operation of the former S-3 Ponds (nitrate is a highly mobile component of the plume), which is a primary source of groundwater contamination in the Maynardville Limestone west of Y-12 and is located approximately 2,600 ft east-northeast (hydraulically upgradient) of the well.

5.2 URANIUM

Four groundwater samples collected to date had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.002 mg/L in May 1989) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected to date: acetone, CTET, chloroform, toluene, TCE, 11DCE, 12DCE, and 4-methyl-2-pentanone (4M2P) (Table 1). The presence of VOCs in the samples indicates that the monitored interval in the well intercepts groundwater flow/transport pathways for VOCs released from one or more upgradient sources that contribute to an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. Available data for the network of wells completed in the Maynardville Limestone west of the flow divide indicate that VOC-contaminated groundwater, as defined by individual or summed VOC concentrations above 5 µg/L, appears to originate near Spoil Area I and to extend hydraulically downgradient for several thousand feet westward (parallel with geologic strike) down the axis of BCV. The apparent distribution of VOCs within the plume reflects the relative influx from multiple source areas, commingling during downgradient groundwater transport, and hydraulic communication with Bear Creek (DOE 1997). In the upper part of BCV, hydraulically upgradient (east) of the well, the primary VOCs are TCE, c12DCE, and PCE and the confirmed or suspected source areas include Spoil Area I, the contaminant plume emplaced during historical operation of the former S-3 Ponds, and the Rust Spoil Area (or nearby source within the Bear Creek floodplain), the latter site considered a primary source of TCE.

Based on frequency of detection and concentration magnitude (Table 1), the primary VOC in the groundwater samples is TCE, which was detected in each sample collected to date and has the highest historical maximum concentration (80 µg/L in January 1991 and February 1994). Moreover, the results for TCE, including the historical minimum value (10 µg/L in September 1993) and the most recent (March and August 2005) sampling results, are all above the drinking water MCL (5 µg/L). In contrast, aside from the acetone concentrations detected in the samples collected in May 1989 (12 µg/L) and January 1990 (13 µg/L), concentrations of all the other VOCs detected in the samples are 5 µg/L or less, and the bulk of these results are estimated concentrations of 1 µg/L or less (Table 1). The Rust Spoil Area or nearby undocumented source within the Bear Creek floodplain is the suspected source of the TCE in the groundwater at this well (DOE 1997). Although hydraulically upgradient of the well, the contaminant plume emplaced during historical operation of the S-3 Ponds seems an unlikely source of TCE or other VOCs in the well, considering the lack of elevated nitrate levels noted in Section 5.1. The only other confirmed source of VOCs upgradient of the well is Spoil Area I, which was used from 1980 to 1988 for the disposal of construction spoil and related debris generated at Y-12 and is the suspected source of the VOCs (primarily PCE, TCE, and 12DCE) in monitoring wells at the site (DOE 1997).

A time-series plot of the TCE concentrations detected in the groundwater samples collected to date shows an indeterminate long-term trend dominated by wide fluctuations (Figure 1). Also, the variability generally correlates with seasonal flow conditions. For example, the lowest levels of TCE (e.g., 10 µg/L in September 1993) were detected in samples collected during summer or fall, whereas the highest TCE concentrations (e.g., 80 µg/L in January 1991 and February 1994) are evident for samples collected during winter or spring. This relationship suggests seasonally variable flux of TCE via the groundwater flow/transport pathways intercepted by the monitored interval in the well, with the greater recharge during seasonally (and episodically) high flow inducing greater transport of TCE. Interestingly, the results for chloroform, which was detected at 2 µg/L or less in most of the samples collected to date (Table 1), do not exhibit wide temporal variability, as illustrated by the chloroform results reported for samples collected in December 1994 (2 µg/L), March 1995 (2 µg/L), and June 1995 (2 µg/L). Assuming a heterogeneous mixture of dissolved VOCs in the karst network at shallow depths in the Maynardville Limestone, it is unclear why the TCE and chloroform concentrations exhibit such divergent temporal trends. Perhaps the TCE and chloroform (and other VOCs) are not well mixed in the groundwater system, but instead occur within separate, discreet transport pathways that are intercepted by the monitored interval in the well. Separate transport from different source areas also may occur, with more temporally variable flux from the source of TCE but more consistent flux of chloroform from a separate upgradient source area (Spoil Area I).

5.4 GROSS ALPHA ACTIVITY

Four groundwater samples collected since January 1990 (the sample-specific MDA and/or CE are not available for previous samples) had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (3.81 pCi/L in December 1994) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

All but one of the groundwater samples collected since January 1990 (the sample-specific MDA and/or CE are not available for previous samples) had gross beta activity above the applicable MDA and corresponding CE, with the highest value (23.86 pCi/L in January 1990) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-313

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in September 1987, completed with a screened monitored interval from 98.2 to 113 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). Located at Spoil Area I, which is at the base of the northern flank of Chestnut Ridge southwest of Y-12, the well is approximately 600 ft south of the headwaters channel of Bear Creek. Spoil Area I was used from 1980 to 1988 for disposal of construction spoil and related debris generated at Y-12.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Sixteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 14 samples between March 1988 and August 1992, and the low-flow sampling method used to obtain samples in March and August 2005. The sampling history includes a quarterly sampling frequency followed by a 13-year period (August 1992 – March 2005) when no samples were collected from the well, with semiannual sampling in 2005.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the intermediate depth (100-300 ft bgs) bedrock interval in the Maynardville Limestone (Conasauga Group), which exhibits the hydrologic characteristics typical of karst aquifers. Most groundwater flow in the Maynardville Limestone, which subcrops along the axis of BCV and underlies the main channel of Bear Creek, occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network), with hydrologic interaction between the creek and the shallow karst network provides the principal exit-pathway for contaminants released from source areas within the Bear Creek watershed west of Y-12. Below the shallow karst network, fractures provide the primary groundwater flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of approximately 69 ft bgs and exhibits seasonal fluctuations up to 10 ft. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV and on Chestnut Ridge, groundwater elevation isopleths indicate northwesterly flow near the well, toward the headwaters channel of the Bear Creek. Note, however, local flow may be more directly west because groundwater flow in the Maynardville Limestone is strongly anisotropic, with preferred flow parallel with geologic strike.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the unfiltered samples collected to date indicate that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 306 – 400 mg/L;
- pH (field measurements) of 6.5 – 7.1;
- very low molar proportions of chloride, potassium, sodium, and sulfate (<5% of total anions/cations); and

- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (9.82 mg/L in August 1992) being slightly below the drinking water MCL for nitrate (10 mg/L). However, this value is a suspected outlier because all other nitrate results are less than 4 mg/L. Nitrate concentrations reported for the most recent samples (March and August 2005) were less than 2 mg/L.

5.2 URANIUM

Three groundwater sample collected to date had uranium concentrations above the applicable analytical reporting limit, with the highest value (0.004 mg/L in May and August 1988) being substantially below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in at least one of the groundwater samples collected to date (Table 1): PCE, TCE, 12DCE, acetone, MC, and chloroform. The presence of VOCs in the samples indicates that the monitored interval in the well intercepts groundwater flow/transport pathways for VOCs released from Spoil Area I, which is believed to contribute to an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. Available data for the network of wells completed in the Maynardville Limestone west of the flow divide indicate that VOC-contaminated groundwater, as defined by individual or summed VOC concentrations above 5 µg/L, appears to originate near Spoil Area I and to extend hydraulically downgradient for several thousand feet westward (parallel with geologic strike) down the axis of BCV. The apparent distribution of VOCs within the plume reflects the relative influx from multiple source areas, commingling during downgradient groundwater transport, and hydraulic communication with Bear Creek (DOE 1997). In the upper part of BCV, the primary VOCs are TCE, c12DCE, and PCE and the confirmed or suspected source areas include Spoil Area I, the contaminant plume emplaced during historical operation of the former S-3 Ponds, and the Rust Spoil Area (or nearby source within the Bear Creek floodplain), the latter site considered a primary source of TCE.

Based on frequency of detection and concentration magnitude, the primary VOC in the groundwater samples is PCE (Table 1), which was detected in every sample collected to date and, excluding a suspected outlier result for 12DCE (120 in January 1991), has the highest historical maximum concentration (18 µg/L in January 1991 and August 1992). Also, the recent sampling results (March and August 2005) show that PCE concentrations remain slightly above the drinking water MCL (5 µg/L). Secondary compounds in the samples are TCE and 12DCE (c12DCE): one or both of which were detected in all but one of the samples collected to date, with the most recent sampling results showing only trace levels of each VOC (i.e., estimated concentrations below 5 µg/L). Spoil Area I is the suspected source of the VOCs in the groundwater at this well.

A time-series plot of the summed concentrations of VOCs detected in the groundwater samples collected to date (excluding the suspected outlier described above) shows slightly decreasing long-term concentration trend dominated by wide fluctuations and the prolonged (13-year) gap in the sampling history (Figure 1). Also, the variability in the summed VOC concentrations generally correlates with seasonal flow conditions. For example, the lowest levels of summed VOCs (e.g., 6 µg/L in April 1991) were detected in samples collected during winter or spring, whereas the highest summed VOC concentrations (e.g., 42 µg/L in August 1992) are evident for samples collected during summer or fall. This relationship suggests reduction in the concentrations of VOCs in the groundwater as a result of "dilution" from seasonal (or episodic) inflow of uncontaminated (or less VOC-contaminated) recharge via the groundwater flow/transport pathways intercepted by the monitored interval in the well. Additionally, the overall decrease in VOC concentrations suggests a corresponding reduction in the relative flux of dissolved VOCs through the Maynardville Limestone in the upper reaches of Bear Creek.

5.4 GROSS ALPHA ACTIVITY

One groundwater sample collected since January 1990 (the sample-specific MDA and/or CE are not available for previous samples) had gross alpha activity above the applicable MDA and corresponding CE, and this result (1.68 pCi/L in July 1991) is substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Five groundwater samples collected since January 1990 (the sample-specific MDA and/or CE are not available for previous samples) had gross beta activity above the applicable MDA and corresponding CE, with the highest value (19.3 pCi/L in May 1992) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-315

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in September 1987, completed with a screened monitored interval from 90 to 104 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). Located at Spoil Area I, which is at the base of the northern (scarp) flank of Chestnut Ridge southwest of Y-12, the well is about 500 ft south of the headwaters channel of Bear Creek. Spoil Area I was used from 1980 to 1988 for disposal of construction spoil and related debris generated at Y-12.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-six groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 32 samples between March 1988 and September 1997, and the low-flow sampling method used to obtain 14 samples between March 1998 and August 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maynardville Limestone (Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 54 ft bgs and exhibits seasonal fluctuations up to 19 ft. Wide fluctuations in groundwater elevations are characteristic of many wells on Chestnut Ridge. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV and on Chestnut Ridge, groundwater elevation isopleths in the vicinity of the well indicate northwesterly flow toward the headwaters channel of the Bear Creek.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the samples collected from the well indicate that the well yields sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 425 – 650 mg/L;
- pH (field measurements) of 6.2 – 7.8;
- elevated sulfate concentrations (>e.g., 77.9 mg/L in February 2004) that are substantially higher than evident in groundwater at other wells completed at similar depths (and hydrogeologic zones) in the Maynardville Limestone, and are the likely source of the unacceptably high relative percent difference (RPD) between respective summed millequivalent concentrations of anions and cations (i.e., the ion-charge balance error exceeds 20%) determined for the sample collected in December 1995 (RPD = -22.8%);
- low molar proportions of chloride, potassium, and sodium (<10% of total anions/cations); and

- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

It is not clear if the unusually high sulfate concentrations typical of the groundwater samples reflect localized geochemical characteristics, such as dissolution of locally disseminated sulfide minerals, or if the elevated concentrations are the result of contamination from one or more sources upgradient of the well.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. Based on the results reported for the groundwater samples collected since January 1991, nitrate and VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Each groundwater sample had nitrate above the analytical reporting limit (Table 1), including results for 16 samples that exceed the MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds, which are unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988. Located about 700 ft directly north of Spoil Area I, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984. The groundwater contaminant plume originating from the site contains a heterogeneous mixture of inorganic, organic, and radiological contaminants. Nitrate, a principal component of the plume, enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale and recharge of nitrate-contaminated surface water in Bear Creek (DOE 1997). Nitrate is chemically stable and highly mobile in groundwater and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells, the extent of nitrate contamination in the Maynardville Limestone in BCV west of Y-12, as defined by concentrations above 10 mg/L, is generally characterized by: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for about 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) than the deeper bedrock and is significantly influenced by hydrologic interactions with surface water in Bear Creek.

As noted previously, nitrate concentrations reported for 16 groundwater samples exceed the MCL (Table 1), including the historical maximum value (34 mg/L in October 1991 and August 1992) and a result (16.8 mg/L in December 1995) considered qualitative because of the ion charge-balance error determined for the sample (see Section 4.0). Also, the nitrate data reflect apparently seasonal concentration fluctuations; the highest nitrate values (22.4 mg/L in July 1991, 34 mg/L in October 1991, 34.05 mg/L in August 1992) were reported for samples obtained during seasonally low groundwater flow conditions and the lowest nitrate values (2.24 mg/L in March 1997, 3 mg/L in January 1991, 3.3 mg/L in February 1994, and 3.4 mg/L in December 1995) were reported for samples obtained during seasonally high groundwater flow conditions. This relationship suggests seasonal (and episodic) "dilution" from uncontaminated (and/or less nitrate-contaminated) recharge via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

A time-series plot of nitrate concentrations in the groundwater samples (excluding the qualitative result noted above) shows a generally decreasing long-term trend dominated by wide temporal (seasonal) concentration fluctuations (Figure 1). Also, the nitrate results obtained with the conventional sampling method seemingly exhibit greater temporal variability than the low-flow sampling results. This may be an artifact of the semiannual sampling frequency used for low-flow sampling (the bulk of the conventional sampling events were performed quarterly), but also may be related to inherent differences in the manner in which each sampling method induces inflow of groundwater into the well. Conventional sampling involves purging up to three well volumes of groundwater from the well at about 1-2 gallons per minute, which may substantially lower the water level in the well and induce inflow from water-producing features (i.e., fractures, cavities, conduits) that may not contribute to well recharge under normal conditions. In contrast, low-flow sampling involves purging the well at flow rate low enough (<300 milliliters per minute) to ensure minimal water-level drawdown in the well (<1 ft per quarter hour), which induces groundwater inflow only from the water-producing feature(s) proximal to the monitored interval.

5.2 URANIUM

All but four of the groundwater samples had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.00289 mg/L in September 2000) being an order-of-magnitude below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample (Table 2): acetone, bromodichloromethane, chloroform, freon-113, PCE, TCE, and 12DCE (isomers). These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. In the Bear Creek watershed west of the flow divide, which occurs near the west end of Y-12, the VOC plume in the Maynardville Limestone, as defined by individual or summed VOC concentrations above 5 μg/L, appears to originate near Spoil Area I and to extend several thousand feet westward (parallel with geologic strike) down the axis of BCV. As with nitrate in the Maynardville Limestone, the VOC plume seems to be contiguous in the fracture-dominated flowpaths at depth in the bedrock, but discontinuous in the shallow karst network. Also, the distribution of VOCs within the plume reflects the relative contributions from multiple source areas and commingling during downgradient transport; Spoil Area I and the former S-3 Ponds are the suspected sources of the dissolved VOCs in the groundwater at this well (DOE 1997).

The primary VOC in the groundwater samples is PCE (Table 2); this compound was detected in every sample, with the historical maximum concentration of 38 μg/L in January 1991. Also, the most recent sampling results show that the PCE concentrations remain slightly above the MCL (5 μg/L). Secondary compounds in the samples are TCE and 12DCE (c12DCE), one or both of which were detected in all of the samples collected to date (Table 2), with respective historical maximum concentrations of 15 μg/L and 32 μg/L in January 1991. The most recent sampling results show TCE concentrations slightly below the MCL (5 μg/L) and c12DCE concentrations substantially below the MCL (70 μg/L). Acetone, bromodichloromethane, chloroform, and freon-113 have been detected much more infrequently, with the bulk of the results being estimated values below 5 μg/L (Table 2).

A time-series plot of the summed concentrations of VOCs detected in the groundwater samples shows a decreasing long-term concentration trend through August 2004 (Figure 2), which established a new historical low value for summed VOCs (11 μg/L) . As with the long-term trend for nitrate, the conventional sampling results show significant temporal (seasonal) changes in summed VOC concentrations, with a sequence of temporal peaks evident in July 1991 (43 μg/L), August 1992 (46 μg/L), August 1994 (51 μg/L), and June 1996 (56 μg/L) (i.e., seasonally low groundwater flow conditions). In contrast, the low-flow sampling results show lower and much less variable VOC concentrations, but it is not clear from the available data if this is an artifact of the change in groundwater sampling methods (see Section 5.1). In any case, the overall decrease in VOC concentrations suggests a corresponding reduction in the relative flux of dissolved VOCs via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

Eleven groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (17.4 pCi/L in August 1992) being slightly above the MCL for gross alpha activity (15 pCi/L). This result appears to be an outlier because all of the other gross alpha results are less than 10 pCi/L. Also, only four of the 27 samples collected since June 1993 had gross alpha activity above the MDA and CE and these results are all less than 3 pCi/L.

5.5 GROSS BETA ACTIVITY

All but one of the groundwater samples had gross beta activity above the applicable MDA and corresponding CE (Table 1), including seven samples with gross beta activity that exceed the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the MCL for gross beta activity). The source of the gross beta activity in the groundwater at this well is believed to be Tc-99 based on the detection of this radionuclide (i.e., >MDA and CE) in the samples collected in February (101 pCi/L), June (194 pCi/L), August (114 pCi/L), and December 1994 (117 pCi/L). Note that these results are all less than the SDWA screening level (3,790 pCi/L) for a 4 mrem/yr dose equivalent from Tc-99. This radionuclide is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, which is the only site at Y-12 that received wastes that contained Tc-99 (DOE 1998). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the transport of Tc-99 in the Maynardville Limestone closely mirrors that of nitrate.

As shown on Table 1, all but one of the groundwater samples had gross beta activity above the MDA, with the highest values reported for samples collected in October 1991 (108 pCi/L) and October 1991 (159 pCi/L) and the lowest values reported for samples collected in January 1991 (8 pCi/L) and February 1994 (7 pCi/L). The gross beta results generally mirror the apparently seasonal fluctuations in nitrate concentrations (see Section 5.1), with the highest values evident during seasonally low groundwater flow and the lowest values evident during seasonally high groundwater flow.

A time-series plot of gross beta activity for groundwater samples shows a generally decreasing long-term trend dominated by wide temporal (seasonal) fluctuations (Figure 3). The overall decrease in gross beta activity is attributable to the reduced flux of Tc-99 from the former S-3 Ponds following closure of the site and installation of the low-permeability cap. Also, as with the long-term concentration trends for nitrate and summed VOCs, the gross beta results reported for samples obtained with the conventional sampling method exhibit substantially more temporal variability than the low-flow sampling results for gross beta activity (Figure 3).

WELL GW-322

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in September 1987, completed with an open-hole monitored interval from 128 to 193 ft bgs, and constructed with nominal 4.5-inch diameter steel riser casing. The well is located on the crest of Chestnut Ridge directly south of Y-12, approximately 100 ft south of the Chestnut Ridge Security Pits (CRSP). The CRSP include two contiguous former waste disposal areas, each consisting of a series of unlined, east-west oriented trenches that were about 8 to 10 ft wide, 10 to 18 ft deep, and 700 to 800 ft long. Beginning in 1973, the disposal trenches at the site received a variety of hazardous waste until December 1984 and nonhazardous wastes until November 1988. All the disposal trenches are covered by a multi-layer low-permeability cap installed during RCRA closure of the site in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-two groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 19 samples between March 1988 and July 1992, and the low-flow sampling method used to obtain samples in January 1998, May 2004, and October 2004.

Presampling depth-to-water measurements show that the static water level in the well exhibits substantial (>25 ft) temporal (seasonal) fluctuations (Figure 1). Similarly distinctive groundwater elevation fluctuations also are evident in other wells completed in the Knox Group on Chestnut Ridge, particularly wells located at or near the crest of the ridge, which is both a recharge area and a groundwater flow divide (Solomon et al. 1992).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the Knox Group (Copper Ridge Dolomite). The Knox Group formations, along with the uppermost formation (Maynardville Limestone) of the underlying Conasauga Group, comprise an aquifer consisting of three vertically gradational subsystems distinguished by groundwater flux, which decreases with depth: (1) the stormflow zone, (2) the vadose zone, and (3) the groundwater zone (Solomon et al. 1992). The stormflow and vadose zones occur at shallow depths within the thick (>100 ft) residuum that has developed on Chestnut Ridge. In the bedrock zone, orthogonal sets of permeable, planar fractures form water-producing zones within an essentially impermeable matrix, and dissolution of carbonates has enlarged fractures and produced an interconnected conduit-flow system characteristic of karst aquifers. Because the occurrence of solution features and the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity of the groundwater zone is vertically gradational. Most groundwater flux occurs within the transitional horizon between residuum and unweathered bedrock (water table interval); lower flux (and longer solute residence times) occurs at successively greater depths in the bedrock (Solomon et al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 151 ft bgs and exhibits wide seasonal fluctuations (see Section 2.0). Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of the CRSP indicate radial flow directions, with components of flow to the north into BCV; to the east along the axis of the ridge (toward well GW-322), parallel with geologic strike of the bedrock; and south toward drainage features that traverse the broad southern flank of the ridge.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date indicate that this well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 154 – 282 mg/L;
- pH of 7.2 – 8.0 (field measurements);
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite);
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Four groundwater samples collected to date had nitrate concentrations at or above the applicable analytical reporting limit, with the highest concentration (0.5 mg/L in February 1991) being substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

One of the groundwater samples collected to date had a uranium concentration at the applicable analytical reporting limit and this result (0.001 mg/L in February 1991) is substantially below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in at least one groundwater sample collected to date: 111TCA, 12DCA, 11DCA, PCE, 11DCE, TCE, ethylbenzene, TCFM, and 1,1,2-trichloro-1,2,2-trifluoroethane, which is also known as Freon-113 (F113). Of the VOCs, 111TCA, 11DCA, 11DCE, PCE, TCFM, and F113 are consistently detected and are components of a dissolved plume of VOCs that originates from the CRSP. Historical operation of the former waste disposal trenches at this site emplaced an elongated plume of dissolved VOCs in the groundwater that extends more than 2,500 ft east-northeast along the ridge crest (parallel with geologic strike) and at least 500 ft to the north and south down the ridges flanks. The existing network of monitoring wells at the site shows that 111TCA, 11DCA, and 11DCE are the primary compounds in the groundwater near the western disposal trench area and PCE, TCE, and 12DCE are the principal compounds in the groundwater near the eastern disposal trench area. Some constituents of the VOC plume (e.g., 11DCA and 11DCE) are probably present as a result of the degradation of 111TCA. Elongation of the VOC plume along the axis of the ridge and the distribution of plume constituents indicate primarily west-to-east groundwater flow/contaminant transport via flowpaths (e.g., bedding-plane fractures) that parallel the geologic strike of the Knox Group strata. Vertical flow/transport occurs parallel with the dip of the strata, with cross-cutting fractures facilitating contaminant migration to the north and south (Shevenell 1994). The vertical extent of the VOC plume has not been determined, but based on the existing network of monitoring wells at the site, the plume extends at least 150 ft bgs near the western disposal trenches and 270 ft bgs near the eastern disposal trenches.

Each groundwater sample collected to date contained 111TCA, 11DCA, and 11DCE, with PCE detected in all but three of the samples (Table 1). Relatively high concentrations of TCFM (34 - 54 μg/L) were detected in the three samples collected most recently, and F113 also was detected in the May and October 2004 samples (Table 1). The sample collected in January 1998 contained trace levels (<5 μg/L) of ethylbenzene and 12DCA, which are considered to be outliers. Historical data for 111TCA, 11DCA, and 11DCE show respective maximum values of 790 μg/L (August 1988), 160 μg/L (January 1998), and 170 μg/L (January 1998), with the most recent sampling results showing that the concentrations of 11DCE remain substantially above the drinking water MCL (7 μg/L). Conversely, much lower concentrations of PCE were detected in the samples, the historical maximum value being only 10 μg/L (January 1998), with the most recent sampling results showing concentrations slightly above the 5 μg/L MCL (Table 1). The dominance of 111TCA, 11DCA, and 11DCE in the groundwater at this well suggests that the monitored interval in the well intercepts some of the primary strike-parallel groundwater flow/contaminant transport pathways for VOCs that originate primarily from the western disposal trenches at the CRSP. Also, assuming that the eastern disposal trenches are the source of the PCE in the well, which is directly south of the eastern trench area, the relatively low levels of PCE in the groundwater at this well suggest there is only a minor cross-strike or down-dip component to the migration/transport of the VOCs from either disposal trench area.

As noted previously, some of the compounds in the CRSP VOC plume are present as a result of the degradation of related parent compounds. Abiotic degradation of 111TCA, which is the only major chlorinated solvent that can be transformed chemically in groundwater under all likely conditions (McCarty 1996), probably explains the frequent detection and relatively high concentrations of 11DCA and 11DCE in the groundwater at well GW-322. This is clearly illustrated by a time-series plot of the proportional distribution of 111TCA, 11DCA, and 11DCE concentrations detected in each groundwater sample collected to date (Figure 2), whereby a substantial decrease in the relative proportion of 111TCA is accompanied by a concurrent increase in combined proportion of 11DCA and 11DCE. In contrast, none of the groundwater samples collected to date contained PCE degradation products, particularly TCE and c12DCE, indicating that the monitored interval for the well does not intercept groundwater flow/transport pathways where biologically mediated degradation (reductive dechlorination) of PCE occurs.

A time-series plot of the summed concentrations of VOCs detected in each groundwater sample (excluding false positive results) shows a clearly decreasing long term trend that spans two large gaps in the sampling history for the well: July 1992 - January 1998 and January 1998 - May 2004 (Figure 3). Before the first sampling gap, the VOC data show a variable but decreasing trend following the historical maximum summed VOC concentration evident in August 1988 (1,025 μg/L), with a total reduction of about 48% through July 1992 (542 μg/L). The relatively rapid concentration decrease, which was probably a direct response to the substantially reduced flux of dissolved VOCs following the closure of the CRSP in 1988 and the installation of the low-permeability cap in 1989, suggests that the shallow source of VOCs has been isolated and the most highly contaminated groundwater has been flushed from the flow/transport pathways intercepted by the monitored interval (128-193 ft bgs) in the well. Although slightly higher summed VOC concentrations subsequently were evident in January 1998 (618 μg/L), the most recent data suggest a continued reduction of about 51% through October 2004 (303 μg/L). Note, however, that the overall downward trend in summed VOC concentrations encompasses: (1) a substantial decrease in the concentration of 111TCA, with the most recent sampling results establishing a historical minimum value (47 μg/L in May 2004) that is an order-of-magnitude lower than the historical maximum value (790 μg/L in August 1988); (2) a significant increase in the concentrations of 11DCA, with the concentration evident in October 2004 (110 μg/L) being about three times higher than the concentration evident in October 1988 (34 μg/L); (3) variable but relatively unchanged concentrations of 11DCE, as illustrated by the results reported for samples collected in August 1988 (93 μg/L), October 1990 (95 μg/L), and October 2004 (93 μg/L); and (4) no significant change in the relative concentrations of PCE, as illustrated by the equal PCE concentrations (6 μg/L) detected in the samples collected in June 1988, October 1991, and October 2004.

5.4 GROSS ALPHA ACTIVITY

Four groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (4.61 pCi/L in October 1991) being substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Ten groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, with the highest value (4.83 pCi/L in October 1991) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-336

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during August 1987, completed with a screened monitored interval from 13.2 to 21.4 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley (BCV) within the west-central section of Y-12, on the east side of the Waste Coolant Processing Area (WCPA), which includes: the Waste Coolant Storage Tanks (WCST), the Waste Coolant Biodegradation Facility (WCBF), and the Waste Coolant Processing Facility (WCPF). These facilities were used between 1977 and 1985 to handle and treat large volumes of waste machine coolants that contained very high levels (several thousand parts per million) total organic carbon, chlorinated hydrocarbons, and methyl ethyl ketone along with metals and depleted uranium (DOE 1998). In August 1988, the WCPA was clean-closed under RCRA, with closure-related wastes sent to the Interim Drum Yard at the west end of Y-12.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twelve groundwater samples have been collected from the well, with the conventional sampling method used to obtain ten samples between May 1989 and March 1997 and the low-flow sampling method used to obtain samples in May and October 2003.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Nolichucky Shale (Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within a highly permeable zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 6 ft bgs and exhibits minimal (<1 ft) seasonal fluctuations. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-336 indicate southeasterly flow toward the Maynardville Limestone and the Upper East Fork Poplar Creek (UEFPC) drainage system. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and original main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, the low-permeability formations of the Conasauga Group, including the Nolichucky Shale, exhibit strongly anisotropic groundwater flow patterns, with preferred flow in directions that parallel geologic strike (i.e., bedding-plane fractures), which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 175 – 250 mg/L;
- pH of 5.7 – 6.4 (field measurements);

- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the analytical results for the five groundwater samples collected since January 1991, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (3.6 mg/L in March 1997) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Only the uranium concentration reported for the sample collected in April 1991 (0.004 mg/L) exceeds the analytical reporting limit, and this result is substantially less than the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, at least one or more of the following VOCs was detected in each groundwater sample (Table 1): methylene chloride (MC), PCE, TCE, trichlorofluoromethane (TCFM), VC, 11DCA, 11DCE, 12DCE (c12DCE and t12DCE), and 111TCA. These compounds are components of a plume of dissolved VOCs in the groundwater emplaced during historical operation of the WCPA. Also, soluble compounds leached from contaminated soils in the vadose zone and dissolution of constituents from potential DNAPL below the saturated zone represent ongoing secondary sources of VOCs in the groundwater at this site (DOE 1998). The current network of monitoring wells does not indicate any strongly preferential groundwater flow/transport patterns in the vicinity of the WCPA, with generally eastward (parallel with geologic strike) transport/migration of the mobile components of the VOC plume suggested by the presence of "signature" VOCs in storm drains to the east of the site and in basements sumps in Bldg. 9204-4 and Bldg. 9201-5 (DOE 1998).

The dominant VOCs in the groundwater samples are c12DCE, PCE and TCE, which have historical maximum concentrations above 500 μg/L (Table 1). Note that the historical minimum concentrations of PCE and TCE were reported for the sample collected in May 2003 (270 μg/L and 370 μg/L, respectively) and the historical maximum concentrations of PCE and TCE were reported for the sample collected in (November 2003 680 μg/L and 610 μg/L, respectively). Secondary VOCs in the samples are VC and 11DCE, each with historical maximum concentrations above 100 μg/L, and 11DCA and 111TCA, which have historical maximum concentrations below 100 μg/L. Other compounds have been detected infrequently, with MC and TCFM each detected in only one sample each, and at lower concentrations than evident for the primary and secondary VOCs (Table 1). Although the summed concentrations of dissolved VOCs detected in the groundwater samples are relatively high, the maximum concentrations of individual compounds (e.g., PCE) are not high enough (i.e., > 1% of pure-phase solubility) to suggest the presence of DNAPL in the subsurface near the well, which is located about 175 ft east of the WCPA. However, substantially higher concentrations of dissolved VOCs in the groundwater at a shallow well (GW-337) to the west suggest DNAPL in the subsurface near the WCST.

Some of the VOCs in the groundwater samples were probably major components of the waste coolants and oils handled and processed at the WCPA, whereas other compounds may be present as a consequence of the natural degradation of related parent compounds. For example, 11DCA may be present as a result of the abiotic degradation of 111TCA, which is the only major chlorinated hydrocarbon (solvent) that chemically degrades in groundwater (McCarty 1996). Likewise, c12DCE and VC may be present because of biologically mediated degradation (sequential dechlorination) of PCE and TCE by anaerobic methanotropic organisms in the groundwater. However, results for several indicator parameters, including the strongly positive REDOX values (Table 2), do not indicate the reducing (methanogenic) conditions necessary to transform parent compounds to DCE isomers (Chapelle 1996). Perhaps the monitored interval intercepts groundwater flow/transport pathways for dissolved VOCs transported from a source where conditions are better suited for biodegradation of chlorinated solvents (e.g., the biodegradation facility within the WCPA).

A time-series plot of the summed concentrations of VOCs detected in each groundwater sample spans two gaps in the sampling history (April 1991 – March 1997 and March 1997 – May 2003) and shows a clearly decreasing long-term trend (Figure 1). As shown by the data summarized in Table 1, the decreasing trend is primarily attributable to the substantial reduction (abut 50%) in the concentrations of 12DCE (Table 1). Although the samples collected since March 1997 were obtained with the low-flow sampling method, the lower VOC concentrations do not appear to be an artifact of change from the conventional sampling method. Also, the decreasing concentration trends are not evident for all of the VOCs in the samples (Table 1), as illustrated by the 11DCA concentrations evident in January 1991 (49 μg/L) and May 2003 (53 μg/L). Assuming a heterogeneous mixture of VOCs from common source(s), it is not clear why the concentrations of individual compounds exhibit divergent concentration trends or if the trends are significant with respect to the relative flux of VOCs along the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

Gross beta activity above the applicable MDA and corresponding CE was reported for the groundwater sample collected in April 1991 and this result (3.77 pCi/L) is substantially below the SDWA screening level (50 pCi/L) for a 4 millirem dose equivalent (the MCL for gross beta activity).

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during August 1987, completed with a screened monitored interval from 15 to 22.1 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley (BCV) within the west-central section of Y-12 at the Waste Coolant Processing Area (WCPA), which includes: the Waste Coolant Storage Tanks (WCST), the Waste Coolant Biodegradation Facility (WCBF), and the Waste Coolant Processing Facility (WCPF). These facilities were used between 1977 and 1985 to handle and treat large volumes of waste machine coolants that contained very high levels (several thousand parts per million) total organic carbon, chlorinated hydrocarbons, and methyl ethyl ketone along with metals and depleted uranium (DOE 1998). In August 1988, the WCPA was clean-closed under RCRA, with closure-related wastes sent to the Interim Drum Yard at the west end of Y-12.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-two groundwater samples have been collected from the well, with the conventional sampling method used to obtain 25 samples between May 1989 and March 1995 and the low-flow sampling method used to obtain seven samples between July 1998 and November 2003.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Nolichucky Shale (Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within a highly permeable zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 7.5 ft bgs and exhibits minimal (<3 ft) seasonal fluctuations. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-337 indicate southeasterly flow toward the Maynardville Limestone and the Upper East Fork Poplar Creek (UEFPC) drainage system. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and original main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, the low-permeability formations of the Conasauga Group, including the Nolichucky Shale, exhibit strongly anisotropic groundwater flow patterns, with preferred flow in directions that parallel geologic strike (i.e., bedding-plane fractures), which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 175 – 250 mg/L;
- pH of 6.2 – 7.1 (field measurements);

- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the analytical results for the 25 groundwater samples collected since January 1991, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Only one groundwater sample had nitrate above the applicable analytical reporting limit, and this result (0.36 mg/L in December 1994) is substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Twenty-two groundwater samples had uranium concentrations at or above the analytical reporting limit, with the highest concentration (0.003 mg/L in August 1994) being an order-of-magnitude below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, at least one or more of the following VOCs was detected in each groundwater sample (Table 1): acetone, benzene, ethylbenzene, methylene chloride, toluene, PCE, TCE, trichlorofluoromethane (TCFM), VC, xylenes, 11DCA, 11DCE, 12DCE (c12DCE and t12DCE), and 111TCA. These compounds are components of a plume of dissolved VOCs in the groundwater emplaced during historical operation of the WCPA. Also, soluble compounds leached from contaminated soils in the vadose zone and dissolution of constituents from potential DNAPL below the saturated zone represents ongoing secondary sources of VOCs in the groundwater at this site (DOE 1998). The current network of monitoring wells does not indicate any strongly preferential groundwater flow/transport patterns in the vicinity of the WCPA, with generally eastward (parallel with geologic strike) transport/migration of the mobile components of the VOC plume suggested by the presence of "signature" VOCs in storm drains to the east of the site and in basements sumps in Bldg. 9204-4 and Bldg. 9201-5 (DOE 1998).

The dominant VOCs in the groundwater samples are 12DCE (c12DCE), with historical maximum concentrations above 10,000 μg/L, along with PCE and TCE, which both have historical maximum concentrations above 1,000 μg/L (Table 1). Secondary VOCs in the samples include VC, 11DCE, 11DCA, and 111TCA, which have historical maximum concentrations of 450 μg/L, 380 μg/L, 220 μg/L, and 500 μg/L respectively. Other compounds have been detected infrequently, with highest concentrations (>500 μg/L) reported for acetone and methylene chloride detected in several samples. The very high concentrations of dissolved VOCs in the groundwater samples from this well, which exceed 1% of pure-phase solubility for several compounds (e.g., PCE), suggest the presence of DNAPL near the well, which is located at the southeast corner of the WCST.

Some of the VOCs in the groundwater samples were probably major components of the machine coolants handled and processed at the WCPA, whereas other compounds may be present as a consequence of the natural degradation of related parent compounds. For example, 11DCA may be present as a result of the abiotic degradation of 111TCA, which is the only major chlorinated hydrocarbon (solvent) that chemically degrades in groundwater (McCarty 1996). Likewise, c12DCE and VC may be present because of biologically mediated degradation (sequential dechlorination) of PCE and TCE by anaerobic methanotropic organisms in the groundwater. However, results for several indicator parameters, including the strongly positive REDOX values (Table 2), do not indicate the reducing (methanogenic) conditions necessary to transform parent compounds to DCE isomers (Chapelle 1996). Perhaps the monitored interval intercepts groundwater flow/transport pathways for dissolved VOCs transported from a source located where geochemical conditions are better suited for biodegradation of chlorinated solvents (e.g., the biodegradation facility within the WCPA).

A time-series plot of the summed concentrations of VOCs detected in each groundwater sample spans two gaps in the sampling history (May 1995 – July 1998 and October 2000 - May 2003) and shows a clearly decreasing long-term trend (Figure 1). As shown by the data summarized in Table 1, the decreasing trend is primarily attributable to the substantial reduction (abut 70%) in the concentrations of 12DCE (Table 1). Although the samples collected since March 1997 were obtained with the low-flow sampling method, the lower VOC concentrations do not appear to be an artifact of change from the conventional sampling method. Also, the decreasing concentration trends are not evident for all of the VOCs in the samples (Table 1), as illustrated by the PCE concentrations evident in January 1991 (790 μg/L) and November 2003 (770 μg/L). Assuming a heterogeneous mixture of VOCs from common source(s), it is not clear why the concentrations of individual compounds exhibit divergent concentration trends or if the trends are significant with respect to the relative flux of VOCs along the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

Six groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (13.5 pCi/L in January 1993) being slightly below the MCL for gross alpha activity (15 pCi/L). However, the historical maximum value for gross alpha activity appears to be an outlier compared to the other results, which are all less than 5 pCi/L.

5.5 GROSS BETA ACTIVITY

Fourteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (19.3 pCi/L in January 1993) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem dose equivalent (the MCL for gross beta activity).

WELL GW-339

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in December 1989, completed with a screened monitored interval from 101 to 114 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located on the crest of Chestnut Ridge south of Y-12, about 100 ft north (hydraulically downgradient) of the United Nuclear Corporation Site (UNCS). The UNCS is a closed facility that was used for the disposal of cement-fixed sludge and radiologically-contaminated soils and demolition debris. A multilayer low-permeability cap was installed at the site in 1992 in accordance with the CERCLA ROD signed in 1991 (DOE 1991).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-eight groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 26 samples between May 1990 and April 1997, and the low-flow sampling method used to obtain 12 samples between November 1997 and August 2003.

A conspicuous characteristic of the groundwater samples from this well are elevated concentrations of chromium and nickel that are most likely attributable to chemical and/or microbiologically-induced corrosion of the stainless steel well casing and/or screen (see Section 5.6).

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the Knox Group. The average static groundwater level in the well is 70 ft below ground surface. Presampling depth-to-water measurements for the well indicate substantial (>25 ft) water-level fluctuations (Figure 1).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- moderate TDS (>150 mg/L<800 mg/L);
- pH (field measurements) of 6. 9 – 8.4;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of potassium and sulfate (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals (except chromium and nickel) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Chloride concentrations above 20 mg/L and sodium levels above 10 mg/L are characteristic of the groundwater samples from the well. Elevated concentrations of these ions may reflect recharge of surface water containing dissolved salt used to de-ice the South Patrol Road. Similarly elevated levels of chloride and sodium also are evident in other wells at the UNCS (1090 and GW-302) that are accessed via this paved road, whereas much lower chloride and sodium concentrations are evident in the wells at the site that are accessed via a gravel road (GW-203, GW-205, and GW-221). In either case, the elevated chloride levels may play a role in maintaining the elevated chromium and nickel concentrations in the samples from the well (see Section 5.6) because chloride may combine with available metal cations to form soluble complexes that may not readily partition to mineral surfaces in the subsurface (McLean and Bledsoe 1992).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion, which is based on the analytical results reported for 35 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Thirty-two groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (2.8 mg/L) being below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Two groundwater samples had uranium concentrations above the applicable analytical reporting limit and both results (0.002 mg/L and 0.001 mg/L) are substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Twenty-one groundwater samples were analyzed for VOCs and the analytical results for 19 samples show non-detect values or false positive results for all of the VOCs that are confirmed groundwater contaminants in the Chestnut Ridge Regime. Low (estimated) concentrations of chloroform were detected in the samples collected in April 1991 (2 µg/L), July 1991 (0.9 µg/L), July 1993 (0.6 µg/L), and July 1994 (0.7µg/L).

5.4 GROSS ALPHA ACTIVITY

Eleven groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (7.91 pCi/L) being below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Thirteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (38.79 pCi/L) being below the SDWA screening level for gross beta activity (50 pCi/L).

5.6 OTHER

Groundwater samples collected from the well since January 1991 contained total nickel concentrations above the respective analytical reporting limit. As shown in Table 1, almost all of these results exceed the background level (UTL) in the Knox Aquifer, with 13 of the results exceeding the MCL, including the nickel concentrations reported for each of the samples obtained with the low-flow sampling method. These results also show that total chromium concentrations in the well sporadically exceed the background UTL, but only one result exceeds the MCL. The following considerations suggest that elevated concentrations of nickel and chromium in the groundwater samples from this well are most likely attributable to corrosion of the stainless steel (Type 304) riser casing and well screen: (1) mobile species of these metals are not typically present in groundwater with the neutral pH evident in the well; (2) Type 304 stainless steel contains 18-20% chromium and 8-12% nickel and is prone to crevice corrosion (Oakley and Korte 1996); (3) groundwater in the well exhibits geochemical conditions that may be corrosive to Type 304 stainless steel (e.g., dissolved oxygen >2 mg/L; Driscoll 1986); (4) as noted in Section 4.0, elevated chloride levels in the groundwater may greatly limit the partitioning of nickel and chromium ions in the well.

Note: Bold typeface denotes results that exceed the MCL.		

In addition to the considerations listed above, results of microbiological sampling of selected Knox Group wells in February 2000 support the possibility of microbiologically induced corrosion (MIC) of the stainless steel riser casing and screen as a potential source of the elevated nickel and chromium concentrations in the groundwater from the well. The microbiological sampling targeted four wells with stainless steel riser casing and screen, including an upgradient/background well (GW-521) and three wells where corrosion is suspected (GW-302, GW-305, and GW-339), and one well with PVC riser casing and screen (GW-203). Qualitative bacterial counts, estimated from the appearance of each groundwater sample after an eight- to nine-day growth period, provided data regarding the relative degree of mmicrobial activity in the groundwater at each well (AJA 2001). As shown in Table 2, the microbiological sampling results indicate: (1) microbial activity in the groundwater samples from each well where corrosion is suspected; (2) negligible microbial activity in the groundwater sample from the upgradient background well; and (3) high bacterial counts for the sample from well GW-203, which has PVC well casing and screen and does not yield groundwater samples with elevated chromium or nickel concentrations.

Table 2. February 2000 Microbiological Sampling Results

Well	Riser/Screen Material	Indication of Corrosion?	Maximum Bacterial Count (colony forming units per milliliter)		
			Iron-Related	Slime-Forming	Sulfate-Reducing
GW-203	PVC	No	5,000	50,000	<100
GW-302	Stainless steel	Yes	<100,000	<50,000	<100
GW-305	Stainless Steel	Yes	5,000	500,000	100
GW-339	Stainless steel	Yes	5,000	50,000	<100
GW-521	Stainless steel	No	<100	<100	<100
Note: Modified from (AJA 2001).					

Iron-related bacteria and slime-forming bacteria have been documented to cause MIC of stainless steel (Sarouhan et al. 1998).

WELL GW-346

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during June 1988, completed with a screened monitored interval from 51.5 to 64.9 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is clustered with wells GW-345 and GW-526 and is located in Bear Creek Valley (BCV) west of Y-12, about 1,300 ft west-southwest of the former S-3 Ponds (hereafter referenced as the S-3 Site). Located near the western end of Y-12, directly north of the headwaters of Bear Creek, the S-3 Site encompasses four contiguous, above-grade, unlined surface impoundments, each with a surface area of approximately 400 x 400 ft and an average total depth of approximately 15 ft. The ponds were used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12, and were closed in 1988 in accordance with requirements of the RCRA regulations applicable to hazardous waste landfills. Closure of the site was completed in 1989 and included the neutralization and removal of liquid wastes and stabilization of neutralization sludge remaining in each pond, which were then filled with crushed limestone and covered with a multilayer low-permeability cap (completed with an asphalt-paved parking lot). Historical operation of the S-3 Site emplaced a heterogeneous mixture of inorganic, organic, and radiological contaminants in the subsurface that remains a primary source of groundwater and surface water contamination in BCV.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Eleven groundwater samples have been collected from the well, with the conventional sampling method used to obtain eight samples between September 1988 and August 1995 and the low-flow sampling method used to obtain three samples between March 1999 and October 2005. The sampling history includes a quarterly sampling frequency, followed by 5-year (January 1990 – August 1995), 4-year (August 1995 – March 1999), and 6-year (March 1999 – June 2005) periods when no groundwater samples were collected from the well.

High total dissolved solids (TDS) is a distinguishing characteristics of the groundwater samples from this well (see Section 4.0), and is a direct consequence of contamination resulting from historical operation of the former S-3 Site.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Nolichucky Shale (Conasauga Group), which trends northeast-southwest along the northern slope of BCV, dips to the southeast at an angle of 45º - 55º, and is bordered on the southeast by the overlying Maynardville Limestone, a highly permeable karst aquifer that provides the principal pathway for subsurface contaminant migration in BCV. The bulk of the groundwater flow in the Nolichucky Shale occurs in a highly permeable zone (the water table interval) that occurs near the transition between unconsolidated material (residuum and weathered bedrock). Also, it is suspected that the highly acidic wastes from the S-3 Site dissolved carbonate strata interbedded within the Nolichucky Shale and greatly enhanced the relative permeability of these strata-bound flowpaths within several hundred feet of the site.

Groundwater flow in the water table interval in the Nolichucky Shale is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek, which traverse the Nolichucky Shale from northeast to southwest throughout BCV west of Y-12 and are numbered in ascending order downstream from the headwaters of the creek; well GW-346 is located on the west side of the tributary (NT-1) closest to the headwaters. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone.

The static water level in the well occurs at an average depth of about 16.5 ft bgs and exhibits seasonal fluctuations up to 6 ft. Also, measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in well GW-346 are typically lower than evident in wells GW-345 and GW-526, which are completed at shallower (GW-345 = 26 ft) and greater (GW-526 = 123 ft bgs) depths in the Nolichucky Shale. Based on the distance between the monitored interval midpoint in each well, the contemporaneous groundwater elevations indicate upward vertical hydraulic gradients (0.06 – 0.13) from the deeper bedrock (GW-526) to the shallow bedrock interval (GW-346) and downward vertical gradients (0.03 – 0.1) from the water table interval (GW-345) to the shallow bedrock interval during seasonally high and low flow conditions.

As indicated by groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for nearby monitoring wells, groundwater near the well flows primarily southwest toward the Maynardville Limestone and the main channel of Bear Creek. However, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 4,400 – 5,316 mg/L;
- pH of 7.05 – 7.2 (field measurements);
- high concentrations calcium (>650 mg/L), magnesium (>200 mg/L), sodium (>100 mg/L), and nitrate (>750 mg/L);
- low molar proportions of chloride, potassium, and sulfate (<5% of total anions/cations);
- high concentrations of barium (>2 mg/L) and strontium (>20 mg/L); and
- total concentrations of trace metals (except barium and strontium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Note that some of the inorganic compounds and trace metals in the groundwater at this well, such as nitrate, were entrained in the acidic wastes disposed at the S-3 Site, whereas other inorganics, such as barium, were dissolved from bedrock minerals by the highly acidic seepage from the site. Also, the high levels of TDS may cause analytical interferences for some laboratory analytes, including gross alpha activity and gross beta activity.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. Based on the results reported for the groundwater samples collected to date, nitrate is the principal contaminant present in the groundwater at this well. Note, however, that the bulk of the historical the analytical results for VOCs, gross alpha activity, and gross beta activity do not meet all applicable DQOs. The QA/QC sample data needed to identify false positive VOC results are not available for groundwater samples collected before January 1991. Similarly, gross alpha activity and gross beta activity reported for the groundwater samples collected before January 1990 are considered unusable because the sample-specific MDA and CE are not available for these analytes.

5.1 NITRATE

All of the groundwater samples collected to date had nitrate concentrations above the analytical detection limit and all of these results are at least an order-of-magnitude higher than the drinking water MCL for nitrate (10 mg/L). Nitrate is the principal component of the contaminant plume emplaced during historical operations of the site, is chemically stable and mobile in groundwater, and is believed to effectively trace the groundwater transport pathways followed by other similarly mobile components of the contaminant plume (DOE 1997). The extent of elevated nitrate concentrations (>10 mg/L) in the shallow groundwater west of the Nolichucky Shale indicate primarily westward transport/migration toward discharge areas in the northern tributaries of Bear Creek (NT-1 and NT-2), with the sampling results for this well demonstrating that the nitrate plume in the shallow groundwater flow system extends west of NT-1.

The highest nitrate concentrations were reported for the groundwater samples collected in September 1988 (1,100 mg/L), November 1988 (4,380 mg/L), and March 1999 (1,005 mg/L), but all of these results are considered qualitative. The ion charge balance error (i.e., the percent difference between respective summed milliequivalent concentrations of the major cations and anions) determined for these samples exceeds 20% (80.8% in September 1988, -60.3% in November 1988, and -42.1 % in March 1999). Unlike the nitrate concentrations evident in groundwater from wells completed at similarly shallow depths in the Nolichucky Shale, the nitrate results do not exhibit any clear relationship with seasonal groundwater flow conditions. This suggests that the monitored interval in the well does not intercept highly permeable groundwater flow/transport pathways. Note also that the most recent sampling results for the well (750-872 mg/L) are lower than the nitrate concentrations (1,290-1,400 mg/L) in groundwater samples collected during CY 2005 from well GW-526, a deeper well (123 ft bgs) clustered with well GW-346 (see Section 3.0).

Excluding the qualitative nitrate results noted above, a time series plot of the nitrate concentrations detected in the groundwater samples collected to date (Figure 1) shows an indeterminate long term trend, encompassing a decreasing trend between February (1,000 mg/L) and September 1989 (806 mg/L) and a fairly steady trend through October 2005 (872 mg/L). The most recent sampling results suggesting a slight concentration decrease, with a new minimum value (750 mg/L) reported for the sample collected in March 2005. The relatively high nitrate concentrations indicated by the most recent sampling results suggest that the closure/capping of the S-3 Site has not (yet) impacted the overall flux of nitrate via the groundwater flow/transport pathways at depth in the Nolichucky Shale along geologic strike to the west of the site.

5.2 URANIUM

All of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit (Table 1), with the highest value (0.011 mg/L in November 1988) being below the MCL for uranium (0.03 mg/L). However, this maximum value is an order of magnitude higher than all other results and is a suspected outlier. Considering the relatively high nitrate concentrations in the groundwater from this well, the low levels of uranium seems conspicuous, especially because, as noted previously, uranium was entrained in the wastewaters disposed at the S-3 Site. Uranium in the acidic seepage from the site probably occurred as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble complexes with a variety of inorganic anions (Fetter 1993). Consequently, elevated concentrations of uranium are generally restricted to the acidic groundwater in the Nolichucky Shale within approximately 500 ft of the site (DOE 1987).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected in four of the groundwater sample collected to date, and all but one of these results are estimated concentrations (3 µg/L) for common laboratory reagents (e.g., acetone). Only a trace of benzene (1 µg/L in October 2005) has been detected in samples collected since January 1991, and the other results are most likely analytical artifacts.

5.4 GROSS ALPHA ACTIVITY

As noted in Section 5.0, only the gross alpha activity reported for the five groundwater samples since January 1990 meet applicable DQOs, and these results are considered qualitative because of inherent analytical interferences associated with the very high TDS levels in the samples (Section 4.0). None of the groundwater samples collected since January 1990 had gross alpha activity above the applicable MDA and corresponding CE (Table 1). Low (background) levels of gross alpha activity in the groundwater from this well are supported by the similarly low levels of U-234 and U-238 reported for the samples collected in June (U-234 = 1.4 pCi/L and U-238 = 0.64 pCi/L) and October 2005 (U-234 = 2.1 pCi/L and U-238= 1 pCi/L). Uranium isotopes were entrained in the wastewater disposed at the S-3 Site and are the primary alpha particle-emitting radionuclides in the contaminant plume emplaced during historical operation of the site (DOE 1997). However, as with the total uranium concentrations in the groundwater from this well, the low levels of uranium isotopes reflect greater attenuation outside the acidic groundwater typically encountered at shallow depths in the Nolichucky Shale within approximately 500 ft of the site.

5.5 GROSS BETA ACTIVITY

As with gross alpha activity, five of the analytical results for gross beta activity reported for the groundwater samples collected to date meet DQOs and recent sampling results are considered qualitative because of analytical interferences associated with the high TDS of the groundwater samples. One groundwater sample collected since January 1990 had gross beta activity above the applicable MDA and corresponding CE (Table 1), with that value (34.7 pCi/L in August 1995) is less than the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

The low levels of gross beta activity in the groundwater collected to date are supported by the analytical results for Tc-99 reported for the samples collected in June and October 2005 (19 pCi/L and 24 pCi/L, respectively). A beta particle-emitting radionuclide, Tc-99 is a “signature” component of the contaminant plume emplaced during historical operation of the S-3 Site, which is the only site at Y-12 known to have received significant volumes of waste that contained Tc-99 (DOE 1997). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Consequently, the distribution of Tc-99 in the shallow groundwater flow system in the Nolichucky Shale downgradient of the S-3 Site, as indicated by the extent of elevated gross beta activity (>50 pCi/L) defined by the network of wells to the south and west (and east) of the site, closely mirrors that of nitrate from the site, which is also highly mobile in groundwater. Thus, it is not clear from the available data why Tc-99 is not present at similarly high concentrations in the groundwater from this well.

WELL GW-363

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in March 1988, completed with an open-hole monitored interval from 50 to 75 ft bgs, and constructed with nominal 6.5-inch diameter steel (SF25) riser casing. The well is located in Bear Creek Valley west of Y-12, near the northwest corner of the Oil Landfarm hazardous waste disposal unit. This site, which was used between 1972 and 1982 for the biological degradation of about one million gallons of waste oils and coolants generated at Y-12, is covered by a low-permeability multi-layer cap installed during RCRA closure of the site in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-three groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 19 samples between September 1988 and August 1997, and the low-flow sampling method used to obtain 14 samples between April 2001 and November 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the shallow bedrock interval (<100 ft bgs) in the Conasauga Group (Nolichucky Shale). The average static groundwater level in the well is 2 ft bgs. Presampling depth-to-water measurements for the well indicate moderate fluctuations (<10 ft) in groundwater surface elevations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 228 – 328 mg/L;
- pH (field measurements) of 7.7–9.9, excluding a suspected outlier (6.56 in December 2002);
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for 26 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Sixteen groundwater samples were analyzed for nitrate (between March 1994 and November 2001), and three of these samples had nitrate concentrations above the applicable analytical reporting limit. The highest nitrate concentration (0.39 mg/L in January 1995) is substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Seventeen groundwater samples were analyzed for uranium (between March 1994 and May 2003), and two of these samples had uranium concentrations above the applicable analytical reporting limit. The highest concentration (0.004 mg/L in May 1994) is substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected at low levels in three groundwater samples: acetone in February 1996 (13 µg/L) and November 2003 (0.4 µg/L); and toluene in November 2003 (0.1 µg/L) and June 2004 (0.2 µg/L). These VOCs are common laboratory reagents and the results are considered to be outliers.

5.4 GROSS ALPHA ACTIVITY

None of the 17 groundwater samples analyzed for gross alpha activity (between March 1994 and May 2003) had results above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

Two of the 17 groundwater samples analyzed for gross beta activity (between March 1994 and May 2003) had results above the applicable MDA and corresponding CE. The highest value (5.85 pCi/L in August 2001) is substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-364

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in May 1988, completed with a screened monitored interval from 47 to 60 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is paired with well GW-365 and is located in Bear Creek Valley (BCV) south of the main channel of Bear Creek approximately 6,000 ft west of Y-12 and 500 ft west of the southwest corner of the Oil Landfarm waste management area (WMA). The Oil Landfarm WMA encompasses the following closed waste management facilities: the Oil Landfarm, Boneyard/Burnyard (BYBY), Hazardous Chemical Storage Area (HCDA), and Sanitary Landfill I.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-six groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 22 samples between September 1988 and December 1993, and the low-flow sampling method used to obtain four samples between March 2001 and September 2005. The sampling history includes a quarterly sampling frequency followed by 7-year (December 1993 – March 2001) and 4-year (August 2001 – March 2005) periods when no samples were collected from the well.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maynardville Limestone (Conasauga Group), which trends northeast-southwest along the axis of BCV, dips southeast at an angle of 45º - 55º, and underlies the main channel of Bear Creek. The Maynardville Limestone exhibits the hydrologic characteristics typical of karst aquifers, with most of the groundwater flow occurring at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (shallow karst network). Hydrologic interaction between Bear Creek and the shallow karst network provides the principal exit-pathway for contaminants released from source areas within the Bear Creek watershed west of Y-12. Deeper in the subsurface, below the shallow karst network, fractures provide the primary groundwater flowpaths, and the bulk permeability generally decreases with depth because of decreased fracture aperture and increased fracture spacing (Solomon et. al. 1992). Also, distinct lithologic and hydrologic characteristics differentiate seven hydrostratigraphic zones (numbered from bottom to top) in the Maynardville Limestone (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

The static water level in the well occurs at an average depth of approximately 16 ft bgs and exhibits maximum seasonal fluctuations up to approximately 18 ft. Also, depth-to-water measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in well GW-364 are typically lower than those evident in well GW-365, which is completed at a greater depth (150 ft bgs) in the Maynardville Limestone. Based on the distance between the monitored interval midpoint in each well (85 ft), the contemporaneous groundwater elevations indicate upward vertical hydraulic gradients (0.024–0.104) from the intermediate depth bedrock (GW-365) to the shallow bedrock interval (GW-364) during seasonally high and low flow conditions.

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-364 indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone. Additionally, the well is located downstream of a reach of Bear Creek south of Sanitary Landfill I that loses substantial flow to the shallow karst network in the Maynardville Limestone and is believed to greatly facilitate the recharge of contaminated surface water into the groundwater flow system downgradient (south and west) of the Oil Landfarm WMA (DOE 1997).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples collected to date show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 188 – 658 mg/L;
- pH of 6.9 – 8.2 (field measurements);
- low molar proportions of chloride, sulfate, potassium, and sodium (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

As illustrated by the following summary of selected data from the most recent sampling events (March and September 2005), the geochemical characteristics of the groundwater in this well differ substantially from those of the deeper groundwater from well GW-365. The difference in groundwater geochemistry probably reflects the relative permeability of the flowpaths intercepted by the monitored interval in each well, whereby the lower TDS indicates shorter residence time for groundwater from well GW-364 as a consequence of the substantially higher permeability of the groundwater flowpaths at shallow depths in the Maynardville Limestone.

Well/Monitored Interval / Sampling Date	pH (st. units)	DO (ppm)	REDOX (mV)	TDS (mg/L)	Calcium (mg/L)	Magnesium (mg/L)	Bicarbonate (mg/L)

09/01/05	7.16	1.95	-195	636	158	41.2	468

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

All but one of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit, with the historical maximum concentration (10.2 mg/L in September 1993) slightly exceeding the drinking water MCL for nitrate (10 mg/L). However, the historical maximum value is a suspected outlier compared to the other results for nitrate, none of which exceed 4 mg/L, with nitrate concentrations below 1 mg/L reported for all the samples collected since March 2001. Nevertheless, the elevated nitrate concentrations shown by the historical sampling results indicate that the monitored interval in the well intercepts water-producing features that are hydraulically connected with the heterogeneous plume of inorganic, organic, and radiological contaminants originating from the former S-3 Ponds. Located hydraulically upgradient approximately 5,500 ft east-northeast of the well, these unlined surface impoundments received several million gallons of nitric-acid wastes generated at Y-12 between 1951 and 1984, and were filled and covered with a low-permeability cap during RCRA closure of the site in 1989. Nitrate is a principal component of the contaminant plume, is chemically stable and highly mobile in groundwater, and is believed to effectively delineate the primary groundwater flow/contaminant transport pathways in the Maynardville Limestone (DOE 1997).

5.2 URANIUM

All but four of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.009 mg/L in December 1992) being substantially below the MCL for uranium (0.03 mg/L). These results indicate that the monitored interval in the well does not intercept the primary groundwater transport pathways for uranium from the former BYBY. Hydraulically upgradient approximately 2,700 ft east-northeast of the well, the BYBY was identified during the CERCLA remedial investigation as the primary source of uranium in Maynardville Limestone hydraulically downgradient (west) of the Oil Landfarm WMA (DOE 1997). Uranium-bearing wastes in the subsurface at the BYBY were below the seasonally high water table and carbonate dissolved from the limestone bedrock combined with uranyl cations leached from the wastes and greatly increased what would otherwise be relatively limited uranium mobility, considering the neutral pH groundwater in the Maynardville Limestone (DOE 1997). As a major source area for uranium, the BYBY was prioritized for CERCLA remedial action, which was completed in May 2003 and involved: (1) the excavation and on-site consolidation/off-site disposal of about 81,000 yd^3 of waste materials; (2) construction of a multi-layer low-permeability cap over waste materials consolidated on site (above the seasonally high water table); and (3) reconstruction of a northern tributary of Bear Creek (NT-3) that drains the site.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected to date (Table 1): CTET, chloroform, ethylbenzene, PCE, toluene, TCE, vinyl acetate, 2-hexanone, 11DCA, 11DCE, 12DCE, and 111TCA. The presence of VOCs in the samples indicates that the monitored interval in the well intercepts groundwater flow/transport pathways for VOCs released from one or more upgradient sources that contribute to an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. Available data for the network of wells completed in the Maynardville Limestone west of the flow divide indicate that VOC-contaminated groundwater, as defined by individual or summed VOC concentrations above 5 µg/L, appears to originate near Spoil Area I and to extend hydraulically downgradient for several thousand feet westward (parallel with geologic strike) down the axis of BCV. The apparent distribution of VOCs within the plume reflects the relative influx from multiple source areas, commingling during downgradient groundwater transport, and hydraulic communication with Bear Creek (DOE 1997). There are several confirmed and suspected sources of VOCs In the upper part of BCV hydraulically upgradient (north and east) of the well, including Spoil Area I, the contaminant plume emplaced during historical operation of the former S-3 Ponds, the Rust Spoil Area, and several potential sources within the Oil Landfarm WMA, including the Oil Landfarm, HCDA, and Sanitary Landfill I.

Based on frequency of detection and concentration magnitude, TCE and 12DCE (c12DCE) are the primary VOCs in the groundwater samples collected to date (Table 1). Both compounds were detected in all but three of the samples, with historical maximum concentrations of 26 µg/L and 12 µg/L respectively. Also, the most recent sampling results show that TCE concentrations remain near the drinking water MCL (5 µg/L), whereas c12DCE concentrations are substantially below the MCL (70 µg/L). Secondary compounds detected in the samples are 11DCA, 11DCE, and 111TCA, each of which were detected in all but five of the samples, although only 11DCE was detected in the samples collected most recently: this result (1 µg/L in September 2005) is less than the MCL for 11DCE (7 µg/L). Historical maximum concentrations of these compounds are all less than 10 µg/L, with concentrations of 5 µg/L or less detected in each sample collected since December 1992. The remaining VOCs were detected infrequently (three samples or less) with most of the results being estimated values below 5 µg/L (Table 1).

Several of the VOCs detected in the groundwater samples collected to date, particularly 11DCA, 11DCE, and c12DCE, are probably present in the groundwater as a result of biologically mediated degradation (sequential dechlorination) of related parent compounds (TCE and 111TCA). However, as illustrated by the data summarized in Table 2, results for several indicator parameters suggest that geochemical characteristics of the groundwater in the well may not be within the optimum ranges for biotic degradation of chlorinated hydrocarbons. Considering the upward vertical hydraulic gradients noted previously, the presence of the VOC-degradation products in the groundwater at his well may be at least partially attributable to upward migration from the deeper flow system, where geochemical conditions may promote more effective biotic degradation.

As illustrated by the selected sampling results summarized below, historical data show that TCE concentrations in the shallow groundwater from well GW-364 were substantially lower than evident in the deeper groundwater from well GW-365, although more recent sampling results show similar TCE concentrations for each well. Considering the upward vertical hydraulic gradients indicated by the presampling groundwater elevations, as noted in Section 4.0, the presence of TCE in the shallower groundwater at well GW-364 may be at least partially attributable to upward migration of TCE from the deeper flow system in the Maynardville Limestone. Additionally, the lower TCE concentrations in well GW-364 reflects the greater permeability of the shallow karst network in the Maynardville Limestone, which facilitates more rapid flushing of the VOC-contaminated groundwater during seasonal (and episodic) recharge/discharge cycles.

TCE (µg/L)			
GW-364 (47-60 ft bgs)		**GW-365 (127-150 ft bgs)**	
03/22/89	16	03/29/89	73
05/12/91	15	05/14/91	26
03/27/93	6	03/28/93	89
03/13/01	7	03/27/01	54
03/07/05	2 J	03/07/05	4 J

A time-series plot of TCE concentrations reported for the groundwater samples collected to date shows a clearly decreasing long-term trend dominated by concentration fluctuations and the prolonged gaps in the sampling history for the well (Figure 1). The decreasing concentration trend probably mirrors a corresponding reduction in the relative flux of TCE in the shallow karst network in the Maynardville Limestone. Reduced flux of TCE (and other VOCs) occurred in response to various remedial actions at the primary sources of VOCs in BCV west of Y-12, including the RCRA closure/capping of the former S-3 Ponds and Oil Landfarm and the CERCLA remedial action at the BYBY, which included excavation and removal of subsurface wastes at the HCDA that were suspected sources of VOCs in the groundwater. Note that several of the "peak" TCE concentrations, such as those evident in September 1991 (21 µg/L) and June 1993 (16 µg/L), were reported for samples collected during seasonally low flow conditions (summer and fall), whereas low TCE concentrations, such as those reported for the samples collected in March 1992 (9 µg/L) and March 1993 (6 µg/L), often correlate with seasonally high flow conditions (winter and spring). This relationship suggests seasonally variable flux of TCE via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

Nine groundwater samples collected since February 1990 (previous results for gross alpha activity do not meet applicable data quality objectives) had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (8.15 pCi/L in October 1990) being below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

All but four of the groundwater samples collected since February 1990 (previous results for gross beta activity do not meet applicable data quality objectives) had gross beta activity above the applicable MDA and corresponding CE, with the highest value (22.3 pCi/L in September 1993) being below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-365

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in May 1988, completed with an open-hole monitored interval from 126.7 to 150 ft bgs, and constructed with nominal 6.5-inch diameter steel (SF25) riser casing. The well is paired with well GW-364 and is located in Bear Creek Valley (BCV) south of the main channel of Bear Creek approximately 6,000 ft west of Y-12 and 500 ft west of the southwest corner of the Oil Landfarm waste management area (WMA). The Oil Landfarm WMA encompasses the following closed waste management facilities: the Oil Landfarm, Boneyard/Burnyard (BYBY), Hazardous Chemical Storage Area (HCDA), and Sanitary Landfill I.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-six groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 22 samples between September 1988 and December 1993, and the low-flow sampling method used to obtain four samples between March 2001 and September 2005. The sampling history includes a quarterly sampling frequency followed by 7-year (December 1993 – March 2001) and 4-year (August 2001 – March 2005) periods when no samples were collected from the well.

Groundwater samples obtained from this well using the low-flow sampling method are significantly more turbid (turbidity >200 NTU and TSS >20 mg/L) than the samples obtained using the conventional method (turbidity <20 NTU and TSS <8 mg/L). This is somewhat unusual because turbid samples are more frequently associated with the conventional sampling method, which involves purging a fixed volume of groundwater from the well at a pumping rate that may substantially lower the water level in the well.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the intermediate depth (100–200 ft bgs) bedrock interval in the Maynardville Limestone (Conasauga Group), which trends northeast-southwest along the axis of BCV, dips southeast at an angle of 45º - 55º, and underlies the main channel of Bear Creek. The Maynardville Limestone exhibits the hydrologic characteristics typical of karst aquifers, with most of the groundwater flow occurring at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (shallow karst network). Hydrologic interaction between Bear Creek and the shallow karst network provides the principal exit-pathway for contaminants released from source areas within the Bear Creek watershed west of Y-12. Deeper in the subsurface, below the shallow karst network, fractures provide the primary groundwater flowpaths, and the bulk permeability generally decreases with depth because of decreased fracture aperture and increased fracture spacing (Solomon et. al. 1992). Also, distinct lithologic and hydrologic characteristics differentiate seven hydrostratigraphic zones (numbered from bottom to top) in the Maynardville Limestone (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

The static water level in the well occurs at an average depth of about 9 ft bgs and exhibits maximum seasonal fluctuations up to approximately 13 ft. Also, depth-to-water measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show groundwater elevations in well GW-365 are higher than evident in well GW-364, which is completed at a shallower depth (60 ft bgs) in the Maynardville Limestone. Based on the distance between the monitored interval midpoint in each well (about 85 ft), the contemporaneous groundwater elevations indicate upward vertical hydraulic gradients (0.024–0.104) from the intermediate depth bedrock (GW-365) to the shallow bedrock interval (GW-364) during seasonally high and low flow conditions.

Groundwater elevation isopleths based on contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-365 indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone. Additionally, the well is located downstream of a reach of Bear Creek south of Sanitary Landfill I that loses substantial flow to the shallow karst network in the Maynardville Limestone and is believed to greatly facilitate the recharge of contaminated surface-water into the groundwater flow system downgradient (south and west) of the Oil Landfarm WMA (DOE 1997).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples collected to date show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 494 – 638 mg/L;
- pH of 6.8 – 7.3 (field measurements);
- low molar proportions of potassium, sodium, and sulfate (<10% of total anions/cations);
- elevated chloride concentrations (>80 mg/L);
- very high iron (>20 mg/L) and slightly elevated boron (>0.2 mg/L) concentrations; and
- total concentrations of other trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The elevated iron concentrations are reported only for samples obtained using the low-flow sampling method, which are significantly more turbid than the samples obtained with the conventional method (see Section 2). Thus, these iron concentrations are likely artifacts of the preservation (acidification) of the turbid samples, with the suspended material in the samples possibly including fine particles of rust from the steel riser casing in the well.

As illustrated by the following summary of selected data from the most recent sampling events (March and September 2005), the geochemical characteristics of the groundwater in this well differ substantially from those of the shallower groundwater from well GW-364. The difference in groundwater geochemistry reflects the relative permeability of the flowpaths intercepted by the monitored interval in each well, whereby the higher TDS indicates longer residence time for groundwater from well GW-365 as a consequence of the substantially lower permeability of the groundwater flowpaths at depth in the Maynardville Limestone.

Well/Monitored Interval / Sampling Date	**pH (st. units)**	**DO (ppm)**	**REDOX (mV)**	**TDS (mg/L)**	**Calcium (mg/L)**	**Magnesium (mg/L)**	**Bicarbonate (mg/L)**

09/01/05	7.16	1.95	-195	636	158	41.2	468

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Eight groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit, with the highest value (5.17 mg/L in September 1993) being below the drinking water MCL for nitrate (10 mg/L). Nevertheless, these nitrate concentrations substantially exceed background levels in uncontaminated groundwater (<0.028 mg/L) in BCV and indicate that the open-hole interval in the well intercepts water-producing features that are hydraulically connected with the heterogeneous plume of inorganic, organic, and radiological contaminants originating from the former S-3 Ponds. Located hydraulically upgradient approximately 5,500 ft east-northeast of the well, these unlined surface impoundments received several million gallons of nitric-acid wastes generated at Y-12 between 1951 and 1984, and were filled and covered with a low-permeability cap during RCRA closure of the site in 1989. Nitrate is a principal component of the contaminant plume, is chemically stable and highly mobile in groundwater, and is believed to effectively delineate the primary groundwater flow/contaminant transport pathways in the Maynardville Limestone (DOE 1997).

5.2 URANIUM

Eighteen groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.00108 mg/L in September 2005) being below the MCL for uranium (0.03 mg/L) and within the range of background levels in the Maynardville Limestone. These results suggest that the water-producing features intercepted by the open-hole interval in the well are not hydraulically connected with the primary groundwater transport pathways for uranium from the former BYBY. Hydraulically upgradient approximately 2,700 ft east-northeast of the well, the BYBY was identified during the CERCLA remedial investigation as the primary source of uranium in Maynardville Limestone hydraulically downgradient (west) of the Oil Landfarm WMA (DOE 1997). Uranium-bearing wastes in the subsurface at the BYBY were below the seasonally high water table and carbonate dissolved from the limestone bedrock combined with uranyl cations leached from the wastes and greatly increased what would otherwise be relatively limited uranium mobility, considering the neutral pH groundwater in the Maynardville Limestone (DOE 1997).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected to date (Table 1): acetone, benzene, CTET, chloroethane, chloroform, ethylbenzene, methylene chloride, PCE, toluene, TCE, vinyl chloride (VC), 11DCA, 11DCE, 12DCE, and 111TCA. The presence of VOCs in the samples indicates that the monitored interval in the well intercepts groundwater flow/transport pathways for VOCs released from one or more upgradient sources that contribute to an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. Available data for the network of wells completed in the Maynardville Limestone west of the flow divide indicate that VOC-contaminated groundwater, as defined by individual or summed VOC concentrations above 5 µg/L, appears to originate near Spoil Area I and to extend hydraulically downgradient for several thousand feet westward (parallel with geologic strike) down the axis of BCV. The apparent distribution of VOCs within the plume reflects the relative influx from multiple source areas, commingling during downgradient groundwater transport, and hydraulic communication with Bear Creek (DOE 1997). There are several confirmed and suspected sources of VOCs In the upper part of BCV hydraulically upgradient (north and east) of the well, including Spoil Area I, the contaminant plume emplaced during historical operation of the former S-3 Ponds, the Rust Spoil Area, and several potential sources within the Oil Landfarm WMA, including the Oil Landfarm, HCDA, and Sanitary Landfill I.

Based on frequency of detection and concentration magnitude, TCE, 11DCE, and 12DCE are the primary VOCs in the groundwater samples collected to date (Table 1). All three compounds were detected in all but one of the samples, with historical maximum concentrations of 89 µg/L, 36 µg/L, and 69 µg/L respectively. Also, the most recent sampling results show that TCE and 11DCE concentrations remain near or slightly above their drinking water MCLs (5 µg/L and 7 µg/L), whereas the concentrations of c12DCE are substantially below the MCL (70 µg/L). Secondary compounds are PCE, 11DCA, and 111TCA, at least one of which was detected in each sample collected to date (Table 1). Results for these VOCs show only the historical maximum concentration of 111TCA (21 µg/L in September 1988) exceeds 10 µg/L, 11DCA was detected in samples collected most recently (March and September 2005), and all results for PCE and 111TCA are less than respective MCLs (5 µg/L and 200 µg/L). The remaining VOCs were detected infrequently, with results for each compound except acetone and t12DCE being estimated values below 5 µg/L (Table 1). Of these, VC was detected the most frequently (seven samples) and the most recent sampling results (5 µg/L in March and September 2005) show that VC concentrations remain above the MCL (2 µg/L).

Several of the VOCs detected in the groundwater samples collected to date, particularly 11DCA, 11DCE, c12DCE, and VC, are probably present in the groundwater as a result of biologically mediated degradation (sequential dechlorination) of related parent compounds (TCE and 111TCA). As illustrated by the data summarized in Table 2, results for several indicator parameters suggest that geochemical characteristics of the groundwater at this well are within the optimum ranges for biotic degradation of chlorinated hydrocarbons. Moreover, the historical data show an often inverse relationship between the concentrations of TCE and 12DCE (total). For example, while TCE concentrations decreased by 25% between September 1988 (84 µg/L) and January 1990 (63 µg/L), 12DCE concentrations increased more than 150% (from 19 µg/L to 50 µg/L) over the same period. Similarly, respective results for samples collected more recently in March 2001 and March 2005 show a substantial decrease in TCE concentrations (from 54 µg/L to 4 µg/L), but relatively unchanged concentrations of 12DCE (17 µg/L and 20 µg/L). This relationship suggests the accumulation of 12DCE through biotic degradation of TCE.

As illustrated by the selected sampling results summarized below, historical data show that TCE concentrations in the deeper groundwater from well GW-365 were substantially higher than evident in the shallower groundwater from well GW-364, although more recent sampling results show similar TCE concentrations for each well. Considering the upward vertical hydraulic gradients indicated by the presampling groundwater elevations, as noted in Section 4.0, the presence of TCE in the shallower groundwater at well GW-364 may be at least partially attributable to upward migration of TCE from the deeper flow system in the Maynardville Limestone. Additionally, the higher TCE concentrations in well GW-365 reflects the lesser permeability of the water-producing features with depth in the Maynardville Limestone, whereas the much higher permeability of the shallow karst network facilitates more rapid flushing of VOC contaminated groundwater during seasonal (and episodic) recharge/discharge cycles.

TCE (µg/L)			
GW-364 (47-60 ft bgs)		**GW-365 (127-150 ft bgs)**	
03/22/89	16	03/29/89	73
05/12/91	15	05/14/91	26

03/13/01	7	03/27/01	54
03/07/05	2 J	03/07/05	4 J

A time-series plot of TCE concentrations reported for the groundwater samples collected to date shows a generally decreasing long-term trend dominated by wide concentration fluctuations and the gaps in the sampling history for the well (Figure 1). The decreasing concentration trend probably reflects a combination of reduced flux of TCE (and other VOCs) and, as discussed previously, biotic degradation of the TCE. Reduced flux of TCE (and other VOCs) in the Maynardville Limestone occurred in response to various remedial actions at the primary sources of VOCs in BCV west of Y-12, including the RCRA closure/capping of the former S-3 Ponds and Oil Landfarm and the CERCLA remedial action at the BYBY, which included excavation and removal of subsurface wastes at the HCDA that were suspected sources of VOCs in the groundwater.

5.4 GROSS ALPHA ACTIVITY

Seven groundwater samples collected since February 1990 (previous results for gross alpha activity do not meet applicable data quality objectives) had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (4.29 pCi/L in March 1993) being below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Eleven groundwater samples collected since February 1990 (previous results for gross beta activity do not meet applicable data quality objectives) had gross beta activity above the applicable MDA and corresponding CE, with the highest value (10.2 pCi/L in March 1992) being below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). Note that gross beta activity has been below the applicable MDA and corresponding CE in all of the groundwater samples collected since March 1993.

WELL GW-368

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in June 1988, completed with an open-hole monitored interval from 225 to 245 ft bgs, and constructed with nominal 6.5-inch diameter steel (SF25) riser casing. The well forms a cluster with wells GW-369 and GW-601 and is located in Bear Creek Valley (BCV) approximately 5,000 ft west of Y-12. The well cluster is on the steep northern (scarp) flank of Chestnut Ridge, approximately 300 ft directly south of the main channel of Bear Creek and 500 ft south of the Oil Landfarm waste management area (WMA). The Oil Landfarm WMA encompasses the following closed hazardous and nonhazardous waste management facilities: the Oil Landfarm, Boneyard/Burnyard (BYBY), Hazardous Chemical Storage Area (HCDA), and Sanitary Landfill I.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Nine groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain seven samples between September 1988 and January 1990, and the low-flow sampling method used to obtain samples in March and September 2005. The sampling history includes a quarterly sampling frequency, followed by a 15-year period (January 1990 – March 2005) when no samples were collected from the well, with semiannual sampling in 2005.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the intermediate depth (100-300 ft bgs) bedrock interval in the Maynardville Limestone (Conasauga Group), which trends northeast-southwest along the axis of BCV, dips southeast at an angle of 45º - 55º, and underlies the main channel of Bear Creek. The Maynardville Limestone exhibits the hydrologic characteristics typical of karst aquifers, with most of the groundwater flow occurring at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (shallow karst network). Hydrologic interaction between Bear Creek and the shallow karst network provides the principal exit-pathway for contaminants released from source areas within the Bear Creek watershed west of Y-12. Deeper in the subsurface, below the shallow karst network, fractures provide the primary groundwater flowpaths, and the bulk permeability generally decreases with depth because of decreased fracture aperture and increased fracture spacing (Solomon et. al. 1992). Also, distinct lithologic and hydrologic characteristics differentiate seven hydrostratigraphic zones (numbered from bottom to top) in the Maynardville Limestone (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

The static water level in the well occurs at an average depth of about 67 ft bgs, with presampling measurements indicating maximum seasonal water-level fluctuations of approximately 6 ft. Groundwater elevation isopleths based on contemporaneous depth-to-water measurements for wells located in the vicinity of well GW-368 indicate westerly local flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone. Additionally, the well is located directly south of a reach of Bear Creek south of Sanitary Landfill I that loses substantial flow to the shallow karst network in the Maynardville Limestone and is believed to greatly facilitate the recharge of contaminated surface water into the groundwater flow system downgradient (south and west) of the Oil Landfarm WMA (DOE 1997).

Presampling depth-to-water measurements recorded during one contemporaneous sampling event (i.e., within 24 hours) show a lower presampling groundwater elevation in well GW-368 (929.1 ft above msl) compared to well GW-601 (931.27 ft above msl), which is completed deeper (356 ft bgs) in the Maynardville Limestone. Based on the distance between the monitored interval midpoint in each well (102 ft), the respective groundwater elevations indicate a slightly upward vertical hydraulic gradient (0.021) from the deep bedrock (GW-601) to the intermediate depth bedrock interval (GW-368). Note that the contemporaneous presampling groundwater elevations were recorded during seasonally low flow (September 2005) and, consequently, may not be representative of the vertical hydraulic gradients evident during seasonally high flow conditions.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples collected to date show that the well yields chloride- and sulfate-enriched, calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 330 – 409 mg/L;
- pH of 7.32 – 7.58 (field measurements);
- low molar proportions of potassium and sodium (<10% of total anions/cations);
- elevated concentrations of chloride (>30 mg/L) and sulfate (>50 mg/L); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

It is not clear if the elevated sulfate and chloride concentrations typical of the groundwater samples reflect natural geochemical characteristics at depth in the Maynardville Limestone, or if the elevated concentrations are the result of contamination from one or more sources hydraulically upgradient of the well. Similarly, it is unclear if the unusually high total iron (3.61 mg/L) reported for the sample collected in September 2005 is a potential artifact related to corrosion of the steel riser casing in the well.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

All groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit (Table 1), although none of these results exceed the drinking water MCL for nitrate (10 mg/L). Nevertheless, the nitrate concentrations exceed background levels in uncontaminated (<0.028 mg/L) groundwater in BCV, particularly considering the depth of the well, and indicates that the open-hole interval in the well intercepts water-producing features that are hydraulically connected with the heterogeneous plume of inorganic, organic, and radiological contaminants originating from the former S-3 Ponds. Located hydraulically upgradient approximately 4,500 ft east-northeast of the well, these unlined surface impoundments received several million gallons of nitric-acid wastes generated at Y-12 between 1951 and 1984, and were filled and covered with a low-permeability cap during RCRA closure of the site in 1989. Nitrate is a principal component of the contaminant plume, is chemically stable and highly mobile in groundwater, and is believed to effectively delineate the primary groundwater flow/contaminant transport pathways in the Maynardville Limestone (DOE 1997).

Nitrate concentrations above background levels in the groundwater flow/transport pathways intercepted by the open-hole interval in this well are attributable to westward (downgradient) transport of nitrate via strike-parallel flowpaths at depth in the Maynardville Limestone (>200 ft bgs). As illustrated by the most recent sampling results summarized below, the nitrate concentrations do not exhibit wide seasonal fluctuations, suggesting that the well does not have a direct hydraulic connection with the shallow karst network, where nitrate concentrations exhibit substantial fluctuations in response to seasonal (and episodic) flow conditions. Without evidence for a more direct hydraulic connection with the shallow karst network, the presence of nitrate in the groundwater from this well does not seem attributable to extensive down-dip inflow (recharge) of nitrate-contaminated surface water via the losing reach of Bear Creek noted in Section 3.0.

Nitrate (mg/L)			
GW-368 (225-245 ft bgs)		**GW-601 (318-356 ft bgs)**	
01/31/90	6	03/05/90	16
03/21/05	8.48	03/15/05	19.6
09/12/05	8.94	09/12/05	18.4

Both historical and more recent sampling results, as illustrated by the data summarized above, indicate that nitrate concentrations in the groundwater in well GW-368 are lower than evident deeper in the Maynardville Limestone in the groundwater from well GW-601. In light of the upward vertical gradient noted in Section 4.0, the presence of nitrate in the groundwater from well GW-368 may be at least partially attributable to upward migration from the deeper flow system. Moreover, considering the depth of open-hole interval in each well relative to the hydrostratigraphic zones in the Maynardville Limestone (see Section 3.0), the lower levels of nitrate in well GW-368 potentially indicate lesser relative flux of nitrate (and other similarly mobile contaminants) via less permeable strike-parallel flowpaths within hydrostratigraphic zones toward the middle of the formation.

Nitrate concentrations detected in the groundwater samples collected to date suggest a fairly indeterminate long-term concentration trend, as illustrated by the nitrate results reported for samples collected in September 1988 (5.9 mg/L), September 1989 (10 mg/L, the historical maximum value), and September 2005 (8.94 mg/L). This indeterminate trend suggests that there has been minimal change in the overall flux of nitrate via the groundwater flow/transport pathways intercepted by the open-hole interval in the well. In the shallow karst network in the Maynardville Limestone, however, clearly decreasing nitrate concentrations indicated by data for wells located both upgradient (east) and downgradient (west) of well GW-368 reflect the substantially reduced flux of nitrate that occurred after closure of former S-3 Ponds and installation of a low-permeability cap at the site.

5.2 URANIUM

Five groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.0018 mg/L in September 2005) being substantially below the MCL for uranium (0.03 mg/L) and within the range of background levels in the Maynardville Limestone. These results suggest that the open-hole interval in the well intercepts water-producing features that are not extensively connected with the primary groundwater transport pathways for uranium from the former BYBY, which is hydraulically upgradient approximately 1,650 ft east-northeast of the well. Uranium-bearing wastes at the BYBY were identified during the CERCLA RI as a principal source of uranium in the Maynardville Limestone downgradient of the Oil Landfarm WMA (DOE 1997). Subsequent

CERCLA remedial action at the BYBY, completed in May 2002, included the excavation and removal of wastes from above and below the saturated zone. Additionally, the low (background) levels of uranium in the well do not indicate extensive down-dip inflow (recharge) of uranium-contaminated surface water via the losing reach of Bear Creek noted in Section 3.0.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected to date (Table 2): acetone, CTET, chloroform, ethylbenzene, PCE, toluene, TCE, 11DCE, and 111TCA. The presence of VOCs in the samples indicates that the monitored interval in the well intercepts groundwater flow/transport pathways for VOCs released from one or more upgradient sources that contribute to an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. Available data for the network of wells completed in the Maynardville Limestone west of the flow divide indicate that VOC-contaminated groundwater, as defined by individual or summed VOC concentrations above 5 µg/L, appears to originate near Spoil Area I and to extend hydraulically downgradient for several thousand feet westward (parallel with geologic strike) down the axis of BCV. The apparent distribution of VOCs within the plume reflects the relative influx from multiple source areas, commingling during downgradient groundwater transport, and hydraulic communication with Bear Creek (DOE 1997).

Based on frequency of detection and concentration magnitude, TCE is the primary VOC detected in the groundwater samples collected to date (Table 2). This compound was detected in all the samples, with TCE concentrations above 100 µg/L, including the historical maximum concentration (130 µg/L in September 1988), reported for all but three of the samples. All the TCE results, including results for the samples collected most recently (March and September 2005), substantially exceed the drinking water MCL (5 µg/L). Other VOCs were detected infrequently, with estimated concentrations below 5 µg/L reported for all these compounds except acetone and CTET (Table 2). Indeed, the general lack of other VOCs in the groundwater samples, particularly c12DCE, suggests minimal biotic degradation of the TCE (and other VOCs) in the groundwater. This interpretation is supported by results for several indicator parameters, which suggest that selected geochemical characteristics are not within the ranges considered optimum for biologically mediated degradation of chlorinated hydrocarbons in the groundwater (Table 3).

The predominance of TCE in the groundwater samples from this well suggests that the primary source of the VOCs is the Rust Spoil Area (or nearby site within the Bear Creek floodplain). The Rust Spoil Area is a closed construction and demolition waste disposal site underlain by the Maynardville Limestone approximately 2,200 ft directly east (parallel with geologic strike) of the wells and is the suspected source of a TCE-dominated plume of dissolved VOCs in the shallow groundwater at the site (DOE 1997). Also, the former S-3 Ponds are a potential source area of VOCs because the presence of nitrate in the well (Section 5.1) demonstrates a connection with the contaminant plume originating from that site. Additional influx of VOCs into the Maynardville Limestone occurs from several potential sources within the Oil Landfarm WMA that are hydraulically upgradient of the well to the north (the Oil Landfarm and Sanitary Landfill I) and east-northeast (the HCDA). However, the previously discussed results for nitrate and uranium suggests strike-parallel contaminant transport from an upgradient source to the east of the well, rather than down-dip inflow (recharge) of contaminants from potential source areas to the north-northeast of the well.

As illustrated by the selected sampling results summarized below, historical data show similar levels of TCE in the groundwater from wells GW-368 and GW-601, which suggests similar relative flux of TCE via the groundwater flow/transport pathways intercepted by the open-hole interval in each well. Additionally, the most recent sampling results for both wells indicate that the TCE concentrations in deeper groundwater remain significantly higher than evident in wells completed at shallower depths in the Maynardville Limestone, including wells located at the Rust Spoil Area (e.g., GW-312). This may reflect the greater permeability of the shallow karst network, which facilitates more rapid flushing of the most contaminated groundwater by seasonal (and episodic) recharge/discharge cycles (DOE 1997).

TCE (µg/L)			
GW-368 (225-245 ft bgs)		**GW-601 (318-356 ft bgs)**	
01/31/90	120	03/05/90	110
03/21/05	62	03/15/05	85
09/12/05	50	09/12/05	72

A time-series plot of TCE concentrations reported for the groundwater samples collected to date (Figure 1) shows an indeterminate or slightly decreasing trend between September 1988 (130 µg/L) and January 1990 (120 µg/L), followed by the prolonged gap (15-year) in the sampling history and substantially lower TCE levels in March (62 µg/L) and September 2005 (50 µg/L). The lower TCE concentrations indicated by the most recent sampling results are probably attributable to a combination of natural attenuation (dilution and dispersion) in the groundwater and the reduced flux of TCE (and other VOCs) via the groundwater flow/transport pathways intercepted by the open-hole interval in the well.

5.4 GROSS ALPHA ACTIVITY

Two of the three groundwater samples collected since January 1990 had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (9.2 pCi/L in September 2005) being below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

All three of the groundwater samples collected since January 1990 had gross beta activity above the applicable MDA and corresponding CE, with the highest value (9.7 pCi/L in March 2005) being below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-380

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1988, completed with a screened monitored interval from 2.8 to 15.5 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with wells GW-381 and GW-382 in Bear Creek Valley near the east end of Y-12, about 500 ft directly west (hydraulically upgradient) of New Hope Pond (NHP). NHP is a closed surface water impoundment formerly used to regulate flow in Upper East Fork Poplar Creek, and is covered with a low-permeability multilayer cap installed during RCRA closure of the site in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-seven groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 34 samples between December 1988 and May 1997, and the low-flow sampling method used to obtain 13 samples between December 1997 and August 2004.

A conspicuous characteristic of the groundwater samples from this well are elevated concentrations of chromium and nickel that are most likely attributable to chemical and/or microbiologically-induced corrosion of the stainless steel well casing and/or screen (see Section 5.6).

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Maynardville Limestone). The average static groundwater level in the well is 10 ft below ground surface. Presampling depth-to-water measurements for the well indicate moderate fluctuations (<6 ft) in seasonal groundwater surface elevations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 215 – 682 mg/L;
- pH (field measurements) of 5.6 – 7.4;
- low molar proportions of nitrate, potassium, and sulfate (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals (except chromium and nickel) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Groundwater samples from this well often contain chloride and sodium concentrations above 50 mg/L, which substantially exceeds the respective UTLs for groundwater in the Maryville Limestone. The source of the chloride and sodium is not known but there are multiple industrial sources of these ions within Y-12 upgradient (west) of the well, including chloride from the biotic degradation of dissolved VOCs in the groundwater. Whatever the source, the elevated chloride levels in the groundwater at the well may play a role in maintaining the elevated chromium and nickel concentrations in the samples from the well (see Section 5.6) because chloride may combine with available metal cations to form soluble complexes that do not readily adsorb to mineral surfaces in the monitored-interval filter pack materials and surrounding bedrock (McLean and Bledsoe 1992).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion, which is based on the analytical results reported for 37 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Four groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (4.43 mg/L in June 1998) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Twenty-eight groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.0045 mg/L in May 1995) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for 25 groundwater samples show non-detect values or false positive results for all of the VOCs that are confirmed groundwater contaminants in the East Fork Regime. As shown in Table 1, low (estimated) concentrations of PCE, TCE, CT chloroform, and ethylbenzene were detected in a total of 12 samples; the maximum concentration of each compound does not exceed the applicable MCL. These compounds are confirmed components of dissolved VOC plumes in the groundwater hydraulically upgradient (west) of the well.

Table 1. Summary of VOC results for well GW-380

Sampling Date	Concentration (µg/L)				
	PCE	TCE	CT	Chloroform	Ethylbenzene
08/23/91	0.6 J	.	.	1 J	.
08/01/92	2 J	1 J	2 J	2 J	1 J
09/21/94	2 J	.	.	1 J	.
05/23/95	3 J	.	.	1 J	.
11/30/95	1 J	.	.	1 J	.
11/19/96	1 J	.	.	2 J	.
12/02/97	2 J	.	.	2 J	.
06/04/99	.	.	.	2 J	.
08/05/02	.	.	.	5 J	.
02/13/03	.	.	3 J	1 J	.
08/12/03	.	.	.	4 J	.
8/11/04	.	.	.	3 J	.

Note: "." = Not detected; J = Estimated concentration; FP = false positive result

The data summarized above also indicate a fairly indeterminate long-term concentration trend for the VOCs in the well, which suggest minimal change in the relative flux of dissolved VOCs transported via the groundwater flowpaths intercepted by the monitored interval in this well.

5.4 GROSS ALPHA ACTIVITY

Twelve groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (7.97 pCi/L in February 1994) being less than the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Twenty-one groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (12.6 pCi/L in November 1994) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

5.6 OTHER

As shown in Table 2, all of the groundwater samples collected from the well since January 1991 had concentrations of chromium and/or nickel above the respective analytical reporting limit, with chromium and/or nickel above respective MCLs reported for all but one of the samples.

Table 2. Chromium and nickel results for well GW-380

Note: Bold typeface denotes results that exceed the MCL.

The following considerations suggest that the elevated concentrations of chromium and nickel in the groundwater samples from this well are most likely attributable to corrosion of the stainless steel riser casing and well screen: (1) chromium and nickel concentrations in groundwater samples from the deeper wells (GW-381 and GW-382) clustered with well GW-380, which both have open-hole monitored intervals, rarely exceed respective analytical reporting limits, although the groundwater in the deeper wells contains the same VOCs detected in well GW-380 (see Section 5.3.); (2) mobile species of each metal are not typically present in groundwater with the neutral pH conditions evident in the well; (3) there are not any confirmed or suspected sources of either metal near the well; (4) neither metal is a primary component of the commingled groundwater contaminant plume in the Maynardville Limestone hydraulically upgradient (east) of the well; (5) Type 304 stainless steel contains 18-20% chromium and 8-12% nickel and is prone to crevice corrosion (Oakley and Korte 1996); (6) groundwater in the well exhibits geochemical conditions known to be corrosive to Type 304 stainless steel (e.g., dissolved oxygen > 2 mg/L; Driscoll 1986); and (7) as noted in Section 4.0, elevated chloride levels in the groundwater may greatly limit the partitioning of nickel and chromium ions in the well.

In addition to the considerations listed above, microbiologically induced corrosion (MIC) of the stainless steel riser casing and screen may be a potential source of the elevated nickel and chromium concentrations in the groundwater samples from this well. Results of microbiologic sampling performed in May 2000 and April 2004, summarized in Table 3, show minimal microbial activity in the deeper groundwater at well GW-381, but substantial microbial activity in the shallower groundwater at well GW-380, including the presence of iron-related bacteria and slime-forming bacteria, which have been demonstrated to cause MIC of stainless steel (Sarouhan et al. 1998).

Table 3. Microbiological sampling results for wells GW-380 and GW-381

Well	Riser/Screen Material	Sampling Date	Maximum Bacterial Count (colony forming units per milliliter)

WELL GW-381

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in April 1988, completed with an open-hole interval from 49.3 to 60.4 ft bgs, and constructed with nominal 6.5-inch diameter steel (SF25) riser casing. This well forms a cluster with wells GW-380 and GW-382 and is located in Bear Creek Valley near the east end of Y-12, adjacent to the Upper East Fork Poplar Creek (UEFPC) distribution channel about 200 ft immediately west-southwest (hydraulically upgradient) of New Hope Pond (NHP)/Lake Reality. Closed in 1988 and covered with a multi-layer, low-permeability cap in 1989, NHP was an unlined surface impoundment constructed in 1963 to regulate the quantity and quality of surface water exiting Y-12 via UEFPC. Lake Reality is a lined surface impoundment that was built in 1988 to replace NHP. During normal operations, flow in UEFPC is directed through the concrete-lined distribution channel, which borders the south and east sides of NHP/Lake Reality.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-eight groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 27 samples between December 1988 and May 1995, and the low-flow sampling method used to obtain 11 samples between May 2000 and November 2004. Note that a five-year gap (June 1995 – April 2000) in the sampling history for the well spans the change in groundwater sampling methods.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maynardville Limestone (upper Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 11 ft bgs and exhibits minor (<2 ft) seasonal fluctuations. Also, presampling groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are typically about 0.5 ft higher in well GW-381 than well GW-382, which is completed deeper (175 ft bgs) in the Maynardville Limestone. Based on the distance (94 ft) between the monitored interval midpoint (elevation) in each well, the contemporaneous groundwater elevations suggest slightly downward vertical hydraulic gradients (0.003 to 0.011) during seasonally high and low flow conditions. However, upward vertical gradients (0.008 to 0.038) are indicated by the unusually high presampling groundwater elevations in well GW-382 during February 1991, October 1992, and September 1994.

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-381 indicate components of flow to the north/northeast toward the UEFPC drainage system and to the east parallel with geologic strike in the Maynardville Limestone. However, a gravel and perforated-pipe underdrain constructed beneath portions of the UEFPC distribution channel (see Section 1.0) substantially influences local groundwater flow directions. Additionally, local groundwater flow patterns near NHP are influenced by the full-time operation of a groundwater extraction and treatment system intended to intercept and contain the VOC-contaminated groundwater in the Maynardville Limestone near the east end of Y-12, as required by the CERCLA Action Memorandum (DOE 1999). Beginning in October 2001, groundwater has been pumped from a well (GW-845) located about 1,300 ft east-southeast (hydraulically downgradient) of well GW-381 and is treated on-site to remove VOCs, particulates, iron, and manganese. Long-term operation of the system has generally maintained 15 to 17 ft of drawdown in the immediate vicinity of well GW-845 and has established an elongated zone of influence that extends parallel with geologic strike for at least 900 ft to the east (downgradient) and 600 ft to the west (upgradient) of the pumping well (DOE 2002).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 330 – 714 mg/L;
- pH (field measurements) of 6.7 – 7.9;
- very high concentrations of chloride (>70 mg/L) and iron (>10 mg/L) compared to other wells that yield groundwater from shallow depths in the Maynardville Limestone;
- low molar proportions of potassium, sulfate, and sodium (<10% of total anions/cations);
- total concentrations of trace metals (except iron) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The unusually high chloride concentrations in the groundwater samples may reflect local geochemical conditions or contamination from one or more sources within Y-12, including numerous potential non-specific sources such as leaking industrial process lines, sanitary sewers, or storm drains. Additionally, elevated chloride concentrations in the groundwater samples may be a consequence of the biologically mediated degradation (dechlorination) of dissolved chlorinated hydrocarbons in the groundwater (Hinchee et al. 1995). Moreover, as illustrated by the most recent monitoring data summarized in Table 1, several indicator parameters suggest that the geochemical characteristics of the groundwater, particularly the REDOX conditions, are conducive to biotic degradation of VOCs (see Section 5.3).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the respective monitoring data reported for the groundwater samples collected from the well since February 1991, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Nine groundwater samples had nitrate concentrations at or above the applicable analytical reporting limit, with the highest concentration (0.62 mg/L in March 1995) being substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Seven groundwater samples had uranium concentrations at or above the applicable analytical reporting limit, with the highest concentration (0.001 mg/L) being an order-of-magnitude lower than the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in at least one of the groundwater samples: acetone, CTET, chloroform, chloromethane, MC, toluene, PCE, TCE, c12DCE, and VC (Table 2). These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and UEFPC watersheds. In the UEFPC watershed east of the flow divide, which occurs near the west end of Y-12, the VOC plume appears to originate near the Fire Training Facility in the southwestern section of Y-12, extends eastward (parallel with geologic strike) and mixes with VOCs released from several sources in the central and eastern Y-12 areas, and enters Union Valley east of the ORR boundary along Scarboro Road (DOE 1998). In October 2000, full-time operation of a groundwater remediation system began to help intercept and contain the (CTET-dominated) portion of the VOC plume in the eastern Y-12 area, as required by the CERCLA Action Memorandum (DOE 1999). Operation of the system involves pumping groundwater from an extraction well (GW-845) completed in the Maynardville Limestone about 1,500 ft east (parallel with geologic strike) of well GW-381; treating the groundwater on-site to remove particulates, iron, manganese, and VOCs; and discharging the effluent into UEFPC.

The principal VOCs in the groundwater samples are CTET and chloroform; each compound was detected in all but one of the samples (Table 2). Historical maximum concentrations exceed 1,000 µg/L for both compounds, including CTET concentrations above 5,000 µg/L reported for most of the samples obtained between February 1991 and May 2000. Results have been substantially lower since May 2000, excluding the chloroform result in June 2003 (1,500 µg/L) (Table 2). All results for CTET still exceed the drinking water MCL (Table 2). Secondary VOCs in the samples are MC, PCE, TCE, c12DCE, and VC. Of these, only MC was detected in any of the samples collected before May 2000 (i.e., obtained with the conventional sampling method and diluted before analysis). Since May 2000, PCE and c12DCE have been detected in all but two of the samples, and TCE and VC were first detected (1 µg/L) in one sample during CY 2004. Concentrations of PCE and c12DCE are all less than 10 µg/L, with the most recent results showing PCE levels slightly above and below the MCL.

A time-series plot of the summed concentrations of VOCs detected in each groundwater sample shows two trends on either side of the five-year gap in the sampling history for this well (Figure 1). Monitoring (conventional sampling) results obtained through May 1995 show an indeterminate or slightly decreasing summed VOC concentrations, with minor temporal fluctuations that often reflect an inverse relationship with seasonal groundwater flow conditions (i.e., concentrations are typically highest in samples obtained during seasonally low flow). However, wide temporal concentration changes are not evident for all of the VOCs in the groundwater samples (Table 2). Also, although the summed VOC concentrations are substantially lower, the monitoring (low-flow sampling) results obtained since April 2000 exhibit wide temporal fluctuations that reflect a more direct correlation with seasonal flow conditions (i.e., concentrations are typically highest in samples obtained during seasonally high flow). Additionally, based on the monitoring data obtained to date, the VOCs concentrations in the groundwater at this well do not appear to exhibit any clear response to the full-time operation of groundwater extraction well GW-845.

5.4 GROSS ALPHA ACTIVITY

Seven groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (6.7 pCi/L in June 2003) being substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Eleven groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (5.89 pCi/L in October 1991) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-382

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in April 1988, completed with an open-hole interval from 125 to 173 ft bgs, and constructed with nominal 6.5-inch diameter steel (SF25) riser casing. This well forms a cluster with wells GW-380 and GW-381 and is located in Bear Creek Valley near the east end of Y-12, adjacent to the Upper East Fork Poplar Creek (UEFPC) distribution channel about 200 ft immediately west-southwest (hydraulically upgradient) of New Hope Pond (NHP)/Lake Reality. Closed in 1988 and covered with a multi-layer, low-permeability cap in 1989, NHP was an unlined surface impoundment constructed in 1963 to regulate the quantity and quality of surface water exiting Y-12 via UEFPC. Lake Reality is a lined surface impoundment that was built in 1988 to replace NHP. During normal operations, flow in UEFPC bypasses Lake Reality and is directed through the concrete-lined distribution channel, which borders the south and east sides of NHP/Lake Reality.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-eight groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 27 samples between December 1988 and May 1995, and the low-flow sampling method used to obtain 11 samples between September 1999 and August 2004. Note that a four-year gap (June 1995 – August 1999) in the sampling history for the well spans the change in groundwater sampling methods.

An evaluation of the monitoring data available through September 2000 indicated that the well may exhibit sensitivity to the groundwater sampling method: samples obtained with the conventional sampling method had substantially higher VOC concentrations than samples obtained with the low-flow sampling method (AJA 2001). It is possible, however, that the disparity in the VOC concentrations is attributable to a decreasing long-term concentration trend (see Section 5.3). Nevertheless, results of "paired" groundwater sampling, with the low-flow sampling method used to collect a sample one day and the conventional sampling method used to collect a sample the next day, are needed to determine if the VOC concentrations are biased by the sampling method.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the intermediate bedrock interval in the Maynardville Limestone (upper Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 11 ft bgs and exhibits moderate (<6 ft) seasonal fluctuations. Also, presampling groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are typically about 0.5 ft lower in well GW-382 than well GW-381, which is completed at a shallower depth (60 ft bgs) in the Maynardville Limestone. Based on the distance (94 ft) between the monitored interval midpoint (elevation) in each well, the contemporaneous groundwater elevations suggest slightly downward vertical hydraulic gradients (0.003 to 0.011) during seasonally high and low flow conditions. However, upward vertical gradients (0.008 to 0.038) are indicated by the unusually high presampling groundwater elevations in well GW-382 during February 1991, October 1992, and September 1994.

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-382 indicate components of flow to the north/northeast toward the UEFPC drainage system and to the east parallel with geologic strike in the Maynardville Limestone. However, a gravel and perforated-pipe underdrain constructed beneath portions of the UEFPC distribution channel (see Section 1.0) substantially influences local groundwater flow directions. Additionally, local groundwater flow patterns near NHP are influenced by the full-time operation of a groundwater extraction and treatment system intended to intercept and contain the VOC-contaminated groundwater in the Maynardville Limestone near the east end of Y-12, as required by the CERCLA Action Memorandum (DOE 1999). Beginning in October 2001, groundwater has been pumped from a well (GW-845) located about 1,300 ft east-southeast (hydraulically downgradient) of well GW-382 and is treated on-site to remove particulates, iron, manganese, and VOCs. Long-term operation of the system has generally maintained 15 to 17 ft of drawdown in the immediate vicinity of well GW-845 and has established an elongated zone of influence that extends parallel with geologic strike for at least 900 ft to the east (downgradient) and 600 ft to the west (upgradient) of the pumping well (DOE 2002).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields chloride-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 248 –502 mg/L;
- pH (field measurements) of 6.9 – 7.9;
- unusually high concentrations of chloride (>50 mg/L) and iron (>5 mg/L) compared to other wells that yield groundwater from the Maynardville Limestone;
- low molar proportions of potassium, sulfate, and sodium (<10% of total anions/cations);
- total concentrations of trace metals (except iron) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The unusually high chloride concentrations in the groundwater samples may reflect local geochemical conditions or contamination from one or more sources within Y-12, including numerous potential non-specific sources such as leaking industrial process lines, sanitary sewers, or storm drains. Additionally, the elevated chloride levels may be a consequence of the biologically mediated degradation (dechlorination) of the chlorinated hydrocarbons in the groundwater (Hinchee et al. 1995). However, as illustrated by the most recent monitoring data summarized in Table 1, several indicator parameters suggest that the geochemical characteristics of the groundwater in the well, particularly the REDOX conditions, are not especially conducive to biotic degradation of VOCs (see Section 5.3).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the respective monitoring data reported for the groundwater samples collected from the well since February 1991, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

All but two of the groundwater samples had nitrate at or above the applicable analytical reporting limit, with the highest concentration (4.5 mg/L in May 1995) being less than the drinking water MCL for nitrate (10 mg/L). The specific source of nitrate in groundwater at this well has not been identified, but a potential source is the S-2 Site, which is an unlined waste site excavated into the lower slope of Chestnut Ridge about 9,000 ft west (hydraulically upgradient) of the well that received an unknown volume of corrosive and toxic aqueous wastes.

5.2 URANIUM

Six groundwater samples had uranium concentrations at or above the applicable analytical reporting limit, with the highest concentration (0.0129 mg/L in July 2001) being substantially below the drinking water MCL for uranium (0.03 mg/L). However, this result is a suspected outlier because most results (21 samples) were below the detection limit and the next highest results are an-order-of magnitude lower (0.001 mg/L, which equals the detection limit, in four samples) than this result.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in at least one of the groundwater samples (Table 2): acetone, CTET, chloroform, chloromethane, MC, toluene, PCE, TCE, 11DCE, 12DCE (c12DCE), carbon disulfide, and 111TCA. These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and UEFPC watersheds. In the UEFPC watershed east of the flow divide, which occurs near the west end of Y-12, the VOC plume appears to originate near the Fire Training Facility in the southwestern section of Y-12, extends eastward (parallel with geologic strike) and mixes with VOCs released from several sources in the central and eastern Y-12 areas, and enters Union Valley east of the ORR boundary along Scarboro Road (DOE 1998). In October 2000, full-time operation of a groundwater plume capture system began to help intercept and contain the (CTET-dominated) portion of the VOC plume in the eastern Y-12 area, as required by the CERCLA Action Memorandum (DOE 1999). Operation of the system involves pumping groundwater from an extraction well (GW-845) completed in the Maynardville Limestone about 1,500 ft east (parallel with geologic strike) of well GW-382; treating the groundwater on-site to remove VOCS, particulates, iron, and manganese; and discharging the effluent into UEFPC.

The primary VOCs in the groundwater samples are CTET, chloroform, and PCE, each of which was detected in each groundwater sample (Table 2). Secondary compounds are TCE, detected in about half of the samples, and c12DCE, which was detected in nine of the 11 samples collected since September 1999. Other VOCs were detected in no more than seven samples, with acetone, carbon disulfide, chloromethane, 11DCE, and 111TCA each detected in only one sample. The highest concentrations were reported for CTET (7,000 µg/L in November 1993), chloroform (1,300 µg/L in October 1992), acetone (490 µg/L in February 1994), and PCE (330 µg/L in February 1994); all the other VOCs have historical maximum concentrations below 100 µg/L. The most recent monitoring results show that the concentrations of CTET, chloroform, and PCE remain above respective drinking water MCLs (Table 2).

Summed concentrations of VOCs detected in the groundwater samples obtained with the conventional sampling method (February 1991 – May 1995) show a widely fluctuating, indeterminate long-term concentration trend (Figure 1). The wide concentration variations indicated by the conventional sampling data do not consistently correlate with seasonal groundwater flow conditions, as illustrated by the temporal low summed concentrations of VOCs detected in the groundwater samples obtained in February 1991 (3,380 µg/L) and October 1992 (2,157 µg/L).

Summed concentrations of VOCs detected in the groundwater samples obtained with the low-flow sampling method (September 1999 – August 2003) show much lower concentrations that exhibit substantially less temporal variability and a clearly decreasing trend through August 2002, followed by higher concentrations through August 2003 (Figure 1). As noted in Section 4, the lower VOC concentrations indicated by the low-flow sampling results may be an artifact of the sampling method. Nevertheless, the lower VOC concentrations generally coincide with the full-time operation the groundwater plume capture system.

5.4 GROSS ALPHA ACTIVITY

Twelve groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (4.72 pCi/L in September 2000) being substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Eighteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (6.6 pCi/L in September 2000) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-383

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in April 1988, completed with a screened monitored interval from 16.6 to 23.6 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with wells GW-384 and GW-385 and is located in Bear Creek Valley near the east end of Y-12, adjacent to Second Street immediately west (hydraulically upgradient) of New Hope Pond (NHP)/Lake Reality. Closed in 1988 and covered with a multi-layer, low-permeability cap in 1989, NHP was an unlined surface impoundment constructed in 1963 to regulate the quantity and quality of surface water exiting Y-12 via Upper East Fork Poplar Creek (UEFPC). Lake Reality is a lined surface impoundment that was built in 1988 to replace NHP. During normal operations, flow in UEFPC is directed through the concrete-lined distribution channel, which borders the south and east sides of NHP/Lake Reality.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fifty-one groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 35 samples between August 1988 and May 1997, and the low-flow sampling method used to obtain 16 samples between December 1997 and November 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Nolichucky Shale (Conasauga Group) and is believed to intercept groundwater flow/transport pathways associated with the buried former channel of UEFPC on the west side of NHP (DOE 2002). The bulk of the groundwater flow in the Nolichucky Shale occurs within the water table interval, which is a highly permeable zone that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into the buried northern tributaries of UEFPC and other components of the subsurface drainage system within the highly industrialized areas of Y-12 (DOE 1998). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that stratigraphically overlies the Nolichucky Shale and subcrops along the axis of BCV and the original main channel of UEFPC.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 7 ft bgs and exhibits minor (<5 ft) seasonal fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-381 indicate east and southeasterly flow toward the UEFPC. Moreover, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred flow in directions that parallel geologic strike (i.e., bedding-plane fractures), which generally coincides with the eastward flow directions indicated by the groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields chloride-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 100 – 400 mg/L;
- pH (field measurements) of 5.8 – 7.6;
- high concentrations of chloride (>50 mg/L) and iron (>1 mg/L) compared to other wells that yield groundwater from the water-table interval in the Nolichucky Shale;
- low molar proportions of potassium, sulfate, and sodium (<10% of total anions/cations);
- total concentrations of trace metals (except iron) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The unusually high chloride concentrations in the groundwater samples may reflect local geochemical conditions or contamination from one or more sources within Y-12, including numerous potential non-specific sources such as application of salt to roadways during winter months or leaking industrial process lines, sanitary sewers, or storm drains. Additionally, the elevated chloride levels may be a consequence of the biologically mediated degradation (dechlorination) of the chlorinated hydrocarbons in the groundwater (Hinchee et al. 1995). As illustrated by the most recent monitoring data summarized in Table 1, several indicator parameters suggest that the geochemical characteristics of the groundwater in the well, particularly the REDOX conditions, are conducive to biotic degradation of VOCs (see Section 5.3).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the respective monitoring data reported for the groundwater samples collected from the well since January 1991, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Four groundwater samples had nitrate above the applicable analytical reporting limit, with the highest concentration (3.9 mg/L in August 2000) being less than the drinking water MCL for nitrate (10 mg/L). However, the historical maximum result appears to be an outlier because the other three nitrate concentrations are less than 1 mg/l.

5.2 URANIUM

Uranium concentrations at or above the applicable analytical reporting limit were reported only for the groundwater samples collected in May 1994 (0.001 mg/L) and June 1999 (0.000666 mg/L) and both of these values are substantially below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, each groundwater sample contained one or more of the following VOCs: acetone, CTET, chloroform, PCE, TCE, VC, 11DCE, c12DCE, t12DCE, and 111TCA. The source of these compounds is believed to be DNAPL that is suspected to be present in the subsurface near Bldg. 9720-6, which is about 500 ft west-southwest of the well (DOE 1998). The former UEFPC channel, intercepted by well GW-382 (see Section 3.0), is believed to be an active pathway for northward transport of VOCs from Bldg. 9720-6 (DOE 2002). Also, the groundwater geochemistry in the well (see section 4.0) appears to be conducive to the biotic degradation of chlorinated hydrocarbons. Thus, some of the compounds (e.g., CTET and PCE) are probably the principal components of the suspected DNAPL at Bldg. 9720-6, whereas other compounds (e.g., c12DCE and VC) are present as a consequence of the biotic degradation of related parent compounds during residence/transit in the groundwater system. Indeed, the low dissolved oxygen and negative REDOX that are characteristic of the groundwater samples potentially indicate the reducing (methanogenic) conditions necessary to transform 12DCE isomers to VC (Chapelle 1996).

The primary VOCs in the groundwater samples are PCE, TCE, and 12DCE, each of which was detected in each sample (Table 2). In contrast, CTET, chloroform, 11DCE, and VC were detected in 24-44% of the samples and 111TCA was detected in only one sample. Respective historical maximum concentrations exceed 100 μg/L for PCE, TCE and 12DCE, whereas the bulk of the results for CTET, chloroform, 11DCE, and VC are estimated values below 5 μg/L. Also, the most recent monitoring data also show that PCE and TCE concentrations remain substantially above respective drinking water MCLs (5 μg/L). Based on the analytical results reported for the samples collected since May 1997, c12DCE is the primary 12DCE isomer in the groundwater samples, with the most recent monitoring data showing c12DCE concentrations substantially above the MCL (80 μg/L). Although detected infrequently (in 13 of 41 samples) and at substantially lower concentrations, all the VC results equal or exceed the MCL (2 μg/L), including the concentration detected in the most recent sample.

A time-series plot of the summed concentrations of VOCs detected in each groundwater sample, show a widely fluctuating but generally increasing long-term concentration trend (Figure 1). However, increasing trends are not evident for all of the VOCs. For instance, between January 1991 and November 2004, the concentrations of PCE, TCE, and 12DCE have increased significantly, whereas there are minimal differences in the initial and most recent concentrations of VC and 11DCE (Table 2). Also, the widely fluctuating summed VOC concentrations reflect sharp temporal changes in the concentrations of PCE, TCE, and 12DCE, with the highest concentrations of each compound typically evident in the groundwater samples collected during seasonally low flow conditions (summer and fall). Additionally, the concentrations of CTET and chloroform have decreased from the peak levels evident during the early 1990s (Figure 2), and have not been detected in samples collected since May 1997 (Table 2).

5.4 GROSS ALPHA ACTIVITY

Five groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (8.8 pCi/L in May 2004) being below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Thirteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (7.4 pCi/L in November 1999) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-505

1.0 *INSTALLATION, CONSTRUCTION, AND LOCATION*

This well was installed during April 1988, completed with a screened monitored interval from 1.5 to 13.5 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley (BCV) near the west end of Y-12, at the Rust Garage (RG) about 400 ft east-southeast of the former S-3 Ponds. The RG once housed several petroleum fuel underground storage tanks (USTs) and associated service lines and dispenser, a fuel unloading station, and drum storage area for used oil (DOE 1998). Note that the large monitored (screened) interval in the well is intended to straddle the water table during seasonally high and low flow conditions and facilitate detection of light non-aqueous phase liquids (LNAPL).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-one groundwater samples have been collected from the well, with the conventional sampling method used to obtain 19 samples between December 1988 and February 1996, and the low-flow sampling method used to obtain samples in May and October 2003.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Nolichucky Shale (Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within a highly permeable zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 1 ft bgs and exhibits minimal (<3 ft) seasonal fluctuations. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-505 indicate east-southeasterly flow toward the Maynardville Limestone and the Upper East Fork Poplar Creek (UEFPC) drainage system. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred flow in directions that parallel geologic strike (i.e., bedding-plane fractures), which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 94 - 226 mg/L;
- pH of 5.2 – 6.76 (field measurements);
- low molar proportions of potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals (except uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of*

Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the analytical results for the 15 groundwater samples collected since March 1991, groundwater contamination at this well is dominated by elevated levels of gross alpha radioactivity.

5.1 NITRATE

Fifteen groundwater samples had nitrate concentrations at or above the analytical reporting limit, with the highest value (2.9 mg/L) being substantially below the MCL for nitrate (10 mg/L). Low nitrate concentrations in the samples at this well is surprising considering the substantially higher concentrations (>100 mg/L) in the groundwater samples from wells completed at similar depths in the Nolichucky Shale along geologic strike to the west (GW-105) and east (GW-270) of the well. The source of the nitrate is the former S-3 Ponds, which emplaced a heterogeneous mixture of inorganic, organic, and radiological contaminants in the Nolichucky Shale and created a mound in the water table that facilitated contaminant transport/migration east of the hydrologic divide separating the Bear Creek and UEFPC watersheds. Nitrate and other inorganic contaminants within the plume were principal components of the wastes disposed at the site, but some of the inorganic contaminants (e.g., barium) were dissolved from bedrock minerals by the acidic seepage from the ponds. With concentrations in excess of 10,000 mg/L, nitrate is the primary inorganic contaminant in the plume and, based on the network of existing monitoring wells completed in the Nolichucky Shale east of the former S-3 Ponds, elevated nitrate concentrations (i.e., >10 mg/L) extend laterally at least 5,000 ft eastward (parallel with geologic strike) and vertically (parallel with geologic dip) at least 150 ft bgs (DOE 1998).

The low nitrate concentrations in the groundwater samples from the well may be attributable to localized hydrologic and/or geochemical attenuation processes. For instance, a section of storm drain that traverses north-south across the RG about 100 ft west of the well may intercept nitrate-contaminated groundwater moving eastward via the shallow flowpaths in the water table interval. Also, groundwater elsewhere at the RG contains a residual plume of dissolved petroleum hydrocarbons that originated from former petroleum fuel underground storage tanks at the site, and the lack of both nitrate and dissolved hydrocarbons in the groundwater at well GW-505 potentially results from their co-metabolic biodegradation in the subsurface.

5.2 URANIUM

As shown on Table 1, each groundwater sample had a total uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.028 mg/L in March 1994) being slightly below the MCL (0.03 mg/L). Although below the MCL, the uranium concentrations are almost an order-of-magnitude above the applicable UTL (0.005 mg/L). The contaminant plume emplaced in the Nolichucky Shale during historical operation of the former S-3 Ponds is the most likely source of the uranium. Considering the acidic pH of the samples from the well (see Section 4.0), uranium probably occurs in the groundwater as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble complexes with a variety of inorganic anions (Fetter 1993).

It seems somewhat unusual that uranium concentrations in the shallow groundwater at this well are higher than evident in well GW-105, which is located about 200 ft directly west (hydraulically upgradient and closer to the former S-3 Ponds) of the well is completed at similar depth in the Nolichucky Shale. Also, as noted in Section 5.1, the available monitoring data show that nitrate concentrations in the shallow groundwater at this well are at least an order-of-magnitude lower than nitrate levels evident in the groundwater at well GW-105. Assuming both wells yield groundwater containing a heterogeneous mixture of uranium and nitrate from a common source (the former S-3 Ponds), the inverse relationships between the uranium and nitrate concentrations in these wells suggest that localized geochemical conditions have lowered the nitrate levels in the groundwater at well GW-505 because localized hydrologic conditions would be expected to influence both nitrate and uranium concentrations in the groundwater.

5.3 VOLATILE ORGANIC COMPOUNDS

Low levels of PCE, TCE, 11DCE, and 12DCE were detected in six of the ten groundwater samples collected between March 1991 and June 1993; all of these results are estimated values below 5 μg/L. Each of these VOCs are components of the contaminant plume originating from the former S-3 Ponds. Acetone, chloroform, and methylene chloride have been detected in several samples but all of these results are false positives. The most recent sampling results (May and October 2003) do not indicate the presence of dissolved VOCs in the groundwater at this well.

5.4 GROSS ALPHA ACTIVITY

Each groundwater sample had gross alpha activity above the applicable MDA and corresponding CE, with values above the MCL for gross alpha activity (15 pCi/L) reported for all but six of the samples (Table 1). The most recent sampling results suggest that uranium isotopes (U-234 and U-238) in the groundwater are the likely source of the alpha activity. Also, a time-series plot of the results for gross alpha activity, which spans a nine-year gap in the sampling history for the well (March 1994 – May 2003), suggests a slightly upward long-term trend (Figure 1). However, this upward trend is of questionable significance and may be an artifact of the change from conventional sampling method to the low-flow sampling method.

5.5 GROSS BETA ACTIVITY

Thirteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE (Table 1), with the highest value (23 pCi/L in October 2003) being less than the SDWA screening level (50 pCi/L) for a 4 millirem dose equivalent (the MCL for gross beta activity). Radiochemical analyses of the samples collected in May and October 2003 show that uranium isotopes (and related daughters) are the source of the gross beta activity in the groundwater; Tc-99, a beta-emitting radionuclide and a principal component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, was not detected (i.e., <MDA) in the samples collected in May and October 2003.

WELL GW-513

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in March 1988, completed with a screened monitored interval from 111 to 125 ft bgs, and constructed nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located on the southern flank of Chestnut Ridge approximately one-half mile south of Y-12, about 300 ft north of the northern (upstream) side of the Filled Coal Ash Pond (FCAP). The FCAP occupies the former basin behind an earthen dam, constructed in 1955 across a northern tributary of McCoy Branch, which had filled with fly-ash slurry pumped from the Y-12 Steam Plant. The final approved ROD for FCAP (DOE 1996) required dam stabilization and wetlands construction as CERCLA corrective actions at the site, which were completed in 1997 (DOE 1997).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 28 samples between December 1988 and April 1996, and the low-flow sampling method used to obtain samples in April and October 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the lower Knox Group, which underlies the steep northern flank of Chestnut Ridge. The Knox Group formations, along with the uppermost formation (Maynardville Limestone) of the underlying Conasauga Group, comprise an aquifer consisting of three vertically gradational subsystems distinguished by groundwater flux, which decreases with depth: (1) the stormflow zone, (2) the vadose zone, and (3) the groundwater zone (Solomon et al. 1992). The stormflow and vadose zones occur at shallow depths within the thick (>100 ft) residuum that has developed on Chestnut Ridge. In the bedrock zone, orthogonal sets of permeable, planar fractures form water-producing zones within an essentially impermeable matrix, and dissolution of carbonates has enlarged fractures and produced an interconnected conduit-flow system characteristic of karst aquifers. Because the occurrence of solution features and the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity of the groundwater zone is vertically gradational. Most groundwater flux occurs within the transitional horizon between residuum and unweathered bedrock (water table interval); lower flux (and longer solute residence times) occurs at successively greater depths in the bedrock (Solomon et al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 20 ft bgs and exhibits substantial (>25 ft) seasonal fluctuations (Figure 1). Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-513 indicate flow directly south toward the FCAP.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date indicate that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 130 – 210 mg/L;
- pH of 7.2 – 7.96 (field measurements);
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite);

- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total (unfiltered sample)concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the respective monitoring data reported for the groundwater samples collected from the well since January 1991, none of the principal contaminants are present at elevated concentrations in the groundwater at this well.

5.1 NITRATE

Four groundwater samples collected to date had nitrate concentrations at or above the applicable analytical reporting limit and these results are all less than 1 mg/L and are substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Two groundwater samples collected to date had uranium concentrations above the applicable analytical reporting limit, and both results (0.001 mg/L in November 1992 and April 1994) are an order-of-magnitude below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were not detected in any of the groundwater samples collected to date.

5.4 GROSS ALPHA ACTIVITY

One of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, and this value (3.5 pCi/L in October 1994) is substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Three of the groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, and the highest result (4.89 pCi/L in December 1993) is substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-521

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in September 1988, completed with a screened monitored interval from 123.2 to 136 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located on the crest of Chestnut Ridge southwest of the west end of Y-12, less than 100 ft directly west (hydraulically upgradient) of the Industrial Landfill IV. In operation since 1989, this landfill receives about 12,000 ft^2 per year of nonhazardous and nonradioactive industrial wastes, including cardboard, plastics, rubber, scrap metal, wood, paper, and special wastes generated from DOE operations on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-six groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 31 samples between September 1989 and July 1997, and the low-flow sampling method used to obtain 15 samples between January 1998 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the bedrock interval in the Knox Group (Copper Ridge Dolomite). Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 80 ft bgs and exhibit substantial (>10 ft) water-level fluctuations, which is typical of many Knox Group wells on Chestnut Ridge. The average result of several falling head permeability tests performed in well GW-521 (Jones 2004) indicates that the hydraulic conductivity of the bedrock near the well is about 4.5×10^{-4} cm/s (1.28 ft/day).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 102 – 230 mg/L;
- pH (field measurements) of 6.0 – 8.6;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for 39 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Twenty-five groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.68 mg/L in July 2000) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Two groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.001 mg/L in July 1994) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, acetone is the only VOC that has been detected in samples from the well. These results (18 μg/L in July 1991, 3 μg/L in January 2000, and 3.3 μg/L in January 2003) are considered sampling or analytical artifacts because acetone in commonly detected in blank samples.

5.4 GROSS ALPHA ACTIVITY

Four groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (2.37 pCi/L in October 1994) being below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Five groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (3.86 pCi/L August 1992) being substantially below the SDWA for gross beta activity (50 pCi/L).

WELL GW-522

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in September 1988, completed with a screened monitored interval from 183 to 195.3 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located on the crest of Chestnut Ridge southwest of the west end of Y-12, less than 100 ft directly south (hydraulically downgradient) of the Industrial Landfill IV. In operation since 1989, this landfill receives about 12,000 ft^2 per year of nonhazardous and nonradioactive industrial wastes, including cardboard, plastics, rubber, scrap metal, wood, paper, and special wastes generated from DOE operations on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-five groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 30 samples between August 1989 and July 1997, and the low-flow sampling method used to obtain 15 samples between January 1998 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the bedrock interval in the Knox Group. The average static groundwater level in the well is 95 ft bgs. Presampling depth-to-water measurements for the well indicate wide (>25 ft) water-level fluctuations, with generally decreasing groundwater elevations evident between January 1994 and January 2001, followed by generally increasing groundwater elevations through July 2003 (Figure 1). The average result of several falling head permeability tests performed in well GW-522 (Jones 2004) indicates that the hydraulic conductivity of the bedrock near the well is about 1.9×10^{-4} cm/s (0.54 ft/day).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 88 – 266 mg/L;
- pH (field measurements) of 5.9 – 8.5;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for 37 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Thirty-six groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.83 mg/L in July 2001) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

The total uranium concentration reported for the groundwater sample collected from the well in July 1994 (0.003 mg/L) exceeds the analytical reporting limit but is substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected at low levels in three groundwater samples. Trace levels of PCE (0.43 μg/L) and 1,1,2,2-tetrachloroethane (0.57 μg/L) were detected in the sample collected in July 2002, and acetone (a common laboratory reagent) was detected in two samples (15 μg/L in July 1991 and 13 μg/L in February 2000). These results may be sampling or analytical artifacts and are considered to be outliers.

5.4 GROSS ALPHA ACTIVITY

Eight groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (35.6 pCi/L in April 1992) exceeding the MCL for gross alpha activity (15 pCi/L). However, this gross alpha result is considered an outlier (none of the other results exceed 5 pCi/L) and is probably an analytical artifact.

5.5 GROSS BETA ACTIVITY

Six groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (9.39 pCi/L in January 1993) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-526

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during June 1988, completed with an open-hole monitored interval from 101 to 123 ft bgs, and constructed with nominal 6.5-inch diameter steel (SF25) riser casing. The well is clustered with wells GW-345 and GW-346 and is located in Bear Creek Valley (BCV) west of Y-12, about 1,300 ft west-southwest of the former S-3 Ponds. The well is adjacent to a northern tributary (NT) of Bear Creek (NT-1), several of which traverse northeast-southwest across the southern flank of Pine Ridge west of Y-12 and are numbered in ascending order downstream from the headwaters of the creek.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-seven groundwater samples have been collected from the well, with the conventional sampling method used to obtain 24 samples between September 1988 and September 1997 and the low-flow sampling method used to obtain 13 samples between February 1998 and August 2004.

Unusually high levels of TDS are a distinguishing characteristic of the groundwater samples from this well and are a direct consequence of contamination from the former S-3 Ponds (see Section 5.0).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the intermediate bedrock interval in the Nolichucky Shale (Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within a highly permeable zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek that traverse the Nolichucky Shale and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that stratigraphically overlies the Nolichucky Shale and subcrops along the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 10 ft bgs and exhibits seasonal fluctuations up to 5 ft. Also, measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in well GW-526 are typically several feet higher than evident in wells GW-345 and GW-346, which are completed at shallower depths (26 ft and 65 ft bgs, respectively) in the Nolichucky Shale. Based on the distance between the monitored interval midpoint (elevation) in each well, the contemporaneous groundwater elevations indicate upward vertical hydraulic gradients (0.06 – 0.13) from the deeper bedrock (GW-526) to the shallow bedrock interval (GW-346) and downward vertical gradients (0.03 – 0.1) from the water table interval (GW-345) to the shallow bedrock interval during seasonally high and low flow conditions.

Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-526 indicate southwesterly flow toward the Maynardville Limestone and the main channel of Bear Creek. However, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields nitrate-contaminated sodium-bicarbonate groundwater generally characterized by:

- TDS of 1,100 – 13,100 mg/L;
- pH of 6.9 – 10 (field measurements);
- very high concentrations of barium (>10 mg/L), strontium (>20 mg/L), nitrate (>1,000 mg/L), and sodium (>1,000 mg/L), the latter of which dominate the ion chemistry of the samples and are the likely sources of the unacceptably high relative percent difference (RPD) between respective summed millequivalent concentrations of anions and cations (i.e., the ion-charge balance error exceeds 20%) determined for samples collected in January 1991 (RPD = -25.8%), April 1991 (RPD = 50.1%), and October 1993 (RPD = -85.3%);
- comparatively low concentrations and molar proportions of calcium, magnesium, chloride, potassium, and sulfate; and
- total concentrations of trace metals (except barium and strontium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Aside from the very high levels of nitrate, these geochemical characteristics reflect the decrease in groundwater flux that occurs with depth in the low-permeability formations of the Conasauga Group (e.g., Nolichucky Shale) in BCV (Solomon et al. 1992). Most of the water table and shallow bedrock wells (i.e., <100 ft bgs) completed in these formations yield calcium-magnesium-bicarbonate groundwater, but a fairly abrupt change to sodium-bicarbonate groundwater occurs at a depth of about 100 ft bgs (in BCV west of Y-12). The sodium-enriched geochemistry of the groundwater is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture and increased fracture spacing (Solomon et al. 1992). Further reduced groundwater flux deeper in the bedrock is indicated by a general increase in TDS and a gradational transition from sodium-bicarbonate groundwater to sodium-chloride groundwater.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the monitoring data reported for 29 groundwater samples collected since January 1990, nitrate and gross beta activity are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Nitrate concentrations above the analytical reporting limit were reported for each groundwater sample, with concentrations above 500 mg/L for all but one of the samples, including 19 samples with concentrations above 1,000 mg/L (Table 1). The source of the nitrate is the contaminant plume emplaced during historical operations of the former S-3 Ponds, which are located near the headwaters of Bear Creek at the west end of Y-12, and are four unlined surface impoundments that were filled and covered with a multilayer low-permeability cap (and an asphalt-paved parking lot) during RCRA closure of the site in 1988. The former S-3 Ponds were used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12, which emplaced an extensive plume of groundwater contamination containing a heterogeneous mixture of inorganic, organic, and radiological contaminants. Some of the inorganic contaminants (e.g., nitrate and uranium) were entrained in the nitric acidic wastes and others (e.g., barium and strontium) were dissolved from bedrock minerals. Nitrate is the primary inorganic contaminant in the plume and, based on the existing network of monitoring wells in the Nolichucky Shale west of the former S-3 Ponds, the extent of elevated nitrate concentrations (i.e., >10 mg/L) in the groundwater suggest: (1) relatively rapid, westward transport/migration via shallow (<30 ft bgs) strike-parallel flowpaths (i.e., bedding-plane fractures) that terminate in the northern tributaries of Bear Creek located about 1,500 ft (NT-1) and 2,500 ft (NT-2) west of the former S-3 Ponds; and (2) substantially slower migration deeper in the bedrock via much longer strike-parallel flowpaths, with upward hydraulic gradients promoting upwelling of nitrate-contaminated groundwater into the shallow flow system near NT-1 and NT-2 (DOE 1997).

Very high nitrate concentrations (and TDS) are characteristic of the groundwater samples from this well, more than half of which had concentrations above 1,000 mg/L, but the historical maximum nitrate value (2,550 mg/L in September 1997) appears to be an outlier (all of the other results are less than 1,500 mg/L) and may be a sampling or analytical artifact. The same can be said of the historical minimum nitrate value (258 mg/L in April 1991), which is less than half the next lowest concentration (657 mg/L in October 1991) and is considered qualitative because of the ion-charge balance error (see Section 4.0). Additionally, the nitrate concentrations do not exhibit a wide range of temporal fluctuations or show a consistent relationship with groundwater flow conditions. These results are representative of concentrations in the deeper bedrock groundwater flow/transport pathways in the Nolichucky Shale near NT-1 and reflect the upwelling of nitrate-contaminated groundwater from deeper in the bedrock (DOE 1997).

A time-series plot of the nitrate concentrations detected in the groundwater samples (Figure 1), excluding the suspected outlier (September 1997) and qualitative results (January 1991, April 1991, and October 1993), shows a generally increasing trend that spans a 4-year gap in the sampling history for the well (September 1993 – September 1997). However, the rate of concentration increase appears to have slowed. For example, nitrate concentrations increased by approximately 53% between January 1990 (732 mg/L) and November 1992 (1,120 mg/L), but only about 14% between September 1997 (1,190 mg/L) and August 2003 (1,360 mg/L). Also, nitrate results obtained after August 2003 suggest a decreasing concentration trend, with the result reported for the sample collected in August 2004 (1,150 mg/L) being the lowest concentration evident since March 1999 (1,190 mg/L). Increasing concentrations of nitrate in the groundwater at this well are interpreted to reflect the westward (strike-parallel) migration of the center of mass of the contaminant plume at depth in the Nolichucky Shale west of the former S-3 Ponds (DOE 1997).

5.2 URANIUM

Eleven groundwater samples had total uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.00201 mg/L in February 2001) being an order-of-magnitude below the MCL for uranium (0.03 mg/L). Uranium is one of the primary components of the contaminant plume emplaced in the Nolichucky Shale during historical operations of the former S-3 Ponds. The low concentrations of uranium in the groundwater at this well, in contrast to the very high nitrate levels, illustrate the significantly greater attenuation of uranium relative to nitrate.

5.3 VOLATILE ORGANIC COMPOUNDS

Several VOCs were detected in a total of four groundwater samples, and all of these results are false positives except for one-time detections of TCE (6 µg/L) and 12DCE (1 µg/L) in the August 1991 sample, and chloroform (2 µg/L) in the October 1993 sample.

5.4 GROSS ALPHA ACTIVITY

Thirteen groundwater samples had gross alpha activity above the applicable MDA and corresponding CE (Table 1), with results for nine samples exceeding the MCL for gross alpha activity (15 pCi/L). However, the gross alpha activity does not consistently exceed the MDA or CE, and results that do range from less than 3 pCi/L to almost 300 pCi/L. The inconsistent detection and widely variable results for gross alpha activity may be related to analytical interference associated with the very high TDS of the (unfiltered) groundwater samples (see Section 4.0). Also, 19 of the samples (including all eight samples collected between February 2000 and August 2004) were analyzed for U-234 and U-238, which are alpha-emitting radionuclides most likely to be present in the groundwater. Eleven of the samples had U-234 and/or U-238 activities above the MDA and corresponding CE, and all of these results are less than 2 pCi/L. The general lack of uranium isotopes in the samples also suggests that the gross alpha results may be inaccurate because of analytical interferences related to the TDS in the samples.

5.5 GROSS BETA ACTIVITY

Eleven groundwater samples had gross beta activity above the applicable MDA and corresponding CE (Table 1), with results for eight of the samples exceeding the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the MCL for gross beta activity). However, as with gross alpha activity, the results for gross beta activity do not consistently exceed the MDA or CE and exhibit widely variable values ranging from less than 5 pCi/L to more than 500 pCi/L. The source of the gross beta activity in the groundwater at this well has not been confirmed. Although the contaminant plume from the former S-3 Ponds contains Tc-99, this beta-emitting radionuclide may not be the source of the gross beta activity in the groundwater at this well; five samples were analyzed for Tc-99, which was detected (i.e., >MDA and CE) in only two samples (4,320 pCi/L in May 1992 and 3,040 pCi/L in August 1992). The inconsistent detection and widely variable results for gross beta activity may be related to analytical interference associated with the very high TDS of the (unfiltered) groundwater samples (see Section 4.0).

WELL GW-537

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during September 1988, completed with a screened monitored interval from 4.8 to 23.3 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley (BCV) west of Y-12, near a northern tributary (NT) of Bear Creek (NT-2) about 2,500 ft west of the former S-3 Ponds.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-six groundwater samples have been collected from the well, with the conventional sampling method used to obtain 30 samples between December 1989 and September 1997 and the low-flow sampling method used to obtain 16 samples between February 1998 and August 2004.

Unusually high levels of TDS are a distinguishing characteristic of the groundwater samples from this well and are a direct consequence of contamination from the former S-3 Ponds (see Section 5.0.).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Nolichucky Shale (Conasauga Group). The water table interval is a highly permeable zone that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock and transmits the bulk of the groundwater in the Nolichucky Shale. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek, which traverse the Nolichucky Shale from northeast to southwest throughout BCV west of Y-12 and are numbered in ascending order downstream from the headwaters of the creek. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that stratigraphically overlies the Nolichucky Shale and subcrops beneath the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 5 ft bgs and exhibits seasonal fluctuations up to about 4 ft. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-537 indicate southwesterly flow toward the Maynardville Limestone and the main channel of Bear Creek. However, as noted previously, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred strike-parallel flow directions that may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields highly mineralized, sodium- and chloride-enriched, nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 3,600 – 7,468 mg/L;
- pH of 6.4 – 7.2 (field measurements);
- total (unfiltered sample) concentrations of barium (>2 mg/L), chloride (>30 mg/L), sodium (>40 mg/L), and strontium (>2 mg/L) that are substantially higher than typically evident in samples from other wells completed at similarly shallow depths in the Nolichucky Shale;

- very high nitrate concentrations (>500 mg/L) that dominate the ion chemistry of the samples and are probably the source of, or are in some way related to, the unacceptably high relative percent difference (RPD) between respective summed millequivalent concentrations of anions and cations (i.e., the ion charge-balance error exceeds 20%) determined for the samples collected in August 1992 (RPD = -26.1%) and September 1994 (RPD = 68.2%);
- low concentrations and molar proportions of potassium and sulfate; and
- total concentrations of trace metals (except barium and strontium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The sodium- and chloride-enriched geochemistry of the groundwater at this well is believed to reflect the upwelling of (contaminated) sodium-bicarbonate groundwater from deeper in the bedrock (DOE 1997). In the low-permeability formations of the Conasauga Group (e.g., Nolichucky Shale) in BCV west of Y-12, a transition from calcium-magnesium-bicarbonate groundwater to sodium-bicarbonate groundwater typically occurs at a depth of about 100 ft bgs. This change in groundwater geochemistry is interpreted to be a function of lower flux and longer residence time as a result of reduced fracture aperture and increased fracture spacing (Solomon et al. 1992). Further reduced groundwater flux deeper in the bedrock is indicated by a general increase in TDS and a gradational transition from sodium-bicarbonate groundwater to sodium-chloride groundwater.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the monitoring data reported for 41 groundwater samples collected since January 1990, nitrate and gross beta activity are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Nitrate concentrations above the analytical reporting limit were reported for each groundwater sample, all but one of which had concentrations above 500 mg/L (Table 1). The source of the nitrate is the contaminant plume emplaced during historical operations of the former S-3 Ponds, which are located near the headwaters of Bear Creek at the west end of Y-12, and are four unlined surface impoundments that were filled and covered with a multilayer low-permeability cap (and an asphalt-paved parking lot) during RCRA closure of the site in 1988. The former S-3 Ponds were used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12, which emplaced an extensive plume of groundwater contamination containing a heterogeneous mixture of inorganic, organic, and radiological contaminants. Some of the inorganic contaminants (e.g., nitrate and uranium) were entrained in the nitric acidic wastes and others (e.g., barium and strontium) were dissolved from bedrock minerals. Nitrate is the primary inorganic contaminant in the plume and, based on the existing network of monitoring wells in the Nolichucky Shale west of the former S-3 Ponds, the extent of elevated nitrate concentrations (i.e., >10 mg/L) in the groundwater suggest: (1) relatively rapid, westward transport/migration via shallow (<30 ft bgs) strike-parallel flowpaths (i.e., bedding-plane fractures) that terminate in the northern tributaries of Bear Creek located about 1,500 ft (NT-1) and 2,500 ft (NT-2) west of the former S-3 Ponds; and (2) substantially slower migration deeper in the bedrock via much longer strike-parallel flowpaths, with upward hydraulic gradients promoting upwelling of nitrate-contaminated groundwater into the shallow flow system near NT-1 and NT-2 (DOE 1997).

Very high nitrate concentrations (and TDS) are characteristic of the groundwater samples from this well: all of the samples have nitrate above 500 mg/L. Also, the nitrate concentrations do not exhibit a wide range of temporal fluctuations or show a consistent relationship with groundwater flow conditions. Note that both the historical maximum nitrate value (1,285 mg/L in August 1992) and the historical minimum nitrate value (81 mg/L in September 1994) are considered qualitative because of the respective ion charge-balance errors determined for these samples (see Section 4.0). The next highest and lowest nitrate concentrations are 1,127 mg/L in February 1994 and 525 mg/L in September 1993. These results are representative of nitrate concentrations in the shallow flow system near NT-1, which are maintained by the upwelling of nitrate-contaminated groundwater from deeper in the bedrock (DOE 1997).

A time-series plot of the nitrate concentrations detected in the groundwater samples (Figure 1), excluding the qualitative results (August 1992 and September 1994), shows a generally indeterminate long-term concentration trend punctuated by temporal concentration "peaks" in February 1994 (1,127 mg/L), June 1995 (980 mg/L), and August 1999 (897 mg/L). The long-term trend suggests generally stable flux of nitrate via the groundwater flowpaths intercepted by the monitoring interval in the well. Additionally, temporal changes in nitrate concentrations do not appear to be strongly influenced by seasonal groundwater flow conditions, as illustrated by the peak concentrations evident for samples collected during seasonally high (winter and spring) and low (summer and fall) flow, and may be of limited significance with regard to the overall flux of nitrate.

5.2 URANIUM

Forty groundwater samples had total uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.00902 mg/L in February 2001) being almost an order-of-magnitude below the drinking water MCL for uranium (0.03 mg/L). Uranium is one of the primary components of the contaminant plume emplaced in the Nolichucky Shale during historical operations of the former S-3 Ponds. The low concentrations of uranium in the groundwater at this well, in contrast to the very high nitrate levels, illustrate the significantly greater attenuation of uranium relative to nitrate.

5.3 VOLATILE ORGANIC COMPOUNDS

Several VOCs were detected in a total of 24 groundwater samples, with all false positive results for each compound except chloroform. As shown in Table 1, very low (estimated) concentrations of chloroform (2 μg/L or less) were detected in 21 samples (excluding false positive results), most recently in the sample collected in August 2004 (2 μg/L). A minor component of the contaminant plume originating from the former S-3 Ponds, chloroform is chemically stable, does not readily partition to soils, and is persistent and mobile in groundwater. Thus, the repeated detection of chloroform in the groundwater samples suggests chloroform is probably present in the groundwater upwelling from the deeper bedrock into the shallow flow system near NT-1 (EPA 2001).

5.4 GROSS ALPHA ACTIVITY

Thirteen groundwater samples had gross alpha activity above the applicable MDA and corresponding CE (Table 1). Results for eight samples exceed the MCL for gross alpha activity (15 pCi/L), with a substantial difference between the historical maximum value (91.5 pCi/L in October 1992) and historical minimum value (4.3 pCi/L in March 1999). Also, only two of the 17 samples collected since March 1996 had gross alpha activity above the MDA and CE. The infrequent detection of gross alpha activity and wide range of results above the MDA may be related to analytical interferences related to the high TDS of the samples. Moreover, relatively low (background) levels of gross alpha activity is supported by results for 11 samples analyzed for U-234 and U-238, which are alpha-emitting radionuclides most likely to be present in the groundwater. Nine of the samples had U-234 and/or U-238 activities above the MDA and corresponding CE, and all but one of these results are less than 3 pCi/L, with the U-234 activity reported for the sample collected in June 1995 (371 pCi/L) being an outlier and potential analytical artifact. The general lack of uranium isotopes in the samples also suggests that the gross alpha results may be inaccurate because of analytical interferences related to the TDS in the samples.

5.5 GROSS BETA ACTIVITY

All but one of the groundwater samples had gross beta activity above the applicable MDA and corresponding CE (Table 1), with results for all but one of these samples exceeding the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the MCL for gross beta activity). Most of the samples had gross beta activity above 100 pCi/L, with the two lowest values (56.9 pCi/L in February 1992) and (29.3 pCi/L in August 1992) being suspected outliers. The source of the gross beta activity in the groundwater at this well is Tc-99, which is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds (the only site at Y-12 to receive wastes containing Tc-99). As shown in Table 1, Tc-99 was detected (i.e., >MDA and CE) in 14 of the 16 samples analyzed for this beta-emitting radionuclide, with the highest value reported for the samples collected in February 1994 (1,460 pCi/L) and the most recent results showing concentrations remain near 1,000 pCi/L August 2001 (940 pCi/L). Note that all the Tc-99 results are substantially below the SDWA screening level (3,790 pCi/L) for a 4 mrem/yr dose equivalent from Tc-99. Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-) which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in Nolichucky Shale west of the former S-3 Ponds, the extent of elevated (>50 pCi/L) gross beta activity in the groundwater suggests that the distribution of Tc-99 closely mirrors that of nitrate, with primarily westward strike-parallel transport in the water table and bedrock intervals toward discharge areas in NT-1 and NT-2 (DOE 1997).

Aside from the suspected outlier results noted above, each groundwater sample had gross beta activity above 100 pCi/L, with a historical maximum value of 760 pCi/L in April 1997 and a historical minimum value of 112 pCi/L in October 1992. As with nitrate concentrations in the samples, gross beta activity also does not exhibit a consistent relationship with groundwater flow conditions, with temporal "peak" concentrations reported for samples obtained during both seasonally high and low flow conditions, and reflects the transport of Tc-99 in groundwater upwelling from deeper bedrock flowpaths in the Nolichucky Shale near NT-2 (DOE 1997). It is also possible that the results for gross beta activity, as with gross alpha activity, reflect analytical interferences related to the high TDS of the samples.

A time-series plot of the gross beta activity reported for the groundwater samples shows a generally increasing long term trend, with the most recent sampling results, including the historical maximum value, being at least 100% higher than reported for samples obtained in the early 1990s (Figure 1). The increasing long-term trend for gross beta activity potentially corresponds with an overall increase in the relative flux of Tc-99 upwelling from the deeper bedrock flowpaths near NT-2. Also, the gross beta results show significant temporal variability, with a sequence of peak values evident in September 1990 (681 pCi/L), February 1994 (713 pCi/L), June 1995 (619 pCi/L), and April 1997 (760 pCi/L). However, the range of temporal variability in gross beta activity seems to have decreased following the change from conventional sampling to low-flow sampling, which suggests that the sampling method may be at least partially responsible for the apparent temporal changes in gross beta activity.

WELL GW-540

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in June 1989, completed with a screened monitored interval from 158.5 to 171.5 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located on the southern flank of Chestnut Ridge directly south of Y-12, about 250 ft east (hydraulically downgradient) of Construction/Demolition Landfill VI. This closed landfill operated from 1994 to 2003 and received nonhazardous and nonradioactive solid wastes, including construction spoil (concrete, wood, metal, plastic, and roofing material) and soil wastes, generated from DOE operations on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-four groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 18 samples between March 1991 and April 1996, and the low-flow sampling method used to obtain 16 samples between March 1998 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the bedrock interval in the Knox Group (Chepultepec Dolomite). The average static groundwater level in the well is 76 ft bgs. Presampling depth-to-water measurements for the well indicate unusually wide (>40 ft) water-level fluctuations, especially the fluctuations evident before March 1999 (Figure 1). The result of a falling head permeability test performed in well GW-540 (Jones 2004) indicates that the hydraulic conductivity of the bedrock near the well is about 8.3×10^{-5} cm/s (0.24 ft/day).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 136 – 270 mg/L;
- pH (field measurements) of 7.2 – 8.4;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Sixteen groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.6 mg/L in February 2000) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Three groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.001 mg/L in September 1991 and March 1993) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected in five groundwater samples: methylene chloride was detected in August 1993 (1 μg/L); 2-butanone was detected in April 1996 (7 μg/L) and March 1998 (2 μg/L); and acetone was detected in October 1998 (1μg/L) and February 2000 (48 μg/L). These results are probably analytical artifacts and are considered to be outliers.

5.4 GROSS ALPHA ACTIVITY

Four groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (3.8 pCi/L in April 1999) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Six groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (4.4 pCi/L in January 2004) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-542

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in May 1989, completed with a screened monitored interval from 59 to 76.5 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located on the southern flank of Chestnut Ridge directly south of Y-12, less than 100 ft west (hydraulically downgradient) of Construction/Demolition Landfill VI. This closed landfill operated from 1994 to 2003 and received nonhazardous and nonradioactive solid wastes, including construction spoil (concrete, wood, metal, plastic, and roofing material) and soil wastes, generated from DOE operations on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-five groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 21 samples between March 1991 and April 1997, and the low-flow sampling method used to obtain 14 samples between April 1998 and July 2004.

This well yields groundwater samples with low TDS (see Section 4.0), which suggests short groundwater residence time and indicates that the monitored interval in the well intercepts hydraulically active flowpaths.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from bedrock in the Knox Group. Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 67 ft bgs and exhibits moderate fluctuations (<7 ft). The result of a falling head permeability test performed in well GW-542 (Jones 2004) indicates that the hydraulic conductivity of the bedrock near the well is about 5.7×10^{-4} cm/s (1.62 ft/day).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 78 – 166 mg/L, excluding suspecte outliers in April (208 mg/L) and October (36 mg/L) 1995;
- pH (field measurements) of 6.1 – 8.0;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Thirty-two groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.73 mg/L in July 2000) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Four groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.001 mg/L) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected at very low levels in five groundwater samples: methylene chloride was detected in June 1992 (1 µg/L) and April 1993 (1 µg/L); acetone was detected in April 1998 (1 µg/L) and January 2004 (3.4 µg/L); and carbon disulfide was detected in October 1998 (1 µg/L). These results are probably analytical artifacts and are considered to be outliers.

5.4 GROSS ALPHA ACTIVITY

Five groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (4.4 in October 1999 pCi/L) being below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Fourteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (19 pCi/L in July 2004) being substantially below the SDWA screening level for gross beta activity (50 pCi/L). Note that the maximum result is considered to be an outlier that is inconsistent with historical measurements; all other gross beta results are less than 7 pCi/L.

WELL GW-543

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in June 1989, completed with a screened monitored interval from 76.2 to 93.6 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located on the southern flank of Chestnut Ridge directly south of Y-12 (unless noted otherwise, directions are in reference to the Y-12 grid system), about 250 ft southwest (hydraulically downgradient) of Construction/Demolition Landfill VI. This closed landfill operated from 1994 to 2003 and received nonhazardous and nonradioactive solid wastes, including construction spoil (concrete, wood, metal, plastic, and roofing material) and soil wastes, generated from DOE operations on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-six groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 21 samples between March 1991 and April 1997, and the low-flow sampling method used to obtain 15 samples between October 1997 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from bedrock in the Knox Group (Chepultepec Dolomite). Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 61 ft bgs and exhibit moderate fluctuations (<6 ft). The result of a falling head permeability test performed in well GW-543 (Jones 2004) indicates that the hydraulic conductivity of the bedrock near the well is about 1.7×10^{-4} cm/s (0.48 ft/day).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 162 – 290 mg/L;
- pH (field measurements) of 6.4 – 7.6;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Twenty-four groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.75 in July 2000 mg/L) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Four groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.002 mg/L in April 1994) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected at very low levels in five groundwater samples: 111TCA in October 1998 (1 μg/L); acetone in July 2001 (2 μg/L); bromoform in January 2002 (0.48 μg/L) and July 2003 (4 μg/L); dibromochloromethane in July 2003 (1.5 μg/L); and toluene in October 1998 (1 μg/L). These results are considered to be outliers.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

Six groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (4.54 pCi/L in September 1991) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-544

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in May 1989, completed with a screened monitored interval from 91 to 109.3 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located on the southern flank of Chestnut Ridge directly south of Y-12 (unless noted otherwise, directions are in reference to the Y-12 grid), about 250 ft directly south (hydraulically downgradient) of Construction/Demolition Landfill (CDL) VI. Operation of CDL VI began in December 1993 and disposal of waste at the site ended in July 2002. The operating permit issued by the TDEC for the landfill, which is covered with a low-permeability re-compacted clay cap, allowed the disposal of nonhazardous and nonradioactive construction spoil and demolition debris (e.g., soil, concrete, masonry, wood, steel rebar, plastics, and roofing materials) generated from DOE operations at Y-12 and elsewhere on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-six groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 21 samples between March 1991 and April 1997, and the low-flow sampling method used to obtain 15 samples between October 1997 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from bedrock in the Knox Group (Chepultepec Dolomite). The average static groundwater level in the well is 58 ft bgs. Presampling depth-to-water measurements for the well indicate wide fluctuations (>25 ft) in seasonal groundwater surface elevations (Figure 1).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 178 – 310 mg/L;
- pH of 7.0 – 8.0 (field measurements);
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, nitrate, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Thirty-five groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.92 mg/L in July 2000) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Eighteen groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.00233 mg/L in October 1999) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs have been detected in 12 groundwater samples from the well. Low concentrations of chloroform were detected in all 10 of the groundwater samples collected since February 2000, and acetone was detected (probable artifacts) in April 1997 (20 μg/L), April 1998 (3 μg/L), and July 2001 (2.2 μg/L). Chloroform and other trihalomethanes (bromodichloromethane, dibromochloromethane, and bromoform) are included in a class of drinking water disinfection byproducts (DBPs) that form through chemical interactions between chlorine and natural organic matter (U.S. Environmental Protection Agency [EPA] 2001). Because DBPs are carcinogenic and their natural formation in chlorinated drinking water is essentially unavoidable, the EPA established an MCL of 80 μg/L as the primary drinking water standard (effective January 2002) for total trihalomethanes. Monitoring results obtained to date show that the total trihalomethanes in the well remain below the MCL

The recent repeated detection of chloroform in the groundwater samples from the well coincides with a change in the laboratory responsible for performing the VOC analyses (Figure 1). The Y-12 Analytical Chemistry Organization (ACO) performed the VOC analyses of groundwater samples collected from the well between March 1991 and July 1999, whereas Severn Trent Laboratories (STL) performed VOC analyses of the samples collected from the well since February 2000. The instrument detection limit (IDL) for the analytical instrumentation used by STL enables the detection of estimated chloroform concentrations at lower reportable levels than the IDL for the analytical instrumentation used by the Y-12 ACO (about 2 μg/L). The first five chloroform results reported by STL (February 2000 through January 2002) were all less than 2 μg/L (Figure 1). This raises the possibility that groundwater samples collected from the well before February 2000 may have contained chloroform, but at very low concentrations that were below the IDL and therefore reported as non-detect values (e.g., <5 μg/L).

Assuming that CDL VI received only the nonhazardous construction spoil and demolition debris for which it was permitted, there is no reason to suspect that the landfill is the source of the trihalomethanes in the groundwater at well GW-544. A more likely source is from the local recharge of chlorinated water associated with Bldg. 9983-44, a portable manufactured building installed in 1984 or 1985 at a site located about 450 ft east (uphill) of the well. The building houses sanitary hand-washing and toilet facilities used by landfill workers on a daily basis throughout the operation of CDL VI and another closed landfill nearby (Y-12 Sanitary Landfill II). The restroom facilities are at the end of a potable (chlorinated) water-supply pipeline from Y-12, with the sink and toilet drains connected to a septic tank/drain field on the west-northwest side of the building. For much of the time the restroom facilities were in use, a bleeder line allowed continuous flow through the water-supply pipeline in order to avoid stagnation of the water in the pipeline and to prevent it from freezing during winter. Chlorinated water from the bleeder line discharged to the ground surface on the west side of Bldg. 9833-44. Additionally, in recent years the septic tank/drain field received continuous inflow of chlorinated water via a slow leak in the fill valve for a toilet in the restroom. Thus, infiltration associated with operation of the water-supply bleeder line and septic tank/drain field at Bldg. 9983-44 has been a long-term source for localized recharge of chlorinated water.

Chloroform is chemically stable, does not readily partition to soils, and is persistent and mobile in groundwater. Given these characteristics, chloroform entrained in the recharge from the

Bldg. 9983-44 area would be expected to move vertically though the vadose zone to the groundwater zone (water table). The groundwater zone in the Knox Group is characterized by preferential flow parallel with the geologic strike of the bedrock. Also, the orientation of the strike-parallel flowpaths (e.g., bedding-plane fractures) may or may not coincide with the flow direction(s) inferred from groundwater elevation isopleths, which generally mimic surface topographic contours. This flow pattern is reflected by the shape of the groundwater contaminant plume originating from the Chestnut Ridge Security Pits (CRSP), a closed hazardous waste landfill located on the crest of Chestnut Ridge northeast of CDLVI. The CRSP is the source of an elongated plume of dissolved VOCs extending at least 2600 ft downgradient to the east-northeast along the axis of the ridge crest (parallel with geologic strike), but only 500 ft north or south down the flanks of the ridge (across geologic strike), despite much steeper hydraulic gradients inferred from groundwater elevation isopleths. As noted previously, well GW-544 is directly downhill to the west of the Bldg. 9983-44, which is parallel with the geologic strike of the underlying bedrock (Chepultepec Dolomite), as indicated by the strike and dip measurement from an outcrop in Dunaway Branch west-northwest of the well (Hatcher et al. 1992). In addition to being hydraulically downgradient in the preferred direction of groundwater flow, well GW-544 is located between Bldg. 9983-44 and the natural groundwater discharge features (springs and seeps) in Dunaway Branch. Thus, any mobile contaminants entrained in the water recharged from the Bldg. 9983-44 bleeder line/septic drain field would be expected to migrate via advective transport in the direction of well GW-544 toward the discharge features west of the well.

In April 2004, the restroom facilities in Bldg. 9983-44 were permanently closed and the flow-control valve for the water supply pipeline to the building was turned off. Thus, the Bldg. 9983-44 septic tank/drain field no longer promotes local recharge of chlorinated water into the Knox Aquifer upgradient of well GW-544. With the presumed source of the chloroform no longer active, continued monitoring would be expected to eventually show reduced levels of chloroform in the groundwater at well GW-544. As shown by a time-series plot of the chloroform concentrations, a sharply increasing trend was reversed after the flow of chlorinated water ended (Figure 1).

5.4 GROSS ALPHA ACTIVITY

Ten groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (4 pCi/L in July 2004) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Eleven groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (9.73 pCi/L in August 1992) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-557

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in December 1988, completed with a screened monitored interval from 112.9 to 138.0 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located on the southern flank of Chestnut Ridge directly south of Y-12, less than 100 ft south (hydraulically downgradient) of Industrial Landfill V, a landfill operated since 1994 and used for disposal of nonhazardous and nonradioactive combustible and decomposable solid waste generated from DOE operations on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-nine groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 15 samples between May 1993 and July 1997, and the low-flow sampling method used to obtain 14 samples between January 1998 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Knox Group (Kingsport Formation/Longview Dolomite). The average static groundwater level in the well is 114 ft bgs. Presampling depth-to-water measurements for the well indicate substantial (>15 ft) water-level fluctuations, which is typical of many Knox Group wells on Chestnut Ridge. The average result of several falling head permeability tests performed in well GW-557 (Jones 2004) indicates that the hydraulic conductivity of the bedrock near the well is about 3.2×10^{-3} cm/s (9 ft/day).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 158 – 206 mg/L;
- pH (field measurements) of 7 – 8.2;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Twenty-seven groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (1.1 mg/L in July 2000) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Two groundwater samples had uranium concentrations above the applicable analytical reporting limit, and both of these results (0.001 mg/L) are substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected in four groundwater samples: acetone in July 1997 (82 µg/L), July 1998 (1 µg/L), and January 2000 (6 µg/L); 2-butanone in July 1998 (2 µg/L); and chloromethane in January 2002 (0.42 µg/L). These results may be sampling or analytical artifacts and are considered to be outliers.

5.4 GROSS ALPHA ACTIVITY

One groundwater sample had gross alpha activity above the applicable MDA and corresponding CE and this result (3.06 pCi/L in October 1994) is substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Six groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (6.66 pCi/L in October 1994) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-560

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in December 1988, completed with a screened monitored interval from 45.2 to 69 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located on the southern flank of Chestnut Ridge directly south of Y-12, about 100 ft south (hydraúlically downgradient) of Construction/Demolition Landfill (CDL) VII. This landfill began operating following the closure of CDL VI in 2003 and is used for disposal of nonhazardous, nonradioactive solid waste, including construction spoil (concrete, wood, metal, plastic, and roofing material) and soil wastes, generated from DOE operations on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-eight groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 15 samples between May 1993 and July 1997, and the low-flow sampling method used to obtain 13 samples between July 2000 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the bedrock interval in the Knox Group (Mascot Dolomite/Kingsport Formation). The average static groundwater level in the well is 30 ft bgs. Presampling depth-to-water measurements for the well indicate unusually wide (>40 ft) water-level fluctuations, with a generally decreasing trend in groundwater elevations between May 1993 and January 2002 followed by an overall rise in groundwater elevations though May 2003 (Figure 1). The average result of several falling head permeability tests performed in well GW-560 (Jones 2004) shows that the hydraulic conductivity of the bedrock near the well is about 4.88×10^{-3} cm/s (13.8 ft/day).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 138 – 190 mg/L;
- pH (field measurements) of 7.16 – 7.9 (excluding an outlier of 4.3 in July 1997);
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Nineteen groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.66 mg/L in July 2000) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

One groundwater sample had a uranium concentration above the applicable analytical reporting limit and this result (0.001 mg/L in April 1994) is substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, acetone was detected (24 μg/L) in one sample (April 1996) and this result is considered an outlier.

5.4 GROSS ALPHA ACTIVITY

Three groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (3.01 pCi/L in October 1994) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Five groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (6.44 pCi/L in October 1994) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-562

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in January 1989, completed with a screened monitored interval from 36 to 60 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located on the southern flank of Chestnut Ridge directly south of Y-12, about 300 ft east (hydraulically downgradient) of Construction/Demolition Landfill (CDL) VII. This landfill began operating following the closure of CDL VI in 2003 and is used for disposal of nonhazardous, nonradioactive solid waste, including construction spoil (concrete, wood, metal, plastic, and roofing material) and soil wastes, generated from DOE operations on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-four groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 16 samples between May 1993 and July 1997, and the low-flow sampling method used to obtain 18 samples between July 2000 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Knox Group (Longview Dolomite/Kingsport Formation). Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 4 ft bgs and exhibit substantial (10 - 25 ft) water-level fluctuations, which is typical of many Knox Group wells on Chestnut Ridge. The average result of several falling head permeability tests performed in well GW-562 (Jones 2004) indicates that the hydraulic conductivity of the bedrock near the well is about 1×10^{-4} cm/s (0.29 ft/day).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 168 – 238 mg/L;
- pH (field measurements) of 6.9 – 8.1 (excluding an outlier of 3.9 in July 1997);
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Twenty-four groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.7 mg/L in July 2000) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

One groundwater sample had a uranium concentration above the analytical reporting limit and this result (0.001 mg/L) is substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, acetone (13 µg/L) and MC (1.4 µg/L) were each detected in one sample (April 1996 and July 2000, respectively). These results are considered to be outliers.

5.4 GROSS ALPHA ACTIVITY

Seven groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (3.2 pCi/L in July 1994) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Five groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (10.6 pCi/L in July 2000) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-564

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in January 1989, completed with a screened monitored interval from 52 to 81 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located on the southern flank of Chestnut Ridge directly south of Y-12 (unless noted otherwise, directions are in reference to the Y-12 grid), about 300 ft southwest (hydraulically downgradient) of Construction/Demolition Landfill VII, which is an operating Class IV disposal facility for nonhazardous solid waste generated from DOE operations on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-eight groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 14 samples between May 1993 and July 1997, and the low-flow sampling method used to obtain 14 samples between July 2000 and July 2004.

The well yields groundwater samples with low TDS (see Section 4.0), which suggests short groundwater residence time and indicates that the monitored interval in the well intercepts hydraulically active flowpaths.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Knox Group. The average static groundwater level in the well is 7 ft bgs. Presampling depth-to-water measurements for the well indicate moderate (11 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 128 – 184 mg/L, excluding an outlier (81 mg/L) in January 2003;
- pH (field measurements) of 6.2 – 7.7;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, nitrate, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Twenty-six groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (1.6 mg/L in January 2002) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Only the groundwater sample collected in April 1994 had a uranium concentration above the applicable analytical reporting limit and the result for this sample (0.001 mg/L) is substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected in five groundwater samples collected from the well. Low (estimated) concentrations of chloroform were detected in the samples collected in October 2000 (0.39 µg/L), November 2000 (0.57 µg/L), December 2000 (0.81 µg/L), November 2001 (0.44 µg/L), and January 2002 (0.3 µg/L). The significance of these chloroform detections is not clear from the available data.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

Four groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (7.89 pCi/L in July 2001) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-601

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1989, completed with an open-hole monitored interval from approximately 318 to 356 ft bgs, and constructed with nominal 7-inch diameter steel (SF25) riser casing. The well forms a cluster with wells GW-368 and GW-369 and is located in Bear Creek Valley (BCV) approximately 5,000 ft west of Y-12. The well cluster is on the steep northern (scarp) flank of Chestnut Ridge, approximately 300 ft directly south of the main channel of Bear Creek and 500 ft south of the Oil Landfarm waste management area (WMA). The Oil Landfarm WMA encompasses the following closed hazardous and nonhazardous waste management facilities: the Oil Landfarm, Boneyard/Burnyard (BYBY), Hazardous Chemical Storage Area (HCDA), and Sanitary Landfill I.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 17 samples between March 1990 and March 1994, and the low-flow sampling method used to obtain three samples between March 1999 and September 2005. The sampling history includes a quarterly sampling frequency followed by a 5-year (March 1994–March 1999) and a 6-year period (March 1999–March 2005) when no samples were collected from the well.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the deep (>300 ft bgs) bedrock interval in the Maynardville Limestone (Conasauga Group), which trends northeast-southwest along the axis of BCV, dips southeast at an angle of 45º - 55º, and underlies the main channel of Bear Creek. The Maynardville Limestone exhibits the hydrologic characteristics typical of karst aquifers, with most of the groundwater flow occurring at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (shallow karst network). Hydrologic interaction between Bear Creek and the shallow karst network provides the principal exit-pathway for contaminants released from source areas within the Bear Creek watershed west of Y-12. Deeper in the subsurface, below the shallow karst network, fractures provide the primary groundwater flowpaths, and the bulk permeability generally decreases with depth because of decreased fracture aperture and increased fracture spacing (Solomon et. al. 1992). Also, distinct lithologic and hydrologic characteristics differentiate seven hydrostratigraphic zones (numbered from bottom to top) in the Maynardville Limestone (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

The static water level in the well occurs at an average depth of about 65 ft bgs and exhibits maximum seasonal water-level fluctuations up to approximately 12 ft. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-601 indicate westerly local flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone. Additionally, the well is located directly south of a reach of Bear Creek south of Sanitary Landfill I that loses substantial flow to the shallow karst network in the Maynardville Limestone and is believed to greatly facilitate the recharge of contaminated surface water into the groundwater flow system downgradient (south and west) of the Oil Landfarm WMA (DOE 1997).

Depth-to-water measurements recorded during one contemporaneous sampling event (i.e., within 24 hours) show a higher presampling groundwater elevation in well GW-601 (931.27 ft above msl) compared to well GW-368 (929.1 ft above msl), which is completed at a shallower depth (245 ft bgs) in the Maynardville Limestone. Based on the distance between the monitored interval midpoint in each well (about 102 ft), the respective groundwater elevations indicate a slightly upward vertical hydraulic gradient (0.021) from the deep bedrock (GW-601) to the intermediate depth bedrock interval (GW-368). Note that the contemporaneous presampling groundwater elevations were recorded during seasonally low flow (September 2005) and, consequently, may not be representative of the vertical hydraulic gradients evident during seasonally high flow conditions.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples collected to date show that the well yields sodium-, chloride-, and sulfate-enriched, calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 270 – 584 mg/L;
- pH of 7.2 – 9.1 (field measurements);
- elevated concentrations of sodium (>40 mg/L), chloride (>70 mg/L), nitrate (>15 mg/L), and sulfate (>80 mg/L); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Elevated levels of nitrate in the groundwater samples are attributable to contamination from the former S-3 Ponds (see Section 5.1), but the elevated levels of sodium, chloride, and sulfate may reflect natural geochemical characteristics at depth in the Maynardville Limestone. Similarly, it is unclear if the unusually high levels of total iron (e.g., 3.14 mg/L in March 2005) in some samples are representative of concentrations in the groundwater or are potential artifacts related to corrosion of the steel riser casing in the well.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that nitrate and VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

As shown on Table 1, all the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit and all of these results exceed the drinking water MCL for nitrate (10 mg/L). Elevated nitrate levels indicate that the open-hole interval in the well intercepts water-producing features that are hydraulically connected with the heterogeneous plume of inorganic, organic, and radiological contaminants originating from the former S-3 Ponds. Located hydraulically upgradient approximately 4,500 ft east-northeast of the well, these unlined surface impoundments received several million gallons of nitric-acid wastes generated at Y-12 between 1951 and 1984, and were filled and covered with a low-permeability cap during RCRA closure of the site in 1989. Nitrate is a principal component of the contaminant plume, is chemically stable and highly mobile in groundwater, and is believed to effectively delineate the primary groundwater flow/contaminant transport pathways in the Maynardville Limestone (DOE 1997).

Nitrate concentrations in the groundwater flow/transport pathways intercepted by the open-hole interval in this well are attributable to westward (downgradient) transport via strike-parallel flowpaths at depth in the Maynardville Limestone (>300 ft bgs). As illustrated by the most recent sampling results summarized below, the nitrate concentrations do not exhibit wide seasonal fluctuations, suggesting that the well does not have a direct hydraulic connection with the shallow karst network, where nitrate concentrations exhibit substantial fluctuations in response to seasonal (and episodic) flow conditions. Without evidence for a more direct hydraulic connection with the shallow karst network, the presence of nitrate in the groundwater from this well does not seem attributable to extensive down-dip inflow (recharge) of nitrate-contaminated surface water via the losing reach of Bear Creek noted in Section 3.0.

Both historical and more recent sampling results, as illustrated by the data summarized above, indicate that nitrate concentrations in the groundwater from well GW-601 are higher than evident shallower groundwater from well GW-368. In light of the upward vertical gradient noted in Section 4.0, the presence of nitrate in the groundwater in well GW-368 may be at least partially attributable to upward migration from the deeper flow system. Moreover, considering the depth of open-hole interval in each well relative to the hydrostratigraphic zones in the Maynardville Limestone (see Section 3.0), the higher levels of nitrate in well GW-601 potentially indicate greater relative flux of nitrate (and other similarly mobile contaminants) via more permeable strike-parallel flowpaths within hydrostratigraphic zones toward the bottom of the formation.

A time-series plot of the nitrate results reported for the groundwater samples collected to date shows an overall decreasing long-term trend (Figure 1). The long-term trend includes an indeterminate concentration trend through the early 1990’s, as illustrated by the nitrate levels evident in October 1990 (36 mg/L) and March 1994 (36.1 mg/L), with substantially lower (50%) levels subsequently evident, as indicated by nitrate results for samples collected in March 1999 (14 mg/L, the historical minimum value) and September 2005 (18.4 mg/L). The lower nitrate levels indicated by the more recent sampling results probably reflects the corresponding decrease in the relative flux of nitrate via the groundwater flow/transport pathways intercepted by the open-hole interval in the well. Substantially decreased flux of nitrate in the Maynardville Limestone occurred in response to the closure of the former S-3 Ponds in 1988 and the installation of a low-permeability cap at the site in 1989.

5.2 URANIUM

Three of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with each result (0.001 mg/L in September 1992, June 1993, and September 2005) being almost and order-of-magnitude below the MCL for uranium (0.03 mg/L) and within the range of background levels in the Maynardville Limestone. These results suggest that the water-producing features intercepted by the open-hole interval in the well are not hydraulically connected with the primary groundwater transport pathways for uranium from the former BYBY, which is located approximately 1,650 ft east-northeast, hydraulically upgradient of the well. Identified during the CERCLA RI as one of the principal sources of uranium in the Maynardville Limestone in BCV (DOE 1997), the BYBY was prioritized for CERCLA remedial action, which was completed in May 2002 and included the excavation and removal of uranium-bearing wastes from above and below the saturated zone. Additionally, the low (background) levels of uranium in the well so not indicate extensive down-dip inflow (recharge) of uranium-contaminated groundwater/surface water via the losing reach of Bear Creek noted in Section 3.0.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected to date (Table 2): acetone, CTET, chloroform, methylene chloride, PCE, TCE, 11DCE, 12DCE, 2-butanone, and 111TCA. The presence of VOCs in the samples indicates that the monitored interval in the well intercepts groundwater flow/transport pathways for VOCs released from one or more upgradient sources that contribute to an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. Available data for the network of wells completed in the Maynardville Limestone west of the flow divide indicate that VOC-contaminated groundwater, as defined by individual or summed VOC concentrations above 5 µg/L, appears to originate near Spoil Area I and to extend hydraulically downgradient for several thousand feet westward (parallel with geologic strike) down the axis of BCV. The apparent distribution of VOCs within the plume reflects the relative influx from multiple source areas, commingling during downgradient groundwater transport, and hydraulic communication with Bear Creek (DOE 1997).

Based on frequency of detection and concentration magnitude, TCE is the primary VOC detected in the groundwater samples collected to date (Table 2). This compound was detected in all the samples, with TCE concentrations above 100 µg/L, including the historical maximum concentration (180 µg/L in October 1990), reported for all but four of the samples. All the TCE results, including results for the samples collected most recently (March and September 2005), substantially exceed the drinking water MCL (5 µg/L), although the most recent concentrations are the lowest values detected to date. Of the other VOCs, CTET was detected the most frequently and is the only VOC other than TCE detected in the samples collected in March and September 2005 (Table 2). Also, aside from a few results for acetone and 2-butanone, which are suspected analytical artifacts, the results for all the other VOCs except TCE are estimated values below 5 µg/L and are less than applicable MCLs. Indeed, the general lack of other VOCs in the groundwater samples, particularly c12DCE, suggests minimal biotic degradation of the TCE (and other VOCs) in the groundwater near this well. This interpretation is supported by results for several indicator parameters, which suggest that selected geochemical characteristics are not within the optimum ranges known to promote biologically mediated degradation of chlorinated hydrocarbons in groundwater (Table 3).

The predominance of TCE in the groundwater samples from this well suggests that the primary source of the VOCs is the Rust Spoil Area (or nearby site within the Bear Creek floodplain). The Rust Spoil Area is a closed construction and demolition waste disposal site underlain by the Maynardville Limestone approximately 2,200 ft directly east (parallel with geologic strike) of the wells and is the suspected source of a TCE-dominated plume of dissolved VOCs in the shallow groundwater at the site (DOE 1997). Additional influx of VOCs into the Maynardville Limestone occurs from several potential sources within the Oil Landfarm WMA located hydraulically upgradient of the well to the north (Oil Landfarm and Sanitary Landfill I) and east-northeast (HCDA). However, the previously discussed results for nitrate and uranium suggests strike-parallel transport from an upgradient source(s) of TCE to the east of the well (the Rust Spoil Area), rather than down-dip inflow (recharge) from potential source areas to the north of the well.

As illustrated by the selected sampling results summarized below, similar levels of TCE occur in the groundwater from wells GW-368 and GW-601. Additionally, the most recent sampling results for both wells indicate that the TCE concentrations in deeper groundwater remain significantly higher than evident in wells completed at shallower depths in the Maynardville Limestone, including wells located at the Rust Spoil Area (e.g., GW-312). This is because the greater permeability of the shallow karst network facilitates more rapid flushing of the most contaminated groundwater by seasonal (and episodic) recharge/discharge cycles (DOE 1997).

TCE (µg/L)			
GW-368 (225-245 ft bgs)		**GW-601 (318-356 ft bgs)**	
01/31/90	120	03/05/90	110
03/21/05	62	03/15/05	85
05/12/05	50	09/12/05	72

A time-series plot of TCE concentrations reported for the groundwater samples collected to date (Figure 1), shows a clearly decreasing long-term trend between May 1990 (170 µg/L) and December 1994 (120 µg/L), and further reduced concentrations evident after the subsequent gaps in the sampling history for the well, with the TCE concentration reported for the sample collected in September 2005 (72 µg/L) being the historical minimum value. However, the rate of decrease appears to have slowed. For instance, the TCE concentration decreased almost 50% between October 1990 (180 µg/L; the historical maximum value) and March 1999 (96 µg/L), but only an additional 25% decrease through September 2005. Decreasing concentrations of TCE in the groundwater from this well are probably attributable to a combination of natural attenuation (dilution and dispersion) in the Maynardville Limestone and the reduced flux of TCE (and other VOCs) via the groundwater flow/transport pathways intercepted by the open-hole interval in the well.

5.4 GROSS ALPHA ACTIVITY

Twelve groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (7.58 pCi/L in August 1990) being below the MCL for gross alpha activity (15 pCi/L). No samples collected since March 1994 had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

Eighteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (47.06 pCi/L in March 1990) being slightly below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). However, this maximum result is a suspected outlier because all other results were much lower, with the next highest result (25.5 pCi/L) reported for the sample collected in March 1994.

WELL GW-605

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during March 1991, completed with a screened monitored interval from 28.2 to 39.9 ft bgs. The well forms a cluster with well GW-606 and is constructed with nominal 4.3-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley (BCV) in the eastern Y-12 area, on the north side of the main channel of Upper East Fork Poplar Creek (UEFPC) about 1,300 ft west (hydraulically upgradient) of New Hope Pond (NHP). Closed in 1988 and covered with a multi-layer, low-permeability cap in 1989, NHP was an unlined surface impoundment constructed in 1963 to regulate the quantity and quality of surface water exiting Y-12 via UEFPC. Lake Reality is a lined surface impoundment that was built in 1988 to replace NHP. During normal operations, flow in UEFPC is directed through a concrete-lined diversion channel bordering the south and east sides of NHP/Lake Reality. Until December 1996, when flow was rerouted to bypass Lake Reality, surface flow in the UEFPC distribution channel discharged into Lake Reality (and exited through a weir in the western berm). Beginning in July 1998, flow in the UEFPC distribution channel was diverted through the Lake Reality spillway, which discharges into the mainstream of UEFPC directly north (downstream) of Lake Reality.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-one groundwater samples have been collected from the well, with the conventional sampling method used to obtain 25 samples between August 1991 and August 1997, and the low-flow sampling method used to obtain 16 samples between March 1998 and July 2004.

An evaluation of the monitoring data available through August 2000 indicated potential bias related to the groundwater sampling method: (unfiltered) samples obtained with the conventional sampling method had substantially higher levels of uranium, VOCs, and gross beta than samples obtained with the low-flow sampling method (AJA 2001). Results of "paired sampling", whereby groundwater samples are collected with the low-flow sampling method one day and the conventional sampling method the next day, are needed to confirm the apparent sampling-method bias.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maynardville Limestone (upper Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 9 ft bgs and exhibits minimal (<2 ft) seasonal fluctuations. Also, presampling groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are higher in well GW-605 than in well GW-606, which is completed at a greater depth (171 ft bgs) in the Maynardville Limestone. Based on the distance (128.9 ft) between the monitored interval midpoint (elevation) in each well, the contemporaneous groundwater elevations indicate downward vertical hydraulic gradients (0.011-0.028) during seasonally high and low flow conditions.

Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-605 indicate flow primarily to the east toward NHP, parallel with geologic strike in the Maynardville Limestone. Additionally, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local groundwater flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998).

4.0 GEOCHEMCICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 258 – 474 mg/L;
- pH of 6.3 – 7.53 (field measurements);
- elevated concentrations (>20 mg/L) of chloride and sulfate relative to other wells of similar depth in the Maynardville Limestone;
- low molar proportions of sodium, potassium, and nitrate (<10% of total anions/cations);
- an unacceptably high relative percent difference (RPD) between respective summed millequivalent concentrations of anions and cations (i.e., the ion-charge balance error exceeds 20%) determined for samples collected in July 1999 (RPD = -55.4%) and January 2000 (RPD = 44.8%); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on respective monitoring data reported for the groundwater samples collected since January 1991, the principal contaminants present in the groundwater at this well are uranium, VOCs, and gross beta activity.

5.1 NITRATE

All but eight of the groundwater samples had nitrate concentrations at or above the analytical reporting limit (Table 1), with the historical maximum value (210 mg/L in July 1999) considered qualitative because of the ion-charge balance error determined for this sample (see Section 4.0). Excluding qualitative results, the maximum nitrate concentration (2.6 mg/L in July 2000) is not only substantially below the MCL for nitrate (10 mg/L), but appears to be an outlier compared to the other nitrate results, all but one of which are less than 1 mg/L. These results show that nitrate levels in the shallow groundwater from well GW-605 are significantly lower than nitrate levels in the deeper groundwater from well GW-606 (e.g., 14.7 mg/L in January 2003). Considering the consistently downward vertical hydraulic gradients indicated by presampling groundwater elevations in these wells, the higher nitrate levels in the deeper groundwater reflect the lateral, strike-parallel transport at depth in the Maynardville Limestone from the source(s) located within Y-12 west (hydraulically upgradient along strike) of the wells.

5.2 URANIUM

All but two groundwater samples had total uranium concentrations above the applicable analytical reporting limit (one sample was not analyzed for uranium; Table 1) and all of these results exceed the MCL for total uranium (0.03 mg/L). The specific source of the uranium in the shallow groundwater at this well has not been identified, but the well penetrates fill material containing low-level radioactive-contaminated debris (based on field scans), presumably derived from historical activities performed in Buildings 9201-1, 9201-2, and 9201-3 (DOE 1998). Considering the relatively neutral pH of the samples, the uranium is probably present as uranyl cations combined with available anions in the groundwater (Fetter 1993), including carbonate dissolved from the Maynardville Limestone, which may greatly increase the relative mobility of uranium in the groundwater flow system.

Aside from the uranium concentration reported for the groundwater sample collected in August 1993 (<0.001 mg/L), which is an outlier and a suspected analytical artifact, all of the other uranium results exceed the MCL, with a historical maximum value of 0.33 mg/L in March 1998 (Table 1). Note that the lowest uranium concentrations, including all of the results below 0.1 mg/L, were reported for samples obtained with the low-flow sampling method (although the historical maximum uranium value was reported for the first sample obtained with this method). As noted in Section 2.0, "paired sampling" results are needed to confirm if the lower uranium concentrations are an artifact of the change in groundwater sampling procedure or if they reflect a corresponding reduction in the relative flux of uranium along the groundwater flow/transport pathways intercepted by the monitored interval in the well. Nevertheless, the sampling results obtained to date show that uranium concentrations in the shallow groundwater from well GW-605 remain at least an order-of-magnitude higher than uranium concentrations in the deeper groundwater from well GW-606 (e.g., 0.00536 mg/L in January 2004). This suggests that the source of the uranium is within the shallow flow system and, despite the vertically downward hydraulic gradients indicated by presampling groundwater elevations in these wells (see Section 3.0), minimal transport of uranium into the deeper flow system.

A time-series plot of the uranium concentrations, excluding the non-detect result noted above, shows two generally indeterminate concentration trends (Figure 1), one defined by the conventional sampling data (August 1991 – August 1997) and one defined by the low-flow sampling results (March 1998 – July 2003). Although the uranium concentrations reported for samples collected since July 1998 are much lower than evident in samples collected previously, the indeterminate nature of the concentrations trend suggest relatively unchanged flux of uranium. Both concentration trends also show significant temporal changes. However, with temporal peak concentrations evident for samples collected during seasonally high and low flow (Figure 1), there does not appear to be any clear and consistent relationship between uranium concentration fluctuations and seasonal groundwater flow conditions.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample (Table 2): PCE, TCE, 12DCE (c12DCE and t12DCE), CTET, chloroform (CLF), 11DCA, 11DCE, VC, MC, and bromodichloromethane. These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide separating the Bear Creek and UEFPC watersheds. East of the flow divide in the UEFPC watershed, the VOC plume in the Maynardville Limestone appears to originate near the Fire Training Facility in the southwestern section of Y-12, extends eastward (parallel with geologic strike) and mixes with VOCs released from several sources in the central and eastern Y-12 areas, and enters Union Valley east of the ORR boundary along Scarboro Road (DOE 1998). In October 2000, full-time operation of a groundwater extraction and treatment system began to intercept and contain the (CTET-dominated) portion of the VOC plume in the Maynardville Limestone near NHP, as required by the CERCLA Action Memorandum (DOE 1999). Groundwater is pumped from extraction well GW-845 at a rate of 25 gpm and is treated on-site to remove particulates, iron, manganese, and VOCs. Long-term operation of the system has generally maintained 15 ft to 17 ft of drawdown in the immediate vicinity of well GW-845 and has established an elongated zone of influence that extends parallel with geologic strike for at least 900 ft to the east (downgradient) and 600 ft to the west (upgradient) of the pumping well (DOE 2002).

The primary VOCs in the groundwater samples are CTET, CLF, PCE, TCE, and 12DCE (c12DCE), with each compound detected (excluding false positive results) in all but four of the samples and the most recent sampling results (January and July 2004) showing CTET, PCE, and TCE concentrations above respective MCLs (Table 2). Secondary VOCs in the samples are VC, 11DCA, and 11DCE, which have been detected in only two samples collected since December 1995, with all the results for each compound being estimated values below 5 µg/L. A similarly low (estimated) concentration of bromodichloromethane was detected in one sample and t12DCE was detected in two samples. Additionally, the analytical results for the samples obtained with the conventional sampling method show substantially higher concentrations of CTET than indicated by the low-flow sampling results, but equivalent or somewhat higher concentrations of several other VOCs, notably PCE and 12DCE (Table 2). Assuming that the groundwater in the well contains a heterogeneous mixture of dissolved VOCs, it is not clear why the concentrations of individual compounds would exhibit different responses to the groundwater sampling method. Perhaps the higher pumping rate during conventional sampling induces upward flow of CTET-contaminated groundwater from the deeper in the Maynardville Limestone, which increases the CTET concentrations relative to other VOCs in the samples from the well, whereas low-flow sampling induces lateral inflow of PCE-, TCE-, and c12DCE-contaminated groundwater from the shallow flow system, resulting in samples with higher concentrations of these compounds relative to CTET. Results of "paired sampling" (see Section 2.0) are needed to determine if the VOC concentrations are biased by the groundwater sampling method.

As illustrated by the selected data summarized below, concentrations of VOCs in the groundwater samples from well GW-605, particularly CTET and CLF, used to be substantially lower than evident in samples of the deeper groundwater from well GW-606.

VOC	Concentration (µg/L)					
	Conventional Sampling		**Low-Flow Sampling**			
	August 1991		**July 1998**		**July 2004**	
	GW-605	**GW-606**	**GW-605**	**GW-606**	**GW-605**	**GW-606**
PCE	18	12	7	7	15	5
TCE	7	0.9 J	2 J	.	21	.
12DCE	17	2 J	5	.	41	.
CTET	26	2,800	170	120	11	72
CLF	4 J	600	16	140	5	120
Summed VOCs	74	3,618	200	269	93	197
Note: "." = Not detected; J = Estimated value below analytical reporting limit						

The large disparity between the recent and historical concentrations of CTET and CLF in these wells may reflect the change from the conventional to the low-flow sampling method. In light of the downward vertical hydraulic gradients indicated by presampling groundwater elevations in each well (see Section 3.0), the concentration trend suggests substantially greater natural attenuation of CTET in groundwater at depth in the Maynardville Limestone. Also, the concentrations of other VOCs in the samples from well GW-605, particularly TCE and 12DCE, are now substantially higher than reported for the samples from well GW-606, as illustrated by the data summarized above. This suggests that the source of these VOCs is separate from that of CTET.

A time-series plot of the summed concentrations of VOCs detected in the groundwater samples shows an indeterminate long-term concentration trend (Figure 2), as illustrated by the relative similarity between the summed VOC concentrations evident in August 1991 (73.6 μg/L) and July 2004 (93 μg/L). Also, conventional sampling and low-flow sampling results both show significant short-term concentration fluctuations, with temporal high summed VOCs typically determined for samples collected during seasonally low groundwater flow conditions. This relationship suggests that the lower summed VOC concentrations potentially result from seasonal (and episodic) recharge of uncontaminated (or less VOC-contaminated) groundwater, rather than wide temporal changes in the relative flux of dissolved VOCs along the groundwater flow/transport pathways intercepted by the well. Additionally, the long-term concentration trend for VOCs does not indicate any clear response to the full-time operation of groundwater extraction well GW-845.

5.4 GROSS ALPHA ACTIVITY

All but two groundwater samples had gross alpha activity above the applicable MDA and corresponding CE (one sample was not analyzed for gross alpha activity; Table 1), and all but one of these results exceed the MCL for gross alpha activity (15 pCi/L). Elevated gross alpha activity in the groundwater at this well is attributable to uranium isotopes, which were detected (i.e., >MDA and CE) in samples collected in October 1996 (U-234 = 74.4 pCi/L and U-238 = 73.5 pCi/L), June 1998 (U-234 = 31.51 pCi/L and U-238 = 31.95 pCi/L), and July 1998 (U-234 = 18.56 pCi/L and U-238 = 18.99 pCi/L). As with the total uranium in the shallow groundwater at this well, the source of the uranium isotopes has not been identified, but may be related to contaminated debris placed as fill along the north bank of UEFPC or historical uranium enrichment activities performed in Buildings 9201-1, 9201-2, and 9201-3 (DOE 1998).

Excluding the non-detect (i.e., <MDA) gross alpha activity results reported for the groundwater sample collected in June 1996 (Table 1), which is an outlier compared to the other results and is a likely analytical artifact, the other samples exhibit a wide range of gross alpha activity, with the historical maximum value (170 pCi/L in March 1997) being about 650% higher than the historical minimum value (26.9 pCi/L in January 2001). Also, the lowest values for gross alpha activity, including all but one of results that are less than 50 pCi/L, were reported for samples obtained with the low-flow sampling method. The highest values for gross alpha activity, including all but one of the results that exceed 100 pCi/L, were reported for the samples collected with the conventional sampling method (Table 1). Results of "paired sampling" (see Section 2.0) are needed to determine if the groundwater sampling method influences the levels of gross alpha activity in the samples. In either case, the available data show that gross alpha activity in the shallow groundwater from well GW-605 is substantially higher than evident in the deeper groundwater from well GW-606 (e.g., 5 pCi/L in January 2003). Substantially higher gross alpha activity in the samples from well GW-605 suggests that a source of uranium isotopes is in the shallow subsurface near these wells. Although there is a downward vertical hydraulic gradient near these wells (see Section 3.0), there appears to be minimal downward transport of uranium isotopes (and alpha-particle emitting daughter products) into the deeper flow system.

A time-series plot of the results for gross alpha activity that exceed the MDA and CE shows two distinctive trends: a fluctuating but generally increasing trend indicated by conventional sampling data and a much less variable, indeterminate trend indicated by the low-flow sampling data

(Figure 3). It is not clear from the available data if these trends are influenced by the respective groundwater sampling method or if they reflect a fairly abrupt decrease in the relative flux of uranium isotopes along the groundwater flow/transport pathways intercepted by the monitored interval in the well. Also, the results for gross alpha activity do not indicate any clear response to the operation of groundwater extraction well GW-845.

5.5 GROSS BETA ACTIVITY

All but three groundwater samples had gross beta activity above the applicable MDA and corresponding CE (one sample was not analyzed for gross beta activity; Table 1), and twelve of these results exceed the SDWA screening level (50 pCi/L) for gross beta activity. Elevated gross beta activity in the groundwater at this well is probably attributable to uranium isotopes (and related daughter products that emit beta particles) and reflects contamination associated with contaminated debris placed as fill along the north bank of UEFPC or historical uranium enrichment activities performed in Buildings 9201-1, 9201-2, and 9201-3 (DOE 1998).

Analytical results obtained in accordance with the RCRA post-closure permit for the UEFPC hydrogeologic regime show that Tc-99 is not the source of the elevated levels of gross beta activity reported for the groundwater samples. Seventeen samples collected since October 1998 were analyzed for Tc-99, a "signature" component of the contaminant plume emplaced in the western part of Y-12 during historical operation of the former S-3 Ponds. The only Tc-99 result that exceeds the MDA was reported for the sample collected in January 2001 (21.76 pCi/L), and this result is probably an analytical artifact (BJC 2002).

Excluding the non-detect (i.e., <MDA) results for gross beta activity (Table 1), the samples contained a wide range of gross beta activity, with the historical maximum value (110 pCi/L in January 1994) being about 650% higher than the historical minimum value (6.22 pCi/L in January 2001). Also, the lowest values for gross beta activity, including nine of the ten results below 25 pCi/L, were reported for samples obtained with the low-flow sampling method. Conversely, the highest values for gross beta activity, including all but one of the results that exceed 50 pCi/L, were reported for the samples collected with the conventional sampling method (Table 1). Thus, "paired sampling" (see Section 2.0) results are needed to determine if the sampling method influences the levels of gross beta activity in the groundwater samples. Also, as with gross alpha activity, the available data show that gross beta activity in the shallow groundwater from well GW-605 is consistently higher than evident in the deeper groundwater from well GW-606 (e.g., 7 pCi/L in January 2003). This too suggests minimal vertical transport of uranium isotopes (and beta particle-emitting daughter products) into the deeper flow system near these wells.

A time-series plot of the results for gross beta activity that exceed the MDA and CE shows two distinctive trends: a widely fluctuating, indeterminate trend indicated by conventional sampling data and a much less variable but similarly indeterminate trend indicated by the low-flow sampling data (Figure 4). Also, the conventional sampling data often show temporal "peak" gross beta activity during seasonally high groundwater (e.g., 110 pCi/L in January 1994), whereas the low-flow sampling results do not show any clear or consistent relationship between temporal peak gross beta activity and seasonal flow conditions.

WELL GW-606

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during March 1991, completed with a screened monitored interval from 155 to 171 ft bgs. The well forms a cluster with well GW-605 and is constructed with nominal 4.3-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot pre-packed, wire-wound). The well is located in Bear Creek Valley (BCV) in the eastern Y-12 area, on the north side of the main channel of Upper East Fork Poplar Creek (UEFPC) about 1,300 ft west (hydraulically upgradient) of New Hope Pond (NHP). Closed in 1988 and covered with a multi-layer, low-permeability cap in 1989, NHP was an unlined surface impoundment constructed in 1963 to regulate the quantity and quality of surface water exiting Y-12 via UEFPC. Lake Reality is a lined surface impoundment that was built in 1988 to replace NHP. During normal operations, flow in UEFPC is directed through a concrete-lined diversion channel bordering the south and east sides of NHP/Lake Reality. Until December 1996 when flow was rerouted to bypass Lake Reality, surface flow in the UEFPC distribution channel discharged into Lake Reality (and exited through a weir in the western berm). Beginning in July 1998, flow in the UEFPC distribution channel was permanently diverted through the Lake Reality spillway, which discharges into the mainstream of UEFPC directly north (downstream) of Lake Reality.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-eight groundwater samples have been collected from the well, with the conventional sampling method used to obtain 24 samples between August 1991 and July 1997, and the low-flow sampling method used to obtain 14 samples between March 1998 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the intermediate bedrock interval in the Maynardville Limestone (upper Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 11 ft bgs and exhibits moderate (<4 ft) seasonal fluctuations. Interestingly, the groundwater elevations indicated by presampling measurements obtained through October 1996 show the typical seasonal fluctuations, but similarly seasonal fluctuations are less clearly evident following the historical maximum groundwater elevation (908 ft above msl) observed in well GW-606 in March 1997 (Figure 1). What may have caused the sharp temporal rise in the groundwater elevation in the well or why the seasonal water-level fluctuations are less pronounced is not evident from the available data, but neither appear to be attributable to the hydrologic testing and full-time operation of a groundwater extraction well (GW-845) located about 2,500 ft directly east of well GW-606 (see Section 5.3). In any case, the presampling groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are lower in well GW-606 than in well GW-605, which is completed at a shallower depth (40 ft bgs) in the Maynardville Limestone. Based on the distance (128.9 ft) between the monitored interval midpoint (elevation) in each well, the contemporaneous groundwater elevations indicate downward vertical hydraulic gradients (0.011-0.028) during seasonally high and low flow conditions.

Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-606 indicate flow primarily to the east toward NHP, parallel with geologic strike in the Maynardville Limestone. Additionally, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local groundwater flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 225 – 445 mg/L, excluding a suspected outlier (900 mg/L) in January 2000;
- pH of 6.9 – 10.61 (field measurements): note that samples collected from January 2001 through January 2002 exhibited characteristics of grout contamination (e.g., pH>8.5), which appears to have been alleviated by redevelopment of the well in June 2002;
- elevated concentrations of nitrate (>10 mg/L), chloride (>20 mg/L), and sulfate (>40 mg/L);
- low molar proportions of sodium and potassium (<10% of total cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on respective monitoring data reported for the groundwater samples collected from the well since January 1991, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples had nitrate (as N) at or above the analytical reporting limit (Table 1), including results for three samples that exceed the MCL for nitrate (10 mg/L). The potential source(s) of the nitrate has not been confirmed, but there are potential source areas within Y-12 west (hydraulically upgradient) of the well, including the contaminant plume emplaced in the Maynardville Limestone during historical operations of the S-2 Site, a closed former surface impoundment located near the southwest end of Y-12. Whatever the source, the elevated nitrate concentrations reflect eastward migration via strike-parallel groundwater flow/transport pathways at depth (>150 ft bgs) in the Maynardville Limestone. This interpretation is supported by the much lower nitrate levels typical of the groundwater samples from well GW-605 (e.g., 0.29 mg/L in July 2004) which, in light of the consistently downward vertical hydraulic gradients indicated by presampling groundwater elevations (see Section 3.0), discounts vertical recharge as the likely source of the nitrate in the deeper groundwater at well GW-606.

As shown on Figure 2, higher nitrate concentrations generally correspond with the change from conventional sampling to low flow sampling (Figure 2), although similar differences are not evident for other contaminants in the groundwater samples (e.g., VOCs). Additionally, the highest nitrate concentrations were reported for samples collected after the well was redeveloped in June 2002 (Figure 2). Moreover, the samples with the highest nitrate concentrations were obtained after the hydrologic testing and full-time operation of the groundwater extraction well (GW-845) being used to remove VOC-contaminated groundwater from the Maynardville Limestone about 2,500 ft east (hydraulically downgradient parallel with geologic strike) of well GW-606 (see Section 5.3). Thus, it is not clear if the higher nitrate concentrations reflect a corresponding increase in the relative flux of nitrate along the groundwater flow/transport pathways intercepted by the monitored interval in the well, or if the nitrate concentrations are artifacts of the sampling method and/or the redevelopment of the well, or if the higher nitrate concentrations are related to the long-term extraction of groundwater from well GW-845.

5.2 URANIUM

Twenty-nine groundwater samples had total uranium concentrations above the applicable analytical reporting limit (one sample was not analyzed for uranium; Table 1), with the historical maximum value (0.0074 mg/L in July 1997) being substantially below the MCL for total uranium (0.03 mg/L). Also, the uranium concentrations are substantially lower than evident in samples of the shallower groundwater from well GW-605 (e.g., 0.0833 mg/L in July 2003). This suggests that, despite the locally downward vertical gradients (see Section 3.0), there is not extensive transport of uranium from the shallow flow system into the deeper flow system near these wells.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample (Table 2): acetone, benzene, CTET, chloroform (CLF), methylene chloride (MC), toluene, PCE, TCE, and 12DCE. These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide, located near the west end of Y-12, that separates the Bear Creek and UEFPC watersheds. East of the flow divide in the UEFPC watershed, the VOC plume in the Maynardville Limestone appears to originate near the Fire Training Facility in the southwestern section of Y-12, extends eastward (parallel with geologic strike) and mixes with VOCs released from several sources in the central and eastern Y-12 areas, and enters Union Valley east of the ORR boundary along Scarboro Road (DOE 1998). In October 2000, full-time operation of a groundwater extraction and treatment system began to help intercept and contain the (CTET-dominated) portion of the VOC plume in the Maynardville Limestone near the east end of Y-12, as required by the CERCLA Action Memorandum (DOE 1999). Groundwater is pumped from the extraction well (GW-845) at a rate of 25 gpm and is treated on-site to remove particulates, iron, manganese, and VOCs. Long-term operation of the system has generally maintained 15 to 17 ft of drawdown in the immediate vicinity of well GW-845 and has established an elongated zone of influence that extends parallel with geologic strike for at least 900 ft to the east (downgradient) and 600 ft to the west (upgradient) of the pumping well (DOE 2002).

The primary VOCs in the groundwater samples are CTET and CLF, both of which were detected in all of the samples, with the most recent sampling results (January and July 2004) showing that concentrations of each compound remain above respective MCLs (Table 2). Tetrachloroethene is the only other VOC that has been consistently detected in the samples, with most concentrations being below 10 μg/L, including the most recent concentrations at or slightly above the MCL (5 μg/L). Additionally, the analytical results for the samples obtained with the conventional sampling method show substantially higher concentrations of CTET than indicated by the low-flow sampling results, but equivalent or somewhat lower concentrations of CLF and PCE. Assuming that the groundwater in the well contains a heterogeneous mixture of dissolved VOCs, it is not clear why the concentrations of individual compounds would exhibit different responses to the groundwater sampling method. The higher pumping rate during conventional sampling potentially induces greater relative inflow from water-producing features that transmit CTET-contaminated groundwater.

As illustrated by the data summarized below, concentrations of VOCs in the groundwater samples from well GW-606, particularly CTET and CLF, used to be substantially higher than evident in the samples of the shallower groundwater from well GW-605.

VOC	Concentration (μg/L)					
	Conventional Sampling		Low-Flow Sampling			
	August 1991		July 1998		July 2004	
	GW-605	GW-606	GW-605	GW-606	GW-605	GW-606
PCE	18	12	7	7	15	5
TCE	7	0.9 J	2 J	.	21	.
12DCE	17	2 J	5	.	41	.
CTET	26	2,800	170	120	11	72
CLF	4 J	600	16	140	5	120
Summed VOCs	74	3,618	200	269	93	197
Note: "." = Not detected; J = Estimated value below analytical reporting limit						

The large disparity between the recent and historical concentrations of CTET and CLF in these wells, in light of the downward vertical hydraulic gradients indicated by presampling groundwater elevations in each well (see Section 3.0), these concentrations suggest that recharge from the shallow flow system near these wells is not the likely source of the CTET and CLF deeper in the Maynardville Limestone. This interpretation is supported by the low concentrations other VOCs in the samples from well GW-606, particularly PCE and 12DCE, compared to samples from well GW-605. Moreover, the difference in the types and concentrations of VOCs suggests that the source of the compounds in the deeper groundwater from well GW-606 may be separate from the source of the compounds in the shallower groundwater at well GW-605.

A time-series plot of the CTET and CLF concentrations reported for each groundwater sample shows concurrently fluctuating and generally decreasing trends between August 1991 and July 1997, with somewhat divergent respective trends thereafter (Figure 3). While CTET concentrations remained relatively unchanged between July 1997 (67 μg/L) and July 2004 (72 μg/L), the concentrations of CLF increased from 66 μg/L in July 1997 to 430 μg/L in July 2000 and subsequently decreased to 120 μg/L in July 2004. Note that the apparent divergence in the CTET and CLF concentration trends coincides with the change from conventional sampling to low-flow sampling. Also, the recent decrease in the concentration of CLF generally corresponds with the full-time operation of groundwater extraction well GW-845, although the CTET concentrations do not exhibit any apparent response to the pumping well (Figure 3). Additionally, the concentrations of CTET and CLF (and other VOCs) do not appear to exhibit any direct response to the redevelopment of the well in July 2000.

5.4 GROSS ALPHA ACTIVITY

Thirty-one groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the historical maximum value (18.3 pCi/L in April 1992) being slightly above the MCL for gross alpha activity (15 pCi/L). However, this result appears to be an outlier compared to the other results for gross alpha activity, none of which exceed 10 pCi/L. Also, the relatively low gross alpha activity in the samples contrasts with the much higher levels typically reported for samples of the shallower groundwater from well GW-605 (e.g., 87 pCi/L in January 2004), which suggests minimal local inflow of uranium isotopes into the deeper flow system in the Maynardville Limestone.

5.5 GROSS BETA ACTIVITY

Twenty-eight groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the historical maximum value (26.6 in April 1992) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem dose equivalent (the MCL for gross beta activity). Also, as with gross alpha activity, the relatively low gross beta activity in the samples contrasts with higher levels reported for the samples of the shallower groundwater from well GW-605 (e.g., 44 pCi/L in July 2004), which likewise indicates little if any local inflow of uranium isotopes (and beta-particle emitting daughter products) into the deeper flow system in the Maynardville Limestone.

WELL GW-610

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in January 1990, completed with a screened monitored interval from 105 to 117 ft bgs, and constructed nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located on the crest of Chestnut Ridge directly south of Y-12, approximately 200 ft northeast of the Chestnut Ridge Security Pits (CRSP). The CRSP include two contiguous former waste disposal areas, each consisting of a series of unlined, east-west oriented trenches that were about 8 to 10 ft wide, 10 to 18 ft deep, and 700 to 800 ft long. Beginning in 1973, the disposal trenches at the site received a variety of hazardous waste until December 1984 and nonhazardous wastes until November 1988. All the disposal trenches are covered by a multi-layer low-permeability cap installed during RCRA closure of the site in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-seven groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 25 samples between February 1990 and February 1996, and the low-flow sampling method used to obtain samples in April and October 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the lower Knox Group (Copper Ridge Dolomite), which forms the steep northern flank of Chestnut Ridge. The Knox Group formations, along with the uppermost formation (Maynardville Limestone) of the underlying Conasauga Group, comprise an aquifer consisting of three vertically gradational subsystems distinguished by groundwater flux, which decreases with depth: (1) the stormflow zone, (2) the vadose zone, and (3) the groundwater zone (Solomon et al. 1992). The stormflow and vadose zones occur at shallow depths within the thick (>100 ft) residuum that has developed on Chestnut Ridge. In the bedrock zone, orthogonal sets of permeable, planar fractures form water-producing zones within an essentially impermeable matrix, and dissolution of carbonates has enlarged fractures and produced an interconnected conduit-flow system characteristic of karst aquifers. Because the occurrence of solution features and the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity of the groundwater zone is vertically gradational. Most groundwater flux occurs within the transitional horizon between residuum and unweathered bedrock (water table interval); lower flux (and longer solute residence times) occurs at successively greater depths in the bedrock (Solomon et al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 81 ft bgs and exhibits moderate (about 19 ft) seasonal fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of the CRSP indicate radial flow directions, with components of flow to the north into BCV (toward well GW-610), to the east along the axis of the ridge (parallel with geologic strike), and south toward drainage features that traverse the broad southern flank of the ridge.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date indicate that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 177 – 231 mg/L;
- pH of 6.5 – 8.92 (field measurements);

- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite);
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the respective monitoring data reported for the groundwater samples collected from the well since January 1991, none of the principal contaminants are generally present in the groundwater at this well.

5.1 NITRATE

Twenty-one groundwater samples had nitrate concentrations at or above the applicable analytical reporting limit, with the highest concentration (1 mg/L in January 1995) being substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Six groundwater samples had uranium concentrations at or above the applicable analytical reporting limit, all results being equal to the reporting limit (0.001 mg/L) and an order-of-magnitude lower than the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, four of the groundwater samples contained trace levels (1 µg/L or less) of PCE, which is a principal component of the dissolved plume of VOCs that originates from the CRSP. Historical operation of the former waste disposal trenches at the CRSP emplaced an elongated plume of dissolved VOCs in the groundwater that extends more than 2,500 ft east-northeast along the ridge crest (parallel with geologic strike) and at least 500 ft to the north and south down the ridges flanks. The existing network of monitoring wells at the site shows that 111TCA, 11DCA, and 11DCE are the primary compounds in the groundwater near the western disposal trench area and PCE, TCE, and 12DCE are the principal compounds in the groundwater near the eastern disposal trench area. Elongation of the VOC plume along the axis of the ridge and the distribution of plume constituents indicate primarily west-to-east groundwater flow/contaminant transport via strike-parallel flowpaths in the Knox Group (e.g., bedding-plane fractures). Nevertheless, the presence of dissolved VOCs in the groundwater at this well indicates that there is a component of groundwater flow/contaminant to the north-northeast, possibly via "quickflow" conduits that cut across geologic strike (Shevenell 1994). The vertical extent of the VOC plume has not been determined, but based on the existing network of monitoring wells at the site, the plume extends at least 150 ft bgs near the western disposal trenches and 270 ft bgs near the eastern disposal trenches.

5.4 GROSS ALPHA ACTIVITY

Seven groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (4.82 pCi/L in June 1993) being substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Four groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (4.79 pCi/L in January 1995) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-611

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in January 1990, completed with a screened monitored interval from 102 to 122 ft bgs, and nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot pre-packed, wire-wound). The well is located on the north flank of Chestnut Ridge directly south of Y-12, approximately 400 ft north of the Chestnut Ridge Security Pits (CRSP). The CRSP include two contiguous former waste disposal areas, each consisting of a series of unlined, east-west oriented trenches that were about 8 to 10 ft wide, 10 to 18 ft deep, and 700 to 800 ft long. Beginning in 1973, the disposal trenches at the site received a variety of hazardous waste until December 1984 and nonhazardous wastes until November 1988. All the disposal trenches are covered by a multi-layer low-permeability cap installed during RCRA closure of the site in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-seven groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 25 samples between February 1990 and February 1996, and the low-flow sampling method used to obtain samples in April 2004 and October 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the Knox Group (Copper Ridge Dolomite). The Knox Group formations, along with the uppermost formation (Maynardville Limestone) of the underlying Conasauga Group, comprise an aquifer consisting of three vertically gradational subsystems distinguished by groundwater flux, which decreases with depth: (1) the stormflow zone, (2) the vadose zone, and (3) the groundwater zone (Solomon et al. 1992). The stormflow and vadose zones occur at shallow depths within the thick (>100 ft) residuum that has developed on Chestnut Ridge. In the bedrock zone, orthogonal sets of permeable, planar fractures form water-producing zones within an essentially impermeable matrix, and dissolution of carbonates has enlarged fractures and produced an interconnected conduit-flow system characteristic of karst aquifers. Because the occurrence of solution features and the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity of the groundwater zone is vertically gradational. Most groundwater flux occurs within the transitional horizon between residuum and unweathered bedrock (water table interval); lower flux (and longer solute residence times) occurs at successively greater depths in the bedrock (Solomon et al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 99 ft bgs and exhibits moderate (about 13 ft) temporal (seasonal) fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of the CRSP indicate radial flow directions, with components of flow to the north into BCV (toward well GW-611); to the east along the axis of the ridge, parallel with geologic strike of the bedrock; and south toward drainage features that traverse the broad southern flank of the ridge.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date indicate that this well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 156 – 332 mg/L;
- pH of 6.9 – 9.4 (field measurements);
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite);
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Twenty-three groundwater samples collected to date had nitrate concentrations at or above the applicable analytical reporting limit (Table 1). Although the nitrate concentrations are all below the drinking water MCL for nitrate (10 mg/L), many exceed the nitrate UTL applicable to Knox Group wells (2.7 mg/L). The source of the nitrate in the groundwater at the well is uncertain. Migration from the CRSP seems unlikely because the site did not receive nitrate wastes and elevated nitrate concentrations are not evident in groundwater at other wells located closer to the former waste disposal trenches. Nitrate is highly mobile in groundwater and the elevated levels in the groundwater at this well potentially reflect strike-parallel, advective transport from the contaminant plume emplaced during historical operations of the former S-2 Site. A closed surface impoundment located on the northern flank of Chestnut Ridge about 4,000 ft to the west (upgradient) of the well, the S-2 Site is a confirmed source of nitrate in the groundwater in the Maynardville Limestone and seasonal (presampling) groundwater elevations in monitoring wells at the site are typically about 50 ft higher that evident in well GW-611. Additionally, the monitored interval for the well is completed in the Copper Ridge Dolomite near the geologic contact with the underlying Maynardville Limestone, and the extent of nitrate-contaminated groundwater in the Maynardville Limestone downgradient of the S-2 Site suggests groundwater flow/contaminant transport toward a highly permeable interval that occurs within the top of the formation and lower part of the Copper Ridge Dolomite.

5.2 URANIUM

Six groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest concentration (0.001 mg/L in January 1991, February 1992, June 1993, September 1993, and May 1994) being below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in all but two of the groundwater samples collected to date: CTET, 11DCA, 11DCE, and 111TCA (Table 2). These compounds are components of a dissolved plume of VOCs that originates from the CRSP. Historical operation of the former waste disposal trenches at this site emplaced an elongated plume of dissolved VOCs in the groundwater that extends more than 2,500 ft east-northeast along the ridge crest (parallel with geologic strike) and at least 500 ft to the north and south down the ridges flanks. The existing network of monitoring wells at the site shows that 111TCA, 11DCA, and 11DCE are the primary compounds in the groundwater near the western disposal trench area and PCE, TCE, and 12DCE are the principal compounds in the groundwater near the eastern disposal trench area. Some constituents of the VOC plume (e.g., 11DCA and 11DCE) are probably present as a result of the degradation of 111TCA. Elongation of the VOC plume along the axis of the ridge and the distribution of plume constituents indicate primarily west-to-east groundwater flow/contaminant transport via flowpaths (e.g., bedding-plane fractures) that parallel the geologic strike of the Knox Group strata. Vertical flow/transport occurs parallel with the dip of the strata, with cross-cutting fractures facilitating contaminant migration to the north and south (Shevenell 1994). The vertical extent of the VOC plume has not been determined, but based on the existing network of monitoring wells at the site, the plume extends at least 150 ft bgs near the western disposal trenches and 270 ft bgs near the eastern disposal trenches.

As shown on Table 2, one or more VOCs were detected in each groundwater sample collected between February 1990 and February 1996, but the samples collected most recently (May and October 2004) did not contain VOCs. The historical data show 111TCA as the most frequently detected compound with the highest concentrations (historical maximum of 17 μg/L in May 1990 and November 1994). The other VOCs were infrequently detected, particularly CTET (detected in only two samples), and all the results for these compounds are estimated values below 5 μg/L (Table 1). The predominance of 111TCA in the samples and repeated detection of 11DCA suggests that the monitored interval in the well intercepts cross-strike groundwater flow/contaminant transport pathways for VOCs that originate primarily from the western disposal trenches at the CRSP.

The lack of VOCs in the groundwater samples collected most recently is consistent with the decreasing concentration trend indicated by a time-series plot of the summed concentrations of VOCs detected in each sample (Figure 1). The decreasing trend, which is evident from initial sampling following installation of the well, is probably attributable to reduced flux of VOCs in response to closure of the CRSP in 1988 and installation of the low-permeability cap in 1989. Additionally, the historical data show substantial temporal fluctuations, with summed VOC concentration "peaks" typically evident for samples collected during seasonally low groundwater flow conditions (summer and fall).

5.4 GROSS ALPHA ACTIVITY

Four groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (2.39 pCi/L in January 1991) being substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Four groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, with the highest value (9.81 pCi/L in July 1992) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-612

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in November 1989, completed with an open-hole monitored interval from 230 to 254 ft bgs, and constructed with nominal 7-inch diameter steel (SF25) riser casing. The well is located on the crest of Chestnut Ridge directly south of Y-12, near the approximate mid-point of the Chestnut Ridge Security Pits (CRSP). The CRSP include two contiguous former waste disposal areas, each consisting of a series of unlined, east-west oriented trenches that were about 8 to 10 ft wide, 10 to 18 ft deep, and 700 to 800 ft long. Beginning in 1973, the disposal trenches at the site received a variety of hazardous waste until December 1984 and nonhazardous wastes until November 1988. All the disposal trenches are covered by a multi-layer low-permeability cap installed during RCRA closure of the site in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Eighteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 14 samples between February 1990 and October 2004, and the low-flow sampling method used to obtain four samples between March 2001 and October 2004.

An evaluation of the monitoring data available through August 2000 indicated potential bias related to the groundwater sampling method: (unfiltered) samples obtained with the conventional sampling method had substantially higher VOC concentrations than samples obtained with the low-flow sampling method (AJA 2001). Results of "paired sampling" performed during May and August 2004, when groundwater samples were collected with the low-flow sampling method one day and the conventional sampling method the next day, confirm the apparent sampling-method bias (Table 1); summed concentrations of VOCs detected in the samples obtained with the low-flow method are about 25 to 75% lower than the corresponding summed VOC concentrations for the samples obtained with the conventional sampling method. Also, samples obtained with the low-flow method were slightly more turbid, surprisingly, than the samples obtained with the conventional method, which may explain why the samples obtained with the low-flow method had elevated total iron concentrations that are substantially higher than reported for the (less turbid) samples obtained with the conventional sampling method (Table 1).

Inherent differences in the manner in which each sampling method induces flow of groundwater into the well may explain the disparity between the conventional and low-flow sampling results for VOCs. Conventional sampling involves purging up to three well volumes of groundwater from the well at about 1-2 gallons per minute, which may substantially lower the water level in the well and induce flow from water-producing features (i.e., fractures, cavities, conduits) that may not contribute to well recharge under normal conditions. In contrast, low-flow sampling involves purging the well at a flow rate low enough (<300 milliliters per minute) to ensure minimal water-level drawdown in the well (<1 ft per quarter hour), which induces groundwater inflow only from the water-producing feature(s) proximal to the monitored interval. Thus, the conventional sampling method appears to induce greater inflow of VOC-contaminated groundwater from water-producing features that are not proximal to the monitored interval, resulting in collection of groundwater samples with higher VOC concentrations than otherwise evident in samples obtained with the low-flow sampling method. It is not clear from the available data which method provides the most representative monitoring results with regard to the concentration of VOCs (and total iron) in the groundwater at the well.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the Knox Group (Copper Ridge Dolomite). The Knox Group formations, along with the uppermost formation (Maynardville Limestone) of the underlying Conasauga Group, comprise an aquifer consisting of three vertically gradational subsystems distinguished by groundwater flux, which decreases with depth: (1) the stormflow zone, (2) the vadose zone, and (3) the groundwater zone (Solomon et al. 1992). The stormflow and vadose zones occur at shallow depths within the thick (>100 ft) residuum that has developed on Chestnut Ridge. In the bedrock zone, orthogonal sets of permeable, planar fractures form water-producing zones within an essentially impermeable matrix, and dissolution of carbonates has enlarged fractures and produced an interconnected conduit-flow system characteristic of karst aquifers. Because the occurrence of solution features and the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity of the groundwater zone is vertically gradational. Most groundwater flux occurs within the transitional horizon between residuum and unweathered bedrock (water table interval); lower flux (and longer solute residence times) occurs at successively greater depths in the bedrock (Solomon et al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 121 ft bgs and exhibits moderate (about 12 ft) temporal (seasonal) fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of the CRSP indicate radial flow directions, with components of flow to the north into BCV; to the east along the axis of the ridge, parallel with geologic strike of the bedrock; and south toward drainage features that traverse the broad southern flank of the ridge.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date indicate that this well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 162 – 260 mg/L;
- pH of 7.2 – 8.8 (field measurements);
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite);
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations);
- total concentrations of trace metals (except boron) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995); and
- boron concentrations of 0.105- 0.338 mg/L.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Thirteen groundwater samples collected to date had nitrate concentrations at or above the applicable analytical reporting limit, with the highest concentration (0.431 mg/L in May 2004) being substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Eleven groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest concentration (0.001 mg/L in February 1991, May 1991, August 1991, October 1991, February 1992, and July 1992) being below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample: PCE, TCE, 12DCE, 11DCE, TCFM, 11DCA, 12DCA, and 111TCA (Table 2). These compounds are components of a dissolved plume of VOCs that originates from the CRSP. These compounds are components of a dissolved plume of VOCs that originates from the CRSP. Historical operation of the former waste disposal trenches at this site emplaced an elongated plume of dissolved VOCs in the groundwater that extends more than 2,500 ft east-northeast along the ridge crest (parallel with geologic strike) and at least 500 ft to the north and south down the ridges flanks. The existing network of monitoring wells at the site show that 111TCA, 11DCA, and 11DCE are the primary compounds in the groundwater near the western disposal trench area and PCE, TCE, and 12DCE are the principal compounds in the groundwater near the eastern disposal trench area. Some constituents of the VOC plume (e.g., 11DCA and 11DCE) are probably present as a result of the degradation of 111TCA. Elongation of the VOC plume along the axis of the ridge and the distribution of plume constituents indicate primarily west-to-east groundwater flow/contaminant transport via flowpaths (e.g., bedding-plane fractures) that parallel the geologic strike of the Knox Group strata. Vertical flow/transport occurs parallel with the dip of the strata, with cross-cutting fractures facilitating contaminant migration to the north and south (Shevenell 1994). The vertical extent of the VOC plume has not been determined, but based on the existing network of monitoring wells at the site, the plume extends at least 150 ft bgs near the western disposal trenches and 270 ft bgs near the eastern disposal trenches.

As noted in Section 2.0, the summed concentrations of VOCs detected in the groundwater samples obtained with the conventional sampling method are higher than the summed VOC concentrations for samples obtained with the low-flow sampling method. As illustrated by the "paired" sampling results summarized below, this is primarily attributable to differences in the concentrations of 111TCA.

VOC	Concentration (µg/L)			
	Low-Flow Sampling May 11, 2004	**Conventional Sampling May 12, 2004**	**Low-Flow Sampling October 4, 2004**	**Conventional Sampling October 5, 2004**
111TCA	16	44	21	40
11DCA	45	67	71	72
11DCE	25	43	41	50
12DCA	2 J	.	.	.
PCE	5	6	2 J	5
TCFM	.	.	.	2 J
SummedVOCs	93	160	134	169

Less significant differences are evident between respective "paired" sampling results for 11DCA and 11DCE, and there does not appear to be any significant difference between the results for PCE. Assuming a heterogeneous mixture of dissolved VOCs in the groundwater at the well, it is not clear why the sampling method influences the concentrations of some compounds and not others. Nevertheless, these findings suggest that the VOC results reflect the apparent tendency for the conventional sampling method to induce inflow of VOC-contaminated groundwater from water-producing features that are not proximal to the well (i.e., further into the formation).

Each groundwater sample collected to date contained 111TCA, 11DCA, and 11DCE, with PCE detected in all but two of the samples (Table 2); trace levels of 12DCE (4 µg/L), TCE (1 µg/L), and TCFM (3 µg/L) were each detected in one sample. Historical data show the highest concentrations for 111TCA and 11DCA, with respective maximum values of 410 µg/L and 170 µg/L in February 1990. The preponderance of these compounds suggests that the well intercepts groundwater flow/contaminant transport pathways for VOCs that originate primarily from the western disposal trenches at the CRSP. However, the most recent (May and October 2004) sampling results show substantially lower concentrations of both compounds, with 111TCA levels substantially below the drinking water MCL (200 µg/L). Results for 11DCE show a historical maximum value of 69 µg/L (August 1991); concentrations above 50 µg/L in all but four of samples collected to date; and concentrations that substantially exceed the MCL (7 µg/L) reported for the samples collected most recently (Table 2). Although detected in most of the samples, PCE is a secondary compound compared to the other VOCs, with a historical maximum value of 12 µg/L (February 1991) and concentrations below 10 reported for all but four of the samples, including each sample collected since February 1992.

As noted previously, some of the compounds in the CRSP VOC plume are present as a result of the degradation of related parent compounds. Abiotic degradation of 111TCA, which is the only major chlorinated solvent that can be transformed chemically in groundwater under all likely conditions (McCarty 1996), probably explains the frequent detection and relatively high concentrations of 11DCA and 11DCE in the groundwater samples from well GW-612. This is clearly illustrated by a time-series plot of the proportional distribution of 111TCA, 11DCA, and 11DCE concentrations in each groundwater sample collected to date (Figure 1), whereby a substantial decrease in the relative proportion of 111TCA is accompanied by a concurrent increase in the proportions of 11DCA and 11DCE. In contrast, aside from the trace of TCE detected in the sample collected in August 1991, the groundwater samples collected to date have not contained PCE degradation products, particularly 12DCE isomers, indicating that the monitored interval for the well does not intercept groundwater flow/transport pathways where biologically mediated degradation (reductive dechlorination) of PCE occurs.

Based on analytical results reported for samples obtained with the conventional sampling method, a time-series plot of the summed concentrations of VOCs detected in each sample (excluding false positive results) shows a clearly decreasing long term trend that spans two gaps in the sampling history for the well: July 1992 – August 1996 and August 1996 – May 2004 (Figure 2). Before the first sampling gap, the VOC data show a sharply decreasing trend following the historical maximum summed VOC concentration evident for the initial sample collected from the well in February 1990 (687 µg/L), with a total reduction of about 48% though October 1990 (337 µg/L), followed by a increasing trend through August 1991 (496 µg/L) and subsequent decrease through July 1992 (266 μg/L). The relatively rapid decrease, which was probably attributable primarily to substantially reduced flux of VOCs after closure of the CRSP in 1988 and installation of the low-permeability cap in 1989, suggests that the most highly contaminated groundwater has been flushed from the flow/transport pathways intercepted by the monitored interval in the well. Subsequent sampling results show that VOC concentrations continued the downward trend through August 1996 (266 μg/L) and October 2004 (169 μg/L). Note that the overall downward trend in summed VOC concentrations encompasses: (1) a substantial decrease in the concentration of 111TCA, with the most recent sampling results being an order-of-magnitude lower than the historical maximum value (410 μg/L in February 1990); (2) an initial decrease in 11DCA concentrations that has slowed considerably, as illustrated by the results for samples collected in July 1990 (160 μg/L), July 1996 (83 μg/L), and October 2004 (72 μg/L); (3) variable but relatively unchanged concentrations of 11DCE, as illustrated by the results reported for samples collected in July 1990 (46 μg/L), August 1996 (52 μg/L), and October 2004 (50 μg/L); and (4) no significant change in the relative concentrations of PCE, as illustrated by the PCE concentrations detected in the samples collected in May 1990 (8 μg/L), April 1991 (7 μg/L), and May 2004(6 μg/L).

5.4 GROSS ALPHA ACTIVITY

Five groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (6.1 pCi/L in August 2001) being below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Three groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (5.9 pCi/L in March 2001) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-615

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during February 1990, completed with an open-hole monitored interval from 223 to 245 ft bgs, nominal 7-inch diameter steel (SF25) riser casing. The well is located in Bear Creek Valley (BCV) west of Y-12, adjacent to the south of the former S-3 Ponds. This site consists of four contiguous, unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988 and completed with an asphalt-paved parking lot. The surface impoundments were used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12. Operation of the ponds created a large mound in the water table that dissipated after the site was closed and capped, and emplaced a large, heterogeneous reservoir of inorganic, organic, and radiological contaminants in the subsurface that remains a primary source of groundwater and surface water contamination in BCV.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Sixteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain eleven samples between May 1990 and August 1992 and the low-flow sampling method used to obtain five samples between February 2000 and August 2004. The sampling history includes a quarterly sampling frequency followed by a nearly eight-year period (September 1992 – February 2000) when no samples were collected from the well, and a subsequent four-year sampling hiatus (August 2000 – March 2004).

Unusually high levels of TDS are a distinguishing characteristic of the groundwater samples from this well (see Section 4.0) and are a direct consequence of contamination associated with historical operation of the former S-3 Ponds (see Section 5.0).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the Nolichucky Shale (Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within a highly permeable zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek that traverse the Nolichucky Shale and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that stratigraphically overlies the Nolichucky Shale and subcrops along the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 9 ft bgs and exhibits minor seasonal fluctuations (<3 ft). Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-615 and the former S-3 Ponds indicate westward (strike-parallel) components of flow in Nolichucky Shale and cross-strike components of flow to the south-south west toward the Maynardville Limestone and the main channel of Bear Creek. However, as noted previously, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred strike-parallel flow directions that may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Dissolution of carbonate strata by the acidic seepage from the site also locally enhanced strata-bound groundwater flow (and contaminant transport) in directions parallel with geologic strike and dip. Moreover, present groundwater flow patterns differ substantially from those evident during the historical operations of the former S-3 Ponds, when the local mound created in the water table enabled groundwater flow to the east of the hydrologic divide near the west end of Y-12 that now separates the Bear Creek and Upper East Fork Poplar Creek drainage basins.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields moderately acidic, highly mineralized (nitrate-contaminated) sodium-bicarbonate groundwater generally characterized by:

- TDS >50,000 mg/L;
- pH of 5.8 – 6.7 (field measurements);
- extremely high concentrations of several inorganic analytes, as illustrated by the most recent (August 2004) sampling results for calcium (9,610 mg/L), sodium (2,430 mg/L), and nitrate (11,000 mg/L);
- analytical limitations associated with quantifying the very high concentrations of inorganic analytes probably explains the unacceptably high percentage difference between respective summed millequivalent concentrations of anions and cations (i.e., the ion-charge balance [CB] error exceeds 20%) determined for samples collected in April 1991 (CB = 63.8%), August 1991 (CB = 35.3%), October 1991 (CB = 22%) and May 1992 (CB = -98.4%); and
- very high total concentrations of several trace metals, notably barium (>400 mg/L) and strontium (>300 mg/L), that are several orders of magnitude above corresponding background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Aside from the very high levels of calcium, which was dissolved from the carbonate bedrock by the acid seepage from the former S-3 Ponds, and the similarly high levels of nitrate, a principal component of the wastes disposed at the site, the very high levels of sodium in the groundwater samples are consistent with the overall decrease in groundwater flux that occurs with depth in the low-permeability formations of the Conasauga Group (e.g., Nolichucky Shale) in BCV (Solomon et al. 1992). Most of the water table and shallow bedrock wells (i.e., <100 ft bgs) completed in these formations yield calcium-magnesium-bicarbonate groundwater, but a fairly abrupt change to sodium-bicarbonate groundwater occurs at a depth of about 100 ft bgs (in BCV west of Y-12). The transition to sodium-enriched geochemistry of the groundwater is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture and increased fracture spacing (Solomon et al. 1992). Sampling results suggest that the geochemistry of the groundwater samples from this well appear to reflect the impact of the nitrate-enriched, acidic seepage from the S-3 Ponds on the sodium-bicarbonate groundwater at depth in the Nolichucky Shale.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, all of these principal contaminants are present in the groundwater at this well.

5.1 NITRATE

Nitrate concentrations reported for each groundwater sample collected to date, including results considered qualitative because of ion charge-balance errors, exceed 1,000 mg/L, with concentration above 10,000 mg/L reported for each sample collected since March 1992 (Table 1). The source of the nitrate is the contaminant plume emplaced in the Nolichucky Shale during historical operations of the former S-3 Ponds. Nitrate is a primary component of the plume, is chemically stable and mobile in groundwater, and effectively traces the groundwater transport pathways followed by other similarly mobile components of the contaminant plume (e.g., Tc-99). Based on the existing network of monitoring wells in the Nolichucky Shale west of the former S-3 Ponds, the extent of elevated nitrate concentrations (i.e., >10 mg/L) in the groundwater suggest: (1) transport/migration in the unconsolidated zone (water table interval) directly south toward the headwaters of Bear Creek; (2) westward transport/migration via shallow (<30 ft bgs) strike-parallel flowpaths (i.e., bedding-plane fractures) that terminate in the northern tributaries of Bear Creek located about 1,500 ft (NT-1) and 2,500 ft (NT-2) west of the former S-3 Ponds; (3) downward vertical migration driven by the greater density of the highly mineralized and acidic wastewater and the hydraulic head created by site operations; and (4) substantially slower migration via much longer and less permeable strike-parallel flowpaths deeper in the bedrock, with upward hydraulic gradients promoting upwelling of nitrate-contaminated groundwater into the shallow flow system near NT-1 and NT-2 (DOE 1997). Nitrate results reported for groundwater samples from this well are representative of concentrations within the strike- and dip-parallel flowpaths at depth in the Nolichucky Shale.

Excluding the qualitative nitrate results noted in Section 4.0, nitrate concentrations reported for the groundwater samples range from just under 8,000 mg/L in October 1990 to almost 15,000 mg/L in June 2000, with the most recent results (March and August 2004) being 11,000 mg/L (Table 1). These results reflect a generally indeterminate long-term concentration trend (Figure 1), skewed slightly upward by the nitrate concentration "spike" evident in August 2000 (14,700 mg/L). The indeterminate trend suggests minimal long-term change in the overall flux of nitrate along the (low-permeability) groundwater flow/transport pathways intercepted by the monitored interval in the well, which seems a little unusual considering that wastewater disposal at the former S-3 Ponds ceased more than 20 years ago and is probably a function of the low permeability of the flowpaths at depth in the Nolichucky Shale. In comparison, much lower nitrate concentrations are evident in groundwater from wells completed at shallower depths in the Nolichucky Shale, where ambient recharge/discharge cycles more rapidly flush nitrate and other similarly mobile contaminants from the more highly permeable flowpaths in the shallow flow system (DOE 1997).

5.2 URANIUM

All but one of the groundwater samples collected to date contained total uranium concentrations at least an order-of-magnitude higher than the drinking water MCL for uranium (0.03 mg/L), with the one non-detect result reported for the sample collected in August 2000 being an obvious outlier and likely analytical artifact (Table 1). As noted previously, the acidic groundwater in the Nolichucky Shale near the former S-3 Ponds contains elevated concentrations of numerous trace metals, some that were entrained in the acidic wastewater disposed at the site (e.g., uranium) and others that were dissolved from carbonate minerals in the underlying bedrock (e.g., barium). The uranium in the acidic groundwater near the site probably occurs as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble complexes with a variety of inorganic anions (Fetter 1993). Thus, the distribution of elevated uranium concentrations in the Nolichucky Shale near the former S-3 Ponds is confined largely to the low-pH groundwater within approximately 500 ft of the site (DOE 1997). Additionally, the very high concentrations of uranium at depth in the Nolichucky Shale beneath the site reflect the downward, density- and head-driven movement of the highly mineralized, uranium-bearing wastewater, rather than vertical advective groundwater transport of the uranyl cations/complexes.

Excluding the suspected outlier result noted above, the uranium concentrations reported for the groundwater samples collected to date reflect a clearly increasing long-term trend (Figure 2), with results for the most recent samples (March and August 2004) being above 1 mg/L and at least 35% higher than the previous maximum concentration (0.877 mg/L in August 1992). The significance of this increasing uranium concentration trend, which spans significant gaps in the sampling history for the well (see Section 2.0), is not clear from the available data, but the trend potentially reflects a corresponding increase in the relative flux of uranium via the groundwater flow/transport pathways intercepted by the monitored interval in the well. However, increasing flux of uranium seems conspicuous considering that the disposal of wastewater at the former S-3 Ponds ceased more than 20 years ago and that similarly increasing flux of other contaminants, particularly nitrate, is not indicated by the historical data. Maybe the increasing flux of uranium corresponds with a temporal increase in the relative amount of uranium (and uranium isotopes) entrained in the wastewater disposed at the site.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected to date: acetone, bromomethane, carbon disulfide, chloromethane, methylene chloride (MC), PCE, and 2-butanone (Table 2). These compounds are components of the contaminant plume originating from the former S-3 Ponds, but are typically present at substantially lower concentrations compared to other components of the plume (e.g., nitrate). This is because chlorinated solvents and other organic chemical were not extensively disposed at the site, with total volumes of organic wastes being substantially less than that of the inorganic wastes disposed at the site. Sampling results obtained to date are representative of dissolved VOC concentrations in the groundwater flow/transport pathways at depth in the Nolichucky Shale beneath the former S-3 Ponds. As with other contaminants in the groundwater at this well, the presence of dissolved VOCs reflects the downward, hydraulic head and density-driven movement of compounds entrained in the highly mineralized wastewater disposed at the site, rather than the vertical (advective) transport in the groundwater (DOE 1997). Note also that the historical maximum concentrations of each compound detected in the samples collected to date are relatively low (<250 μg/L) and do not suggest the presence of DNAPL in the subsurface near this well.

Based on the frequency of detection and relative concentrations, acetone and MC are the primary VOCs in the groundwater samples (Table 2). All but two of the samples collected through August 1992 contained acetone concentrations above 100 μg/L, although only a trace of acetone (2 μg/L) was detected in only one of the samples collected between February 2000 and August 2004. The sharply lower acetone concentrations follow the long-gap in the sampling history for the well (see Section 2.0) and coincide with the change to the low-flow sampling method. Conversely, although acetone and MC have similar solubility and mobility in groundwater, MC was detected at much lower concentrations that do not show any obvious difference coincident with the long sampling gap and/or the change in the sampling method. Aside from acetone and MC, other VOCs were detected only in six samples collected to date (Table 2), with the highest concentrations reported for bromomethane (29 μg/L), 2-butanone (27 μg/L), and chloromethane (15 μg/L). The apparently sporadic detection of these VOCs, some of which may be analytical artifacts, does not appear to be significant with respect to the groundwater migration/transport of contaminants from the former S-3 Ponds.

A time-series plot of the summed concentrations of VOCs detected in the groundwater samples collected to date spans the gaps in the sampling history for the well (see Section 2.0) and shows a clearly decreasing long-term trend (Figure 3). This decreasing trend is directly attributable to the sharply lower concentrations of acetone that follow a nearly 8-year gap in the sampling history and coincide with the change to the low-flow sampling method. However, MC concentrations have changed little over time, as illustrated by the MC results reported for the samples collected in July 1990 (6 μg/L), May 1992 (5 μg/L), and August 2004 (6 μg/L). Moreover, coincident changes (decrease or increase) in the concentrations of other contaminants (nitrate and uranium) are not evident. Thus, the lower acetone concentrations do not seem to be directly attributable to the change to the low flow sampling method. Also, assuming a heterogeneous mixture of acetone and MC (and other contaminants) in the groundwater, the similar solubility/mobility of these compounds suggests that the divergent concentration trends may not be attributable to differential advective migration/transport (flux) via the groundwater flowpaths intercepted by the monitored interval in the well. Perhaps the substantially lower concentrations of acetone reflect a corresponding decrease in the relative flux of acetone that is in some way related to the waste disposal history for the former S-3 Ponds. For example, the volume of acetone-bearing wastes disposed at the site may have decreased over time, while the amount of wastes containing MC remained more constant. Alternatively, the geochemical characteristics of the groundwater may more effectively (and selectively) degrade acetone relative to the other chlorinated hydrocarbons in the groundwater.

5.4 GROSS ALPHA ACTIVITY

Twelve groundwater samples collected to date were analyzed for gross alpha activity and results above the applicable MDA and corresponding CE were reported for all but four of these samples (Table 3), with all but four of these results substantially exceeding the MCL for gross alpha activity (15 pCi/L). Additionally, nine of the samples collected to date were analyzed for uranium isotopes and the analytical results show maximum U-234 and U-238 activities above 150 pCi/L and 350 pCi/L, respectively (Table 1). Note that there is no clear or consistent correlation between the isotopic uranium activities and gross alpha activity reported for corresponding samples (Table 3), probably because of analytical interferences associated with the very high TDS of the samples. The uranium isotopes, like total uranium, are probably present in the acidic groundwater as uranyl cations that were transported at depth in the Nolichucky Shale primarily as a consequence of the downward, density-driven vertical migration of the highly mineralized wastewater from the former S-3 Ponds (DOE 1997).

5.5 GROSS BETA ACTIVITY

Twelve groundwater samples collected to date were analyzed for gross beta activity and results above the applicable MDA and corresponding CE were reported for all but three of these samples (Table 3), and all of these results are at least an order of magnitude higher than the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the MCL for gross beta activity). Although uranium isotopes and related daughter products contribute to the levels of gross beta activity, the primary beta-particle emitting radionuclide in the groundwater near the former S-3 Ponds is Tc-99, which is a "signature" component of the contaminant plume from this site (the only site to have received wastes that contained Tc-99) that is highly mobile in groundwater. Six of the samples collected to date were analyzed for Tc-99 and the results are fairly ambiguous (Table 3). The Tc-99 concentrations were below the respective CE reported for samples collected in August and October 1991, yet very high Tc-99 concentrations reported for the samples collected in May 1992 (6,650 pCi/L), which exceeds the SDWA screening level for a 4 mrem/yr dose equivalent from Tc-99 (3,470 pCi/L), and August 1992 (2,840 pCi/L). Substantially lower Tc-99 concentrations were reported for the samples collected in March (41 pCi/L) and August 2004 (38 pCi/L). Additionally, there is no clear or consistent correlation between Tc-99 concentrations and gross beta activity reported for corresponding samples (Table 3), probably because of analytical interferences associated with the very high TDS of the samples.

WELL GW-616

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during March 1990, completed with an open-hole monitored interval from 219 to 269 ft bgs, and constructed with nominal 7-inch diameter steel (SF25) riser casing. The well is located in Bear Creek Valley (BCV) west of Y-12, on the south side of Bear Creek approximately 350 ft southwest of the former S-3 Ponds (hereafter referenced as the S-3 Site). Located near the western end of Y-12, directly north of the headwaters of Bear Creek, the S-3 Site encompasses four contiguous, above-grade, unlined surface impoundments, each with a surface area of approximately 400 x 400 ft and an average total depth of approximately 15 ft. The ponds were used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12, and were closed in 1988 in accordance with requirements of the RCRA regulations applicable to hazardous waste landfills. Closure of the site was completed in 1989 and included the neutralization and removal of liquid wastes and stabilization of neutralization sludge remaining in each pond, which were then filled with crushed limestone and covered with a multilayer low-permeability cap (completed with an asphalt-paved parking lot). Historical operation of the S-3 Site emplaced a heterogeneous mixture of inorganic, organic, and radiological contaminants in the subsurface that remains a primary source of groundwater and surface water contamination in BCV.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fourteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain ten samples between May 1990 and September 1992 and the low-flow sampling method used to obtain four samples between March 2001 and August 2005. The sampling history includes a quarterly sampling frequency followed by a nearly nine-year period (September 1992 – March 2001) when no samples were collected from the well.

Unusually high levels of TDS are a distinguishing characteristic of the groundwater samples from this well (see Section 4.0) and are a direct consequence of contamination associated with historical operation of the former S-3 Site.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the intermediate bedrock interval in the Nolichucky Shale (Conasauga Group), which trends northeast-southwest along the northern slope of BCV, dips to the southeast at an angle of 45º - 55º, and is bordered on the southeast by the overlying Maynardville Limestone, a highly permeable karst aquifer that provides the principal pathway for subsurface contaminant migration in BCV. (Note that the well is located within the outcrop area of the Maynardville Limestone). The bulk of the groundwater flow in the Nolichucky Shale occurs in a highly permeable zone (the water table interval) that occurs near the transition between unconsolidated material (residuum and weathered bedrock). Also, it is suspected that the highly acidic wastes from the S-3 Site dissolved carbonate strata interbedded within the Nolichucky Shale and greatly enhanced the relative permeability of these strata-bound flowpaths within several hundred feet of the site.

Groundwater flow in the water table interval in the Nolichucky Shale is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek, which traverse the Nolichucky Shale from northeast to southwest throughout BCV west of Y-12 and are numbered in ascending order downstream from the headwaters of the creek. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals

(shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone.

The static water level in the well occurs at an average depth of about 8 ft bgs and exhibits minor (<3 ft) seasonal fluctuations. The direction(s) of groundwater flow near the well, as indicated by groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for nearby monitoring wells, is primarily westward, parallel with geologic strike of bedding in Nolichucky Shale, with cross-strike components of flow to the south-south west toward the Maynardville Limestone and the main channel of Bear Creek. Also, dissolution of carbonate strata by acidic seepage during historical operation of the S-3 Site locally enhanced strata-bound groundwater flow/contaminant transport in directions parallel with geologic strike and dip. Moreover, present groundwater flow patterns differ substantially from those evident during the historical operations of the former S-3 Site, when the local mound created in the water table enabled groundwater flow to the east of the hydrologic divide near the west end of Y-12 that now separates the Bear Creek and Upper East Fork Poplar Creek drainage basins.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the (unfiltered) groundwater samples collected to date show that the well yields nitrate-contaminated sodium-bicarbonate groundwater generally characterized by:

- TDS of 1,422 – 2,066 mg/L;
- pH of 9 – 9.95 (field measurements);
- low molar proportions of calcium, magnesium, and potassium, chloride, and sulfate (<5% of total anions /cations);
- high concentrations of sodium (>500 mg/L) and nitrate (>200 mg/L); and
- total concentrations of trace metals (except uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Although dominated by the high concentrations of nitrate, which is a primary component of the contaminant plume emplaced during historical operation of the S-3 Site, the sodium-bicarbonate geochemistry of the groundwater from this well is consistent with other wells completed at similar depths in the Nolichucky Shale west of Y-12 and is believed to reflect the overall decrease in groundwater flux that occurs with depth in the low-permeability formations of the Conasauga Group in BCV (Solomon et al. 1992). Most of the water table and shallow bedrock wells (i.e., <100 ft bgs) completed in these formations yield calcium-magnesium-bicarbonate groundwater, but a fairly abrupt change to sodium-bicarbonate groundwater occurs at a depth of about 100 ft bgs (in BCV west of Y-12). The transition to sodium-enriched geochemistry of the groundwater is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture and increased fracture spacing (Solomon et al. 1992). Note that the high levels of TDS may cause analytical interferences for some laboratory analytes, including gross alpha activity and gross beta activity.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. Based on the results reported for the groundwater samples collected to date, nitrate is the principal contaminant present in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected to date had nitrate concentrations above the drinking water MCL for nitrate (10 mg/L) and, as shown in the following data summary, all of the results exceed 200 mg/L, including the most recent sampling results (March and August 2005). Nitrate is the principal component of the contaminant plume emplaced during historical operations of the S-3 Site. Chemically stable and mobile in groundwater, nitrate is believed to effectively trace the groundwater transport pathways followed by other similarly mobile components of the contaminant plume (DOE 1997). Additionally, the greater density of the highly mineralized acidic wastewater disposed at the site promoted density-driven vertical migration via strike- and dip-parallel flowpaths in the Nolichucky Shale.

Sampling Date	Nitrate (mg/L)

07/27/91	240
10/07/91	222
03/23/92	291
05/15/92	260
09/08/92	320
03/27/01	277
08/09/01	265
03/29/05	228
08/23/05	265
MCL	**10**
Note: [ ] = qualitative result because of ion charge balance error	

As shown in the above data summary, only two of the nitrate results exceed 400 mg/L and the these results are considered to be qualitative because of the ion charge balance error (i.e., the percent difference between respective summed milliequivalent concentrations of the major cations and anions exceeds 20%). The bulk of the remaining results are less than 250 mg/L, with the historical minimum value of 202 mg/L in May 1990. Also, unlike nitrate concentrations in groundwater from other wells near the S-3 Site that monitor more permeable flowpaths at shallower depths in the Nolichucky Shale, the levels of nitrate in the groundwater from this well do not exhibit clearly seasonal fluctuations. Indeed, a time-series plot of the nitrate results is dominated by the long gap in the sampling history for the well, but shows a fairly indeterminate concentration trend (Figure 1), as illustrated by the similar concentrations of nitrate detected in the groundwater samples collected in April 1991 (246 mg/L), August 2001 (265 mg/L), and August 2005 (265 mg/L). This trend does not reflect any clear response to the closure or capping of the S-3 Site and suggests minimal change in the relative flux of nitrate via the low-permeability flowpaths at depth in the Nolichucky Shale down-dip of the S-3 Site.

5.2 URANIUM

Thirteen groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.012 mg/L in September 2005) being below the MCL for uranium (0.03 mg/L). In light of the relatively high levels of nitrate in the groundwater from this well, the low levels of uranium seem somewhat conspicuous because, as noted previously, uranium was entrained in the wastewaters disposed at the S-3 Site. The uranium in the acidic seepage probably occurred as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble complexes with a variety of inorganic anions (Fetter 1993). Consequently, elevated concentrations of uranium are generally restricted to the acidic groundwater in the Nolichucky Shale within approximately 500 ft of the site (DOE 1987). Moreover, the basic pH and low REDOX of the groundwater from this well (e.g., field measurements in August 2005 show pH = 9.84 and REDOX = -26 mV) indicate reducing geochemical conditions that, in the presence of reduced species of iron (total iron = 1.1 mg/L in August 2005), promote removal of uranium from solution (Fetter 1993).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, no VOCs have been detected in the groundwater samples collected from the well to date.

5.4 GROSS ALPHA ACTIVITY

Low levels of gross alpha activity slightly above the applicable MDA and corresponding CE were reported for the samples collected in April 1991 (6.4 pCi/L) and October 1991 (7.24 pCi/L), both being less than the MCL for gross alpha activity (15 pCi/L). Uranium isotopes are the most abundant alpha-particle emitting radionuclides in the contaminant plume emplaced during historical operation of the S-3 Site and the low (background) levels of gross alpha activity in the groundwater from this well reflect a corresponding lack of uranium isotopes in the Nolichucky Shale down-dip of the site. The migration/transport of uranium isotopes are greatly restricted by the geochemical factors described in Section 5.2.

5.5 GROSS BETA ACTIVITY

Four groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, including one value (211 pCi/L in May 1992) that exceeds the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity), but is a suspected outlier compared to the other results. Also, none of groundwater samples collected since May 1992 had gross beta activity above the applicable MDA and corresponding CE.

As with the low levels of gross alpha activity, the lack of elevated gross beta activity in the groundwater samples seems conspicuous in light of the elevated nitrate levels, especially considering that Tc-99, a beta-particle emitting radionuclide, is a “signature” component of the contaminant plume emplace during historical operation of the S-3 Site (the former S-3 Ponds were the only site at Y-12 that received wastes containing Tc-99). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-) which is soluble and highly mobile in groundwater (Gee et al. 1983). Consequently, the distribution of Tc-99 in the shallow groundwater flow system in the Nolichucky Shale downgradient of the S-3 Site, as indicated by the extent of elevated gross beta activity (>50 pCi/L) defined by the network of wells to the south and west (and east) of the site, closely mirrors that of nitrate from the site, which is also highly mobile in groundwater. However, with the low levels of gross beta activity indicating a corresponding lack of Tc-99, it appears that the reducing geochemistry of the groundwater, which promotes removal of uranium (and uranium isotopes) from solution as noted in Section 5.2, likewise similarly inhibits the transport/migration of Tc-99 in the groundwater at depth in the Nolichucky Shale.

WELL GW-618

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in March 1990, completed with a screened monitored interval from 26 to 37 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-617 and is located in the southwestern Y-12 area, east of Bldg. 9720-13 and the Former Roofing Waste Pile (FRWP), which was used from mid-1986 to mid-1987 as a temporary storage area for mercury-contaminated roofing waste materials generated at Y-12. No releases of contaminants from the FRWP have been documented and the site is not considered a likely source of groundwater contamination (DOE 1998).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-one groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 27 samples between May 1990 and May 1997, and the low-flow sampling method used to obtain four samples between November 1997 and October 2003.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Conasauga Group (Maynardville Limestone). Presampling depth-to-water measurements for the well show that the static groundwater level in the well occurs at an average depth of about 11 ft bgs and exhibits minor (<5 ft) seasonal fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- moderate TDS (>300 mg/L);
- pH (field measurements) of 5.9 – 7.1;
- relatively high sodium concentrations (>15 mg/L) compared to other wells completed at similar depths in the Maynardville Limestone
- low molar proportions of chloride, potassium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Also, as illustrated by the most recent monitoring data summarized in Table 1, several indicator parameters suggest that the geochemical conditions in groundwater at this well are conducive to the biotic degradation of chlorinated hydrocarbons, which may account for the presence of some of the dissolved VOCs in the well (see Section 5.3).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the respective monitoring data reported for the 38 groundwater samples collected from the well since January 1991, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Nitrate concentrations above the analytical reporting limit were reported for all but two of the groundwater samples, one of which was not analyzed for nitrate. The historical maximum nitrate concentration (4.89 mg/L in April 1991) is less than the MCL for nitrate (10 mg/L). Although the nitrate concentrations in samples from this well are below the MCL, they exceed the applicable UTL (2.7 mg/L) and most likely reflect low-level nitrate contamination from one or more upgradient source areas. Nitrate is chemically stable and highly mobile in groundwater and is believed to effectively trace the primary groundwater flow and contaminant transport pathways in the Maynardville Limestone. Known sources of nitrate that are hydraulically upgradient of this well include the contaminant plumes emplaced during historical operations of the S-3 Ponds (1951-1984) and the S-2 Site (1943-1951). The S-3 Ponds, former unlined surface impoundments used primarily for the disposal of nitric acid wastes generated at Y-12, are covered with a multilayer low-permeability cap (and asphalt parking lot) constructed during RCRA closure of the site in 1988. Operation of the former S-3 Ponds emplaced a heterogeneous plume of inorganic, organic, and radiological contaminants in the Nolichucky Shale west-northwest of the well. Nitrate is a principal component of the plume and it enters the Maynardville Limestone upgradient of the well via inflow of contaminated groundwater from the Nolichucky Shale and from the buried tributaries of UEFPC that channel contaminants into the Maynardville Limestone (DOE 1998). The groundwater system in the Maynardville Limestone west-southwest of the well also received nitrate and other inorganic, organic, and radiological contaminants during historical operations of the S-2 Site, which is an unlined waste site excavated into the lower slope of Chestnut Ridge that received an unknown volume of corrosive and toxic aqueous wastes.

5.2 URANIUM

Five groundwater samples had uranium concentrations at or above the applicable analytical reporting limit, with the highest concentration (0.001 mg/L) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, each groundwater sample contained one or more of the following VOCs: acetone, ethylbenzene, PCE, TCE, c12DCE, t12DCE, and VC. These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and UEFPC watersheds. In the UEFPC watershed east of the flow divide, which occurs near the west end of Y-12, the VOC plume appears to originate near the Fire Training Facility in the southwestern section of Y-12, extends eastward (parallel with geologic strike) and mixes with VOCs released from several sources within Y-12, including the S-2 Site, and enters Union Valley east of the ORR boundary along Scarboro Road (DOE 1998).

The primary VOCs in the groundwater samples are PCE, TCE, and 12DCE; each compound was detected in all but one of the groundwater samples, with respective historical maximum concentrations above 60 μg/L for 12DCE and 40 μg/L for PCE and TCE. In contrast, VC was detected in less than half (18 of 38) of the samples, and acetone and ethylbenzene were detected in one sample each (both results are probably analytical artifacts). Based on the analytical results reported for the samples collected since May 1997, c12DCE is the primary 12DCE isomer, with the most recent monitoring data showing c12DCE concentrations substantially below the MCL (70 μg/L). The most recent monitoring data also show that PCE levels fluctuate above and below the MCL (5 μg/L), with concentrations of TCE remaining above the MCL (5 μg/L). Although VC has been detected much more sporadically than PCE, TCE, or 12DCE (Table 2), all but one of the results equals or exceeds the MCL (2 μg/L), including the concentration detected in the most recent sample. Additionally, some of these VOCs, particularly c12DCE, t12DCE, and VC, are probably present as a natural consequence of the biologically mediated degradation (reductive dechlorination) of PCE and TCE in the groundwater (Chapelle 1996). As noted in Section 4.0, several indicator parameters suggest that the geochemical conditions in groundwater at this well (particularly the low dissolved oxygen and negative REDOX) are conducive to the biotic degradation of these VOCs.

A time-series plot of the summed concentrations of VOCs detected in each groundwater sample shows a temporally variable but generally decreasing long-term concentration trend (Figure 1). Summed VOC concentrations determined from conventional sampling show substantial temporal fluctuations, with the highest concentrations typically evident in samples obtained during seasonally high groundwater flow conditions (winter and spring). The low-flow sampling results for VOCs exhibit less temporal variability, with the highest concentrations typically reported for the samples obtained during seasonally low-flow conditions (summer and fall). Additionally, decreasing concentration trends are not evident for all of the VOCs, as illustrated by the VC concentrations reported for the groundwater samples collected in January 1992 (2 μg/L) and October 2003 (3 μg/L). The overall decrease in VOC concentrations probably reflects a combination of reduced flux from the source area(s) and the cumulative effects of natural attenuation processes, including biotic degradation. However, it is not clear from the available data if the cyclical changes in VOC concentrations are significant with respect to the relative flux of dissolved VOCs along the groundwater flow/transport pathways intercepted by the monitored interval in this well, or if the apparent change in the pattern of cyclical concentration peaks is related in some way to the change from conventional sampling to low-flow sampling.

5.4 GROSS ALPHA ACTIVITY

Six groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (4.99 pCi/L in April 1992) being less than the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Twenty groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (37.6 pCi/L in April 1992) being less than the SDWA screening level for gross beta activity (50 pCi/L). However, the historical maximum value for gross beta activity may be an outlier because only one other result exceeds 10 pCi/L.

WELL GW-620

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in March 1990, completed with a screened monitored interval from 61.7 to 75 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-619 and is located in Bear Creek Valley (BCV) in the southwestern section of Y-12, about 100 ft east of the Fire Training Facility (FTF).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-four groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 27 samples between May 1990 and May 1997, and the low-flow sampling method used to obtain 17 samples between December 1997 and October 2004.

Groundwater samples from the well exhibit conspicuous geochemical characteristics that may be attributable to localized contamination from cement grout circulated into the bedrock during installation/construction of the well (see Section 4.0).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Maynardville Limestone (upper Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements for the well show that the static groundwater level in the well typically occurs at an average depth of about 23 ft bgs and exhibits substantial (>25 ft) seasonal fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-620 indicate components of flow to the north/northeast toward the UEFPC drainage system and to the east parallel with geologic strike in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields chemically distinctive calcium-carbonate groundwater characterized by:

- TDS 51 – 558 mg/L, excluding an outlier (20,056 mg/L) in April 1991;
- pH (field measurements) of 7.6 – 12.3 (>11.5 in six samples collected since October 1999);
- unusually low bicarbonate (<1 mg/L);
- unusually high concentrations of potassium (>10 mg/L);
- nitrate concentrations above 1 mg/L;
- low molar proportions of chloride, magnesium, and sodium (<10% of total anions/cations), although the percent difference (error) between respective summed milequivalent concentrations of anions and cations typically (in more than half of the samples) exceeds 20% (negatively and positively); and

- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The atypical geochemistry of the groundwater samples from this well may reflect contamination from cement grout circulated into the bedrock during its installation. Unlike other wells at Y-12 that experienced grout contamination, however, the geochemical characteristics of the groundwater samples have not improved over time, as illustrated by the ion charge balance error (24.3 %) evident for the most recent sample (October 2004).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the respective monitoring data reported for the groundwater samples collected from the well since January 1991, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Thirty-nine of the groundwater samples were analyzed for nitrate and concentrations at or above the applicable analytical reporting limit were reported for all of the samples, with the highest value (7.042 mg/L in May 1998) being less than the drinking water MCL for nitrate (10 mg/L). However, the historical maximum value may be an outlier because all but five of the remaining nitrate results are less than 2 mg/L.

5.2 URANIUM

Uranium concentrations at or above the applicable analytical reporting limit were reported for the groundwater samples collected in September 1993 (0.001 mg/L), May 1995 (0.0012 mg/L), and September 1995 (0.00051 mg/L); these results are substantially below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples (Table 1): acetone, chloroethane, total xylene, PCE, TCE, toluene, 11DCE, 12DCA, 12DCE (isomers), and 111TCA. These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and UEFPC watersheds. In the UEFPC watershed east of the flow divide, which occurs near the west end of Y-12, the VOC plume appears to originate near the FTF in the southwestern section of Y-12, extends eastward (parallel with geologic strike) and mixes with VOCs released from several sources in the central and eastern Y-12 areas, and enters Union Valley east of the ORR boundary along Scarboro Road (DOE 1998).

The primary VOCs in the groundwater samples are PCE, TCE, and 12DCE, which were detected in all but eight of the groundwater samples, with historical maximum concentrations above 1,000 μg/L for 12DCE (total), 900 μg/L for PCE, and 300 μg/L for TCE (Table 1). The most recent monitoring data show that the concentrations of each compound, except for one PCE result (6 μg/L in October 2004), are below respective drinking water MCLs. Other VOCs were detected infrequently and have substantially lower historical maximum concentrations (<100 μg/L). Also, it appears that the 12DCA and 12DCE (total) results reported for the sample collected in October 1991 were juxtaposed, with the likely 12DCE result (1,100 μg/L) reported for 12DCA and the likely 12DCA result (<5 μg/L) reported for 12DCE (see Table 1).

A time-series plot of the summed concentrations of VOCs detected in each groundwater sample, excluding the suspect 12DCA result reported for the sample collected in October 1991, show a clearly decreasing long-term concentration trend (Figure 1). The overall trend also exhibits cyclic concentration fluctuations that appear to have changed over time and may be related in some way to the groundwater sampling method. Summed concentrations of VOCs detected in the samples obtained with the conventional sampling method (May 1990 – May 1997) are typically highest during seasonally low flow conditions (summer and fall). Conversely, the summed concentrations of VOCs detected in the samples obtained with the low-flow sampling method (December 1997 – October 2003) show more distinctive cyclical fluctuations, with higher concentrations typically evident during seasonally high flow conditions (winter and spring).

5.4 GROSS ALPHA ACTIVITY

Eight groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (10 pCi/L in October 2003) being less than the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Thirty-one groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (39.3 pCi/L in January 1992) being slightly below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). The elevated levels of gross beta activity may be related to the elevated potassium concentrations in the grout-contaminated groundwater samples from the well (see Section 4.0). Potassium-40 (K-40) is a beta-emitting isotope and, based on the natural ratio of K-40 to total K (K-40 = 0.0119% total K; Brownlow 1979), should be present in the groundwater samples. The elevated potassium (and gross beta activity) may be related to fire suppressants (e.g., "Blue K") used to extinguish fires at the nearby Fire Training Facility.

WELL GW-624

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in January 1990, completed with a screened monitored interval from 14.4 to 27.2 ft bgs; and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-625 and is located in Bear Creek Valley (BCV) west of Y-12, approximately 150 ft directly south of the southwestern-most section of the Bear Creek Burial Grounds (BCBG) waste management area (WMA), near a northern tributary (NT) of Bear Creek that trends northeast-southwest across the central section of the WMA. The BCBG includes numerous hazardous and nonhazardous waste disposal units that received a mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. Liquid wastes included oils, machine coolants, and borax waste water, all or most of which may have contained varying amounts of radioisotopes (primarily uranium isotopes). In 1989, most of the waste-disposal units in the BCBG waste-management area were covered with multi-layer, low-permeability caps installed during RCRA closure of the site.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Eleven groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain seven samples between June 1990 and October 2005, and the low-flow sampling method used to obtain four samples between June 1998 and October 2005. The sampling history includes an initial quarterly sampling frequency followed by two prolonged (7-year) periods (June 1991 – June 1998 and July 1998 – June 2005) when no samples were collected from the well.

An evaluation of the monitoring data available through December 2004 indicated potential bias related to the groundwater sampling method: samples obtained with the conventional sampling method before June 1998 had substantially lower contaminant (VOC) concentrations than samples subsequently obtained with the low-flow sampling method. However, results of “paired” sampling performed during June and October 2005, when groundwater samples were collected with the low-flow sampling method one day and the conventional sampling method the next day, do not confirm the suspected sampling-method bias. As illustrated by the data summarized in Table 1, groundwater samples obtained with each sampling method have similar geochemical characteristics and the VOC results are inconclusive. For example, the summed concentration of VOCs detected in the sample collected with the low-flow method in June 2005 is approximately 5% higher than the summed concentration of VOCs detected in the sample collected the next day with the conventional sampling method, whereas the reverse is evident from the sampling results obtained in October 2005, with the summed VOC concentrations for the low-flow method being more than 20% lower than evident in the sample obtained with the conventional sampling method. In the absence of more conclusive indications of bias attributable to the sampling method, the difference between the historical conventional sampling VOC data and the more recent low-flow sampling results for VOCs may conservatively be attributable to an overall increase in VOC concentrations over the long term (see Section 5.3).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Nolichucky Shale (the Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within this highly permeable zone, which occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek that traverse the Nolichucky Shale and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that stratigraphically overlies the Nolichucky Shale and subcrops along the axis of BCV and the main channel of Bear Creek.

Depth-to-water measurements obtained for hydrologic monitoring and groundwater sampling purposes show that the static groundwater level in the well typically occurs at an average depth of about 9 ft bgs and exhibit seasonal fluctuations of about 5 ft. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-624 indicate south and southwesterly flow toward the Maynardville Limestone and the main channel of Bear Creek. However, groundwater flow in the Nolichucky Shale is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Consequently, the direction(s) of groundwater flow in the vicinity of well GW-624 may be primarily eastward (parallel with geologic strike) toward discharge areas in NT-7, the main channel of which is less than 50 ft east of the well.

As noted in previously, well GW-624 is paired with well GW-625, which is completed with a an open-hole interval from 231.5 – 283 ft in the Nolichucky Shale. However, none of the depth to water measurements for these wells are contemporaneous and, consequently, are not suitable for determining the vertical hydraulic gradient indicated by respective groundwater elevations in each well.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples collected to date show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 198 – 358 mg/L;
- pH (field measurements) of 7 – 7.4;
- moderately negative REDOX (e.g., -92 mV in October 2005);
- low molar proportions of chloride, sulfate, potassium, and sodium (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Groundwater samples from the well appear to be characterized by slightly elevated chloride concentrations (e.g., 18.1 mg/L in October 2005) relative to much lower levels (<2 mg/L) typical of groundwater samples from other wells in BCV that are completed at similarly shallow depths (<30 ft bgs) in the Nolichucky Shale. It is possible the chloride concentrations reflect localized geochemical characteristics. Also, because the groundwater contains chlorinated hydrocarbons (see Section 5.3), the elevated levels also may be at least partially attributable to the biologically mediated degradation of these compounds, which often results in the accumulation of inorganic chloride (Hinchee et al. 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

No groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

Eight groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.008 mg/L in December 1990) being substantially below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected to date (Table 2): PCE, TCE, c12DCE, t12DCE, 11DCE, VC, 11DCA, 12DCA, 111TCA, benzene, CTET, chloroethane, chloroform, MC, TCFM, and 1,1,2-trichloro-1,2,2-trifluoroethane, which is also known as Freon-113. Waste disposal areas within Burial Ground A (North and South), which received about two million gallons of waste oils and coolants, are the most likely source of the plume of dissolved VOCs in the shallow groundwater at this well (DOE 1997). Waste disposal trenches in this area, particularly Burial Ground A-South, also are the suspected source of DNAPL (primarily PCE and TCE) that was encountered more at than 300 ft bgs in a well installed directly south (down-dip) of this area (Haase and King 1990).

The primary VOCs in the groundwater samples are PCE, TCE, c12DCE, and VC, each of which has a historical maximum concentration above 500 µg/L (Table 2). Moreover, the most recent sampling results (June and October 2005) show that the concentrations of each of these VOCs remain about two orders-of-magnitude higher than their respective drinking water MCLs. Secondary compounds in the groundwater samples are 11DCE and 11DCA, which have historical maximum values above 100 µg/L and were detected in each sample collected to date, with the most recent results showing 11DCE concentrations more than an order-of-magnitude higher than the MCL (7 µg/L). Most of the other VOCs were detected in samples collected the most recently, and only the maximum concentration of benzene (33 µg/L in July 1998) exceeds the applicable MCL (Table 2). Additionally, as noted in Section 2.0, the results obtained from "paired" sampling in June and October 2005 show that the VOC concentrations in the groundwater samples from the well do not show any clear bias attributable to the sampling method. This is illustrated by the VOC results summarized below, which do not display any consistent difference that appears to correlate in any way with the groundwater sampling method.

VOC	Concentration (µg/L)			
	Low-Flow Sampling June 15, 2005	**Conventional Sampling June 16, 2005**	**Low-Flow Sampling October 11, 2005**	**Conventional Sampling October 12, 2005**
PCE	310	280	420	550
TCE	380	320	410	500
c12DCE	1,600	1,600	2,100	2,500
t12DCE	5 J	4 J	6	7
11DCE	98	94	120	130
VC	220	190	240	380
111TCA	5 J	8	11	11
12DCA	.	7	.	.
11DCA	130	120	170	180
CTET	2 J	2 J	2 J	1 J
Chloroform	16	15	23	23
Benzene	19	19	24	25
Freon-113	13	12	22	20
TCFM	19	19	25	26
Note: "." = Not detected; J = Estimated value below laboratory reporting limit				

Many of the VOCs in the groundwater samples, particularly c12DCE and VC, are probably present in the groundwater as a consequence of biotic degradation (sequential dechlorination) of related parent compounds (PCE and TCE) which, as noted in Section 2.0, also may account for the elevated chloride levels typical of the samples. Also, the dissolved petroleum hydrocarbons (benzene) in the groundwater may serve as electron donors for biotic dechlorination of PCE and related compounds (Chapelle 1996). However, the VOC results do not show concentration trends potentially indicative of biotic degradation, such as decreasing concentrations of parent compounds (e.g., PCE) and concurrently increasing concentrations of degradation daughter products (e.g., c12DCE). Nevertheless, results for several indicator parameters, suggest that the geochemical conditions in the groundwater at this well are within the optimum range for biotic degradation of chlorinated hydrocarbons, although the REDOX conditions do not suggest the strongly reducing (methanongenic) conditions necessary to transform VC to chloroethane (Chapelle 1996), which may explain why the VC concentrations in the shallow groundwater at this well remain very high relative to the MCL (2 µg/L). It is possible that the monitored interval in the well intercepts groundwater flowpaths for VOCs transported from source areas deeper in the flow system (e.g., DNAPL) where geochemical conditions may be more amenable to biotic degradation.

The presence of benzene is a distinguishing characteristic of the VOC data for this well. Indeed, a review of the historical data indicates that, excluding benzene results for wells located in areas of Y-12 known to be impacted by historical releases from petroleum fuel underground storage tanks (USTs) and benzene results for other wells (and springs) that are obvious outliers compared to available data for the sampling location, benzene concentrations above the drinking water MCL (5 µg/L) have been reported only for the groundwater samples from the following wells, all of which are located within the BCBG WMA.

Well No.	Depth (ft bgs)	Benzene Concentration (µg/L) / Sampling Date			
		Maximum		Most Recent	
GW-014	13.2	180	11/05/87	4	10/19/05
GW-046	20.3	240	07/09/03	72	07/07/05
GW-068	83.6	51	10/18/05	51	10/18/05
GW-071	219	1,300	06/30/05	1,200	10/20/05
GW-082	34.4	99	08/07/03	ND	10/13/05
GW-117	530	6	11/13/87	ND	09/17/92
GW-118	575	67	11/19/88	1	10/10/93
GW-119	510	20	07/06/88	ND	09/17/92
GW-624	27.2	33	07/15/98	25	10/12/05

Of these, well GW-082 is located on the southwest side of Burial Grounds C-West, and all of the remaining wells are located near Burial Ground A-South: wells GW-014, GW-071, and GW-119 along the eastern boundary; wells GW-117 and GW-118 along the southern boundary; and wells GW-046, GW-068, and GW-624 near the western boundary. Note also the wide range in the total depth of these wells, particularly wells GW-117, GW-118, and GW-119, each of which is artesian. The apparent “clustering” of these wells suggest that benzene is a distinguishing component of the groundwater plume of dissolved VOCs originating from the waste disposal trenches in Burial Ground-A South.

A time-series plot of the summed concentrations of VOCs detected in the groundwater samples encompasses the gaps in the sampling history for the well (June 1991 – June 1998 and July 1998 – June 2005) and shows an indeterminate or possibly decreasing long-term concentration trend (Figure 1). Also, results for several individual compounds show such wide temporal variability that evaluation of the long-term trend seems too subjectively influenced by selection of the start date for the trend. For example, the concentrations of PCE and TCE indicated by the conventional sampling results from June 1990 (570 µg/L and 550 µg/L, respectively) and October 2005 (550 µg/L and 500 µg/L, respectively) suggest an indeterminate long-term trend, whereas a clearly decreasing trend for both compounds is indicated when the October 2005 results are compared to the PCE and TCE concentrations evident in September 1990 (790 µg/L and 690 µg/L, respectively).

5.4 GROSS ALPHA ACTIVITY

Four groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (3.89 pCi/L in June 1990) being substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Five groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, with the highest value (8.57 pCi/L in December 1990) being below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-626

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in December 1989, completed with a screened monitored interval from 63 to 78 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-627, and is located in Bear Creek Valley (BCV) west of Y-12, directly west of the southwest corner of the Bear Creek Burial Grounds (BCBG) waste management area (WMA). The BCBG includes numerous hazardous and nonhazardous waste disposal units that received a mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. Liquid wastes included oils, machine coolants, and borax waste water, all or most of which may have contained varying amounts of radioisotopes (primarily uranium isotopes). In 1989, most of the waste-disposal units in the BCBG waste-management area were covered with multi-layer, low-permeability caps installed during RCRA closure of the site.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-four groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 18 samples between February 1990 and October 2005, and the low-flow sampling method used to obtain six samples between June 1998 and October 2005. The sampling history includes an initial period of quarterly sampling (February 1990 and October 1993), with subsequent sampling performed semiannually in 1998, 2002, and 2005.

An evaluation of the monitoring data available through December 2004 indicated potential bias related to the groundwater sampling method: samples obtained with the conventional sampling method before June 1998 had lower contaminant (VOC) concentrations than samples subsequently obtained with the low-flow sampling method. Thus, it was not clear if the change in sampling method explained the apparent increase in VOC concentrations or if the higher concentrations are the result of a corresponding increase in the relative flux of VOCs along the flowpaths intercepted by the monitored interval in the well. Results of "paired" sampling performed during June and October 2005, when groundwater samples were collected with the low-flow sampling method one day and the conventional sampling method the next day, do not confirm sampling-method bias. As illustrated by the data summarized in Table 1, groundwater samples obtained with each sampling method have similar geochemical characteristics and the VOC results are inconclusive. For example, the summed concentration of VOCs detected in the sample collected with the low-flow method in June 2005 (81 µg/L) is approximately 50% lower than the summed concentration of VOCs detected in the sample collected the next day with the conventional sampling method (191 µg/L), whereas the sampling results obtained in October 2005 show the summed VOC concentrations for the low-flow method (351 µg/L) being about 20% higher than evident in the sample obtained with the conventional sampling method (290 µg/L). In the absence of more conclusive indications of bias attributable to the sampling method, the difference between the historical conventional sampling and the more recent low-flow sampling results for VOCs may be conservatively assumed to reflect an overall increase in VOC concentrations over the long term (see Section 5.3).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow (<100 ft bgs) bedrock interval in the Nolichucky Shale (the Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within the water table interval, which is a highly permeable zone that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek that traverse the Nolichucky Shale and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that stratigraphically overlies the Nolichucky Shale and subcrops along the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements for the well show that the static groundwater level in the well typically occurs at an average depth of about 24 ft bgs and exhibits seasonal fluctuations of about 7 ft. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-626 indicate south and southeasterly flow toward the Maynardville Limestone and the main channel of Bear Creek. However, groundwater flow in the Nolichucky Shale is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

As noted previously, well GW-626 is paired with well GW-627, which is completed with a open-hole interval at significantly greater depth (250 ft bgs). Depth-to-water measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in well GW-626 are typically lower than evident in well GW-627. Based on the distance between the monitored interval midpoint (elevation) in each well (191.06), these respective groundwater elevations indicate upward vertical hydraulic gradients (0.021 –0.005) from the intermediate depth bedrock interval (GW-627) to the shallow bedrock interval (GW-626).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples collected to date show that the well yields calcium-bicarbonate groundwater generally characterized by:

- TDS of 104 – 349 mg/L;
- pH (field measurements) of 7.28 – 8.9;
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- unusually low concentrations of magnesium (<5 mg/L);
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Four groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.113 mg/L in October 2005) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Two groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.004 mg/L in August 1993) being an order-of-magnitude below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected to date (Table 2): acetone, benzene, bromodichloromethane (BCDM), CTET, chloroethane, chloroform, ethylbenzene, freon-113 (F113), MC, PCE, toluene, TCE, TCFM, VC, xylenes, 11DCA, 12DCA, 11DCE, c12DCE, t12DCE, 4-methyl-2-pentanone (4M2P), 111TCA, 112TCA, and 1,1,2-trichloro-1,2,2-trifluoroethane, which is also known as Freon-113 (F-113). Waste disposal areas within Burial Ground A (North and South), which received about two million gallons of waste oils and coolants, are the most likely source of the plume of dissolved VOCs in the shallow groundwater at this well (DOE 1997). Waste disposal trenches in Burial Ground A-South also are the suspected source of DNAPL (primarily PCE and TCE) that was encountered more than 300 ft bgs in a well installed directly south (down-dip) the area (Haase and King 1990).

The primary VOCs in the groundwater samples are PCE, TCE, and c12DCE, each of which have a historical maximum concentration above 800 µg/L (Table 2), although the value for c12DCE (7,213 µg/L) appears to be an outlier compared to subsequent results for c12DCE and historical data for total 12DCE. Additionally, the most recent sampling results (June and October 2005) show that the concentrations of these VOCs remain above their drinking water MCLs (5 µg/L, 5 µg/L, and 70 µg/L, respectively). Secondary compounds in the groundwater samples are 11DCE, 11DCA, and 11TCA, at least one of which was detected in all but one of the samples collected to date. However, the historical maximum concentrations for 11DCE (340 µg/L in December 1991), 11DCA (290 µg/L in February 2002), and 111TCA (290 µg/L in December 1991) appear to be outliners compared to the other data for each compound (Table 2). Aside from the primary and secondary VOCs, the remaining compounds were detected infrequently, mostly in samples collected since February 2002. Excluding a few outlier results (e.g., 1,200 µg/L for VC in February 2002), few concentrations of these VOCs exceed 100 µg/L (the majority are less than 10 µg/L), and the most recent results show concentrations below MCLs for applicable compounds.

As noted in Section 2.0, the results of “paired” sampling performed in June and October 2005 show that the VOC concentrations in the groundwater samples from the well do not exhibit any bias attributable to the sampling method. This is clearly illustrated by the VOC results summarized below, which do not exhibit any consistent difference that appears to correlate with the groundwater sampling method.

VOC	Concentration (µg/L)			
	Low-Flow Sampling June 15, 2005	Conventional Sampling June 16, 2005	Low-Flow Sampling October 11, 2005	Conventional Sampling October 12, 2005
PCE	13	24	71	49
TCE	9	20	47	34
c12DCE	54	130	200	180
11DCE	2 J	4 J	7	5
VC	.	.	.	1 J
111TCA	.	2 J	2 J	2 J
12DCA	.	1 J	2 J	1 J
11DCA	3 J	8	11	10
Chloroform	.	2 J	7	4 J
F-113	.	.	4 J	4 J
Note: "." = Not detected; J = Estimated value below laboratory reporting limit				

Some of the VOCs in the groundwater samples, particularly c12DCE, are probably present in the groundwater as a consequence of biologically-mediated degradation (sequential dechlorination) of related parent compounds (PCE and TCE). Also, the dissolved petroleum hydrocarbons in the groundwater may serve as electron donors for biotic dechlorination of PCE and related compounds (Chapelle 1996). However, the VOC results do not show concentration trends potentially indicative of biotic degradation, such as concurrently decreasing and increasing trends, respectively, for parent compounds (e.g., PCE) and degradation daughter products (e.g., c12DCE). Also, results for several indicator parameters suggest that the geochemical conditions in the groundwater at this well are not especially conducive to biotic degradation of chlorinated hydrocarbons. It is possible that the monitored interval in the well intercepts groundwater flowpaths for VOCs transported from source areas deeper in the flow system (e.g., DNAPL) where geochemical conditions may be more amenable to biotic degradation.

A time-series plot of the summed concentrations of VOCs detected in the groundwater samples collected to date not only encompasses several extended periods when samples were not collected from the well (October 1993 – June 1998; July 1998 – February 2002; and July 2002 – June 2005), but is largely dominated by the historical maximum summed VOC concentration (10,838 µg/L) evident in February 2002. Excluding the February 2002 outlier (Figure 1), which is attributable to a very high concentration of c12DCE (7,213 µg/L), a plot of the summed VOC concentrations shows a widely variable but increasing trend between June 1990 (12.6 µg/L) and December 1991 (2,792 µg/L) followed by an equally variable but decreasing trend though August 1993 (348 µg/L), with the more recent sampling results suggesting a subsequent indeterminate concentration trend through October 2005 (351 µg/L). These results suggest that there has not been any substantial overall change in the relative flux of dissolved VOCs via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

Two of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (1.82 pCi/L in March 1991) being substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Nine groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, with the highest value (25.9 pCi/L in March 1992) being below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). However, this result is a suspected outlier because all other gross beta results are less than 7 pCi/L.

WELL GW-627

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in December 1989; completed with an open-hole monitored interval from 254 to 270 ft bgs; and completed with nominal 7-inch diameter steel (SF25) riser casing. The well is located in the central part of the Bear Creek Burial Grounds (BCBG) waste management area. The BCBG includes numerous hazardous and nonhazardous waste disposal units that received a mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. Liquid wastes included oils, machine coolants, and borax waste water, all or most of which may have contained varying amounts of radioisotopes (primarily uranium isotopes). In 1989, the waste-disposal units in the BCBG waste-management area were covered with multi-layer, low-permeability caps installed during RCRA closure of the site.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-six groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 30 samples between February 1990 and August 2000, and the low-flow sampling method used to obtain 16 samples between March 1998 and August 2004.

An evaluation of the monitoring data available through August 2000 indicated potential bias related to the groundwater sampling method: (unfiltered) samples obtained with the conventional sampling method had substantially lower contaminant (VOC) concentrations than samples obtained with the low-flow sampling method (AJA 2001). Results of "paired sampling" performed during February and October 2000, when groundwater samples were collected with the low-flow sampling method one day and the conventional sampling method the next day, confirm the apparent sampling-method bias. As shown by the data summarized in Table 1, groundwater samples obtained with each sampling method have similar geochemical characteristics (aside from the less strongly negative REDOX evident for the samples obtained with the conventional sampling method), but the samples obtained with the low-flow method have substantially higher VOC concentrations.

Inherent differences in the manner in which each sampling method induces inflow of groundwater into the well may explain the disparity between the conventional and low-flow sampling results for VOCs. Conventional sampling involves purging up to three well volumes of groundwater from the well at about 1-2 gallons per minute, which may substantially lower the water level in the well and induce inflow from water-producing features (i.e., fractures, cavities, conduits) that may not contribute to well recharge under normal conditions. In contrast, low-flow sampling involves purging the well at flow rate low enough (<300 milliliters per minute) to ensure minimal water-level drawdown in the well (<1 ft per quarter hour), which induces groundwater inflow only from the water-producing feature(s) proximal to the monitored interval. Thus, the conventional sampling method has much greater local hydrologic influence (particularly in directions parallel with geologic strike) and substantially increases the relative inflow of clean groundwater into the well, and effectively dilutes the VOC concentrations.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the intermediate bedrock interval in the Nolichucky Shale (the Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within this highly permeable zone, which occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek that traverse the Nolichucky Shale and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1%

of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that stratigraphically overlies the Nolichucky Shale and subcrops along the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements for the well show that the static groundwater level in the well typically occurs at an average depth of about 21 ft bgs and exhibit seasonal fluctuations up to 6 ft. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-627 indicate south and southeasterly flow toward the Maynardville Limestone and the main channel of Bear Creek. However, groundwater flow in the Nolichucky Shale is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Consequently, the direction(s) of groundwater flow in the vicinity of well GW-627 may be primarily westward (parallel with geologic strike) toward discharge areas in a northern tributary of Bear Creek (NT-7) that traverses the west-central section of the BCBG waste management area approximately 300 ft east of the well.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields mineralized, chloride-enriched, sodium-bicarbonate groundwater generally characterized by:

- TDS of 650 – 803 mg/L;
- pH (field measurements) of 8.6 – 11.0;
- unusually high concentrations of chloride (>40 mg/L), carbonate (>50 mg/L), and fluoride concentrations (>5 mg/L);
- low molar proportions of calcium, magnesium, potassium and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

These geochemical characteristics reflect the decrease in groundwater flux that occurs with depth in the low-permeability Conasauga Group formations (e.g., Nolichucky Shale) in BCV (Solomon et al. 1992). Most of the water table and shallow (i.e., <100 ft bgs) bedrock wells in these formations yield calcium-magnesium-bicarbonate groundwater. A fairly abrupt change to sodium-bicarbonate groundwater occurs at a depth of about 100 ft bgs and is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture or increased fracture spacing (Solomon et al. 1992). Further reduced groundwater flux deeper in the bedrock is indicated by a general increase in TDS and a gradational transition from sodium-bicarbonate groundwater to sodium-chloride groundwater.

Elevated chloride levels in the groundwater samples from this well potentially reflect natural geochemical conditions or contamination from inorganic wastes disposed at the BCBG. Additionally, the groundwater in the well contains a mixture of dissolved chlorinated hydrocarbons (see Section 5.3) and elevated chloride concentrations may be a consequence of the biologically mediated degradation (dechlorination) of these compounds (Hinchee et al. 1995). As illustrated by the recent monitoring data summarized in Table 2, most of the geochemical characteristics of the groundwater (particularly the REDOX conditions) appear to be conducive to biotic degradation of VOCs.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the respective monitoring data reported for the groundwater samples collected from the well since January 1991, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Only the nitrate concentration reported for the groundwater sample collected in July 1993 (0.2 mg/L) exceeds applicable analytical reporting limit and this results is substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Five groundwater samples had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.001 mg/L) being an order-of-magnitude below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples (Table 3): acetone, chloroethane, PCE, TCE, toluene, 11DCA, 11DCE, c12DCE and t12DCE. Waste disposal areas within BG-A (North and South), which received about two million gallons of waste oils and coolants, are the most likely source of the plume of dissolved VOCs in the shallow groundwater at this well (DOE 1997). Moreover, PCE and TCE were first detected in the groundwater sample collected in June 1990 following the January 1990 discovery of a free-phase mixture of PCE and TCE (DNAPL) in the Nolichucky Shale at a depth of 260 to 330 ft down dip of BG-A South (Haase and King 1990). The presence of the dissolved VOCs in the groundwater at this well reflects their westward transport from the DNAPL via strike-parallel flowpaths in the Nolichucky Shale more than 250 ft bgs VOCs (DOE 1997).

The primary VOCs in the groundwater samples are PCE, TCE, and 11DCA, each of which was detected in all but four of the samples (Table 3). Historical maximum concentrations exceed 500 µg/L for PCE, 200 µg/L for TCE, and 50 µg/L for 11DCA, with the most recent monitoring data showing that the concentrations of PCE and TCE remain substantially above respective drinking water MCLs (Table 3). Secondary compounds in the samples are 11DCE, 12DCE (c12DCE and t12DCE) and VC. These VOCs have been detected primarily in the groundwater samples obtained with the low-flow sampling method (12DCE was not detected in any of the samples obtained with the conventional sampling method), with historical maximum concentrations below 40 µg/L, and the most recent monitoring results showing VC and 11DCE concentrations remain above respective MCLs (Table 3). Acetone, chloroethane, and toluene have been detected the least frequently (four samples or less). Also, as noted in Section 2.0 and illustrated by the data summarized in Table 4, VOC concentrations detected in samples obtained with the conventional method are substantially lower than the corresponding VOC concentrations detected in samples obtained with the low flow method.

The time-series plots of the summed concentrations of VOCs detected in the groundwater samples (Figure 1) show increasing long-term concentration trends obtained with the conventional sampling method (Figure 2) and low-flow sampling method (Figure 3). For example, the low-flow sampling data show that the concentration of PCE (and other VOCs) increased by an order-of-magnitude between June 1998 (51 μg/L) and February 2000 (500 μg/L), dropped sharply in August 2000 (340 μg/L), which may be an artifact of the consecutive daily low-flow/conventional sampling (see Section 2.0), and again steadily increased through August 2004 (830 μg/L). Also, the primary and secondary VOCs in the samples exhibit concurrently increasing concentration trends, which suggest an overall increase in the advective flux of VOCs via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity above the applicable MDA and corresponding CE was reported for the groundwater samples collected in September 1991 (3.41 pCi/L), June 1995 (4.26 pCi/L), and July 2002 (19 pCi/L). The latter result exceeds the drinking water MCL for gross alpha activity (15 pCi/L), but is an outlier compared to the other gross alpha results.

5.5 GROSS BETA ACTIVITY

Eight groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (22 pCi/L in September 1996) being below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-631

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in May 1990, completed with a screened monitored interval from 4 to 16 ft bgs, and constructed with 4.5-inch diameter PVC riser casing and well screen (0.01 slot). The well is located in Bear Creek Valley, at the Rust Garage Area near the west end of Y-12, about 650 ft directly east of the former S-3 Ponds, a major source of groundwater contamination at Y-12 that was closed and capped in accordance with a RCRA closure plan in 1988. The S-3 Ponds consisted of four unlined and contiguous surface impoundments that were used from 1951 to 1984 primarily for percolation/evaporation of nitric acid effluent (with depleted uranium in solution) discharged into the ponds via a pipeline (the Abandoned Nitric Acid Pipeline) connected to process buildings in the central Y-12 area. Operation of the site emplaced a heterogeneous plume of inorganic, organic, and radiological contaminants into the Conasauga Group (Nolichucky Shale) and created a mound in the water table (which dissipated after disposal of wastes in the ponds ceased) that enabled transport/migration of contaminants into areas that now lie east of the hydrologic divide separating the Bear Creek and Upper East Fork Poplar Creek watersheds. Additionally, operation of the Rust Garage Area emplaced a dissolved plume of petroleum hydrocarbons in the shallow groundwater that intermingled with the contaminant plume originating from the former S-3 Ponds.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Sixteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 14 samples between March 1991 and March 1994, and the low-flow sampling method used to obtain samples in May and October 2003.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water interval in the Conasauga Group (Nolichucky Shale). The average static groundwater level in the well is 7 ft below ground surface. Note that the large monitored (screened) interval in the well is intended to straddle the water table during seasonally high and low flow conditions and facilitate detection of light non-aqueous phase liquids (LNAPL). Presampling depth-to-water measurements for the well indicate moderate fluctuations (<4 ft) in seasonal groundwater surface elevations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- low to moderate TDS (<150 mg/L <300 mg/L);
- pH (field measurements) of 3.9 – 5;
- unexpectedly low nitrate concentrations (<15 mg/L) considering the location of the well relative to the former S-3 Ponds;
- unusually low concentrations of calcium (<20 mg/L) and magnesium (<10 mg/L) along with unusually high chloride (>50 mg/L) and sodium (>15 mg/L); and
- total (unfiltered sample) concentrations of several trace metals, notably manganese (>2 mg/L) and strontium (>50 mg/L), that exceed the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion, which is based on the analytical results reported for five groundwater samples collected from the well since January 1991.

5.1 NITRATE

Each groundwater sample had nitrate concentrations above the analytical reporting limit, with concentrations above the MCL for nitrate (10 mg/L) evident in November 1992 (13.4 mg/L) and June 1993 (14 mg/L). However, nitrate concentrations below 1 mg/L were reported for the samples collected most recently (May and October 2003). Considering the location of the well relative to the former S-3 Ponds, the low nitrate levels in the shallow groundwater at the well are somewhat unexpected, particularly considering the nitrate levels evident in other nearby wells, such as wells GW-107 (nitrate >100 mg/L), GW-108 (nitrate >15,000 mg/L), and GW-109 (nitrate >10,000 mg/L), which form a cluster less than 200 ft southeast of well GW-631. It is not clear from the available data why the nitrate levels in the groundwater at this well are so low.

5.2 URANIUM

Two groundwater samples had uranium concentrations at the applicable analytical reporting limit (0.001 mg/L in June 1991 and March 1992) and substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

One or more of the following VOCs were detected in each groundwater sample collected from the well before CY 2003: PCE, TCE, 12DCE, 11DCA, chloromethane, methylene chloride, benzene, ethylbenzene, toluene, and xylene (BTEX). The historical maximum concentrations of PCE (38 µg/L in December 1991) and benzene (12 µg/L in March 1991) exceed the respective MCLs (both 5 µg/L). A time-series plot of the summed concentration of VOCs shows a clearly decreasing trend that spans a nine-year gap in the sampling history (Figure 1). No VOCs were detected in the samples collected from the well in May and October 2003.

5.4 GROSS ALPHA ACTIVITY

Nine groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (5.2 pCi/L in May 1993) being less than the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Eight groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (12 pCi/L in March 1994) being less than the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-633

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during May 1990, completed with a screened monitored interval from 3.5 to 15 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and well screen (0.01 slot). Note that the proportionately long (11.5 ft) monitored interval for the well is intended to straddle the water table and facilitate the detection of immiscible petroleum products. The well is located in Bear Creek Valley (BCV) near the west end of Y-12, at the Rust Garage (RG) about 700 ft southeast of the former S-3 Ponds. The RG once housed several petroleum fuel underground storage tanks (USTs) and associated service lines and dispenser, a fuel unloading station, and drum storage area for used oil (DOE 1998). Located directly west of the RG, the former S-3 Ponds were four unlined surface impoundments that were used from 1951 to 1984 primarily for the percolation/evaporation of nitric acid effluent (with depleted uranium in solution) piped from process buildings in the central section of Y-12. Each pond contains several feet of sludge produced during the neutralization of the liquid wastes prior to RCRA closure of the site in 1988, when the ponds were filled with aggregate and covered with a multilayer low-permeability cap (including an asphalt-paved parking lot).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-five groundwater samples have been collected from the well, with the conventional sampling method used to obtain 17 samples between March 1991 and October 2003, and the low-flow sampling method used to obtain eight samples between June 2000 and October 2004. Note that the sampling history spans a six-year period (March 1994 – June 2000) when samples were not collected from the well.

An evaluation of the monitoring data available through August 2000 indicated potential bias related to the groundwater sampling method: (unfiltered) samples obtained with the conventional sampling method had substantially higher nitrate concentrations and lower VOC concentrations and gross beta activities than samples obtained with the low-flow sampling method (AJA 2001). However, as illustrated by the data summarized in Table 1, the results of "paired sampling" performed during May and October 2003, when groundwater samples were collected with the low-flow sampling method one day and the conventional sampling method the next day, do not confirm the sampling-method bias. Thus, the significant difference between the historical conventional sampling results and the more recent low-flow sampling results probably reflect a corresponding change in contaminant flux at some time during the six-year gap (March 1994 to June 2000) in the sampling history for the well.

Very high total dissolved solids (TDS) and acidic pH are distinguishing characteristics of the groundwater samples from this well and are a direct consequence of contamination emplaced during the historical operation of the former S-3 Ponds (see Section 5.0).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Nolichucky Shale (Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within a highly permeable zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 3 ft bgs and exhibits moderate (<5 ft) seasonal fluctuations. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-633 indicate southeasterly flow toward the Maynardville Limestone and the Upper East Fork Poplar Creek (UEFPC) drainage system. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and original main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred flow in directions that parallel geologic strike (i.e., bedding-plane fractures), which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 4,316 – 33,798 mg/L, excluding an outlier (1,326 mg/L) in November 1993;
- pH of 5.1 – 5.84 (field measurements), excluding an outlier (9) in November 1993;
- high concentrations (>1,000 mg/L) of nitrate and calcium;
- low molar proportions of chloride, potassium, and sulfate (<10% of total anions/cations);
- various causes (low ion concentrations and/or elevated detection limits) of an unacceptably high relative percent difference (RPD) between respective summed millequivalent concentrations of anions and cations (i.e., the ion-charge balance error exceeds 20%) determined for samples collected June 1991 (RPD = -70.2%), September 1991 (RPD = 23.4%), August 1992 (RPD = -24%), November 1993 (RPD = -62.9%), and March 1994 (RPD = 40.9%); and
- elevated total concentrations of several trace metals, particularly barium (>8 mg/L) and strontium (>4 mg/L), that substantially exceed the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on respective monitoring data reported for the 21 groundwater samples collected from the well since March 1991, the principal contaminants present in the groundwater at this well are nitrate, VOCs, and gross beta activity.

5.1 NITRATE

Each groundwater sample contained nitrate concentrations of at least 800 mg/L, with concentrations above 1,000 mg/L reported for all but two of the samples (Table 1). The source of the nitrate is the former S-3 Ponds, the operation of which emplaced a heterogeneous mixture of inorganic, organic, and radiological contaminants in the Nolichucky Shale and created a mound in the water table that facilitated contaminant transport/migration east of the hydrologic divide separating the Bear Creek and UEFPC watersheds. Nitrate and other inorganic contaminants within the plume (e.g., uranium) were principal components of the wastes disposed at the site, but some of the inorganic contaminants (e.g., barium and strontium) were dissolved from bedrock minerals. With concentrations in excess of 10,000 mg/L, nitrate is the primary inorganic contaminant in the plume. Based on the network of existing monitoring wells completed in the Nolichucky Shale east of the former S-3 Ponds, elevated nitrate concentrations (i.e., >10 mg/L) extend laterally at least 5,000 ft eastward (parallel with geologic strike) and vertically (parallel with geologic dip) at least 150 ft bgs. The distribution of nitrate in the groundwater is believed to reflect: (1) relatively rapid transport/migration via shallow groundwater flow/transport pathways (<30 ft bgs) which terminate in buried storm drains and utilities, building basement sumps, and the buried northern tributaries and original mainstem of UEFPC within 1,000 ft of the former S-3 Ponds; and (2) substantially slower migration deeper in the bedrock via much longer strike-parallel groundwater flow/transport pathways (e.g., bedding-plane fractures), possibly bound to a relatively narrow band near the middle of the Nolichucky Shale, toward basement sumps in Bldgs. 9204-4, 9201-5, 9201-4, and 9204-2 (DOE 1998).

Excluding the nitrate results that are considered qualitative because of ion charge-balance errors determined for the applicable groundwater samples (see Section 4.0), all of the samples had nitrate concentrations exceed 1,000 mg/L (Table 2), including the samples collected most recently (May and October 2004). Nevertheless, the nitrate concentrations detected in the samples obtained with the low-flow sampling method since May 2003 (1,390 mg/L) are the lowest ever reported for the well and are substantially below the historical maximum value (5,501 mg/L in September 1993). These results illustrate the clearly decreasing long-term concentration trend shown by a time-series plot of the nitrate data (Figure 1), which spans a 6-year gap (March 1994 – June 2000) in the sampling history for the well. Decreasing concentrations of nitrate (and other inorganic contaminants) in the shallow groundwater at this well suggest that the center of mass of the S-3 Ponds contaminant plume in the Nolichucky Shale east of the site currently lies along geologic strike to the east of the well (DOE 1998).

Excluding the nitrate results for groundwater samples with unacceptable ion charge-balance errors (see Section 4.0), a times-series plot of the nitrate concentrations shows two trend lines separated by gap in the sampling history (Figure 1). Both trends reflect decreasing nitrate concentrations and show substantial temporal variability. The decreasing concentration trends are consistent with continued eastward migration of the center of mass of the S-3 Ponds contaminant plume (DOE 1998), although this seems an unlikely explanation for the wide temporal concentration changes. Additionally, there is not any consistent relationship between seasonal flow conditions and temporal fluctuations in nitrate concentrations, with temporal "peak" concentrations reported for samples collected during both seasonally high and low groundwater flow conditions (Figure 1).

5.2 URANIUM

Total uranium concentrations at or above the applicable analytical reporting limits were detected in all of the groundwater samples (Table 1), although the historical maximum concentration (0.011 mg/L in March 1994) is less than the MCL (0.03 mg/L). However, the historical maximum value appears to be an outlier compared to the other uranium results, all of which are less than the uranium UTL (0.005 mg/L) applicable to this well (HSW 1996). As noted previously, uranium (and uranium isotopes) was entrained in the nitric-acid wastes disposed at the former S-3 Ponds and is a primary component of the contaminant plume originating from the site. Assuming a heterogeneous mixture of nitrate and uranium within the contaminant plume, the combination of relatively low uranium levels with very high nitrate concentrations seems conspicuous, especially considering that the acidic pH of the groundwater (see Section 4.0) would be expected to accommodate uranium species (uranyl cations) known to form mobile complexes in groundwater (Fetter 1993). Nevertheless, other nearby wells at the RG (e.g., wells GW-505 and GW-631) also yield groundwater samples with similarly low uranium concentrations. This suggests that local geochemical conditions may selectively enhance the relative attenuation of uranium compared to that of nitrate.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample (Table 3): benzene, bromoform, chloroform (CLF), dimethylbenzene (DMB), ethylbenzene, methylene chloride (MC), PCE, styrene, toluene, TCE, 11DCE, and 12DCE (c12DCE). Although some of these compounds (e.g., PCE) are confirmed components of the contaminant plume originating from the former S-3 Ponds, others (e.g., benzene) are not, and their presence in the groundwater at well GW-633 indicates transport/migration from other potential sources of VOCs, including former petroleum fuel underground storage tanks at the RG that are known local sources of the petroleum hydrocarbons in the shallow groundwater (DOE 1998).

Based on frequency of detection and relative concentrations, the primary VOCs in the groundwater samples are benzene and PCE, both of which were detected in all of the samples (Table 3), with the most recent sampling results (May and October 2004) showing benzene concentrations above 850 µg/L and PCE concentrations at or above 200 µg/L. Secondary VOCs in the samples are CLF, MC, TCE, and toluene, each of which was detected (excluding false positive results) in all but six of the samples (Table 3), with the most recent sampling results showing TCE and toluene concentrations above respective MCLs (5 µg/L). The remaining VOCs have been more consistently and frequently detected in samples collected since June 2000 and show a wide range of concentrations, including estimated values below 5 µg/L for several compounds (e.g., 11DCE) and dimethylbenzene concentrations above 100 µg/L (Table 3).

As illustrated by the data summarized below, the concentrations of some of the VOCs in the groundwater samples, notably PCE and benzene, have increased substantially since the early 1990s, whereas the concentrations of other compounds in the samples, including TCE and 12DCE (total), have not.

VOC	Concentration (µg/L)							
	March 1991	March 1992	March 1993	March 1994	June 2000	April 2002	May 2003	May 2004
PCE	70	91	60	57	200	180	290	240
TCE	8	11	7	4 J	9	8	8	8
12DCE	2 J	.	3 J	.	7	10	9	14
Chloroform	FP	40	24	12	26	20	18	18
MC	18	FP	18	FP	35	36	30	28
Benzene	3 J	3 J	6	6	650	840	1,200	1,300
Toluene	3 J	3 J	3 J	5	150	4 J	6	3 J
DMB	5	.	1 J	.	250	110	130	140
Note: "." = Not detected; J = Estimated value below analytical reporting limit								

It is not clear from the available data why individual compounds exhibit such divergent long-term concentration trends. Results from "paired" sampling during May and October 2003 (see Section 2.0) suggest that the divergent trends probably are not artifacts of the change from conventional sampling to low-flow sampling. Likewise, the divergent concentrations trends are probably not sampling and/or analytical artifacts. Assuming the groundwater contains a generally heterogeneous mixture of dissolved VOCs, differential advective flux (different transport rates for different compounds) in the shallow flow system also seems unlikely.

A time-series plot of summed VOCs in samples from the well shows an increase in VOC concentrations that spans a six-year time gap in the sampling history of the well (Figure 2). Although originally interpreted as a potential artifact of the change in sampling methods (see Section 2.0), this significant increase in VOC concentrations probably reflects increased contaminant flux from the S-3 Site contaminant plume and the RG.

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity reported for nine groundwater samples exceed the MDA and corresponding CE (Table 2), and all but two of these results exceed the MCL for gross alpha activity (15 pCi/L). However, none of the samples collected since April 2002 had gross alpha activity above the MDA, although the apparent lack of gross alpha activity may be an artifact of the elevated MDAs (e.g., MDA = 290 pCi/L in October 2003). The high MDAs reflect the analytical interferences caused the very high TDS in the (unfiltered) samples. Nevertheless, available data do not indicate the presence of alpha particle-emitting isotopes in the groundwater at this well; five samples were analyzed for uranium isotopes, with U-234 and U-235 values that exceed the corresponding MDA and CE reported only for the sample collected in December 1991 (U-234 = 246 pCi/L and U-238 = 287 pCi/L).

5.5 GROSS BETA ACTIVITY

Each groundwater sample had gross beta activity above the MDA and corresponding CE (Table 2), with the most recent sampling results (May and October 2004) showing values above 2,000 pCi/L, which is several orders-of-magnitude higher than the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the MCL for gross beta activity). The primary source of the gross beta activity is Tc-99, which is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds (the only site at Y-12 to receive wastes containing Tc-99). As shown in the following data summary, Tc-99 was detected (i.e., > MDA and CE) at very high concentrations in five of the seven samples that were analyzed for Tc-99.

Sampling Date	Tc-99 (pCi/L)	Gross Beta Activity (pCi/L)
09/19/91	<CE	852
12/14/91	27,200	584
04/30/92	7,920	441
08/14/92	2,740	512
11/04/92	<CE	40
06/08/00	6,600	6,100
10/24/00	7,500	4,100

The Tc-99 results substantially exceed the SDWA screening level (3,790 pCi/L) for a 4 mrem/yr dose equivalent from Tc-99. Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-) which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in Nolichucky Shale east of the former S-3 Ponds, the extent of elevated (>50 pCi/L) gross beta activity in the groundwater suggests that the distribution of Tc-99 closely mirrors that of nitrate (see Section 5.1). Accordingly, the sampling results for well GW-633 are representative of gross beta/Tc-99 activity at shallow depths in relatively short groundwater flow/transport pathways that terminate in buried storm drains and utilities, building basement sumps, and the buried northern tributaries and original mainstem of UEFPC (DOE 1998).

Aside from the unusually low levels of gross beta activity reported for the groundwater samples collected in November 1992 (40 pCi/L), March 1993 (75.6 pCi/L), and November 1993 (43.8 pCi/L), which are all outliers compared to the other results (Table 2), the remaining samples had gross beta activity ranging between 261 pCi/L (March 1994) and 6,100 pCi/L (June 2000). Also, gross beta activity above 2,000 pCi/L was reported for each sample collected since June 2000, whereas all the samples collected before then had gross beta activity below 1,000 pCi/L. Moreover, the results of "paired" sampling in May and October 2003 suggest that the difference in gross beta activity is not an artifact of the groundwater sampling method (see Section 2.0). Thus, the higher levels of gross beta activity potentially reflect a significant increase in the relative flux of Tc-99 along the groundwater flow/transport pathways intercepted by the monitored interval in the well.

Excluding the suspected outliers noted above, a times-series plot of the other results for gross beta activity shows two trend lines separated by the six-year gap in the sampling history for the well (Figure 3). Data obtained before the sampling gap define an indeterminate trend and the data obtained after the sampling gap show a generally decreasing trend. Also, there is not any consistent relationship between seasonal flow conditions and temporal fluctuations in gross beta activity, with temporal "peak" concentrations reported for samples collected during both seasonally high and low groundwater flow conditions.

WELL GW-639

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in June 1990, completed with an open-hole monitored interval from 95.5 to 125.5 ft bgs, and constructed with 7-inch diameter steel (SF25) riser casing. The well forms a cluster with wells GW-640 and GW-641 and is located in Bear Creek Valley west of Y-12, about 750 ft north of Bear Creek Road and 1,000 ft east (hydraulically upgradient) of the Bear Creek Burial Grounds (BCBG) waste management area. The BCBG encompass several closed former hazardous waste disposal units, including numerous waste disposal trenches that received a diverse mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. The various components of the BCBG are covered by low-permeability, multilayer caps installed during RCRA closure of the site in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-seven groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 13 samples between December 1990 and October 1993, and the low-flow sampling method used to obtain 14 samples between April 2001 and November 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Nolichucky Shale). The average static groundwater level in the well is 9 ft bgs. Presampling depth-to-water measurements for the well indicate moderate water-level fluctuations (<10 ft).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 526 – 587 mg/L;
- pH (field measurements) of 8.9 – 9.7;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for 26 groundwater samples collected from the well since January 1991.

5.1 NITRATE

None of the groundwater samples analyzed for nitrate (between March 1991 and November 2001) had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

Three of the groundwater samples (between March 1991 and May 2003) had uranium concentrations above the analytical reporting limit, with the concentration (0.001 mg/L in each sample) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected at very low levels in three of the 24 groundwater samples analyzed for VOCs: benzene (2 μg/L) in November 2001, acetone (0.4 μg/L) in November 2003; and toluene (0.1 μg/L) in September 2004. These results may be sampling or analytical artifacts and are considered to be outliers.

5.4 GROSS ALPHA ACTIVITY

Three of the groundwater samples (between March 1991 and May 2003) had gross alpha activity above the applicable MDA and corresponding CE, with the maximum activity (2.15 pCi/L in September 1991) being substantially below the MCL for gross alpha activity (15 pCi/L November 1991).

5.5 GROSS BETA ACTIVITY

One of the groundwater samples (between March 1991 and May 2003) had gross beta activity above the applicable MDA and corresponding CE, and the result (3.61 pCi/L) is substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-653

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1990, completed with a screened monitored interval from 26.3 to 39 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located at the Bear Creek Burial Grounds (BCBG) waste management area (WMA), about 500 ft west of Burial Ground (BG) A-South. The BCBG includes numerous hazardous and nonhazardous waste disposal units that received a mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. Liquid wastes included about two million gallons of waste oils and machine coolants, and borax waste water, all or most of which may have contained varying amounts of radioisotopes (primarily uranium isotopes). In 1989, the waste-disposal units in the BCBG WMA were covered with multi-layer, low-permeability caps installed during RCRA closure of the site.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 26 samples between March 1991 and August 2003, and the low-flow sampling method used to obtain 14 samples between March 1998 and August 2004.

An evaluation of the monitoring data available through August 2000 indicated potential bias related to the groundwater sampling method: samples obtained with the conventional sampling method had substantially different contaminant (VOC) concentrations than samples obtained with the low-flow sampling method (AJA 2001). However, results of "paired" sampling performed during February and October 2003, when groundwater samples were collected with the low-flow sampling method one day and the conventional sampling method the next day, do not confirm the apparent sampling-method bias. As illustrated by the data summarized in Table 1, groundwater samples obtained with each sampling method have similar geochemical characteristics and the VOC results are somewhat inconclusive, with the highest and lowest summed VOC concentrations reported for the samples obtained with the low-flow method. Thus, the difference between the conventional sampling and low-flow sampling results are probably attributable to an overall increase in VOC concentrations (see Section 5.3).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Nolichucky Shale (the Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within this highly permeable zone, which occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek that traverse the Nolichucky Shale and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that stratigraphically overlies the Nolichucky Shale and subcrops along the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements for the well show that the static groundwater level in the well typically occurs at an average depth of about 19 ft bgs and exhibit seasonal fluctuations up to 8 ft. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring in the vicinity of well GW-653 indicate south and southwesterly flow toward the Maynardville Limestone and the main channel of Bear Creek. However, groundwater flow in the Nolichucky Shale is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Consequently, the direction(s) of groundwater flow in the vicinity of well GW-653 may be primarily westward (parallel with geologic strike) toward discharge areas in a northern tributary of Bear Creek (NT-8) approximately 400 ft west of the well.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields distinctive and unique calcium-magnesium-bicarbonate groundwater generally characterized by:

- extremely low TDS (<50 mg/L), which suggests short groundwater residence time and indicates that the monitored interval in the well intercepts hydraulically active flowpaths;
- pH (field measurements) of about 4.4 - 5.9;
- very low concentrations of all the major anions and cations, including calcium (2 mg/L), magnesium (1 mg/L), and bicarbonate (15 mg/L); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Only the nitrate concentration reported for the groundwater sample collected in August 1999 (0.04766 mg/L) exceeds the applicable analytical reporting limit, and this result is substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Nine groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.002 mg/L in March and June 1991) being substantially below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected to date (Table 2): acetone, PCE, TCE, 11DCA, 11DCE, 12DCE (c12DCE), and 111TCA. Each of these compounds, except acetone, is a confirmed component of a plume of dissolved VOCs in the groundwater downgradient of the waste disposal areas within BG-A North and BG-A South. Considering the shallow depth of the well and the hydrogeologic characteristics of the Nolichucky Shale, the VOCs are probably moving westward via strike-parallel groundwater flow/transport pathways that discharge into the northern tributary of Bear Creek (NT-8) west the BCBG WMA (DOE 1997).

The primary VOCs in the groundwater samples are PCE, TCE and 12DCE (c12DCE); at least one of these compounds was detected in each groundwater sample (Table 2). The bulk of the results for PCE and TCE are estimated values below 5 µg/L, whereas the historical maximum concentration of 12DCE exceeds 150 µg/L. Also, the most recent monitoring results show concentrations of PCE, TCE and c12DCE below respective drinking water MCLs (Table 2). Acetone was detected only in one sample and is considered to be an outlier.

A time-series plot of the summed concentrations of VOCs detected in each groundwater sample (Figure 1) shows an indeterminate trend between March 1991 (17 µg/L) and August 1999 (24 µg/L), followed by an increasing trend through March 2003 (100 µg/L), then significantly lower VOC concentrations from August 2003 (55 µg/L) through August 2004 (38 µg/L). Although the increasing trend nearly coincides with the change from conventional sampling to low-flow sampling, the higher VOC concentrations do not appear to be an artifact of the latter sampling method (see Section 2.0 and Table 3). Thus, the increasing concentration trend probably reflects a corresponding increase in the relative flux of dissolved VOCs along the groundwater flow/transport pathways intercepted by the monitored interval in the well. Also, the VOC data show cyclic temporal concentration fluctuations that correlate with seasonal groundwater flow conditions: summed VOC concentrations are highest in the samples collected during seasonally high flow conditions (winter and spring). This relationship suggests seasonally (and episodically) variable flux of dissolved VOCs along the groundwater flow/transport pathways monitored by the well. Furthermore, the recent decrease in concentrations suggests that a "pulse" of dissolved VOCs may have been intercepted by the monitored interval of the well.

5.4 GROSS ALPHA ACTIVITY

Fourteen groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (12.9 pCi/L) being slightly below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Thirteen groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, with the highest value (19 pCi/L in December 1994) being below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-658

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1990, completed with a screened monitored interval from 6.9 to 19.1 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). Note that the large monitored (screened) interval in the well is intended to straddle the water table during seasonally high and low flow conditions and facilitate detection of light non-aqueous phase liquids (LNAPL). The well is located near Bldg. 9754-2 at the East End Fuel Facility, which is in Bear Creek Valley near the east end of Y-12, at the intersection of First Street and Agate Drive.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 14 samples between March 1991 and March 1997, and the low-flow sampling method used to obtain six samples between June 1998 and May 2004.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Nolichucky Shale (Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within this highly permeable zone, which occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into the buried northern tributaries of Upper East Fork Poplar Creek (UEFPC) and other components of the subsurface drainage system within the highly industrialized areas of Y-12 (DOE 1998). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that stratigraphically overlies the Nolichucky Shale and subcrops along the axis of BCV and the original main channel of UEFPC.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 8 ft bgs and exhibits minor (<2 ft) seasonal fluctuations. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-658 indicate south and southeasterly flow toward the Maynardville Limestone and the UEFPC drainage system. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and original main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, groundwater flow in the Nolichucky Shale is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 216 – 624 mg/L;
- pH (field measurements) of 5.6 – 6.5;
- low molar proportions of chloride, potassium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

None of the groundwater samples collected to date had nitrate concentrations at or above the applicable analytical reporting limit.

5.2 URANIUM

Four groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest concentration (0.005 mg/L in August 1992) being substantially below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample collected to date (Table 1): acetone, benzene, ethylbenzene, total xylene, toluene, MC, 1,2-dichloropropane (12DCP), TCE, 12DCE, 12DCA, and 111TCA. These compounds are components of a plume of dissolved VOCs, dominated by petroleum hydrocarbons, emplaced during historical operations of three former underground storage tanks (USTs) at the Bldg. 9754-2 Fuel Facility. The USTs (the Garage Underground Tanks and the East End Fuel Facility) were used to store gasoline, diesel fuel, spent chlorinated solvents and waste oils; they were excavated and removed during RCRA closure of the site in 1989 (DOE 1998). The RCRA closure addressed cadmium-contaminated soils at the site, which were excavated and removed, but did not encompass groundwater remediation, including recovery of free-product.

The primary compounds in the groundwater samples are petroleum hydrocarbons; concentrations of benzene, ethylbenzene, total xylene, and toluene reported for all but one of the groundwater samples exceed 1,000 µg/L, with respective historical maximum concentrations of 20,000 µg/L, 2,300 µg/L, 43,000 µg/L, and 12,000 µg/L (Table 1). The substantially lower concentrations of these compounds reported for the sample collected in March 1992 are possibly outliers. Also, the most recent sampling results show that the summed concentrations of these petroleum hydrocarbons remain above 10,000 µg/L and most results substantially exceed respective drinking water MCLs. Presampling measurements show very low levels of dissolved oxygen in the groundwater at this well (e.g., 0.78 in May 2004), and anaerobic conditions are not conducive to biotic degradation of petroleum hydrocarbons. This may explain why the concentrations of these compounds remain so high considering that the gasoline and diesel USTs were removed from service 15 years ago.

Aside from the petroleum hydrocarbons, 12DCA is the only other VOC consistently detected in the groundwater samples; 12DCA was detected in all but four of the samples, with four of the concentrations exceeding 1,000 µg/L or more (Table 1). The conspicuously low 12DCA concentration evident in March 1992 (34 µg/L) and the non-detect 12DCA result for the sample collected in October 2002 are possible outliers. The remaining VOCs have been detected sporadically, with TCE, 12DCE, and 111TCA detected only in one sample each.

Excluding the analytical results for the sample collected in March 1992, a time-series plot of summed benzene, ethylbenzene, total xylene, and toluene concentrations reported for each groundwater sample (Figure 1) shows a progressively increasing concentration trend between March 1991 (8,100 µg/L) and November 1993 (32,300 µg/L) followed by a more widely fluctuating but decreasing trend through May 2004 (21,500 µg/L). Interestingly, a plot of the summed concentrations of 12DCA and the other VOCs generally mirrors that of the petroleum hydrocarbons (Figure 2). This suggests a common source (the USTs) for both types of VOCs, with the increasing and decreasing concentration trends reflecting corresponding changes in the relative flux of VOCs along the groundwater flow/transport pathways intercepted by the monitored interval in this well.

5.4 GROSS ALPHA ACTIVITY

Six groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (14.2 pCi/L in May 1992) being slightly below the drinking water MCL for gross alpha activity (15 pCi/L). However, compared to the other gross alpha results which are all less than 5 pCi/L, the historical maximum value is an outlier.

5.5 GROSS BETA ACTIVITY

Four groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, with the highest value (21.2 pCi/L in May 1992) being less than the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-679

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1990, completed with a screened monitored interval from 117 to 132 ft bgs, and constructed nominal 2.5-inch diameter PVC (#40) riser casing and well screen (0.01 slot). The well is located on the southern flank of Chestnut Ridge approximately one-half mile south of Y-12, about 400 ft west of the northwestern side of the Filled Coal Ash Pond (FCAP). The FCAP occupies the former basin behind an earthen dam, constructed in 1955 across a northern tributary of McCoy Branch, which had filled with fly-ash slurry pumped from the Y-12 Steam Plant. The final approved ROD for FCAP (DOE 1996) required dam stabilization and wetlands construction as CERCLA corrective actions at the site, which were completed in 1997 (DOE 1997).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Two groundwater samples have been collected from the well to date; the low-flow sampling method was used to obtain the samples in April and October 2004.

Groundwater samples from the well exhibit conspicuous geochemical characteristics (see Section 4.0) potentially attributable to localized contamination from cement (grout). Redevelopment of the well before sampling also may be necessary to obtain more representative (i.e., the least grout-contaminated) groundwater samples.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the lower Knox Group (Chepultepec Dolomite), which forms a series of prominent hills across the broad southern flank of Chestnut Ridge. The Knox Group formations, along with the uppermost formation (Maynardville Limestone) of the underlying Conasauga Group, comprise an aquifer consisting of three vertically gradational subsystems distinguished by groundwater flux, which decreases with depth: (1) the stormflow zone, (2) the vadose zone, and (3) the groundwater zone (Solomon et al. 1992). The stormflow and vadose zones occur at shallow depths within the thick (>100 ft) residuum that has developed on Chestnut Ridge. In the bedrock zone, orthogonal sets of permeable, planar fractures form water-producing zones within an essentially impermeable matrix, and dissolution of carbonates has enlarged fractures and produced an interconnected conduit-flow system characteristic of karst aquifers. Because the occurrence of solution features and the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity of the groundwater zone is vertically gradational. Most groundwater flux occurs within the transitional horizon between residuum and unweathered bedrock (water table interval); lower flux (and longer solute residence times) occurs at successively greater depths in the bedrock (Solomon et al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 45 ft bgs and exhibits moderate (about 10 ft) seasonal fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-679 indicate radial flow directions, with components of flow eastward and southeastward toward FCAP.

4.0 GEOCHEMICAL CHARACTERISTICS

Based on analytical results for the groundwater samples collected to date, this well appears to yield calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 164 and 210 mg/L;
- strongly basic pH of 9.24 and 9.27 (field measurements);

- unusually low levels of calcium (<6 mg/L) coupled with atypical high potassium concentrations (>40 mg/L) and carbonate alkalinity (>30 mg/L);
- elevated total (unfiltered sample) concentrations of lithium (>0.1 mg/L); and
- total concentrations of trace metals (except lithium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The unusual geochemistry of the groundwater samples, in particular the atypical levels of carbonate and bicarbonate, strongly basic pH, and unusually high potassium concentrations, are evident in other wells at Y-12 and are believed to be the result of localized contamination by cement grout circulated into the surrounding bedrock during their installation and construction.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, gross beta activity is the principal contaminant present at somewhat elevated concentrations in the groundwater samples from this well.

5.1 NITRATE

Both groundwater samples collected to date had nitrate concentrations at or above the applicable analytical reporting limit, and these results are less than 1 mg/L and are substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Both groundwater samples collected to date had uranium concentrations above the applicable analytical reporting limit, and these results are less than 0.00075 mg/L and are orders-of-magnitude lower than the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Neither of the groundwater samples collected to date contained VOCs.

5.4 GROSS ALPHA ACTIVITY

Neither of the groundwater samples collected to date had gross alpha activity above the applicable MDA.

5.5 GROSS BETA ACTIVITY

Both groundwater samples collected to date had gross beta activity above the MDA and corresponding CE, and these results (35 pCi/L in April 2004 and 30 pCi/L in October 2004) are below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). The elevated levels of gross beta activity may be related to the elevated potassium concentrations in the grout-contaminated groundwater samples from the well. Potassium-40 (K-40) is a beta-emitting isotope and, based on the natural ratio of K-40 to total K (K-40 = 0.0119% total K; Brownlow 1979), should be present in the groundwater samples.

WELL GW-680

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1990, completed with a screened monitored interval from 107 to 120 ft bgs, and constructed nominal 2.5-inch diameter PVC (#40) riser casing and well screen (0.01 slot). The well is located on the southern flank of Chestnut Ridge approximately one-half mile south of Y-12, about 300 ft east of the northeastern side of the Filled Coal Ash Pond (FCAP). The FCAP occupies the former basin behind an earthen dam, constructed in 1955 across a northern tributary of McCoy Branch, which had filled with fly-ash slurry pumped from the Y-12 Steam Plant. The final approved ROD for FCAP (DOE 1996) required dam stabilization and wetlands construction as CERCLA corrective actions at the site, which were completed in 1997 (DOE 1997).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Two groundwater samples have been collected from the well to date; the low-flow sampling method was used to obtain the samples in June and October 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the lower Knox Group (Chepultepec Dolomite), which subcrops south of the ridge crest and forms a series of prominent hills across the broad southern flank of Chestnut Ridge. The Knox Group formations, along with the uppermost formation (Maynardville Limestone) of the underlying Conasauga Group, comprise an aquifer consisting of three vertically gradational subsystems distinguished by groundwater flux, which decreases with depth: (1) the stormflow zone, (2) the vadose zone, and (3) the groundwater zone (Solomon et al. 1992). The stormflow and vadose zones occur at shallow depths within the thick (>100 ft) residuum that has developed on Chestnut Ridge. In the bedrock zone, orthogonal sets of permeable, planar fractures form water-producing zones within an essentially impermeable matrix, and dissolution of carbonates has enlarged fractures and produced an interconnected conduit-flow system characteristic of karst aquifers. Because the occurrence of solution features and the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity of the groundwater zone is vertically gradational. Most groundwater flux occurs within the transitional horizon between residuum and unweathered bedrock (water table interval); lower flux (and longer solute residence times) occurs at successively greater depths in the bedrock (Solomon et al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 26 ft bgs and exhibits minor (about 2 ft) seasonal fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-680 indicate components of flow to the west and southwest toward FCAP.

4.0 GEOCHEMICAL CHARACTERISTICS

Based on analytical results for only the groundwater samples collected to date, this well appears to yield calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 168 and 170 mg/L;
- neutral pH of 7.63 and 7.54 (field measurements);
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite);

- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, none of the principal contaminants are present at elevated concentrations in the groundwater from this well.

5.1 NITRATE

Both groundwater samples collected to date had nitrate concentrations at or above the applicable analytical reporting limit, and these results are less than 1 mg/L and are substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Neither of the groundwater samples collected to date had uranium concentrations above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Neither of the groundwater samples collected to date contained VOCs.

5.4 GROSS ALPHA ACTIVITY

Neither of the groundwater samples collected to date had gross alpha activity above the applicable MDA.

5.5 GROSS BETA ACTIVITY

Neither of the groundwater samples collected to date had gross beta activity above the applicable MDA.

WELL GW-683

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in December 1990, completed with a screened monitored interval from about 133.9 to 196.8 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire wound). The well is located on the steep northern flank of Chestnut Ridge, about two miles west of Y-12 and 500 ft directly south of the confluence of the main channel of Bear Creek and a northern tributary (NT) of the creek (NT-8) that drains the western sections of the Bear Creek Burial Grounds (BCBG) waste management area (WMA). This well is a component of Exit Pathway Picket A, which consists of a series of wells (GW-056, GW-683, GW-684, and GW-685) completed at different depths (and hydrostratigraphic zones) along a strike-normal transect across the Maynardville Limestone (Figure 1). The Maynardville Limestone subcrops along the axis of Bear Creek Valley (BCV) and underlies the main channel of Bear Creek.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-five groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 19 samples between May 1991 and August 1997, and the low-flow sampling method used to obtain 16 samples between February 1998 and August 2004.

The well does note exhibit distinguishing sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the intermediate bedrock interval in the Maynardville Limestone (Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 85 ft bgs and exhibits seasonal fluctuations up to about 12 ft. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV and on Chestnut Ridge, groundwater elevation isopleths in the vicinity of Exit-Pathway Picket A indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields chloride- and sodium-enriched, nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 100 – 500 mg/L;
- pH of 6.5 – 8.4 (field measurements);
- sporadically elevated levels of TSS (>50 mg/L), with preservation of these samples (i.e., acidification to a pH below 2) often resulting in elevated concentrations of aluminum (>2 mg/L) and iron (>3 mg/L);
- low molar proportions of chloride, potassium, sodium and sulfate (<10% of total anions/cations); and

- total concentrations of trace metals (except aluminum and iron) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, all of the principal contaminants have been detected in the groundwater at this well.

5.1 NITRATE

All but one of the groundwater samples that were analyzed for nitrate had a concentration above the analytical reporting limit (Table 1), with results for 11 samples exceeding the drinking water MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds, which are unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988. Located about 11,000 ft east-northeast of the Exit Pathway Picket A, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984. The groundwater contaminant plume originating from the site contains a heterogeneous mixture of inorganic, organic, and radiological contaminants. Nitrate, a principal component of the plume, enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale and recharge of nitrate-contaminated surface water in Bear Creek, which receives substantial influx of nitrate (and other contaminants) from the catchments of northern Bear Creek tributaries (NT-1 and NT-2) west of the former S-3 Ponds (DOE 1997). Nitrate is chemically stable and highly mobile in groundwater and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells, the extent of nitrate contamination in the Maynardville Limestone in BCV west of Y-12, as defined by concentrations above 10 mg/L, is generally characterized by: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for about 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) and is significantly influenced by hydrologic interactions with surface water in Bear Creek.

Nitrate concentrations detected in the groundwater samples range between the historical minimum and maximum values of 0.5 mg/L (March 1994) and 32 mg/L (October 1993), respectively (Table 1). Most of the nitrate results are less than the MCL, with the concentrations reported for the most recently collected samples (March and August 2004) being less than 1 mg/L. Also, the nitrate concentrations exhibit clearly seasonal concentration fluctuations, but the relationship between seasonally high and low concentrations abruptly changed after July 1999. Before then, nitrate concentrations were typically highest (including the historical maximum value) in the samples collected during seasonally low groundwater flow conditions (summer and fall) and were typically lowest (including the historical minimum value) in samples collected during seasonally high groundwater flow conditions (winter and spring). This relationship suggests recharge of uncontaminated (i.e., less-nitrate contaminated) groundwater during seasonally high flow conditions. After July 1999, the opposite relationship between nitrate concentrations and seasonal flow conditions is evident, with the highest concentrations typically reported for samples collected during seasonally high flow and the lowest nitrate concentrations typically reported for the samples collected during seasonally low flow. This relationship suggests recharge of nitrate-contaminated groundwater (i.e., increased nitrate flux) during seasonally high flow conditions. Note that the change in the seasonal fluctuations of nitrate concentrations does not coincide with the transition from conventional sampling to low-flow sampling and, therefore, does not appear to be an artifact of the sampling method.

A time-series plot of nitrate concentrations in the groundwater samples shows a generally decreasing long-term trend dominated by wide temporal (seasonal) fluctuations (Figure 2). The long-term decrease in nitrate concentrations is attributable to the reduced flux of nitrate from the former S-3 Ponds following closure of the site and installation of the low-permeability cap (DOE 1997).

5.2 URANIUM

All of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit (Table 1), with the results for 20 samples exceeding the drinking water MCL for uranium (0.03 mg/L). There are several sources of uranium in BCV hydraulically upgradient of Exit Pathway Picket A, including the contaminant plume originating from the former S-3 Ponds and inflow of uranium-contaminated groundwater and surface water from the catchments of the northern Bear Creek tributaries (NT-7 and NT-8) that traverse the BCBG WMA. However, the CERCLA remedial investigation identified the former Boneyard/Burnyard (BYBY) as the primary source of uranium in groundwater from the Maynardville Limestone hydraulically downgradient (west) of the site (DOE 1997), which is about 6,500 ft east of Exit Pathway Picket A. Uranium-bearing wastes disposed at the BYBY were below the seasonally high water table and the limestone bedrock provided a ready source of dissolved carbonate, which combined with uranyl cations leached from the wastes and greatly increased what would otherwise be relatively limited uranium mobility in the neutral pH groundwater in the Maynardville Limestone (DOE 1997). As a major source area, the BYBY was prioritized for CERCLA remedial action, which was completed in May 2003 and involved: (1) the excavation and on-site consolidation/off-site disposal of about 81,000 yd^3 of waste materials; (2) construction of a multi-layer low-permeability cap over waste materials consolidated on site; and (3) reconstruction of a northern tributary of Bear Creek (NT-3) that drains the site (BJC 2004).

Uranium concentrations detected in the groundwater samples range over several orders-of-magnitude (Table 1), with respective historical minimum and maximum concentrations of 0.004 mg/L (March 1994) and 0.11 mg/L (October 1993), and the most recent sampling results (February and August 2004) show concentrations below the MCL. The uranium results also are characterized by wide temporal (seasonal) concentration fluctuations which, like the nitrate results, exhibit distinctly different relationships before and after July 1999. Before then, uranium concentrations were typically highest (including the historical maximum value) in the samples collected during seasonally low groundwater flow conditions (summer and fall) and were typically lowest (including the historical minimum value) in samples collected during seasonally high groundwater flow conditions (winter and spring). This relationship suggests seasonal (and episodic) recharge of uncontaminated (or less uranium-contaminated) groundwater during seasonally high flow conditions. After July 1999, the opposite relationship between uranium concentrations and seasonal flow conditions is evident, with the highest concentrations typically reported for samples collected during seasonally high flow and the lowest nitrate concentrations typically reported for the samples collected during seasonally low flow. This relationship suggests seasonal (and episodic) recharge of uranium-contaminated groundwater (i.e., increased uranium flux) during seasonally high flow conditions. As with the nitrate results, the change in seasonal concentration fluctuations for uranium does not coincide with the transition from conventional sampling to low-flow sampling and, therefore, does not appear to be an artifact of the sampling method.

A time-series plot of uranium concentrations in the groundwater samples shows a generally decreasing long-term trend dominated by wide temporal (seasonal) fluctuations (Figure 3). The long-term decrease in uranium levels in the groundwater at this well is attributable to the reduced flux of uranium as a result of the closure of the former S-3 Ponds and BCBG and the installation of low-permeability caps at each site. Additionally, following a fairly steady concentration decrease between January 2000 (0.0667 mg/L) and July 2002 (0.0231 mg/L), uranium levels have remained near 0.01 mg/L (i.e., below the MCL for uranium) through July 2004 (Figure 3), with the concentration evident in August 2003 (0.0103 mg/L) being the lowest value since March 1995 (0.0061 mg/L). The recent decrease in uranium concentrations probably reflects a corresponding decrease in the relative flux of uranium (and uranium isotopes) via the groundwater flow/transport pathways intercepted by the monitored interval in the well, which may be directly attributable to the CERCLA remedial action at the BYBY.

5.3 VOLATILE ORGANIC COMPOUNDS

Aside from false positive results, low concentrations (estimated values below 5 µg/L) of acetone, benzene, ethylbenzene, TCE, and 12DCE were detected in a total of six groundwater samples collected to date. Of these VOCs, TCE and 12DCE are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone in BCV, and the maximum concentrations of these compounds do not exceed applicable MCLs (5 and 70 µg/L, respectively).

5.4 GROSS ALPHA ACTIVITY

All but one of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE (Table 1), with results for 17 of the samples exceeding the drinking water MCL for gross alpha activity (15 pCi/L). Uranium isotopes (and alpha-emitting daughters) transported from the former BYBY (see Section 5.2) are the source elevated gross alpha activity in the shallow groundwater at this well, as illustrated by the following data for samples that have been analyzed for U-234 and U-238.

Date Sampled	Activity (pCi/L)		
	Gross Alpha	**U-234**	**U-238**
03/05/98	Not reported	5.5	7.9
07/13/98	Not reported	6.8	8.07
01/09/01	27	9.7	18
07/10/01	19	8.7	15
03/31/03	7.81	3.9	4.74
08/20/03	14.52	2.44	2.09
02/19/04	14.54	2.52	3.35
08/16/04	7.9	3.35	3.86

Results for gross alpha activity that exceed the MDA and CE range between historical minimum and maximum values of 2 pCi/L (March 1995) and 36 pCi/L (October 1993), with the most recent results (February and August 2004) being below the MCL (Table 1). Also, the levels of gross alpha activity exhibit the same large temporal (seasonal) fluctuations that are characteristic of the nitrate and uranium concentrations in the samples. As with the nitrate and uranium concentrations, the gross alpha activity reported for samples collected before July 1999 show temporal highs and lows during seasonally low and seasonally high groundwater flow conditions, respectively, whereas the reverse is evident after July 1999. This reversal in the apparent correlation between gross alpha activity and seasonal flow conditions, as noted previously with nitrate and uranium concentrations, does not coincide with the transition from conventional sampling to low-flow sampling and, therefore, does not appear to be an artifact of the sampling method.

A time-series plot of the gross alpha activity reported for the groundwater samples shows an indeterminate or slightly decreasing long-term trend totally dominated by wide (seasonal) fluctuations (Figure 4). Also, gross alpha activity appears to have decreased following the temporal "peak" in January 2000 (31 pCi/L), with the results reported for samples collected in March 2003 (7.81 pCi/L) and August 2004 (7.9 pCi/L) being the lowest levels evident since March 1996 (7.95 pCi/L). This decreasing trend probably reflects corresponding decreases in the relative flux of U-234 and U-238 via the groundwater flow/transport pathways intercepted by the monitored interval in the well. As noted in the discussion of decreasing total uranium concentrations, the reduced flux of uranium isotopes may be attributable to the CERCLA remedial actions completed at the BYBY (see Section 5.2).

5.5 GROSS BETA ACTIVITY

All but three of the groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE (Table 1), with results for six samples exceeding the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). There are two potential sources of the gross beta activity in the groundwater at this well: uranium isotopes (and related decay products) and Tc-99. As noted in the discussion of results for gross alpha activity, the former BYBY is the source of the uranium isotopes. However, the contaminant plume emplaced during historical operation of the former S-3 Ponds is the source of the Tc-99, which is a beta particle-emitting radionuclide detected (i.e., >MDA and CE) in the samples collected in March 1994 (166 pCi/L), September 1994 (67 pCi/L), January 2001 (49 pCi/L), July 2001 (33 pCi/L), and March 2003 (9 pCi/L); Tc-99 was not detected in the samples collected most recently (February and July 2004). These Tc-99 results reflect a clearly decreasing long-term concentration trend and are substantially below the SDWA screening level (3,790 pCi/L) for a 4 mrem/yr dose equivalent from Tc-99. This radionuclide is a "signature" component of the contaminant plume from the S-3 Ponds, the only site at Y-12 which received wastes that contained Tc-99 (DOE 1997). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the groundwater transport of Tc-99 in the Maynardville Limestone closely mirrors that of nitrate.

Results for gross beta activity that exceed the MDA and CE range between historical minimum and maximum values of 6 pCi/L (March 1995) and 93 pCi/L (September 1991), with the most recent results (February and August 2004) being substantially below the SDWA screening level (Table 1). Also, the levels of gross beta activity exhibit the same large temporal (seasonal) fluctuations that are characteristic of gross alpha activity (and nitrate and uranium concentrations) in the samples. As with gross alpha activity, the gross beta activity results reported for samples collected before July 1999 show temporal highs and lows during seasonally low and seasonally high groundwater flow conditions, respectively, whereas the reverse is evident after July 1999. This reversal in the apparent correlation between gross beta activity and seasonal flow conditions, as noted previously with gross alpha activity (and nitrate and uranium concentrations), does not coincide with the transition from conventional sampling to low-flow sampling and, therefore, does not appear to be an artifact of the sampling method.

A time-series plot of the gross beta activity reported for the groundwater samples shows a generally decreasing long-term trend that is dominated by wide (seasonal) fluctuations (Figure 5). Also, gross beta activity appears to have decreased following the temporal "peak" in January 2001 (77 pCi/L), with the result reported for the sample collected in August 2004 (7.67 pCi/L) being the lowest level evident since March 1995 (6 pCi/L). This decreasing trend reflects corresponding decreases in the relative flux of Tc-99 and uranium isotopes via the groundwater flow/transport pathways intercepted by the monitored interval in the well. As noted previously, the reduced flux of U-234 and U-238 may be attributable to the CERCLA remedial actions completed at the BYBY (see Section 5.2).

WELL GW-684

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1990, completed with a screened monitored interval from 106.4 to 129.6 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire wound). The well is located in Bear Creek Valley at the base of the steep northern flank of Chestnut Ridge, about two miles west of Y-12 stainless and 300 ft directly south of the confluence of the main channel of Bear Creek and a northern tributary (NT) of the creek (NT-8) that drains the western sections of the Bear Creek Burial Grounds (BCBG) waste management area (WMA). This well is a component of Exit Pathway Picket A, which consists of a series of wells (GW-056, GW-683, GW-684, and GW-685) completed at different depths (and hydrostratigraphic zones) along a strike-normal transect across the Maynardville Limestone (Figure 1). The Maynardville Limestone subcrops along the axis of BCV and underlies the main channel of Bear Creek.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-five groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 19 samples between May 1991 and August 1997, and the low-flow sampling method used to obtain 16 samples between February 1998 and August 2004.

The well does note exhibit distinguishing sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the intermediate bedrock interval in the Maynardville Limestone (Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 12 ft bgs and exhibits seasonal fluctuations up to about 3 ft. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV and on Chestnut Ridge, groundwater elevation isopleths in the vicinity of Exit-Pathway Picket A indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields chloride- and sodium-enriched, nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 175 – 450 mg/L;
- pH of 6.9 – 8.4 (field measurements);
- low molar proportions of chloride, potassium, sodium and sulfate (<10% of total anions/cations); and

- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, each of the principal contaminants are present in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected to date had nitrate concentrations above the analytical reporting limit (Table 1), with results for seven samples exceeding the drinking water MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds, which are unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988. Located about 11,000 ft east-northeast of the Exit Pathway Picket A, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984. The groundwater contaminant plume originating from the site contains a heterogeneous mixture of inorganic, organic, and radiological contaminants. Nitrate, a principal component of the plume, enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale and recharge of nitrate-contaminated surface water in Bear Creek, which receives substantial influx of nitrate (and other contaminants) from the catchments of northern Bear Creek tributaries (NT-1 and NT-2) west of the former S-3 Ponds (DOE 1997). Nitrate is chemically stable and highly mobile in groundwater and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells, the extent of nitrate contamination in the Maynardville Limestone in BCV west of Y-12, as defined by concentrations above 10 mg/L, is generally characterized by: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for about 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) and is significantly influenced by hydrologic interactions with surface water in Bear Creek.

Nitrate concentrations detected in the groundwater samples range between the historical minimum and maximum values of 0.98 mg/L (July 1999) and 18.9 mg/L (October 1993), respectively (Table 1). Most of the nitrate results are less than the MCL, with the concentrations reported for the most recently collected samples (February and August 2004) being less than 2 mg/L. Also, the nitrate concentrations exhibit clearly seasonal concentration fluctuations, but the relationship between seasonally high and low concentrations appear to have changed after July 1999. Before then, nitrate concentrations typically were highest in the samples collected during seasonally low groundwater flow conditions (summer and fall) and typically were lowest in samples collected during seasonally high groundwater flow conditions (winter and spring). This relationship suggests recharge of uncontaminated (or less nitrate-contaminated) groundwater during seasonally high flow conditions. After July 1999, the opposite relationship between nitrate concentrations and seasonal flow conditions is evident, with the highest concentrations typically reported for samples collected during seasonally high flow and the lowest nitrate concentrations typically reported for the samples collected during seasonally low flow. This relationship suggests recharge of nitrate-contaminated groundwater (i.e., increased nitrate flux) during seasonally high flow conditions. Note that the change in seasonal concentration fluctuations for nitrate does not coincide with the transition from conventional sampling to low-flow sampling and, therefore, does not appear to be an artifact of the sampling method.

A time-series plot of nitrate concentrations in the groundwater samples shows a decreasing long-term trend dominated by wide temporal (seasonal) fluctuations (Figure 3). The long-term decrease in nitrate concentrations is attributable to the reduced flux of nitrate from the former S-3 Ponds following closure of the site and installation of the low-permeability cap (DOE 1997).

5.2 URANIUM

All of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit (Table 1), with the results for 17 samples exceeding the drinking water MCL for uranium (0.03 mg/L). There are several sources of uranium in BCV hydraulically upgradient of Exit Pathway Picket A, including the contaminant plume originating from the former S-3 Ponds and inflow of uranium-contaminated groundwater and surface water from the catchments of the northern Bear Creek tributaries (NT-7 and NT-8) that traverse the BCBG WMA. However, the CERCLA remedial investigation identified the former Boneyard/Burnyard (BYBY) as the primary source of uranium in groundwater from the Maynardville Limestone hydraulically downgradient (west) of the site (DOE 1997), which is about 6,500 ft east of Exit Pathway Picket A. Uranium-bearing wastes disposed at the BYBY were below the seasonally high water table and the limestone bedrock provided a ready source of dissolved carbonate, which combined with uranyl cations leached from the wastes and greatly increased what would otherwise be relatively limited mobility in the neutral pH groundwater in the Maynardville Limestone (DOE 1997). As a major source area, the BYBY was prioritized for CERCLA remedial action, which was completed in May 2003 and involved: (1) the excavation and on-site consolidation/off-site disposal of about 81,000 yd^3 of waste materials; (2) construction of a multi-layer low-permeability cap over waste materials consolidated on site; and (3) reconstruction of a northern tributary of Bear Creek (NT-3) that drains the site (BJC 2004).

Uranium concentrations detected in the groundwater samples range between respective historical maximum and minimum concentrations of 0.114 mg/L (October 1993) and 0.011 mg/L (March 1995), and the most recent sampling results (February and August 2004) show concentrations below the MCL (Table 1). The uranium results also are characterized by wide temporal (seasonal) concentration fluctuations which, like the nitrate results, exhibit distinctly different relationships with seasonal groundwater flow conditions evident before and after July 1999. Before then, uranium concentrations typically were highest in the samples collected during seasonally low groundwater flow conditions (summer and fall), and typically were lowest in samples collected during seasonally high groundwater flow conditions (winter and spring). This relationship suggests seasonal (and episodic) recharge of uncontaminated (or less uranium-contaminated) groundwater during seasonally high flow conditions. The opposite relationship between uranium concentrations and seasonal flow conditions is evident after July 1999, with the highest concentrations typically reported for samples collected during seasonally high flow and the lowest concentrations typically reported for the samples collected during seasonally low flow. This relationship suggests seasonal (and episodic) recharge of uranium-contaminated groundwater (i.e., increased uranium flux) during seasonally high flow conditions. As with the nitrate results, the change in seasonal concentration fluctuations for uranium does not coincide with the transition from conventional sampling to low-flow sampling and, therefore, does not appear to be an artifact of the sampling method.

A time-series plot of uranium concentrations in the groundwater samples shows a generally decreasing long-term trend dominated by wide temporal (seasonal) fluctuations, although the samples collected since March 1995 show much less temporal variability than previous data (Figure 3). The long-term decrease in uranium levels in the groundwater at this well is attributable to the reduced flux of uranium as a result of the closure former S-3 Ponds and the BCBG and the installation of low-permeability caps at each site. Additionally, the uranium concentrations reported for groundwater samples collected since January 2002 suggest a more steeply decreasing trend than previously evident, with the concentration reported for the sample collected in August 2003 (0.0185 mg/L) being the lowest value reported for the well since July 1999 (0.0178 mg/L). The recent decrease in uranium concentrations may be attributable to the CERCLA remedial action at the BYBY.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, low concentrations of acetone, ethylbenzene, methylene chloride, TCE, and 12DCE were detected in a total of five groundwater samples collected to date, most recently the sample collected in August 1995. Of these VOCs, TCE and 12DCE are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone in BCV, and the maximum concentrations of these compounds (2 µg/L for both VOCs) do not exceed applicable drinking water MCLs (5 and 70 µg/L, respectively).

5.4 GROSS ALPHA ACTIVITY

All of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE (Table 1), with results for 13 of the samples exceeding the drinking water MCL for gross alpha activity (15 pCi/L). Uranium isotopes (and alpha-emitting daughters) transported from the former BYBY (see Section 5.2) are the source elevated gross alpha activity in the shallow groundwater at this well, as illustrated by the following data for samples that have been analyzed for U-234 and U-238.

Date Sampled	Activity (pCi/L)		
	Gross Alpha	**U-234**	**U-238**
02/12/98	Not reported	7.33	7.33
07/13/98	Not reported	4.83	11.37
01/09/01	22	6.3	12
07/10/01	21	7.5	12
03/26/03	12.24	4.23	7.81
08/18/03	10..94	3.68	6.04
02/19/04	14.45	3.42	6.62
08/16/04	8.72	5.35	5.85

Results for gross alpha activity that exceed the MDA and CE range between historical minimum and maximum values of 1.6 pCi/L (September 1991) and 38 pCi/L (October 1993), with the most recent results (February and August 2004) being below the MCL (Table 1). Also, the levels of gross alpha activity exhibit the same large temporal (seasonal) fluctuations that are characteristic of the nitrate and uranium concentrations in the samples. As with the nitrate and uranium concentrations, the gross alpha activity reported for samples collected before July 1999 show temporal highs and lows during seasonally low and seasonally high groundwater flow conditions, respectively, whereas the reverse is evident after July 1999. This reversal in the apparent correlation between gross alpha activity and seasonal flow conditions, as noted previously with nitrate and uranium concentrations, does not coincide with the transition from conventional sampling to low-flow sampling and, therefore, does not appear to be an artifact of the sampling method.

A time-series plot of the gross alpha activity reported for the groundwater samples shows an indeterminate long-term trend that is dominated by wide (seasonal) fluctuations (Figure 4). Also, gross alpha activity appears to have steadily decreased following the temporal "peak" in January 2002 (23 pCi/L), with the result reported for the sample collected in August 2004 (8.72 pCi/L) being the lowest level evident since April 1993 (5.89 pCi/L). This decreasing trend probably reflects a corresponding decrease in the relative flux of U-234 and U-238 via the groundwater flow/transport pathways intercepted by the monitored interval in the well. As noted in the discussion of decreasing total uranium concentrations, the reduced flux of uranium isotopes may be attributable to the CERCLA remedial actions completed at the BYBY (see Section 5.2).

5.5 GROSS BETA ACTIVITY

All but two of the groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE (Table 1), with results for six samples exceeding the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). There are two primary sources of the gross beta activity in the groundwater at this well: uranium isotopes (see Section 5.4) and Tc-99, a beta particle-emitting radionuclide that is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, the only site at Y-12 that received wastes containing Tc-99 (DOE 1998). As shown in the following data summary, Tc-99 was detected (i.e., >MDA and CE) in each sample collected to date that was analyzed for this radionuclide.

Date Sampled	Tc-99 Activity (pCi/L)
03/04/94	125
09/20/94	101
01/09/01	35
07/10/01	30
03/26/03	7.42
08/18/03	6.8
02/19/04	10.5
08/16/04	11.03

These Tc-99 levels are substantially below the SDWA screening level (3,790 pCi/L) for a 4 mrem/yr dose equivalent from Tc-99 and show a substantial decrease from the Tc-99 levels evident during the mid-1990s. Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the groundwater transport of Tc-99 in the Maynardville Limestone closely mirrors that of nitrate.

Results for gross beta activity that exceed the MDA and CE range between historical minimum and maximum values of 13 pCi/L (March 1992) and 77 pCi/L (June 1992), with the most recent results (February and August 2004) being substantially below the SDWA screening level (Table 1). Also, the levels of gross beta activity exhibit the same large temporal (seasonal) fluctuations that are characteristic of gross alpha activity (and nitrate and uranium concentrations) in the samples. As with gross alpha activity, the gross beta activity results reported for samples collected before July 1999 show temporal highs and lows during seasonally low and seasonally high groundwater flow conditions, respectively, whereas the reverse is evident after July 1999. This reversal in the apparent correlation between gross beta activity and seasonal flow conditions, as noted previously with gross alpha activity (and nitrate and uranium concentrations), does not coincide with the transition from conventional sampling to low-flow sampling and, therefore, does not appear to be an artifact of the sampling method.

A time-series plot of the gross beta activity reported for the groundwater samples shows an indeterminate or slightly decreasing long-term trend totally dominated by wide (seasonal) fluctuations (Figure 5). Also, gross beta activity appears to have decreased following the temporal "peak" in January 2001 (49 pCi/L) to less than 20 pCi/L through August 2004. This decreasing trend reflects corresponding decreases in the relative flux of Tc-99 (and uranium isotopes) via the groundwater flow/transport pathways intercepted by the monitored interval in the well. Substantially reduced flux of Tc-99 is attributable to closure of the former S-3 Ponds and installation of the low-permeability cap (DOE 1997), and installation of remedial/removal systems near the site (1998-2001).

WELL GW-690

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1990, completed with a screened monitored interval from 40.8 to 52.8 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-691 and is located in the south-central Y-12 area, about 200 ft east of the coal stockpile for the Y-12 Steam Plant.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Five groundwater samples have been collected to date, with the conventional sampling method used to obtain one sample in June 1996, and the low-flow sampling method used to obtain four samples between October June 2000 and November 2003.

The unfiltered groundwater samples from this well are distinguished by high TDS attributable to very high sulfate (see Section 4.0).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Conasauga Group (Maynardville Limestone). Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 11 ft bgs and exhibits minor (<2 ft) seasonal fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields highly mineralized, sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- high TDS (>900 mg/L);
- pH (field measurements) of 6.7 – 7.2;
- very high sulfate concentrations (>350 mg/L);
- low molar proportions of chloride, potassium, and sodium (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Although elevated sulfate levels in groundwater from the Maynardville Limestone may reflect the geochemical influence of secondary minerals in the bedrock (e.g., pyrite), the extremely high sulfate concentrations in the groundwater at this well most likely reflect contamination. Sulfur leached from the coal stockpile for the Y-12 Steam Plant, which is hydraulically upgradient along geologic strike to the west of the well, is the most likely source of the sulfate. There are other potential non-specific sources within Y-12, such as leaking industrial process lines, sanitary sewers, or storm drains.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Five groundwater samples had nitrate concentrations at or above the applicable analytical reporting limit, with the highest concentration (4.32 mg/L in May 2000) being less than the MCL for nitrate (10 mg/L).

5.2 URANIUM

The uranium concentration reported for the groundwater sample collected in June 1996 (0.00093 mg/L) exceeds the applicable analytical reporting limit, but is substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, each groundwater sample contained each of the following VOCs: PCE, TCE, and 12DCE (Table 1). The source of the VOCs in the groundwater at this well has not been determined, but each compound is a known component of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and UEFPC watersheds. In the UEFPC watershed east of the flow divide, which occurs near the west end of Y-12, the VOC plume appears to originate near the Fire Training Facility in the southwestern section of Y-12, extends eastward (parallel with geologic strike) and mixes with VOCs released from several sources in the central and eastern Y-12 areas, and enters Union Valley east of the ORR boundary along Scarboro Road (DOE 1998).

The highest concentrations have been reported for PCE (720 µg/L) and 12DCE (71 µg/L), with the most recent sampling results showing that PCE and TCE concentrations remain above respective MCLs (Table 1). Although there are significant gaps in the sampling history for this well, the available monitoring results show clearly decreasing summed VOC concentrations (Figure 1). The decreasing concentration trend is primarily attributable to PCE levels, which dropped by almost 95% between June 1996 (720 µg/L) and November 2003 (48 µg/L). The decreasing VOC concentrations potentially reflect corresponding decreases in the relative flux of VOCs along the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity reported for the sample collected in June 2000 (6.3 pCi/L) exceeds the applicable MDA and corresponding CE, but is less than the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Gross beta activity reported for the groundwater samples collected in June 1996 (51.8 pCi/L) and May 2003 (15 pCi/L) exceed the applicable MDA and corresponding CE. The June 1996 result slightly exceeds the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-691

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during October 1990, completed with a screened monitored interval from 8 to 20 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01-inch slot wire-wound). The well forms a cluster with well GW-690 and is located in Bear Creek Valley (BCV) in the west-central Y-12 area, approximately 150 ft directly east of the Coal Pile Trench, which underlies the coal stockpile for the Y-12 Steam Plant.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Three groundwater samples have been collected from the well, with the conventional sampling method used to obtain a sample in June 1996 and the low-flow sampling method used to obtain samples in June and November 2004.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maynardville Limestone (upper Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 12 ft bgs. Also, groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are lower in well GW-691 than in well GW-690, which is completed at a greater depth (53 ft bgs) in the Maynardville Limestone. Based on the distance between the monitored interval midpoint (elevation) in each well (33 ft), the contemporaneous groundwater elevations indicate an upward vertical gradient (0.026) from the shallow bedrock interval (GW-690) to the water table interval (GW-691).

Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-691 indicate flow primarily to the east, parallel with the original main channel of UEFPC and geologic strike in the Maynardville Limestone. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local groundwater flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and main channel of UEFPC, and the intermittent and continuous operation of building basement dewatering sumps (DOE 1998).

4.0 GEOCHEMCICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples collected to date show that the well yields highly mineralized, sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 1,462 – 1,980 mg/L;
- pH of 6.3 – 6.8 (field measurements);
- extremely high concentrations (>1,000 mg/L) of sulfate;
- low molar proportions of chloride, nitrate, potassium, and sodium (<10% of total anions/cations);
- unusually elevated total (unfiltered sample) concentrations of manganese (>9 mg/L); and
- total concentrations of trace metals (except manganese) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

High TDS, attributable to the very high sulfate levels, and the elevated manganese concentrations appear to be distinguishing characteristics of the groundwater samples from the well. Sulfur leached from the coal stockpile overlying the Coal Pile Trench is the most likely source of the sulfate and likewise may be the source of the manganese in the groundwater at this well.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Two of the groundwater samples collected to date had nitrate concentrations at or above the analytical reporting limit, and both of these results (0.217 mg/L in June 2004 and 1.08 mg/L in November 2004) are substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Each groundwater sample collected to date had a total uranium concentration above the applicable analytical reporting limit, with the highest value (0.0016 mg/L in June 1996) being an order-of-magnitude below the drinking water MCL for total uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

As shown in the data summary below, each of the groundwater samples collected to date contained PCE, TCE, and 12DCE (c12DCE), with the most recent results indicating a substantial increase in PCE concentrations, relatively unchanged levels of TCE, and lower levels of 12DCE.

Date Sampled	**Concentration (µg/L)**			
	PCE	**TCE**	**Total 12DCE**	**c12DCE**
06/08/96	120	7	27	NR
06/09/04	1,300	10	9	9
11/17/04	980	8	7	7
MCL	**5**	**5**	**NA**	**70**
Note: J = Estimated value; NA = Not applicable; NR = Not reported				

Note that the lowest PCE concentration was reported for the groundwater sample obtained with the conventional sampling method; consequently, the substantial concentration increase indicated by the recent low-flow sampling results may be an artifact of the change in the sampling method. In any case, the compounds detected in the samples are all components of an essentially contiguous commingled plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide separating the Bear Creek and UEFPC watersheds. East of the flow divide in the UEFPC watershed, the VOC plume in the Maynardville Limestone appears to originate near the Fire Training Facility in the southwestern section of Y-12, extends eastward (parallel with geologic strike) and mixes with VOCs released from several sources in the central and eastern Y-12 areas, and enters Union Valley east of the ORR boundary along Scarboro Road (DOE 1998). Additionally, the upward hydraulic gradients indicated by presampling groundwater elevations in wells GW-690/GW-691 (see Section 3.0) suggest that the presence of VOCs in the shallow groundwater at well GW-691 may be at least partially attributable to local upward migration/transport of VOCs from deeper in the flow system of the Maynardville Limestone.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA.

WELL GW-692

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during October 1990, completed with a screened monitored interval from 41 to 53 ft bgs. The well forms a cluster with well GW-693 and is located in Bear Creek Valley (BCV) in the west-central Y-12 area, approximately 250 ft southeast of the Coal Pile Trench, which underlies the coal stockpile for the Y-12 Steam Plant. This is a flush-mounted well, and at some point the manhole was damaged and possibly allowed inflow of surface water runoff until August 2004 when the manhole was replaced.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Four groundwater samples have been collected from the well, with the conventional sampling method used to obtain samples in March and June 1996, and the low-flow sampling method used to obtain samples between June and November 2004.

The groundwater samples collected in June 2004 contained very high (227 mg/L) total suspended solids (TSS). A much lower but significant level of TSS (39 mg/L) also was reported for the sample in November 2004, which was after the manhole was replaced (see Section 1.0). Consequently, both samples contained unusually high total concentrations of several trace metals, particularly iron (>10 mg/L), aluminum (>5 mg/L), and manganese (>1 mg/L), that were dissolved from the solids by the acid preservative, which reduced the sample pH below 2. This is clearly illustrated by the substantial disparity between the total concentrations of these (and other) trace metals detected in the unfiltered and filtered samples collected in June 2004.

Analyte	Concentration (mg/L)	
	Unfiltered Sample	Filtered Sample
Calcium	97.5	95.5
Magnesium	24.5	23.2
Potassium	6.65	4.66
Sodium	12.8	12.7
Suspended Solids	227	Not analyzed
Aluminum	8.13	<0.2
Arsenic	0.0083	<0.005
Barium	0.124	0.0603
Beryllium	0.00077	<0.001
Chromium	0.0181	<0.01
Copper	0.0244	<0.02
Iron	14.4	<0.05
Lead	0.0249	<0.0005
Lithium	0.0253	0.0142
Manganese	0.188	<0.005
Mercury	0.00521	<0.0002
Nickel	0.0172	<0.005
Strontium	0.318	0.293
Thallium	0.000505	0.00255
Uranium	0.000966	<0.0005
Zinc	0.224	<0.05

These results suggest that the low-flow sampling activities disturbed the silt, clay, and other similarly fine-grained material distributed within the filter pack surrounding the well screen and/or settled onto the bottom of the well. This material probably remains in place because the initial development of the well and the few subsequent groundwater sampling events did not completely flush this material from the well/filter pack. Assuming that the intake for the dedicated sampling pump in the well is near the midpoint of the monitored interval, the filter pack may be the source of the suspended material because the low-flow sampling procedure would not be expected to disturb sediments on the bottom of the well, which would be approximately 6 ft below the pump intake. Alternatively, continued collection of samples with high TSS may indicate that the intake for the sampling pump is closer to the materials settled on the bottom of the well than to the monitored interval midpoint. In either case, the well should be redeveloped to ensure collection of representative groundwater samples, or the conventional sampling method should be used to ensure collection of the least turbid samples.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maynardville Limestone. Most groundwater flow in this uppermost formation of the Conasauga Group occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 9 ft bgs. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-692 indicate flow primarily to the east, parallel with the original main channel of UEFPC and geologic strike in the Maynardville Limestone. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local groundwater flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples collected to date show that the well yields somewhat mineralized, sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 570 – 778 mg/L;
- pH of 7 – 7.3 (field measurements);
- elevated concentrations of sulfate (>100 mg/L);
- low molar proportions of chloride, nitrate, potassium, and sodium (<10% of total cations); and
- as discussed in Section 2.0, total concentrations of several trace metals that are sampling artifacts related to the preservation of unfiltered samples containing high levels of TSS. The elevated TSS may reflect impacts from inflow of surface water during the time period when the manhole was damaged (see Section 1.0).

Elevated sulfate concentrations appear to be a distinguishing characteristic of the groundwater samples from the well. Sulfur leached from the coal stockpile overlying the Coal Pile Trench is the most likely source of the sulfate.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Two of the groundwater samples collected to date had nitrate concentrations at or above the analytical reporting limit, and both of these results are less than 1 mg/L and are an order-of-magnitude below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Each groundwater sample collected to date had a total uranium concentration above the applicable analytical reporting limit, with the highest value (0.000968 mg/L in June 2004) being several orders-of-magnitude below the drinking water MCL for total uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

As shown in the data summary below, chloroform was detected in each of the groundwater samples collected to date, with PCE, TCE, and c12DCE detected in the samples collected most recently (June and November 2004).

Date Sampled	Concentration (µg/L)			
	Chloroform	**PCE**	**TCE**	**c12DCE**
06/08/96	14	.	.	NR
06/08/04	12	4 J	1 J	5
11/17/04	8	8	2 J	12
MCL	**80***	**5**	**5**	**70**

Note: J = Estimated value; NR = Not reported; * = MCL is for total trihalomethanes

These compounds are all components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide separating the Bear Creek and UEFPC watersheds. East of the flow divide in the UEFPC watershed, the VOC plume in the Maynardville Limestone appears to originate near the Fire Training Facility in the southwestern section of Y-12, extends eastward (parallel with geologic strike) and mixes with VOCs released from several sources in the central and eastern Y-12 areas, and enters Union Valley east of the ORR boundary along Scarboro Road (DOE 1998).

5.4 GROSS ALPHA ACTIVITY

Two of the groundwater samples collected to date had gross alpha activity above the applicable MDA and CE, with the highest value (15 pCi/L in June 2004) equaling the drinking water MCL for gross alpha activity. This somewhat elevated gross alpha activity is probably related to the high level of suspended solids (>200 mg/L) in samples from the well (see Section 2.0).

5.5 GROSS BETA ACTIVITY

One of the groundwater samples collected to date had gross beta activity above the applicable MDA and CE, and this result (16 pCi/L in November 2004) is substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-694

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in February 1991, completed with an open-hole monitored interval from 153 to 204.5 ft bgs, and constructed with nominal 7-inch diameter steel (SF25) riser casing. The well is located in Bear Creek Valley (BCV) west of Y-12 and is a component of Exit Pathway Picket B, which consists of a series of wells (GW-694, GW-695, GW-703, GW-704, GW-705, and GW-706) completed at different depths (and hydrostratigraphic zones) along a strike-normal transect across the Maynardville Limestone (Figure 1). The Maynardville Limestone subcrops along the axis of BCV and underlies the main channel of Bear Creek.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-three groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 17 samples between June 1991 and August 1996, and the low-flow sampling method used to obtain six samples between March 1998 and July 2005. Note that the samples collected in March and July 1998 were collected specifically for the CERCLA Remedial Investigation (RI) for BCV and were analyzed by a different laboratory (DOE 1997).

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the intermediate depth (100 to 300 ft bgs) bedrock interval in the Maynardville Limestone (Conasauga Group), which exhibits the hydrologic characteristics typical of karst aquifers. Most groundwater flow in the Maynardville Limestone, which subcrops along the axis of BCV and underlies the main channel of Bear Creek, occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Hydrologic interaction between the creek and the shallow karst network provides the principal exit-pathway for contaminants released from source areas within the Bear Creek watershed west of Y-12. Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 25 ft bgs and exhibits seasonal fluctuations of about 9 ft. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV and on Chestnut Ridge, groundwater elevation isopleths in the vicinity of Exit-Pathway Picket B indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone. Moreover, measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in well GW-694 are typically higher than evident in well GW-695, which is completed at a shallower depth (62.6 ft bgs) in the Maynardville Limestone (Figure 1). Based on the distance between the monitored interval midpoint (elevation) in each well (121.3 ft), the contemporaneous groundwater elevations indicate upward vertical hydraulic gradients (0.004 – 0.042) from the deeper bedrock interval (GW-694) to the shallow bedrock interval (GW-695).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the unfiltered groundwater samples collected to date show that the well yields nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 150 – 662 mg/L;
- pH of 6.6 – 7.62 (field measurements);
- nitrate concentrations that exceed the drinking water MCL (10 mg/L);
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, all of these contaminants are present in the groundwater at this well.

5.1 NITRATE

All but two of the groundwater samples collected to date had nitrate concentrations above the analytical reporting limit (Table 1), including 14 samples with concentrations that exceed the drinking water MCL (10 mg/L). The source of the nitrate is the former S-3 Ponds, which are RCRA-regulated, unlined surface impoundments that were closed in 1988 and covered with a multilayer low-permeability cap in 1989. Located about 7,200 ft east-northeast (hydraulically upgradient) of the Exit Pathway Picket B, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984. The groundwater contaminant plume originating from the site contains a heterogeneous mixture of inorganic, organic, and radiological contaminants. Nitrate, a principal component of the plume, enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale and recharge of nitrate-contaminated surface water in Bear Creek (DOE 1997). Nitrate is chemically stable and highly mobile in groundwater and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells, the extent of nitrate contamination in the Maynardville Limestone in BCV west of Y-12, as defined by concentrations above 10 mg/L, is generally characterized by: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for about 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) and is significantly influenced by hydrologic interactions with surface water in Bear Creek.

As noted previously, most of the groundwater samples had nitrate concentrations above the MCL, with the highest concentrations reported for samples collected in September 1992 (48.9 mg/L) and November 1992 (47 mg/L). However, all the samples collected since March 1996 had nitrate concentrations below the 10 mg/L MCL. Additionally, the nitrate concentrations exhibit apparently seasonal fluctuations, with the lowest concentrations typically reported for samples collected during seasonally high groundwater flow conditions (winter and spring). This relationship suggests dilution of nitrate from seasonal (and episodic) recharge of less contaminated groundwater via the flow/transport pathways intercepted by the monitored interval in the well. Also, the magnitude of the temporal fluctuations indicated by nitrate results reported for the samples obtained with the conventional sampling method is notably greater than indicated by the nitrate results reported for the samples obtained with the low-flow sampling method. This may be at least partially attributable to inherent differences in the manner in which each sampling method induces flow of groundwater into the well. Conventional sampling involves aggressively purging the well (1-2 gallons per minute), which may substantially lower the water level in the well and induce inflow from water-producing features (e.g., conduits or fractures) that may not be proximal to the well. In contrast, low-flow sampling involves purging the well at flow rate low enough (<300 milliliters per minute) to ensure minimal water-level drawdown in the well (<1 ft per quarter hour), which induces groundwater flow from the water-producing features more proximal to the well.

A time-series plot of nitrate results shows a generally decreasing long-term concentration trend dominated by wide fluctuations (Figure 2). The rate of decrease appears to have slowed substantially, as illustrated by the nitrate concentrations detected in the groundwater samples collected in June 1992 (40.5 mg/L), August 1996 (3.57 mg/L), July 2002 (3.69 mg/L), and July 2005 (5.7 mg/L). Interestingly, the latter results suggest that the nitrate levels may have increased slightly since the mid-1990s. Nevertheless, the overall decrease from the nitrate concentrations evident in the early-1990s undoubtedly reflects the substantially reduced flux of nitrate in the Maynardville Limestone in response to the closure of the former S-3 Ponds in 1988 and installation of the low-permeability cap at the site in 1989.

5.2 URANIUM

All but two of the groundwater samples collected to date had uranium concentrations above the analytical reporting limit (Table 1), and each of these samples had concentrations that exceed the drinking water MCL for uranium (0.03 mg/L). There are several sources of uranium in BCV that are hydraulically upgradient of Exit Pathway Picket B, including the contaminant plume originating from the S-3 Ponds and inflow of uranium-contaminated surface water in Bear Creek. Also, the CERCLA remedial investigation identified the former Boneyard/Burnyard (BYBY) as the primary source of uranium in the Maynardville Limestone hydraulically downgradient (west) of the site (DOE 1997), which is about 2,500 ft east of Exit Pathway Picket B. Uranium-bearing wastes disposed at the BYBY were below the seasonally high water table and the limestone bedrock provided a ready source of dissolved carbonate, which combined with uranyl cations leached from the wastes and greatly increased what would otherwise be relatively limited mobility under the neutral pH conditions typical of the groundwater in the Maynardville Limestone (DOE 1997). As a major source area, the BYBY was prioritized for CERCLA remedial action, which was completed in May 2003 and involved: (1) the excavation and on-site consolidation/off-site disposal of about 81,000 yd^3 of waste materials; (2) construction of a multi-layer low-permeability cap over waste materials consolidated on site; and (3) reconstruction of a northern tributary of Bear Creek (NT-3) that drains the site (BJC 2004).

As noted previously, total uranium concentrations reported for most of the groundwater samples, including the samples collected most recently (March and July 2005), exceed the 0.03 mg/L MCL (Table 1). Uranium concentrations reported for the samples collected in March and July 1998 are the only results that are below the MCL, appear to be outliers (too low) compared to the other data, and may be analytical artifacts. Additionally, the uranium concentrations exhibit apparently seasonal fluctuations, with the highest concentrations typically reported for samples collected during seasonally low groundwater flow conditions (summer and fall). This relationship suggests increased flux of uranium from seasonal (and episodic) recharge of uranium-contaminated groundwater via the flow/transport pathways intercepted by the monitored interval in the well. Note also that this contrasts with the relationship between nitrate concentrations and seasonal flow conditions, as discussed in Section 5.1, which may indicate largely separate sources of the uranium (BYBY) and nitrate (S-3 Site) in the groundwater from this well. Additionally, as noted in the discussion of nitrate results for the well, the uranium results reported for the samples obtained with the conventional sampling method likewise exhibit significantly more temporal variation than indicated by the uranium results reported for the samples obtained with the low-flow sampling method, probably because of the inherent differences in the manner in which each sampling method induces flow of groundwater into the well.

A time-series plot of the uranium results shows a generally decreasing long-term trend dominated by wide fluctuations (Figure 3), although the rate of decrease appears to have slowed, as illustrated by the uranium concentrations detected in the groundwater samples collected in December 1993 (0.3 mg/), August 1996 (0.062 mg/L), January 2002 (0.0393 mg/L), and July 2005 (0.0324 mg/L). Nevertheless, the overall decrease in uranium concentrations probably reflect the substantially reduced flux of uranium in response to the CERCLA remedial action at the BYBY in 2001 as well as the previous closure and capping of the S-3 Ponds in 1988/1989.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater sample collected to date (Table 2): PCE, TCE, 12DCE, 11DCE, 111TCA, 11DCA, CTET, benzene, chlorobenzene, toluene, 2-butanone, and acetone. These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. In the Bear Creek watershed west of the flow divide, the VOC plume in the Maynardville Limestone appears to originate near Spoil Area I and to extend several thousand feet westward (parallel with geologic strike) down the axis of BCV, with influx of various VOCs from several different downgradient source areas. The distribution of VOCs within the plume reflects the relative contributions from the source areas and commingling during downgradient transport. Plume constituents in the upper part of BCV are TCE, c12DCE, and PCE; source areas include Spoil Area I and the former S-3 Ponds. Farther downstream (west), major inputs of VOCs occur from the Rust Spoil Area or a nearby source in the Bear Creek floodplain; the Oil Landfarm waste management area (WMA), including the BYBY, Hazardous Chemical Disposal Area (HCDA), and Sanitary Landfill I; and inflow of VOC-contaminated groundwater and surface water that discharges from a northern tributary of Bear Creek (NT-7) that traverses the Bear Creek Burial Grounds WMA. The highest VOC concentrations within the Maynardville Limestone exceed 300 µg/L and occur in the deeper groundwater south (down dip) of the HCDA, about 2,200 ft east-northeast (hydraulically upgradient) of Exit Pathway Picket B. These high concentrations coincide with downward vertical hydraulic gradients in the Maynardville Limestone in this area and a major losing reach of the main channel of Bear Creek (DOE 1997).

The primary VOC in the groundwater samples is TCE, which was detected in all but two of the samples collected to date and is the only compound detected in any of the samples collected since July 2002 (Table 2). The historical maximum concentration of TCE is 41 µg/L (September 1991), although this result appears to be an outlier compared to the other TCE concentrations, which are all less than 20 µg/L. Moreover, TCE concentrations in all the samples collected since March 1996 have been below the 5 µg/L drinking water MCL (Table 2). Of the other VOCs detected in the groundwater samples, 12DCE has been detected the most frequently, with a historical maximum concentration of 38 µg/L (September 1991), which is substantially below the MCL (70 µg/L). No other VOCS were detected at concentrations greater than 5 µg/L with the exception of acetone in June 1991 (180 µg/L; suspected outlier) and toluene in March (12 µg/L) and July 1998 (11 µg/L).

As shown on Figure 4, a time-series plot of TCE concentrations detected in the groundwater samples collected to date shows a variable but generally decreasing long-term concentration trend between September 1991 (41 µg/L) and August 1996 (3 µg/L). However, the trend shows little if any concentration change thereafter, as illustrated by the TCE results reported for the samples collected in July 1998 (3 µg/L), July 2002 (3 µg/L), and July 2005 (2 µg/L). The overall decrease in TCE levels in the groundwater at this well probably reflects reduced flux of TCE (and other VOCs) in response to corrective actions at the primary sources of VOCs in BCV west of Y-12, including the closure of the Oil Landfarm WMA and the installation of low-permeability caps at the site, and the CERCLA remedial actions at the BYBY/HCDA, which involved the excavation and removal of contaminated soils above and below the saturated zone (BJC 2004).

5.4 GROSS ALPHA ACTIVITY

All but three of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE (Table 1), including 17 results that exceed the drinking water MCL for gross alpha activity (15 pCi/L). Uranium isotopes (and alpha-emitting daughters) are the source of elevated gross alpha activity in the groundwater at this well. The contaminant plumes originating from the former S-3 Ponds and the BYBY are primary sources of uranium isotopes in groundwater and surface water in BCV west of Y-12, with the latter site being the closest and most likely source of the uranium isotopes in the groundwater at the Exit Pathway Picket B wells (DOE 1997). As with total uranium (see Section 5.2), U-234 and U-238 leached from wastes disposed at the BYBY probably combined with carbonate dissolved from the (limestone) bedrock, which greatly increased their relatively limited mobility in the neutral pH groundwater in the Maynardville Limestone (DOE 1997).

As noted previously, most of the groundwater samples had gross alpha activity that exceeded the drinking water MCL (15 pCi/L). The historical maximum concentration of 108 pCi/L in December 1993 is a suspected outlier, with all other results below 65 pCi/L. Gross alpha activity reported for all samples collected since January 1992 has been below the water MCL, with the most result reported for the sample collected in October 2005 (12 pCi/L) being the historical minimum value (above the MDA).

A time-series plot of the available results for gross alpha activity shows a variable but generally decreasing long-term trend (Figure 5). This concentration trend generally mirrors the similar trend defined by the sampling results for total uranium and likewise may be attributed to reduced flux of uranium isotopes in response to the CERCLA remedial action at the BYBY and the previous closure/capping of the former S-3 Ponds. Thus, the decreasing levels of gross alpha activity suggest a corresponding decrease in the relative flux of uranium isotopes along the groundwater flowpaths intercepted by the monitored interval in the well.

5.5 GROSS BETA ACTIVITY

All but one of the groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE (Table 1), including eleven results that exceed the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). The source of the gross beta activity in the groundwater at this well is most likely Tc-99, which was detected (i.e., >MDA and CE) in a series of groundwater samples collected between March 1993 and August 1996. Analytical results for these samples show a maximum Tc-99 concentration of 4,290 pCi/L (March 1993), which is the only value that exceeds the Tc-99 SDWA screening level (900 pCi/L) for a 4 mrem/yr dose equivalent, and is an outlier compared to the other Tc-99 concentrations. In any case, Tc-99 is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, which is the only site at Y-12 that received wastes containing this radionuclide (DOE 1997). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the transport of Tc-99 in the Maynardville Limestone closely mirrors that of nitrate, which reflects their common source and their similar transport characteristics in the groundwater.

As noted previously, most of the groundwater samples had gross beta activity above 50 pCi/L, with a historical maximum value of 161 pCi/L (December 1993). However, as shown by the data summarized in Table 1, results below 50 pCi/L were reported for all the samples collected since August 1995. Additionally, the gross beta results reported for the samples obtained with the conventional sampling method (i.e., before March 1998) exhibit significantly more temporal variation than indicated by the gross beta results reported for the samples subsequently obtained with the low-flow sampling method.

A time-series plot of the results for gross beta activity shows a generally decreasing long-term trend dominated by wide fluctuations, some of which may be attributable to inherent analytical variability (Figure 6). These fluctuations often correspond with seasonal flow conditions, whereby the lowest gross beta activities are reported for samples collected during seasonally high groundwater flow conditions (winter and spring). Also, the rate at which the levels of gross beta activity have decreased over the long term appears to have slowed considerably, with the results reported for the samples collected in July 1998 (3.85 pCi/L) and July 2005 (34 pCi/L) suggesting an increasing trend.

WELL GW-695

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in February 1991, completed with a screened monitored interval from 50.6 to 62.6 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley (BCV) west of Y-12 and is a component of Exit Pathway Picket B, which consists of a series of wells (GW-694, GW-695, GW-703, GW-704, GW-705, and GW-706) completed at different depths (and hydrostratigraphic zones) along a strike-normal transect across the Maynardville Limestone (Figure 1). The Maynardville Limestone subcrops along the axis of BCV and underlies the main channel of Bear Creek.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-three groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 19 samples between June 1991 and August 1997, and the low-flow sampling method used to obtain 14 samples between February 1998 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maynardville Limestone (Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 26 ft bgs and exhibits seasonal fluctuations up to about 8 ft. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV and on Chestnut Ridge, groundwater elevation isopleths in the vicinity of Exit-Pathway Picket B indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 200 – 350 mg/L;
- pH of 7.1 – 8.7 (field measurements);
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, nitrate, VOCs, and gross beta activity are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected to date had nitrate concentrations above the analytical reporting limit (Table 1), including twelve samples with concentrations that exceed the MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds, which are unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988. Located about 7,200 ft east-northeast (hydraulically upgradient) of the Exit Pathway Picket B, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984. The groundwater contaminant plume originating from the site contains a heterogeneous mixture of inorganic, organic, and radiological contaminants. Nitrate, a principal component of the plume, enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale and recharge of nitrate-contaminated surface water in Bear Creek (DOE 1997). Nitrate is chemically stable and highly mobile in groundwater and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells, the extent of nitrate contamination in the Maynardville Limestone in BCV west of Y-12, as defined by concentrations above 10 mg/L, is generally characterized by: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for about 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) and is significantly influenced by hydrologic interactions with surface water in Bear Creek.

Nitrate concentrations detected in the groundwater samples range between the historical minimum and maximum values of 0.25 mg/L (March 1992) and 12 mg/L (July 2001 and January 2002), respectively (Table 1). As noted previously, most of the nitrate concentrations are less than the MCL, with all but one of the samples with nitrate above the MCL collected since July 2000. Also, unlike other nitrate levels evident in groundwater samples from other wells in Exit Pathway Picket B (e.g., GW-704), the nitrate concentrations do not exhibit any clear of consistent seasonal fluctuations, as indicated by the temporal "peak" concentrations evident for samples collected during seasonally high and low groundwater flow conditions. A time-series plot of nitrate results shows an increasing long-term concentration trend (Figure 2), which probably reflects a corresponding increase in the relative flux of nitrate via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.2 URANIUM

All but one of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.00969 mg/L in February and July 2004) being less than the drinking water MCL for uranium (0.03 mg/L). Nevertheless, the most recent uranium results reflect an order-of-magnitude increase from the uranium concentrations evident during the early 1990s (e.g., 0.009 mg/L in November 1991).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample collected to date (Table 2): acetone, methylene chloride, TCE, 11DCE, 12DCE (isomers), and 111TCA. These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. In the Bear Creek watershed west of the flow divide, the VOC plume in the Maynardville Limestone appears to originate near Spoil Area I and to extend several thousand feet westward (parallel with geologic strike) down the axis of BCV, with influx of various VOCs from several different downgradient source areas. The distribution of VOCs within the plume reflects the relative contributions from the source areas and commingling during downgradient transport. Plume constituents in the upper part of BCV are TCE, c12DCE, and PCE; source areas include Spoil Area I and the former S-3 Ponds. Farther downstream (west), major inputs of VOCs occur from the Rust Spoil Area or a nearby source in the Bear Creek floodplain; the Oil Landfarm waste management area (WMA), including the former Boneyard/Burnyard (BYBY), Hazardous Chemical Disposal Area (HCDA), and Sanitary Landfill I; and inflow of VOC-contaminated groundwater and surface water that discharges from a northern tributary of Bear Creek (NT-7) that traverses the Bear Creek Burial Grounds WMA. The highest VOC concentrations within the Maynardville Limestone exceed 300 μg/L and occur in the deeper groundwater south (down dip) of the HCDA, about 2,200 ft east-northeast (hydraulically upgradient) of Exit Pathway Picket B. These high concentrations coincide with downward vertical hydraulic gradients in the Maynardville Limestone in this area and a major losing reach of the main channel of Bear Creek (DOE 1997).

The primary VOCs in the groundwater samples are TCE and 12DCE (Table 2), with one or both compounds detected in all but two of the samples. Each compound was detected at relatively low concentrations, most of which are estimated values below 5 μg/L. The most recent sampling results show TCE concentrations at the MCL (5 μg/L) and c12DCE concentrations at least an order-of-magnitude below the MCL (70 μg/L). Aside from TCE and 12DCE, trace concentrations (1 μg/L or less) of methylene chloride, 11DCE, and 111TCA were detected in one sample each, and acetone was reported (42 μg/L and 94 μg/L) for two samples (both results are suspected outliers).

A time-series plot of TCE concentrations in the groundwater samples shows a generally increasing long-term trend with proportionally large temporal fluctuations (Figure 3), some of which may be attributed to analytical variability often associated with relatively low VOC concentrations (most of the TCE results are estimated values). Also, the temporal concentration fluctuations do not exhibit any consistent relationship with groundwater flow conditions, as illustrated by the equal concentrations of TCE reported for samples collected during seasonally high and low groundwater flow conditions (e.g., 5 μg/L in February and July 2004). Moreover, the concentrations of 12DCE detected in the groundwater samples do not exhibit an increasing trend (Table 2), as illustrated by the 12DCE results for the samples collected in March 1993 (2 μg/L), February 1998 (2 μg/L), and July 2004 (1 μg/L). Assuming the plume of dissolved VOCs in the Maynardville Limestone contains a heterogeneous mixture of compounds, it is not clear from the available data why the concentrations of individual compounds exhibit divergent concentration trends or if such variations are significant with respect to the relative flux of dissolved VOCs via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

Twenty-two groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the highest values (25 pCi/L in July 2000 and 26 pCi/L in January 2003) being the only results to exceed the drinking water MCL for gross alpha activity (15 pCi/L). Both of these results appear to be outliers compared to the other results for gross alpha activity, which are all 10 pCi/L or less.

5.5 GROSS BETA ACTIVITY

All but two of the groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE (Table 1). All but the historical maximum value (50 pCi/L in January 2002) are less than the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the MCL for gross beta activity). The source of the gross beta activity in the groundwater at this well is Tc-99, which was detected (i.e., >MDA and CE) in the samples collected in January 2001 (39 pCi/L), July 2001 (48 pCi/L), January 2002 (45 pCi/L), and July 2002 (45 pCi/L). Note that all the Tc-99 results are substantially below the SDWA screening level (3,790 pCi/L) for a 4 mrem/yr dose equivalent. Technetium-99 is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, which is the only site at Y-12 that received wastes containing this radionuclide (DOE 1997). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the transport of Tc-99 in the Maynardville Limestone closely mirrors that of nitrate.

A time-series plot of gross beta activity reported for the groundwater samples shows a generally increasing long-term trend dominated by wide temporal fluctuations, some of which may be attributed to inherent analytical variability (Figure 4). Also, the results for gross beta activity do not exhibit any clear or consistent relationship with seasonal groundwater flow conditions. Additionally, the levels of gross beta activity appear to have decreased following the temporal "peak" value in January 2002 (50 pCi/L).

WELL GW-696

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in September 1990, completed with a screened monitored interval from 18.5 to 32.5 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-698 located in Bear Creek Valley within the south central section of Y-12, near the southeast corner of Bldg. 81-10.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Groundwater samples were collected from this well in March 1997 and May 2003.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Maynardville Limestone). Presampling depth-to-water measurements show the average static groundwater level in the well is 14 ft below ground surface.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the two samples collected in from the well indicate that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- moderate TDS (>150 mg/L<800 mg/L);
- pH (field measurements) of 6.6;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals (except iron and manganese) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Neither groundwater sample had nitrate above the applicable analytical reporting limit.

5.2 URANIUM

Neither groundwater sample had uranium above the analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Low levels of PCE (0.5 μg/L), TCE (2 μg/L), c12DCE (7 μg/L) and VC (0.6 μg/L) were detected in the groundwater sample collected in March 1997. These compounds are confirmed components of dissolved VOC plumes in the groundwater hydraulically upgradient to the west and northwest of the well. None of these compounds (or other VOCs) was detected in the groundwater sample collected in May 2003.

5.4 GROSS ALPHA ACTIVITY

Neither groundwater sample had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

Neither groundwater sample had gross beta activity above the applicable MDA and corresponding CE.

WELL GW-698

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in November 1990, completed with a screened monitored interval from 63 to 75 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with wells GW-696 and GW-697 and is located in Bear Creek Valley (BCV) at the former location of Bldg. 81-10 (only the concrete foundation remains in place), which is in the south-central section of Y-12 at the intersection of Third Street and G Road. Building 81-10 began use as a tin shop in 1943. A roasting furnace was installed in the building in 1957 and used until 1962 to recover mercury from contaminated equipment, soils, sludge, and other solid wastes. An estimated 3,000 lb of mercury was spilled and lost to the subsurface soils through cracks in the concrete floor during operation of the furnace. An initial clean up of the site in 1971 recovered about 130,000 lb of mercury from contaminated materials, including 2,700 lb from a sump located at the northeast corner of the concrete foundation building. Also, contaminated soils and sludge that were placed in steel drums and stored on site reportedly leaked before they were removed in 1993 (DOE 1998).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain three samples between March 1996 and November 2004, and the low-flow sampling method used to obtain ten samples between June 1998 and November 2004.

An evaluation of the monitoring data available through August 2000 indicated potential bias related to the groundwater sampling method: (unfiltered) samples obtained with the conventional sampling method appeared to have substantially lower summed VOC concentrations than samples obtained with the low-flow sampling method (AJA 2001). Results of "paired sampling" performed during May and November 2004, when groundwater samples were collected with the low-flow sampling method one day and the conventional sampling method the next day, confirm the apparent sampling-method bias (Table 1). Summed concentrations of VOCs detected in the samples obtained with the low-flow method are about 30% higher than the corresponding summed VOC concentrations for the samples obtained with the conventional sampling method the next day. Also, the conventional sampling method appears to yield less mineralized groundwater samples with nitrate concentrations that are at least 50% lower than detected in the samples obtained the previous day with the low flow method.

Inherent differences in the manner in which each sampling method induces flow of groundwater into the well may explain the disparity between the conventional and low-flow sampling results for nitrate and VOCs. Conventional sampling involves purging up to three well volumes of groundwater from the well at about 1-2 gallons per minute, which may substantially lower the water level in the well and induce flow from water-producing features (i.e., fractures, cavities, conduits) that may not contribute to well recharge under normal conditions. Conventional sampling also appears to disturb fine-grained particles in the bottom of the well or in the fractures intercepted by the monitored interval, as illustrated by the total suspended solids (TSS) reported for the (unfiltered) samples collected in May 2003 (47 mg/L). In contrast, low-flow sampling involves purging the well at flow rate low enough (<300 milliliters per minute) to ensure minimal water-level drawdown in the well (<1 ft per quarter hour), which induces groundwater inflow only from the water-producing feature(s) proximal to the monitored interval. Thus, the conventional sampling method appears to induce greater relative inflow of uncontaminated (or less nitrate- and VOC-contaminated) groundwater from water-producing features that are not proximal to the monitored interval, whereas low-flow sampling appears to primarily induce inflow of contaminated groundwater from the water producing feature(s) close to the well.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maynardville Limestone (upper Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static groundwater level in the well occurs at an average depth of about 32 ft bgs and exhibits wide temporal fluctuations (Figure 1). The groundwater elevations generally decreased by 15 ft from June 1996 (942.41 ft above msl) to November 2001 (927.35 ft above msl), then steadily increased by about 25 ft through May 2003 (952.87 ft above msl), sharply dropped approximately 15 ft from May to November 2003 (937.39 ft above msl) and has remained fairly steady since that time. It is not clear from the available data what may have caused the steady increase and sudden decrease in groundwater elevations in the well.

Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-698 indicate flow primarily to the east, parallel with geologic strike in the Maynardville Limestone. Additionally, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local groundwater flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 364 – 1,610 mg/L;
- pH (field measurements) of 6.7 – 7.4;
- nitrate concentrations above 100 mg/L;
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations);
- total concentrations of other trace metals that are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, nitrate and VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected to date that were analyzed for nitrate (as N) had concentrations above the analytical reporting limit (Table 1), and all but one of these results exceed the MCL for nitrate (10 mg/L). There are two primary sources of nitrate located hydraulically upgradient (west) of the well: the former S-3 Ponds and the S-2 Site. Nitrate is chemically stable and highly mobile in groundwater and effectively traces the primary groundwater flow/transport pathways in the Maynardville Limestone that are followed by other similarly mobile contaminants originating from the contaminant plumes emplaced during operation of these sites. Based on the relatively limited existing network of monitoring wells within the heavily industrialized areas of Y-12, the extent of nitrate contamination in the Maynardville Limestone, as defined by concentrations above 10 mg/L, is generally characterized by: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>50 ft bgs) in the bedrock that extends from the former S-2 Site eastward along geologic strike (i.e., bedding plan fractures) for at least as far as well GW-698 and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) and is significantly influenced by hydrologic interactions with the UEFPC surface water drainage system (DOE 1998).

Groundwater samples obtained with the low-flow sampling method exhibit a fairly wide range of nitrate concentrations, with the highest levels reported for samples collected in May and November 2001 (177 mg/L and 221 mg/L, respectively) and the lowest levels reported for samples collected in November 2002 (48 mg/L) and May 2003 (8.74 mg/L). Also, the nitrate results for these samples show wide temporal concentration fluctuations that do not consistently correlate with seasonal groundwater flow conditions, as illustrated by the order-of-magnitude difference between the nitrate concentrations reported for samples collected during seasonally high flow conditions in May 2001 and May 2003.

A time-series plot of the nitrate concentrations reported for the groundwater samples obtained with the low-flow sampling procedure (Figure 2), which spans a nearly three-year gap (July 1998 – May 2001) in the sampling history, suggests a generally indeterminate long-term concentration trend. In general, nitrate levels appear to have increased between June 1996 (25.3 mg/L) and November 2001 (221 mg/L), steadily decreased through May 2003 (8.74 mg/L), and sharply returned above 100 mg/L through November 2004 (118 mg/L). Interestingly, the nitrate concentration trend exhibits a directly inverse relationship with the presampling groundwater elevations in the well (see Section 2.0), with the increased groundwater elevations accompanied by decreased nitrate levels and the subsequent drop in groundwater elevations accompanied by a sharp increase in nitrate concentrations. This relationship suggests a temporal increase in the relative recharge of uncontaminated (or less nitrate-contaminated) groundwater via the flowpaths intercepted by the monitored interval in the well.

5.2 URANIUM

Uranium concentrations above the analytical reporting limit were reported for eleven of the groundwater samples collected to date, with the historical maximum concentration (0.0.0021 mg/L) obtained from conventional sampling in June 1996 being an order-of-magnitude below the drinking water MCL for total uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample collected to date (Table 1): CTET, chloroform, freon-113 (F113), PCE, TCE, and 12DCE (c12DCE). These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and UEFPC watersheds. In the UEFPC watershed east of the flow divide, the VOC plume in the Maynardville Limestone appears to originate near the Fire Training Facility in the southwestern section of Y-12, extends eastward (parallel with geologic strike) and mixes with VOCs released from several sources in the central and eastern Y-12 areas, and enters Union Valley east of the ORR boundary along Scarboro Road (DOE 1998). In October 2000, full-time operation of a groundwater remediation system began to help intercept and contain the (CTET-dominated) portion of the VOC plume in the Maynardville Limestone near the east end of Y-12, as required by the CERCLA Action Memorandum (DOE 1999).

The primary VOCs in the groundwater samples are PCE and TCE, both of which were detected at concentrations above 100 µg/L in all but two of the samples (Table 1). Also, the most recent sampling results (May and November 2004) show that PCE and TCE concentrations remain substantially above the respective MCLs (5 µg/L). Secondary compounds are CTET, chloroform (CLF), and 12DCE (c12DCE), which were all detected in all but two of the samples, with the highest concentrations (>40 µg/L) reported for c12DCE, and the most recent sampling results showing CTET concentrations above the MCL (5 µg/L). Based on analytical results for the samples collected in May and November 2004, F113 is another secondary compound in the groundwater (previous samples were not analyzed for this compound), with concentrations near 10 in samples obtained with the low-flow sampling method. Also, temporal fluctuations in the concentrations of primary and secondary VOCs do not exhibit a clear and consistent relationship with seasonal groundwater flow conditions, as illustrated by the substantial difference between the summed VOC concentrations reported for samples collected during seasonally high flow in March 2001 (762 µg/L) and March 2003 (55 µg/L).

As noted in Section 2.0, the low-flow sampling method appears to yield groundwater samples with higher summed VOC concentrations than samples collected with the conventional sampling method. However, as illustrated by the following data summary, the concentrations of some compounds (e.g., TCE) are highest in samples collected with the low flow method and the concentrations of some compounds (e.g., F113) are highest in samples collected with the conventional sampling method.

VOC	Concentration (µg/L)			
	Low-Flow Sampling May 18, 2004	**Conventional Sampling May 19, 2004**	**Low-Flow Sampling November 2, 2004**	**Conventional Sampling November 3, 2004**
PCE	120	120	120	150
TCE	300	130	440	200
c12DCE	14	33	38	64
CTET	7	.	6	.
Chloroform	13	3 J	14	5
F113	7	40	12	29
Summed VOCs	461	326	630	448
Notes: "." = Not detected; J = Estimated concentration below analytical reporting limit				

Assuming that the groundwater in the well contains a heterogeneous mixture of dissolved VOCs, it is not clear from the available data why each sampling method appears to influence the concentrations of some compounds and not others. Perhaps the conventional sampling method induces inflow of groundwater that contains higher relative concentrations of some compounds (c12DCE, F113, and possibly PCE) than does the groundwater inflow induced by the low-flow sampling method. Regardless, there is uncertainty as to which groundwater sampling method provides the more representative monitoring results for VOCs. The conservative approach is to assume that representative results are obtained with the low-flow sampling method because this method appears to yield groundwater samples with the highest VOC concentrations.

A time-series plot of the summed concentrations of VOCs detected in groundwater samples obtained with the low-flow sampling method shows a long-term concentration trend which generally mirrors that of nitrate (Figure 3): it spans the three-year gap in the sampling history for the well and shows an increase in VOC concentrations between June 1996 (20 μg/L) and November 2001 (762 μg/L), followed by a steadily decreasing concentrations through May 2003 (55 μg/L), and a sharp rebound in November 2003 (649 mg/L). Also, as with the nitrate concentrations, the summed VOC concentrations show an inverse relationship with the presampling groundwater elevations in the well (Figure 1). This relationship suggests what appears to be a temporal increase in the relative recharge of uncontaminated (or less VOC-contaminated) groundwater via the flowpaths intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

Five groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (5.89 pCi/L in July 1998) being less than the drinking water MCL for gross alpha activity (15 pCi/L). Low levels of gross alpha activity are supported by the analytical results for uranium isotopes (U-234 and U-238), which were detected (i.e., >MDA and CE) at very low levels (<1.5 pCi/L) in the samples collected in June 1996, May 2002, and November 2002.

5.5 GROSS BETA ACTIVITY

Four groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE was reported for each groundwater sample (Table 1), with the highest value (23.21 pCi/L in July 1998) being less than the SDWA screening level (50 pCi/L) for a 4 millirem dose equivalent (the drinking water MCL for gross beta activity). Low levels of gross beta activity are consistent with the analytical results showing very low (background) levels of uranium isotopes (see Section 5.4). Technetium-99 (Tc-99), a beta-emitting radionuclide that is a "signature" of the contaminant plume emplaced during operation of the former S-3 Ponds and is chemically and mobile in groundwater, was not detected in the samples collected in June 1996, May 2001, and November 2001 (the only samples that have been analyzed for Tc-99). The lack of Tc-99 in samples from this well suggests that the S-2 Site, and not the S-3 Site, is the source of elevated nitrate concentrations at this well (see Section 5.1).

WELL GW-700

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1990 in association with the Bldg 81-10 characterization, completed with a screened monitored interval from 19 to 31 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well 56-7A and is located in the south-central Y-12 area, about 750 ft directly west of the North/South Pipe, which is at the upstream (west) end of an exposed section of Upper East Fork Poplar Creek (UEFPC). Several thousand feet of the main channel of UEFPC, including all its northern tributaries in the western and central Y-12 areas, have been filled and replaced with an extensive network of underground storm drains. The storm drains direct surface runoff into the exposed portion of the UEFPC channel at several locations, including the North/South Pipe.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Five groundwater samples have been collected to date, with the conventional sampling method used to obtain one sample in June 1996, and the low-flow sampling method used to obtain four samples between October June 2000 and November 2003. The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Conasauga Group (Maynardville Limestone). Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 17 ft bgs and exhibits seasonal fluctuations of about 4 ft.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- relatively high TDS (350 - 425 mg/L);
- neutral pH (field measurements) of 6.3 – 7.1;
- very high sulfate concentrations (>90 mg/L);
- low molar proportions of chloride, potassium, and sodium (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Although elevated sulfate levels in groundwater from the Maynardville Limestone may reflect the geochemical influence of secondary minerals in the bedrock (e.g., pyrite), the very high sulfate concentrations in the groundwater at this well most likely indicate contamination. There are numerous potential non-specific sources within Y-12, such as leaking industrial process lines, sanitary sewers, or storm drains, but sulfur leached from the coal stockpile for the Y-12 Steam Plant, which is about 1,100 ft directly west (hydraulically upgradient) of the well, is the most likely source of the sulfate.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Five groundwater samples had nitrate concentrations at or above the applicable analytical reporting limit, all less than 1 mg/L and substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Four groundwater samples had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.00119 mg/L in October 2000) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, each of the following VOCs were detected in each groundwater sample: PCE, TCE, and 12DCE (Table 1). The source of the VOCs in the groundwater at this well has not been determined, but each compound is a known component of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and UEFPC watersheds. In the UEFPC watershed east of the flow divide, which occurs near the west end of Y-12, the VOC plume appears to originate near the Fire Training Facility in the southwestern section of Y-12, extends eastward (parallel with geologic strike) and mixes with VOCs released from several sources in the central and eastern Y-12 areas, and enters Union Valley east of the ORR boundary along Scarboro Road (DOE 1998).

The highest concentrations have been reported for PCE (360 μg/L) and 12DCE (66 μg/L), with the most recent sampling results showing that PCE and TCE concentrations remain above respective MCLs (Table 1). Although there are significant gaps in the sampling history for this well, the available monitoring results show clearly decreasing summed VOC concentrations (Figure 1). The decreasing concentration trend is primarily attributable to PCE levels, which dropped by almost 65% between June 1996 (360 μg/L) and November 2003 (130 μg/L). However, a similar proportional concentration decrease is less evident for 12DCE (c12DCE), which exhibits a much more indeterminate concentration trend (Table 1). The significance of these divergent concentrations trends with respect to the relative flux of dissolved VOCs via the groundwater flow/transport pathways is not apparent from the available data.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

Gross beta activity above the applicable MDA and corresponding CE was reported for the groundwater sample collected in June 1996 (15.9 pCi/L), and this result is substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-703

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in December 1990, completed with an open-hole monitored interval from 133.8 to 182 ft bgs, and constructed with nominal 7-inch diameter steel (SF25) riser casing. The well is located in Bear Creek Valley (BCV) west of Y-12 and is a component of Exit Pathway Picket B, which consists of a series of wells (GW-694, GW-695, GW-703, GW-704, GW-705, and GW-706) completed at different depths (and hydrostratigraphic zones) along a strike-normal transect across the Maynardville Limestone (Figure 1). The Maynardville Limestone subcrops along the axis of BCV and underlies the main channel of Bear Creek.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-three groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 19 samples between June 1991 and August 1997, and the low-flow sampling method used to obtain 14 samples between February 1998 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the intermediate bedrock interval in the Maynardville Limestone (Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 40 ft bgs and exhibits seasonal fluctuations up to about 10 ft. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV and on Chestnut Ridge, groundwater elevation isopleths in the vicinity of Exit-Pathway Picket B indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 225 – 450 mg/L;
- pH of 6.5 – 8.4 (field measurements);
- elevated concentrations of chloride (>30 mg/L) and sulfate (>25 mg/L) relative to other wells completed at similar depths in the Maynardville Limestone;
- low molar proportions of potassium and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

It is not clear if the elevated chloride and sulfate concentrations typical of the groundwater samples reflect localized geochemical characteristics, such as dissolution of locally disseminated sulfide minerals, or if the elevated concentrations are the result of contamination from one or more sources upgradient of the well.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, nitrate, VOCs, and gross beta activity are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Nitrate concentrations above the analytical reporting limit were reported for all the groundwater samples collected to date (Table 1), with 24 samples having concentrations that exceed the drinking water MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds, which are unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988. Located about 7,200 ft east-northeast (hydraulically upgradient) of the Exit Pathway Picket B, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984. The groundwater contaminant plume originating from the site contains a heterogeneous mixture of inorganic, organic, and radiological contaminants. Nitrate, a principal component of the plume, enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale and recharge of nitrate-contaminated surface water in Bear Creek (DOE 1997). Nitrate is chemically stable and highly mobile in groundwater and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells, the extent of nitrate contamination in the Maynardville Limestone in BCV west of Y-12, as defined by concentrations above 10 mg/L, is generally characterized by: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for about 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) and is significantly influenced by hydrologic interactions with surface water in Bear Creek.

Nitrate concentrations detected in the groundwater samples range from less than 1 mg/L to just under 25 mg/L (Table 1). However, the historical minimum concentration (0.98 mg/L in February 1999) appears to be an outlier compared to the remaining nitrate values, all of which exceed 5 mg/L. As noted previously, more than half of the samples had nitrate concentrations above the MCL, and half of these samples had concentrations near 20 mg/L, including the samples collected most recently (February and July 2004). The nitrate concentrations do not exhibit significant temporal variations or reflect any consistent relationship with seasonal groundwater flow conditions.

A time-series plot of nitrate concentrations in the groundwater samples shows an indeterminate trend with a sharp concentration increase between March and November 1992, followed by generally decreasing concentrations through December 1999, and subsequent concentration increase through January 2002 and fairly steady concentrations thereafter (Figure 2). The initial rise and fall in the concentration of nitrate suggests a temporal "pulse" or "slug" in the relative flux of nitrate via the groundwater flow/transport pathways intercepted by the monitored interval in the well. Increasing concentrations of nitrate evident since December 1999 may represent another such temporal change in nitrate flux.

5.2 URANIUM

All but two of the groundwater samples collected to date (one sample was not analyzed for uranium) had uranium concentrations at or above the applicable analytical reporting limit, with the highest values (0.00765 mg/L and 0.00763 mg/L in February and July 2004, respectively) being almost an order-of-magnitude below the drinking water MCL for uranium (0.03 mg/L). Nevertheless, the most recent uranium results reflect an order-of-magnitude increase from the uranium concentrations evident during the early 1990s (e.g., 0.001 mg/L in November 1991).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample collected to date (Table 2): benzene, CTET, chloroform, PCE, TCE, 11DCE, 12DCE (isomers), and 111TCA. These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. In the Bear Creek watershed west of the flow divide, the VOC plume in the Maynardville Limestone appears to originate near Spoil Area I and to extend several thousand feet westward (parallel with geologic strike) down the axis of BCV, with influx of various VOCs from several different downgradient source areas. The distribution of VOCs within the plume reflects the relative contributions from the source areas and commingling during downgradient transport. Plume constituents in the upper part of BCV are TCE, c12DCE, and PCE; source areas include Spoil Area I and the former S-3 Ponds. Farther downstream (west), major inputs of VOCs occur from the Rust Spoil Area or a nearby source in the Bear Creek floodplain; the Oil Landfarm waste management area (WMA), including the former Boneyard/Burnyard (BYBY), Hazardous Chemical Disposal Area (HCDA), and Sanitary Landfill I; and inflow of VOC-contaminated groundwater and surface water that discharges from a northern tributary of Bear Creek (NT-7) that traverses the Bear Creek Burial Grounds WMA. The highest VOC concentrations within the Maynardville Limestone exceed 300 µg/L and occur in the deeper groundwater south (down dip) of the HCDA, about 2,200 ft east-northeast (hydraulically upgradient) of Exit Pathway Picket B. These high concentrations coincide with downward vertical hydraulic gradients in the Maynardville Limestone in this area and a major losing reach of the main channel of Bear Creek (DOE 1997).

The primary VOCs in the groundwater samples are TCE and 12DCE (Table 2). The dominant compound is TCE, which was detected in every sample, with the historical maximum concentration of 28 µg/L in March 1993. The most recent sampling results show that the TCE concentrations remain above the drinking water MCL (5 µg/L). Low concentrations of 12DCE were detected in all but five of the samples, with all but one of the results being less than 10 µg/L and the most recent data showing c12DCE concentrations substantially below the MCL (70 µg/L). The remaining VOCs were detected in only eight of the groundwater samples, all collected between September 1992 and August 1998, and all of the reported concentrations are estimated values below 5 µg/L (Table 2).

A time-series plot of TCE concentrations in the groundwater samples shows a generally decreasing long-term concentration trend (Figure 3), with the most recent TCE concentration (12 µg/L in July 2004) being about 45% lower than evident during the early 1990s. The overall decrease in TCE levels probably results from corrective actions at the primary sources of VOCs in BCV west of Y-12, including the closure of the Oil Landfarm WMA and the installation of low-permeability caps at the site, and the CERCLA remedial actions at the BYBY/HCDA, which involved the excavation and removal of contaminated soils above and below the saturated zone (BJC 2003). Additionally, the TCE results show significant temporal variation, with cyclical "peak" concentrations typically reported for samples obtained during seasonally high groundwater flow conditions (winter and spring). These fluctuations potentially correspond with changes in the relative flux of TCE along the groundwater flow/transport pathways intercepted by the monitored interval in the well.

Unlike TCE, the concentrations of the other VOCs detected in the groundwater samples do not exhibit any discernable long-term trend or significant temporal concentration fluctuations (Table 2), as illustrated by the 12DCE (total) concentrations reported for the samples collected in March 1992 (5 μg/L), July 1996 (4 μg/L), January 2000 (5 μg/L), and July 2004 (4 μg/L). Assuming the groundwater contaminant plume in the Maynardville Limestone contains a heterogeneous mixture of dissolved VOCs, it is not clear from the available data why the concentrations of individual compounds exhibit divergent long-term trends and temporal variations, or if such variations are significant with respect to the relative flux of dissolved VOCs in the groundwater.

5.4 GROSS ALPHA ACTIVITY

Twenty-two of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the two highest values (18.4 pCi/L in June 1992 and 24 pCi/L in January 2000) exceeding the drinking water MCL for gross alpha activity (15 pCi/L). However, these results appear to be outliers compared to the other results for gross alpha activity, which are all less than 10 pCi/L, including the results reported for the samples collected most recently (February and July 2004).

5.5 GROSS BETA ACTIVITY

All but two of the groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE (Table 1), including four samples with gross beta activity above the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). The source of the gross beta activity in the groundwater at this well is Tc-99, which was detected (i.e., >MDA and CE) in the samples collected in January 2001 (54 pCi/L), July 2001 (65 pCi/L), January 2002 (66 pCi/L), and July 2002 (62 pCi/L). Note that all the Tc-99 results are substantially below the SDWA screening level (3,790 pCi/L) for a 4 mrem/yr dose equivalent from Tc-99. This beta-emitting radionuclide is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, which is the only site at Y-12 that received wastes that contained Tc-99 (DOE 1997). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the transport of Tc-99 in the Maynardville Limestone closely mirrors that of nitrate.

A time-series plot of gross beta activity reported for the groundwater samples shows a generally increasing long-term trend dominated by wide temporal fluctuations, some of which may be attributable to inherent analytical variability (Figure 4). Nevertheless, the overall increase in gross beta activity suggests a corresponding increase in the relative flux of Tc-99 via the groundwater flow/transport pathways intercepted by the monitored interval in the well. The temporal changes in gross beta activity do not exhibit any consistent relationship with seasonal groundwater flow conditions, as illustrated by the comparable "peak" concentrations reported for samples collected during low flow conditions in June (48.2 mg/L) and September 1992 (47.8 mg/L) and during high flow conditions in December 1993 (42.7 mg/L) February 1994 (44.5 mg/L).

WELL GW-704

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in December 1990, completed with an open-hole monitored interval from 244.5 to 256 ft bgs, and constructed with nominal 7-inch diameter steel (SF25) riser casing. The well is located in Bear Creek Valley (BCV) west of Y-12 and is a component of Exit Pathway Picket B, which consists of a series of wells (GW-694, GW-695, GW-703, GW-704, GW-705, and GW-706) completed at different depths (and hydrostratigraphic zones) along a strike-normal transect across the Maynardville Limestone (Figure 1). The Maynardville Limestone subcrops along the axis of BCV and underlies the main channel of Bear Creek.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-five groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 19 samples between June 1991 and August 1997, and the low-flow sampling method used to obtain 16 samples between January 1998 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the intermediate bedrock interval in the Maynardville Limestone (Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 31 ft bgs and exhibits seasonal fluctuations up to about 17 ft. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV and on Chestnut Ridge, groundwater elevation isopleths in the vicinity of Exit-Pathway Picket B indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 180 – 440 mg/L;
- pH of 7.2 – 8.4 (field measurements);
- elevated concentrations of chloride (>25 mg/L) and sulfate (>30 mg/L) relative to other wells completed at similar depths in the Maynardville Limestone;
- low molar proportions of potassium and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

It is not clear if the elevated chloride and sulfate concentrations typical of the groundwater samples reflect localized geochemical characteristics, such as dissolution of locally disseminated sulfide minerals, or if the elevated concentrations are the result of contamination from one or more sources upgradient of the well.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, nitrate, VOCs, and gross beta activity are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Nitrate concentrations above the analytical reporting limit were reported for all but one of the groundwater samples collected to date (Table 1), with 24 samples having concentrations that exceed the drinking water MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds, which are unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988. Located about 7,200 ft east-northeast (hydraulically upgradient) of the Exit Pathway Picket B, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984. The groundwater contaminant plume originating from the site contains a heterogeneous mixture of inorganic, organic, and radiological contaminants. Nitrate, a principal component of the plume, enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale and recharge of nitrate-contaminated surface water in Bear Creek (DOE 1997). Nitrate is chemically stable and highly mobile in groundwater and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells, the extent of nitrate contamination in the Maynardville Limestone in BCV west of Y-12, as defined by concentrations above 10 mg/L, is generally characterized by: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for about 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) and is significantly influenced by hydrologic interactions with surface water in Bear Creek.

As noted previously, most of the groundwater samples had nitrate concentrations above the MCL (Table 1), with the highest concentrations reported for samples collected in November 1992 (19 mg/L), February 1994 (20.8 mg/L), and December 1994 (18 mg/L). Also, the unusually low nitrate concentrations reported for samples collected in December 1993 (0.23 mg/L) and July 2004 (0.0429 mg/L) are substantially less than the other nitrate results and may be analytical artifacts. Additionally, the nitrate concentrations exhibit apparently seasonal fluctuations, with the highest concentrations typically reported for samples collected during seasonally high groundwater flow conditions (winter and spring). This relationship suggests increased flux of nitrate from seasonal (and episodic) recharge of nitrate-contaminated groundwater via the flow/transport pathways intercepted by the monitored interval in the well.

A time-series plot of nitrate concentrations in the groundwater samples shows a generally decreasing long-term trend dominated by wide temporal fluctuations (Figure 2). The overall decrease in nitrate concentrations probably reflect the substantially reduced flux of nitrate following closure of the former S-3 Ponds and installation of the low-permeability cap at the site. Also, the nitrate results reported for the samples obtained with the low-flow sampling method exhibit significantly more temporal variation than indicated by the nitrate results reported for the samples obtained with the conventional sampling method. This may be at least partially attributable to inherent differences in the manner in which each sampling method induces flow of groundwater into the well. Conventional sampling involves aggressively purging the well (1-2 gallons per minute), which may substantially lower the water level in the well and induce inflow from water-producing features (e.g., conduits or fractures) that may not be proximal to the well. In contrast, low-flow sampling involves purging the well at flow rate low enough (<300 milliliters per minute) to ensure minimal water-level drawdown in the well (<1 ft per quarter hour), which induces groundwater flow from the water-producing features more proximal to the well.

5.2 URANIUM

Twenty-eight groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.0194 mg/L in February 2004) being less than the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample collected to date (Table 2): benzene, bromoform, CTET, chloroform, PCE, TCE, 11DCA, 11DCE, 12DCE (isomers), and 111TCA. These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. In the Bear Creek watershed west of the flow divide, the VOC plume in the Maynardville Limestone appears to originate near Spoil Area I and to extend several thousand feet westward (parallel with geologic strike) down the axis of BCV, with influx of various VOCs from several different downgradient source areas. The distribution of VOCs within the plume reflects the relative contributions from the source areas and commingling during downgradient transport. Plume constituents in the upper part of BCV are TCE, c12DCE, and PCE; source areas include Spoil Area I and the former S-3 Ponds. Farther downstream (west), major inputs of VOCs occur from the Rust Spoil Area or a nearby source in the Bear Creek floodplain; the Oil Landfarm waste management area (WMA), including the former Boneyard/Burnyard (BYBY), Hazardous Chemical Disposal Area (HCDA), and Sanitary Landfill I; and inflow of VOC-contaminated groundwater and surface water that discharges from a northern tributary of Bear Creek (NT-7) that traverses the Bear Creek Burial Grounds WMA. The highest VOC concentrations within the Maynardville Limestone exceed 300 µg/L and occur in the deeper groundwater south (down dip) of the HCDA, about 2,200 ft east-northeast (hydraulically upgradient) of Exit Pathway Picket B. These high concentrations coincide with downward vertical hydraulic gradients in the Maynardville Limestone in this area and a major losing reach of the main channel of Bear Creek (DOE 1997).

The primary VOCs in the groundwater samples are TCE, 11DCE, and 12DCE (Table 2). The dominant compound is TCE, which was detected in every sample, with the historical maximum concentration of 120 µg/L (March 1993). The more recent sampling results show lower concentrations of TCE that nonetheless remain substantially above the drinking water MCL (5 µg/L). Concentrations of 11DCE and 12DCE are much lower than those of TCE, with most of the results for these compounds being estimated values below 5 µg/L. Although the historical maximum concentration of 11DCE (8 µg/L in December 1994 and February 1998) slightly exceeds the MCL (7 µg/L), the most recent sampling results show 11DCE concentrations below the MCL. Results for c12DCE reported for all the samples collected since 1997 show concentrations at least an order-of-magnitude below the MCL (70µg/L). Secondary compounds in the groundwater samples are CTET, 11DCA, and 111TCA (Table 2). None of these VOCs have been detected in groundwater samples collected since January 2000 and all of the results for each compound are estimated concentrations of 2 µg/L or less. Benzene, bromoform, chloroform, and methylene chloride were each detected at trace concentrations (1 µg/L or less) in no more than two of the samples, and each of these results may be a sampling or analytical artifact.

A time-series plot of TCE concentrations in the groundwater samples shows a generally decreasing long-term concentration trend (Figure 3), with the most recent TCE concentration (37 µg/L in July 2004) being about 66% lower than the historical maximum concentration (120 µg/L in March 1993). The overall decrease in TCE levels probably results from corrective actions at the primary sources of VOCs in BCV west of Y-12, including the closure of the Oil Landfarm WMA and the installation of low-permeability caps at the site, and the CERCLA remedial actions at the BYBY/HCDA, which involved the excavation and removal of contaminated soils above and below the saturated zone (BJC 2003). Additionally, the TCE results show significant temporal variation, with cyclical "peak" concentrations typically reported for samples obtained during seasonally low groundwater flow conditions (summer and fall), and the lowest TCE levels detected in samples obtained during seasonally high flow conditions (winter and fall). This relationship suggests that the lower TCE concentrations reflect "dilution" from seasonal (or episodic) recharge of uncontaminated (or less TCE-contaminated) groundwater via the flow/transport pathways intercepted by the monitored interval in the well.

Unlike TCE, the concentrations of the other VOCs detected in the groundwater samples do not exhibit any discernable long-term trend or significant temporal concentration fluctuations (Table 2), as illustrated by the 12DCE concentrations reported for the samples collected in June 1992 (3 µg/L), August 1997 (3 µg/L), and January 2004 (2 µg/L). Assuming the groundwater contaminant plume in the Maynardville Limestone contains a heterogeneous mixture of dissolved VOCs, it is not clear from the available data why the concentrations of individual compounds exhibit divergent long-term trends and temporal variations, or if such variations are significant with respect to the relative flux of dissolved VOCs.

5.4 GROSS ALPHA ACTIVITY

Nineteen groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (31.3 pCi/L in August 1996) exceeding the MCL for gross alpha activity (15 pCi/L). However, the historical maximum appears to be an outlier compared to the other results for gross alpha activity, which are all near 10 pCi/L (e.g., 11 pCi/L in February 2004).

5.5 GROSS BETA ACTIVITY

Twenty-two groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE (Table 1). Although all of the results are less than the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the MCL for gross beta activity), most exceed background levels of gross beta activity in groundwater. The source of the beta activity has not been conclusively determined. Some of the beta activity may be from uranium isotopes and related beta-emitting decay products based on the relatively low levels of U-234 (1.31 – 3.07 pCi/L) and U-238 (1.03 – 5.34 pCi/L) detected in the ten groundwater samples that were analyzed for these isotopes. None of the samples were analyzed for Tc-99, which is the primary beta-emitting isotope in groundwater samples from other Exit Pathway Picket B wells (e.g., GW-703). Technetium-99 is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, which is the only site at Y-12 that received wastes containing this radionuclide (DOE 1998). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the transport of Tc-99 in the Maynardville Limestone closely mirrors that of nitrate.

A time-series plot of gross beta activity reported for the groundwater samples shows a generally increasing long-term trend dominated by wide temporal fluctuations, some of which may be attributable to inherent analytical variability (Figure 4). The results for gross beta activity do not exhibit any clear or consistent relationship with seasonal groundwater flow conditions, as illustrated by the results for samples collected during low-flow conditions in July 2001 (16 pCi/L), July 2002 (41 pCi/L), July 2003 (13 pCi/L), and July 2004 (<MDA). Moreover, the gross beta results reported for the samples obtained with the low-flow sampling method exhibit significantly more temporal variation than indicated by the nitrate results reported for the samples obtained with the conventional sampling method. As noted previously regarding the nitrate concentrations in the samples, this may be at least partially attributable to inherent differences in the manner in which each sampling method induces inflow of groundwater into the well (see Section 5.1).

WELL GW-706

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in January 1991, completed with an open-hole monitored interval from about 156.1 to 182.5 ft bgs, and constructed with nominal 7-inch diameter steel (SF25) riser casing. The well is located in Bear Creek Valley (BCV) approximately 7,000 ft west of Y-12, near the base of the steep northern flank of Chestnut Ridge, about 200 ft directly south of the main channel of Bear Creek. The well is a component of Exit Pathway Picket B, which consists of a series of wells (GW-621, GW-694, GW-695, GW-703, GW-704, GW-705, and GW-706) completed at different depths (and hydrostratigraphic zones) along a strike-normal transect across the Maynardville Limestone (Figure 1). The Maynardville Limestone subcrops along the axis of BCV and underlies the main channel of Bear Creek throughout BCV.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-nine groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 21 samples between June 1991 and July 2000, and the low-flow sampling method used to obtain 18 samples between January 1998 and July 2004.

An evaluation of the monitoring data available through August 2000 indicated potential bias related to the groundwater sampling method: samples obtained with the conventional sampling method had substantially lower nitrate concentrations than samples obtained with the low-flow sampling method (AJA 2001). Results of "paired sampling" performed during January/February and July 2000, when groundwater samples were collected with the low-flow sampling method one day and the conventional sampling method the next day, confirm the apparent sampling-method bias (Table 1); nitrate concentrations in the samples obtained with the low-flow method are about 50% higher than the corresponding nitrate concentrations in the samples obtained with the conventional sampling method. Also, the conventional sampling method appears to promote the inflow of less mineralized groundwater into the well, as illustrated by the lower TDS (and sharply lower calcium levels) evident with the conventional sampling event in February 2000 (Table 1). Unfiltered samples obtained with the conventional sampling method also typically have higher total suspended solids (TSS), which show a direct correlation with total iron concentrations (see Section 4.0).

Inherent differences in the manner in which each sampling method induces flow of groundwater into the well may explain the disparity between the conventional and low-flow sampling results for nitrate. Conventional sampling involves aggressively purging the well (1-2 gallons per minute), which may substantially lower the water level in the well and induce flow from water-producing features that may not be near the monitored interval of the well. Conventional sampling also appears to disturb fine-grained particles in the bottom of the well or in the fractures intercepted by the open-hole interval, which frequently results in the collection of unfiltered samples with significant levels of TSS, including the samples collected in September 1991 (13 mg/L), November 1992 (10 mg/L), September 1993 (27 mg/L), and February 2000 (15 mg/L). In contrast, low-flow sampling involves purging the well at flow rate low enough (<300 milliliters per minute) to ensure minimal water-level drawdown in the well (<1 ft per quarter hour), which induces groundwater inflow from the water-producing feature(s) near the well. Thus, the conventional sampling method appears to induce inflow of less mineralized groundwater (with lower nitrate levels) from water-producing features that are not proximal to the well. If so, it seems unusual that the inflow does not seem to influence the concentrations of other analytes in the samples, including groundwater contaminants (e.g., VOCs).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the intermediate bedrock interval in the Maynardville Limestone (Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 12 ft bgs and exhibits seasonal fluctuations up to about 10 ft. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV and on Chestnut Ridge, groundwater elevation isopleths in the vicinity of Exit-Pathway Picket B indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields chloride- and sodium-enriched, nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 165 – 820 mg/L;
- pH of 5.2 – 8 (field measurements);
- iron (total) concentrations that sporadically exceed 10 mg/L;
- elevated concentrations of chloride (>40 mg/L) and sulfate (>30 mg/L) relative to other wells completed at shallower depths in the Maynardville Limestone
- low molar proportions of potassium and sodium (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

It is not clear if the chloride and sodium concentrations typical of the groundwater samples reflect localized geochemical characteristics, or if the elevated concentrations are the result of contamination from one or more sources upgradient of the well. Also, the unusually high total iron concentrations in the samples show a direct correlation with the TSS in the samples and are clearly artifacts of the preservation of the unfiltered samples (i.e., acidification below a pH of 2).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, these contaminants are all present at elevated levels in the groundwater at this well.

5.1 NITRATE

Nitrate concentrations above the analytical reporting limit were reported for all but two of the groundwater samples collected to date that were analyzed for nitrate (Table 2), and all of these results equal or exceed the drinking water MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds, which are unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988. Located about

7,200 ft east-northeast of the Exit Pathway Picket B, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984. The groundwater contaminant plume originating from the site contains a heterogeneous mixture of inorganic, organic, and radiological contaminants. Nitrate, a principal component of the plume, enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale and recharge of nitrate-contaminated surface water in Bear Creek (DOE 1997). Nitrate is chemically stable and highly mobile in groundwater and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells, the extent of nitrate contamination in the Maynardville Limestone in BCV west of Y-12, as defined by concentrations above 10 mg/L, is generally characterized by: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for about 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) and is significantly influenced by hydrologic interactions with surface water in Bear Creek.

As shown on Table 1, nitrate concentrations above the analytical reporting limit range between the historical minimum and maximum values of 10 mg/L (June 1991) and 99 mg/L (January 2001), with the highest concentrations (including the historical maximum value) reported for samples obtained using the low-flow sampling method (see Section 2.0). Compared to the other low-flow sampling results, which are all less than 50 mg/L, the historical maximum value appears to be an outlier. Nevertheless, the low-flow sampling results show wide seasonal fluctuations in nitrate concentrations, and the historical maximum value may be an unusually high temporal peak, which often correlate with samples obtained during seasonally high groundwater flow conditions (winter and spring). Although the highest nitrate concentration reported for samples obtained with the conventional sampling method (84 mg/L in November 1991) is comparable to the historical maximum nitrate value, most of the conventional sampling results for nitrate are below 40 mg/L, including three non-detect results (Table 1). Also, unlike the low-flow sampling data, the temporal peak nitrate concentrations indicated by the conventional sampling results often correlate with samples obtained during seasonally low groundwater flow conditions (summer and fall).

Respective time-series plots of nitrate concentrations in the groundwater samples obtained with the low-flow sampling method (Figure 2) and conventional sampling method (Figure 3) show generally decreasing long-term concentrations trends punctuated by wide temporal (seasonal) fluctuations. The low-flow sampling results, for instance, show an overall decrease of about 45% between January 1998 (45.7 mg/L and July 2004 (24.2 mg/L). The long-term decrease in nitrate concentrations is attributable to the reduced flux of nitrate from the former S-3 Ponds following closure of the site and installation of the low-permeability cap (DOE 1997).

5.2 URANIUM

All of the groundwater samples collected to date that were analyzed for uranium had concentrations at or above the applicable analytical reporting limit (Table 2), and the results for most of these samples exceed the drinking water MCL for uranium (0.03 mg/L). There are several sources of uranium in BCV hydraulically upgradient of Exit Pathway Picket B, including the contaminant plume originating from the former S-3 Ponds and inflow of uranium-contaminated surface water in Bear Creek. The CERCLA remedial investigation identified the former Boneyard/Burnyard (BYBY) as the primary source of uranium in groundwater from the Maynardville Limestone hydraulically downgradient (west) of the site (DOE 1997), which is about 2,500 ft east of Exit Pathway Picket B. Uranium-bearing wastes disposed at the BYBY were below the seasonally high water table and the limestone bedrock provided a ready source of dissolved carbonate, which combined with uranyl cations leached from the wastes and greatly increased what would otherwise be relatively limited mobility in the neutral pH groundwater in the Maynardville Limestone (DOE 1997). As a major source area, the BYBY was prioritized for CERCLA remedial action, which was completed in May 2003 and involved: (1) the excavation and on-site consolidation/off-site disposal of about 81,000 yd^3 of waste materials; (2) construction of a multi-layer low-permeability cap over waste materials consolidated on site; and (3) reconstruction of a northern tributary of Bear Creek (NT-3) that drains the site (BJC 2004).

As noted previously, total uranium concentrations reported for most of the groundwater samples, including the samples collected most recently (February and July 2004), exceed the MCL (0.03 mg/L). The three results that are below the MCL (June 1991, March 1993, and September 1993) appear to be outliers (too low) and may be analytical artifacts (Table 2). Also, the results of paired low-flow and conventional sampling (see Section 2.0) are inconclusive with respect to uranium concentrations (Table 1), with sample obtained with the low-flow sampling method in February 2000 having a substantially lower uranium concentration (0.0808 mg/L) then the sample obtained with the conventional sampling method (0.277 mg/L) the next day, but nearly equal uranium concentrations reported for the samples obtained with the from low-flow and conventional methods in July 2000. Also, the uranium concentrations do not exhibit any consistent correlation with seasonal flow conditions, as illustrated by the temporal peak concentrations reported for samples collected during both seasonally low (e.g., 0.139 mg/L in July 1998) and seasonally high (e.g., 0.23 mg/L in December 1993) groundwater flow conditions.

A time-series plot of uranium concentrations in the groundwater samples shows an indeterminate long-term trend (Figure 3). Also, the uranium concentrations reported for groundwater samples collected since January 2002 suggest a decreasing trend, with the concentration reported for the sample collected in July 2003 (0.0662 mg/L) being the lowest value reported for the well since March 1995 (0.078 mg/L). The recent decrease in uranium concentrations may be attributable to the CERCLA remedial action at the BYBY.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in all but four of the groundwater samples collected to date (Table 3): PCE, TCE, 11DCE, and 12DCE (isomers). These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. In the Bear Creek watershed west of the flow divide, the VOC plume in the Maynardville Limestone appears to originate near Spoil Area I and to extend several thousand feet westward (parallel with geologic strike) down the axis of BCV, with influx of various VOCs from several different downgradient source areas. The distribution of VOCs within the plume reflects the relative contributions from the source areas and commingling during downgradient transport. Plume constituents in the upper part of BCV are TCE, c12DCE, and PCE; source areas include Spoil Area I and the former S-3 Ponds. Farther downstream (west), major inputs of VOCs occur from the Rust Spoil Area or a nearby source in the Bear Creek floodplain; the Oil Landfarm waste management area (WMA), including the former Boneyard/Burnyard (BYBY), Hazardous Chemical Disposal Area (HCDA), and Sanitary Landfill I; and inflow of VOC-contaminated groundwater and surface water that discharges from a northern tributary of Bear Creek (NT-7) that traverses the Bear Creek Burial Grounds WMA. The highest VOC concentrations within the Maynardville Limestone exceed 300 μg/L and occur in the deeper groundwater south (down dip) of the HCDA, about 2,500 ft east-northeast (hydraulically upgradient) of Exit Pathway Picket B. These high concentrations coincide with downward vertical hydraulic gradients in the Maynardville Limestone in this area and a major losing reach of the main channel of Bear Creek (DOE 1997).

The primary VOCs in the groundwater samples are TCE and 12DCE (c12DCE), at least one of which was detected in all but four of the samples (Table 3), with respective historical maximum concentrations of 30 μg/L and 34 μg/L in March 1992. The most recent sampling results (February and July 2004) show TCE concentrations slightly above the drinking water MCL (5 μg/L) and c12DCE concentrations substantially below the MCL (70 μg/L). Other VOCs (PCE and 11DCE) were detected only in the four samples collected between March and November 1992, and all of these results are estimated values below 5 μg/L. Additionally, as noted in Section 2.0 and illustrated by the data summarized below, there are not any significant differences between concentrations of VOCs detected in the groundwater samples obtained with the conventional and low-flow sampling methods.

VOC	Concentration (μg/L)			
	Low-Flow Sampling January 31, 2000	**Conventional Sampling February 1, 2000**	**Low-Flow Sampling July 25, 2000**	**Conventional Sampling July 26, 2000**
TCE	9	11	13	12
c12DCE	3 J	6	7	8

These findings suggest that the VOC concentrations are not strongly influenced by the apparent tendency for the conventional sampling method to induce inflow of less mineralized (and less nitrate-contaminated) groundwater from the water-producing features intercepted by the monitored interval in the well.

A time-series plot of the summed VOC concentrations reported for the groundwater samples shows an indeterminate long-term trend dominated by wide temporal concentration fluctuations (Figure 5). Relatively unchanged concentrations of the VOCs in the groundwater at this well, as illustrated by the 12DCE results reported for the samples collected in November 1991 (11 μg/L) and January 2003 (12 μg/L), suggest minimal overall change in the relative flux of VOCs along the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

All but one of the groundwater samples collected to date that were analyzed for gross alpha activity had results above the applicable MDA and corresponding CE, and all but two of these results exceed the drinking water MCL for gross alpha activity (Table 4). Uranium isotopes (and alpha-emitting daughters) are the source elevated gross alpha activity in the groundwater at this well, with the most recent (February and July 2004) sampling results showing U-234 and U-238 levels near 15 pCi/L and 25 pCi/L, respectively (Table 4). The contaminant plumes originating from the former S-3 Ponds and the BYBY are primary sources of uranium isotopes in groundwater and surface water in BCV west of Y-12, with the latter site being the closest and most likely source of the uranium isotopes in the groundwater at the Exit Pathway Picket B wells (DOE 1997). As with total uranium (see Section 5.2), U-234 and U-238 ions leached from wastes disposed at the BYBY probably combined with carbonate dissolved from the (limestone) bedrock, which greatly increased their relatively limited mobility in the neutral pH groundwater in the Maynardville Limestone (DOE 1997).

Thirty-five groundwater samples had gross alpha activity above the MDA and corresponding CE (Table 4). The widest range of gross alpha activities, including the historical minimum (4.58 pCi/L in June 1991) and historical maximum values (120 pCi/L in February 2000), were reported for the samples obtained with the conventional sampling method. A smaller range of values for gross alpha activity is evident from the low-flow sampling results, with activities for all but three of the samples ranging between 20 and 60 pCi/L. Nevertheless, the "paired" sampling results for gross alpha activity do not suggest a clear and consistent bias from either sampling method (Table 1). Additionally, the gross alpha results reported for samples obtained with either method do not exhibit any clear and consistent relationship with seasonal groundwater flow conditions, as illustrated by temporal high levels reported for samples collected during seasonally high (e.g., 60 pCi/L in January 2003) and seasonally low (e.g., 88.5 pCi/L in November 1992) flow.

A time-series plot of the gross alpha activity reported for each groundwater sample shows an indeterminate long-term trend (Figure 6). This suggests minimal overall changes in the relative flux of alpha-emitting radionuclides along the groundwater flow/transport pathways intercepted by the well. However, the long-term trend is dominated by a series of temporal "peaks" evident in November 1991 (58.4 pCi/L), November 1992 (88.5 pCi/L), December 1993 (99.2 pCi/L), and February 2000 (120 pCi/L). It is not clear if these peak gross alpha activities are outliers (i.e., analytical artifacts) or if they are significant with respect to the relative flux of alpha-emitting radionuclides via the groundwater flow/transport pathways intercepted by the monitored interval in the well. Also, results for samples collected after February 2000 define a decreasing trend, with the gross alpha activity evident in July 2004 (20 pCi/L) being the lowest value reported for any sample collected since September 1997 (29 pCi/L). As with the recent decrease in total uranium concentrations (see Section 5.2), the apparent decrease in the levels of gross alpha activity in the groundwater at this well may be attributable to reduced flux of uranium isotopes as a result of the CERCLA remedial actions at the BYBY.

5.5 GROSS BETA ACTIVITY

All but three of the groundwater samples analyzed for gross beta activity had results above the applicable MDA and corresponding CE (Table 4), and all but four of these results exceed the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). Although uranium isotopes and related daughter products contribute to the gross beta activity in the groundwater at this well, Tc-99 is the primary source of the beta activity. Ten groundwater samples collected between March 1993 and August 1996 were analyzed for this beta-emitting radionuclide, and results that exceed the MDA and CE range from 25.3 pCi/L (August 1995) to 686 pCi/L (September 1993) and are substantially below the SDWA screening level (3,790 pCi/L) for a 4 mrem/yr dose equivalent (Table 4). Technetium-99 is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, the only site at Y-12 which received wastes that contained Tc-99 (DOE 1998). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the groundwater transport of Tc-99 in the Maynardville Limestone closely mirrors that of nitrate.

As noted previously, most of the groundwater samples had gross beta activity above the SDWA screening level (Table 4), including the samples collected most recently (February and July 2004). The lowest gross beta activities, including the historical minimum value (7.42 pCi/L in March 1993), were reported for samples obtained with the conventional sampling method, whereas the highest gross beta activities, including the historical maximum value (310 pCi/L in

January 2001), were reported for samples obtained with the low-flow sampling method. Nevertheless, as shown on Table 1, the results for gross beta activity obtained from "paired" sampling do not suggest consistent bias from either sampling method. Additionally, the gross beta activity reported for samples obtained with each method show wide temporal fluctuations, with the highest levels typically evident in samples obtained during seasonally high groundwater flow conditions (winter and spring). This potentially reflects seasonal (and episodic) inflow of Tc-99 contaminated recharge via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

A time-series plot of the gross beta activity reported for each groundwater sample shows an indeterminate or slightly increasing long-term trend dominated by prominent "spikes" evident in January 1991 (197 pCi/L), December 1993 (150 pCi/L), and January 2001 (310 pCi/L). The indeterminate long-term trend suggests minimal overall changes in the relative flux of beta-emitting radionuclides along the groundwater flow/transport pathways intercepted by the well. However, as illustrated by the data summarized in Table 4, the available results for Tc-99 show a clearly decreasing trend, with the Tc-99 activity reported for the sample collected in August 1996 (65.5 pCi/L) being an order-of-magnitude lower than the Tc-99 activity reported for the sample collected in December 1993 (686 pCi/L). This trend suggests a substantial reduction in the relative flux of Tc-99 as a direct consequence of the closure of the former S-3 Ponds and the installation of the low-permeability cap at the site.

WELL GW-709

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in April 1991, completed with a screened monitored interval from 68.7 to 80.6 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located on the southern flank of Chestnut Ridge directly south of Y-12, about 500 ft south (hydraulically downgradient) of Industrial Landfill II. This closed landfill operated from 1983 to 1996 and received combustible and decomposable nonhazardous solid waste, including construction spoil material (scrap metal, glass, paper, plastics, wood, asphalt roofing material) and special wastes (such as asbestos and beryllium oxide) generated from DOE operations on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-seven groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 21 samples between June 1991 and April 1997, and the low-flow sampling method used to obtain 16 samples between October 1997 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the bedrock interval in the Knox Group. The average static groundwater level in the well is 26 ft bgs. Although presampling depth-to-water measurements for the well suggest substantial (>30 ft) water-level fluctuations (Figure 1), excluding the unusually low water level in July 1994 and the unusually high water levels in April 1998 and January 2001, the groundwater elevations in the well typically fluctuate by less than 5 ft. The average result of several falling head permeability tests performed in well GW-709 (Jones 2004) indicates that the hydraulic conductivity of the bedrock near the well is about 1.26×10^{-5} cm/s (0.036 ft/day).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 100 – 251 mg/L;
- pH (field measurements) of 7.6 – 9.7;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Fourteen groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.58 mg/L in January 1995) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Thirteen groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.002 mg/L in June 1991) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for each groundwater sample show non-detect values or false positive results for all of the VOCs that are confirmed groundwater contaminants in the Chestnut Ridge Regime. Acetone was detected in groundwater samples collected in April 1999 (4 μg/L), October 1997 (76 μg/L), April 1999 (6 μg/L), and February 2000 (11 μg/L). Trace levels of toluene were reported for samples collected in July 1994 (0.3 μg/L) and July 2004 (0.27 μg/L). These results may be sampling or analytical artifacts because acetone and toluene are common laboratory reagents.

5.4 GROSS ALPHA ACTIVITY

Nine groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (25.6 pCi/L in November 1991) exceeding the MCL for gross alpha activity (15 pCi/L). However, this result is probably an outlier because none of the other gross alpha results exceed 5 pCi/L.

5.5 GROSS BETA ACTIVITY

Twelve groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (20.4 pCi/L in November 1991) being less than the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-710

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in July 1991, completed with an open-hole monitored interval from 539.7 to 744.5 ft bgs, and constructed with 7-inch diameter steel (SF25) riser casing. The well is located in Bear Creek Valley about three miles west of Y-12. It is a component of Exit Pathway Picket W, which consists of a series of wells (GW-710, GW-711, GW-712, GW-713, GW-714, and GW-715) completed at different depths (and hydrostratigraphic zones) along a strike-normal transect across the Maynardville Limestone (Figure 1), which underlies Bear Creek throughout the Bear Creek Regime. The interaction between the creek and the shallow karst network in the Maynardville Limestone provide the primary exit-pathways for groundwater and surface water contaminants originating from source areas in Bear Creek Valley west of Y-12.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Nineteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 17 samples between December 1991 and August 1997, and the low-flow sampling method used to obtain samples in January and July 2003.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the deep bedrock interval (>400 ft bgs) in the Maynardville Limestone. Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 65 ft bgs and exhibit moderate fluctuations (<10 ft).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields highly mineralized, sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- very high TDS (>1,000 mg/L);
- pH (field measurements) of 5.9 – 7.8; and
- total (unfiltered sample) concentrations of trace metals [except unusually high concentrations of several trace metals, notably boron (>1 mg/L) and strontium (>5 mg/L)] that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

A combination of several natural processes may account for the high boron and strontium concentrations in the groundwater at this well, including: mixing of the sulfate-enriched groundwater with brines in the deeper bedrock, which may cause precipitation of barite and celestite ($SrSO_4$); upward diffusion of the solutes from the deeper bedrock; and matrix diffusion from the bedrock (Saunders and Toran 1992).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Excluding a suspected outlier (74.9 mg/L) reported for a sample collected from the well in April 1993, none of the groundwater samples had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

None of the groundwater samples had uranium concentrations above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for each groundwater sample show non-detect values or false positive results for all of the VOCs that are principal groundwater contaminants in the Bear Creek Regime. However, benzene was detected in both samples collected in CY 2003 (10 μg/L in each sample) which may reflect naturally occurring concentrations at this depth (>700 ft bgs) in the Maynardville Limestone (known to be petroliferous). Very low (estimated values) single detections of acetone (1 μg/L in February 1997) and chloromethane (1 μg/L in July 2003) are considered outliers.

5.4 GROSS ALPHA ACTIVITY

Three groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with one result (32.3 pCi/L in December 1991) above and two results (5.2 pCi/L in September 1992, and 8.08 pCi/L in November 1992) below the MCL for gross alpha activity (15 pCi/L). The inconsistent detection and widely variable results for gross alpha activity may be related to analytical interference associated with the very high TDS of the (unfiltered) groundwater samples (see Section 4.0).

5.5 GROSS BETA ACTIVITY

Five groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (63 pCi/L in August 1997) exceeding the SDWA screening level for gross beta activity (50 pCi/L). As described for gross alpha activity, the inconsistent detection and widely variable results (6.8 pCi/L to 63 pCi/L) for gross beta activity may be related to analytical interference associated with the very high TDS of the groundwater samples (see Section 4.0).

WELL GW-711

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in July 1991, completed with an open-hole monitored interval from 616 to 666.2 ft bgs, and constructed with 7-inch diameter steel (SF25) riser casing. The well is located in Bear Creek Valley about three miles west of Y-12. It is a component of Exit Pathway Picket W, which consists of a series of wells (GW-710, GW-711, GW-712, GW-713, GW-714, and GW-715) completed at different depths (and hydrostratigraphic zones) along a strike-normal transect across the Maynardville Limestone (Figure 1), which underlies Bear Creek throughout the Bear Creek Regime. The interaction between the creek and the shallow karst network in the Maynardville Limestone provide the primary exit-pathway for groundwater and surface water contaminants originating from source areas in Bear Creek Valley west of Y-12.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Nineteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 17 samples between December 1991 and August 1997, and the low-flow sampling method used to obtain samples in January and July 2003.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the deep bedrock interval (<400 ft bgs) in the Maynardville Limestone. The average static groundwater level in the well is 59 ft bgs. Presampling depth-to-water measurements for the well indicate moderate (<10 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields highly mineralized, sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- very high TDS (>1,000 mg/L);
- pH (field measurements) of 6.6 – 9.7; and
- total (unfiltered sample) concentrations of trace metals [except unusually high concentrations of several trace metals, notably boron (>1 mg/L) and strontium (>5 mg/L)] that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

A combination of several natural processes may account for the high boron and strontium concentrations in the groundwater at this well, including: mixing of the sulfate-enriched groundwater with brines in the deeper bedrock, which may cause precipitation of barite and celestite ($SrSO_4$); upward diffusion of the solutes from the deeper bedrock; and matrix diffusion from the bedrock (Saunders and Toran 1992).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

None of the groundwater samples had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

None of the groundwater samples had uranium concentrations above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for each groundwater sample show non-detect values or false positive results for all of the VOCs that are confirmed groundwater contaminants in the Bear Creek Regime.

5.4 GROSS ALPHA ACTIVITY

Two groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with one result (23.8 pCi/L in December 1991) above and one result (3.31 pCi/L in March 1992) below the MCL for gross alpha activity (15 pCi/L). Both results are probably sampling or analytical artifacts.

5.5 GROSS BETA ACTIVITY

Four groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (22.3 pCi/L in March 1992) being less than the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-712

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in June 1991, completed with an open-hole monitored interval from 441.5 to 457.5 ft bgs, and constructed with 7-inch diameter steel (SF25) riser casing. The well is located in Bear Creek Valley about three miles west of Y-12. It is a component of Exit Pathway Picket W, which consists of a series of wells (GW-710, GW-711, GW-712, GW-713, GW-714, and GW-715) completed at different depths (and hydrostratigraphic zones) along a strike-normal transect across the Maynardville Limestone (Figure 1), which underlies Bear Creek throughout the Bear Creek Regime. The interaction between the creek and the shallow karst network in the Maynardville Limestone provide the primary exit-pathway for groundwater and surface water contaminants originating from source areas in Bear Creek Valley west of Y-12.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-one groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 17 samples between December 1991 and August 1997, and the low-flow sampling method used to obtain 14 samples between January 1998 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the deep bedrock interval (<400 ft bgs) in the Maynardville Limestone. Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 30 ft bgs and exhibit substantial (11 ft) fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

This well yields sulfate-enriched (>50% of total anions) calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 250 – 898 mg/L;
- pH (field measurements) of 7.3 – 8.5;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Eighteen groundwater samples had nitrate concentrations above the analytical reporting limit, with the highest concentration (1.4 mg/L in July 2000) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Seven groundwater samples had uranium concentrations above the analytical reporting limit, with the highest concentration (0.001 mg/L) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for each groundwater sample show non-detect values or false positive results for all of the VOCs that are confirmed groundwater contaminants in the Bear Creek Regime. The single detections of acetone (6 µg/L in July 1998), chlorobenzene (2 µg/L in January 2000), and bromomethane (2 µg/L in January 2001) are considered to be outliers.

5.4 GROSS ALPHA ACTIVITY

Six groundwater samples had gross alpha activity above the applicable MDA and corresponding CE. The highest activity (12.31 pCi/L in January 2003) is below the MCL for gross alpha activity (15 pCi/L) and is considered to be an outlier because the other results are below 6 pCi/L.

5.5 GROSS BETA ACTIVITY

Thirteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest activity (20.78 pCi/L in January 1999) being below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-713

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in January 1992, completed with an open-hole monitored interval from 305 to 315.2 ft bgs, and constructed with 7-inch diameter steel (SF25) riser casing. The well is located in Bear Creek Valley about three miles west of Y-12. It is a component of Exit Pathway Picket W, which consists of a series of wells (GW-710, GW-711, GW-712, GW-713, GW-714, and GW-715) completed at different depths (and hydrostratigraphic zones) along a strike-normal transect across the Maynardville Limestone (Figure 1), which underlies Bear Creek throughout the Bear Creek Regime. The interaction between the creek and the shallow karst network in the Maynardville Limestone provide the primary exit-pathway for groundwater and surface water contaminants originating from source areas in Bear Creek Valley west of Y-12.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-nine groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 15 samples between June 1992 and August 1997, and the low-flow sampling method used to obtain 14 samples between January 1998 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the intermediate bedrock interval in the Maynardville Limestone. The average static groundwater level in the well is 34 ft bgs. Presampling depth-to-water measurements for the well indicate substantial (10 - 25 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

This well yields sulfate-enriched (>50% of total anions) calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 319 – 564 mg/L;
- pH (field measurements) of 6.7 – 8.4;
- fluoride concentrations near 0.5 mg/L; and
- total (unfiltered sample) concentrations of trace metals (except unusually high concentrations [>1 mg/L] of total strontium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

A combination of several natural processes may account for the high strontium concentrations in the groundwater at this well, including: mixing of the sulfate-enriched groundwater with brines in the deeper bedrock, which may cause precipitation of barite and celestite ($SrSO_4$); upward diffusion of the solutes from the deeper bedrock; and matrix diffusion from the bedrock (Saunders and Toran 1992).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion

5.1 NITRATE

Fourteen groundwater samples had nitrate concentrations above the analytical reporting limit, with the highest concentration (1.4 mg/L in April 1993) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Six groundwater samples had uranium concentrations above the analytical reporting limit, with the highest concentration (0.0052 mg/L on February 1997) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for each groundwater sample show non-detect values or false positive results for all of the VOCs that are confirmed groundwater contaminants in the Bear Creek Regime. A single detection of 2-butanone (16 µg/L in December 1992) is considered a sampling or analytical artifact.

5.4 GROSS ALPHA ACTIVITY

Ten groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest activities reported for the samples collected in July 2001 (19.45 pCi/L) and July 2002 (15.75 pCi/L). Both results exceed the MCL for gross alpha activity (15 pCi/L). Much lower levels of gross alpha activity are evident before and after these "peak" concentrations. Also, the frequency of detection of gross alpha activity above the MDA appears to have increased. Only three of 15 samples collected between June 1992 and August 1997 had gross alpha above the MDA (and CE), whereas seven of 14 samples collected between January 1998 and July 2004 had gross alpha above the MDA.

5.5 GROSS BETA ACTIVITY

Eleven groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest activities reported for the samples collected in January 2000 (17.92 pCi/L), July 2001 (28.57 pCi/L), and July 2002 (39.75 pCi/L). These results exceed background levels evident in uncontaminated groundwater from shallower depths in the Maynardville Limestone, but are less than the SDWA screening level for gross beta activity (50 pCi/L). Much lower levels of gross beta activity are evident before and after these "peak" concentrations. Also, the frequency of detection of gross beta activity above the MDA appears to have increased. Only one of 15 samples collected between June 1992 and August 1997 had gross beta above the MDA (and CE), whereas nine of 14 samples collected between January 1998 and July 2004 had gross beta above the MDA.

WELL GW-714

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in January 1992, completed with an open-hole monitored interval from 115 to 145 ft bgs, and constructed with 7-inch diameter steel (SF25) riser casing. The well forms a cluster with well GW-715 and is located in Bear Creek Valley about three miles west of Y-12. It is a component of Exit Pathway Picket W, which consists of a series of wells (GW-710, GW-711, GW-712, GW-713, GW-714, and GW-715) completed at different depths (and hydrostratigraphic zones) along a strike-normal transect across the Maynardville Limestone (Figure 1), the principal groundwater exit pathway for contaminants originating from source areas in the Bear Creek Regime.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 14 samples between September 1992 and August 1997, and the low-flow sampling method used to obtain 16 samples between January 1998 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the intermediate bedrock interval in the Conasauga Group (Maynardville Limestone). The average static groundwater level in the well is 25 ft bgs. Presampling depth-to-water measurements for the well indicate moderate (12 ft) water-level fluctuations. Also, presampling groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are typically lower in well GW-714 than in well GW-715, which is completed at a shallower depth (44 ft bgs) in the Maynardville Limestone. Based on the distance (91.9 ft) between the monitored interval midpoint (elevation) in each well, the contemporaneous groundwater elevations indicate downward vertical hydraulic gradients (average 0.01) from well GW-715 to GW-714 during seasonally high and low flow conditions.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 228 – 324 mg/L, excluding an outlier (160 mg/L) in July 2000;
- pH of 6.6 – 8.1 (field measurements);
- sulfate concentrations above 40 mg/L;
- low molar proportions of chloride, potassium, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Twenty-six groundwater samples had nitrate concentrations above the applicable analytical reporting limit. Although all the nitrate results are below the MCL (10 mg/L), most of the concentrations exceed background levels in the Bear Creek Regime, with the historical maximum concentration just under 5 mg/L (4.8 mg/L in November 1992 and April 1993). The source of the nitrate is the contaminant plume emplaced during operation of the former S-3 Ponds, which are located near the headwaters of Bear Creek about 2.5 miles east of Exit Pathway Picket W. Nitrate is a principal component of the plume and is highly mobile in groundwater. Elevated nitrate concentrations essentially delineate the maximum extent of contaminant transport from the former S-3 Ponds and effectively trace the principal migration pathways in the Maynardville Limestone. In the deeper bedrock flowpaths (>100 ft bgs), the existing network of wells in the Maynardville Limestone defines a more or less continuous plume extending from directly south (down geologic dip) of the former S-3 Ponds for about 10,000 ft along strike to the west, whereas attenuation from more active recharge and groundwater flux has reduced nitrate levels and produced a more discontinuous nitrate plume in the shallow karst network (DOE 1997). However, the presence of nitrate more than 100 ft bgs in the groundwater at well GW-714 probably does not indicate the contiguous downgradient extension of the plume. Instead, two observations suggest that localized inflow of contaminated surface water in Bear Creek is the likely source of nitrate in the well (Bechtel Jacobs Company LLC [BJC] 2003). First, presampling groundwater elevations in wells GW-714 and GW-715 show vertically downward hydraulic gradients (see Section 3.0), which suggests that the main channel of Bear Creek may locally lose flow to the Maynardville Limestone. Second, the monitoring results for Bear Creek sampling station BCK-07.87, which is located in a sharp meander of the main channel of the creek directly northeast (upstream) of Exit Pathway Picket W, show nitrate concentrations above the MCL.

5.2 URANIUM

Uranium concentrations above the applicable analytical reporting limit were reported for the 14 groundwater samples collected between September 1992 and August 1997, with the highest concentration (0.0032 mg/L in August 1997) being substantially below the MCL for uranium (0.03 mg/L). Uranium concentrations have been below the reporting limit (0.004 mg/L) in all samples collected since January 1998.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected in two groundwater samples: acetone in July 1998 (36 μg/L) and a trace of 12DCA in July 1999 (3 μg/L). These results may be sampling or analytical artifacts and are considered to be outliers.

5.4 GROSS ALPHA ACTIVITY

Twelve groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (8.78 pCi/L in November 1992) being less than the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Sixteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (24.8 pCi/L in November 1992) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-715

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in January 1992, completed with a screened monitored interval from 32 to 44 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and continuous wire-wound stainless steel screen (0.01 slot). The well forms a cluster with well GW-714 and is located in Bear Creek Valley about three miles west of Y-12. It is a component of Exit Pathway Picket W, which consists of a series of wells (GW-710, GW-711, GW-712, GW-713, GW-714, and GW-715) completed at different depths (and hydrostratigraphic zones) along a strike-normal transect across the Maynardville Limestone (Figure 1), the principal groundwater exit pathway for contaminants originating from source areas in the Bear Creek Regime.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty groundwater samples have been collected from the well, with the conventional sampling method used to obtain 15 samples between September 1992 and July 2003, and the low-flow sampling method used to obtain 15 samples between January 1998 and July 2004. To evaluate suspected sampling method bias (higher contaminant concentrations in low-flow samples than in conventional samples), "paired sampling" was performed during July 2003 when groundwater samples were collected with the low-flow sampling method one day and the conventional sampling method the next day. The results of the paired sampling did not confirm the suspected bias, because contaminant concentrations (except for chromium, iron, manganese, and nickel) were similar in both samples (Elvado Environmental LLC 2004).

A conspicuous characteristic of the groundwater samples from this well are elevated concentrations of chromium and nickel that are most likely attributable to corrosion of the Type 304 stainless steel riser casing and screen used in construction of the well (see Section 5.6).

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Maynardville Limestone. The average static groundwater level in the well is 25 ft bgs. Presampling depth-to-water measurements for the well indicate substantial (12 ft) water-level fluctuations. Also, presampling groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are typically higher in well GW-715 than in well GW-714, which is completed at a greater depth (145 ft bgs) in the Maynardville Limestone. Based on the distance (91.9 ft) between the monitored interval midpoint (elevation) in each well, the contemporaneous groundwater elevations indicate downward vertical hydraulic gradients (average 0.01) from well GW-715 to GW-714 during seasonally high and low flow conditions.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 249 – 567 mg/L;
- pH of 5.2 – 7.4 (field measurements);
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are less than 0.5 mg/L.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Twenty-seven groundwater samples had nitrate concentrations above the applicable analytical reporting limit. Although all the nitrate results are below the MCL (10 mg/L), most of the concentrations exceed background levels in the Bear Creek Regime, with the historical maximum concentration less than 5 mg/L (4.2 mg/L in July 2002). The source of the nitrate is the contaminant plume emplace during operation of the former S-3 Ponds, which are located near the headwaters of Bear Creek about 2.5 miles east of Exit Pathway Picket W. Nitrate is a principal component of the plume and is highly mobile in groundwater. Elevated nitrate concentrations essentially delineate the maximum extent of contaminant transport from the former S-3 Ponds and effectively trace the principal migration pathways in the Maynardville Limestone. In the deeper bedrock flowpaths (>100 ft bgs), the existing network of wells in the Maynardville Limestone defines a more or less continuous plume extending from directly south (down geologic dip) of the former S-3 Ponds for about 10,000 ft along strike to the west, whereas attenuation from more active recharge and groundwater flux has reduced nitrate levels and produced a more discontinuous nitrate plume in the shallow karst network (DOE 1997). Therefore, the presence of nitrate in the groundwater at well GW-715 probably does not indicate the contiguous downgradient extension of the plume. Instead, two observations suggest that localized inflow of contaminated surface water in Bear Creek is the likely source of nitrate in the well (Bechtel Jacobs Company LLC [BJC] 2003). First, presampling groundwater elevations in wells GW-714 and GW-715 show vertically downward hydraulic gradients (see Section 3.0), which suggests that the main channel of Bear Creek may locally lose flow to the Maynardville Limestone. Second, the monitoring results for Bear Creek sampling station BCK-07.87, which is located in a sharp meander of the main channel of the creek directly northeast (upstream) of Exit Pathway Picket W, show nitrate concentrations above the MCL.

5.2 URANIUM

Total uranium concentrations above the applicable analytical reporting were detected in 21 groundwater samples, with the concentration evident in July 2002 (0.043 mg/L) exceeding the previous high for the well (0.0194 mg/L in January 2000) and the MCL (0.03 mg/L). As with nitrate in the shallow groundwater at this well, the elevated uranium concentrations in the well probably reflect localized recharge of contaminated surface water in Bear Creek; monitoring results for Bear Creek sampling station BCK-07.87 show total uranium concentrations almost an order-of-magnitude above the MCL (0.03 mg/L). Additionally, a very large washed-out area at the top of bedrock (about 35 ft bgs) noted during well installation may have enhanced flowpaths for surface water infiltration; construction of the filter pack required 60 sacks of sand.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were not detected in the groundwater samples from this well except for a trace of 12DCA (2 μg/L) in the sample collected in July 1999. This result is considered to be an outlier.

5.4 GROSS ALPHA ACTIVITY

Eleven groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, including each of the samples collected from the well since January 2001. Only one of these results, the historical maximum (17.96 pCi/L in July 2002), exceed the MCL for gross alpha activity (15 pCi/L), with the remaining results all less than 10 pCi/L. Available monitoring results confirm that U-234 and U-238 are the source of the alpha radioactivity, with the historical maximum value for each isotope (4.77 pCi/L and 10.15 pCi/L, respectively) corresponding with the historical maximum gross alpha activity (July 2002). As with total uranium, localized recharge of contaminated surface water in Bear Creek probably explains the presence of U-234 and U-238 in the shallow groundwater at this well; monitoring results for Bear Creek sampling station BCK-07.87 show gross alpha activity substantially above 15 pCi/L, U-234 activity above 25 pCi/L, and U-238 activity above 50 pCi/L.

5.5 GROSS BETA ACTIVITY

Eighteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (158 pCi/L in February 1999) being substantially above the SDWA screening level for gross beta activity (50 pCi/L). However, this result appears to be an outlier because only one of the remaining results (39 pCi/L in July 2002) exceeds 20 pCi/L. Nevertheless, the confirmed presence of uranium isotopes (and presumed presence of daughter products) in the groundwater at this well may account for the elevated gross beta activity. Additionally, low levels (<25 pCi/L) of Tc-99 were detected in three samples collected from the well between July 2001 and July 2002. The contaminant plume emplaced during operation of the former S-3 Ponds is the only source of Tc-99 in the Bear Creek Regime (only the S-3 Ponds received wastes containing Tc-99) and Tc-99 is the principal beta-emitting isotope in the intermingled contaminant plume in the Maynardville Limestone upgradient of the well. As with the other primary contaminants in the well, the presence of Tc-99 in the shallow groundwater probably reflects localized recharge of contaminated surface water in Bear Creek; monitoring results for Bear Creek sampling station BCK-07.87 show gross beta activity ranging above and below the SDWA screening level (50 pCi/L) and corresponding Tc-99 values ranging between 15 and 90 pCi/L.

5.6 OTHER

A total of 25 groundwater samples had concentrations of chromium and/or nickel above the respective analytical reporting limit, including four results for chromium and eight results for nickel that exceed the respective MCLs. As shown in Table 2, the samples obtained with the conventional sampling method in July 2003 had substantially higher concentrations than samples obtained with the low-flow sampling method (see Section 2.0).

Table 2. Chromium and nickel results for well GW-715

07/01/02	0.019	0.0281
01/07/03	**0.17**	0.0296
07/07/03	0.0083	0.0145

Note: Bold typeface denotes results that exceed the MCL.

Based on the following considerations, the elevated concentrations of chromium and nickel in the groundwater samples from this well are most likely attributable to corrosion of the stainless steel well casing and screen: (1) mobile species of each metal are not typically present in groundwater with the neutral pH conditions evident in the well; (2) there are not any known sources of either metal near the well; (3) neither metal is a primary component of the commingled groundwater contaminant plume in the Maynardville Limestone hydraulically upgradient (east) of the well; (4) Type 304 stainless steel contains 18-20% chromium and 8-12% nickel and is prone to crevice corrosion (Oakley and Korte 1996); (5) groundwater in the well exhibits geochemical conditions that could be corrosive to Type 304 stainless steel (e.g., dissolved oxygen > 2 mg/L; Driscoll 1986); and (6) results of biological sampling performed in February 2000 indicate that the biomass observed in the well during a downhole video inspection in August 1999 is composed of slime-forming bacteria (Energy Systems 2000) and slime-forming bacteria have been associated with microbiologically induced corrosion of Type 304 stainless steel (Sarouhan et al. 1998).

WELL GW-722
Sampling Port 06

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1991, completed with an open-hole interval from 74 to 644 ft bgs, constructed with nominal 4.5-inch diameter steel (SF25) riser casing, and equipped with a multiport monitoring system (Westbay™) that enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval. The well is located in Bear Creek Valley near the east end of Y-12, about 350 ft west of the ORR boundary along Scarboro Road.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 06 being 560 ft bgs (Figure 1). A total of 27 samples were collected from the sampling port between July 1997 and October 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 06 yields groundwater from the Conasauga Group (Maynardville Limestone).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 06 yields sulfate- and chloride-enriched sodium-bicarbonate groundwater generally characterized by:

- TDS of 510 – 633 mg/L, excluding an outlier (15 mg/L) in July 1998;
- pH (field measurements) of 6.2 – 8.3;
- chloride concentrations above 100 mg/L and sulfate levels above 50 mg/L;
- low molar proportions of calcium, magnesium, and potassium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals (except strontium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Four groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.36 mg/L in November 2002) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Two groundwater samples had uranium concentrations above the applicable analytical reporting limit and both results (0.0014 mg/L in July 1999 and 0.004 mg/L in November 2000) are substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Several VOCs have been detected in one or more of the groundwater samples, including acetone, acrylonitrile, and compounds that are confirmed groundwater contaminants in the East Fork Regime (PCE and petroleum hydrocarbons). The results for acetone, including the clear outlier result (530 μg/L) reported for the sample collected in November 2000, are analytical artifacts. Low concentrations (5 – 15 μg/L) of acrylonitrile were detected in five samples. The Westbay™ system contains several components made with acrylonitrile and detection of this compound is often an artifact from sampling ports in low permeability zones (Westbay Instruments, Inc. 1999). Trace levels (<2 μg/L) of benzene, ethylbenzene, toluene, and an associated degradation product (styrene) were detected in seven samples.

There are several potential sources of the petroleum hydrocarbons in the groundwater samples from this well/sampling port: (1) downgradient transport from a groundwater contaminant plume originating from one or more potential sources within Y-12, including leaks and spills during historical operation of former petroleum fuel underground storage tanks (USTs); (2) residual contamination from installation of the well; (3) contamination from components of the Westbay sampling equipment that are made of or contain petroleum-based materials; (4) contamination of the samples during sampling or handling; and (5) traces of natural hydrocarbons in the low-permeability bedrock.

Migration from an upgradient source area(s) in Y-12 seems an unlikely source of the hydrocarbons considering the depth of the sampling port (>500 ft bgs), the extremely low hydraulic conductivity of the groundwater flowpaths intercepted by the monitored interval, the substantial distance (>5,000 ft) to the nearest potential source area (Tank 2331-U near Building 9201-1), and the various natural attenuation processes (including biologically mediated degradation) operative during transport to the well.

Residual contamination from installation/construction of the well also seems an unlikely source of the hydrocarbons in light of the age of the well (>12 years). Moreover, well installation and construction was closely supervised and controlled to exclude usage of petroleum-based drilling equipment lubricants. Additionally, well installation/ construction records do not note any accidental spills/leaks of petroleum-based fluids from the drilling rig or support equipment during installation of the well.

Contamination from components of the Westbay sampling equipment in the well is possible, as several components of the sampling apparatus contain petroleum hydrocarbons. However, it is not known if the hydrocarbons are leachable from these components and repeated sampling since installation of the equipment would be expected to "flush" any leached constituents from the sampling port. Also, such systemic contamination from components of the Westbay sampling equipment would be expected to result in consistent contamination of samples from multiple if not all sampling ports. However, only some of the other ports repeatedly yield samples that contain petroleum hydrocarbons. Indeed, these compounds have not been detected consistently in any of the samples collected to date from eight of the sampling ports in the well. In addition, these hydrocarbons have been observed in groundwater samples from some deeper wells that are not instrumented with Westbay sampling equipment.

Contamination of the samples during collection or handling also may be possible, but is not indicated by results for associated quality assurance samples (i.e., petroleum hydrocarbons are not detected in the field or trip blanks). Similarly, data for laboratory blank samples do not support contamination during storage and/or analysis in the laboratory. Also, contamination of the samples during collection at the well head seems very unlikely again because such systemic contamination would result in the detection of petroleum hydrocarbons in the samples collected from other ports in the well.

5.4 GROSS ALPHA ACTIVITY

Five groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (11.13 pCi/L in May 2003) being less than the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Nine groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the two highest values being slightly below (43 pCi/L in May 2001) and substantially above (342 pCi/L in May 2003) the SDWA screening level for gross beta activity (50 pCi/L). Both of these results, however, appear to be outliers (none of the other gross beta results exceed 20 pCi/L) and are probably analytical artifacts.

WELL GW-722
Sampling Port 10

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1991, completed with an open-hole interval from 74 to 644 ft bgs, constructed with nominal 4.5-inch diameter steel (SF25) riser casing, and equipped with a multiport monitoring system (Westbay™) that enables collection of groundwater samples from multiple discreet depth intervals within the open-hole interval. The well is located in Bear Creek Valley near the east end of Y-12, about 350 ft west of the ORR boundary along Scarboro Road.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 10 being 500 ft bgs (Figure 1). A total of 28 samples were collected from the sampling port between July 1997 and October 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 10 yields groundwater from the Conasauga Group (Maynardville Limestone).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 10 yields chloride-, sodium-, and sulfate-enriched calcium-magnesium bicarbonate groundwater generally characterized by:

- TDS of 322 – 630 mg/L, excluding a suspected outlier (41 mg/L) in July 1997;
- pH (field measurements) of 6.5 – 8.4;
- chloride and sodium concentrations near 100 mg/L and sulfate levels above 50 mg/L;
- low molar proportions of potassium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals (except strontium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Thirteen groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.45 mg/L in February 1998) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Three groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest value (0.004 mg/L in November 2000) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

One or more of the following VOCs were detected in each groundwater sample collected between July 1997 and July 2000: PCE, TCE, c12DCE, 11DCE, CTET, chloroform, methylene chloride, and TCFM. The highest concentrations were reported for CTET (>50 μg/L), chloroform (>25 μg/L), and PCE (>10 μg/L). This sampling port yields groundwater from migration pathways for the CTET-dominated plume of dissolved VOCs in the Maynardville Limestone that originates from multiple sources in Y-12 and extends eastward (along strike) beneath New Hope Pond into Union Valley east of the ORR boundary along Scarboro Road (DOE 1998); sampling ports 14, 17, 20, and 22 are believed to monitor the center of mass of the plume (DOE 2002). Available data for port 10 show that summed VOC concentrations exceeded 100 μg/L between July 1997 and August 1998, decreased below 75 μg/L through July 2000, sharply dropped to zero in September 2000, and subsequently has remained below 10 μg/L (Figure 2). This sharp decrease in VOC concentrations follows the hydrologic testing and subsequent operation of a groundwater extraction well (GW-845) installed about 600 ft east of well GW-722 as part of the contaminant plume capture system required under a CERCLA Action Memorandum (DOE 1999). Based on results of a long-term aquifer pumping test (and dye trace study) performed in July 1998, full-time operation of the system began in October 2000 and has involved pumping groundwater from the extraction well at a rate of 25 gpm (the pump intake is about 300 ft bgs) and treating the groundwater to remove VOCs, particulates, iron, and manganese. Operation of the system has produced 15 to 17 ft of drawdown in the immediate vicinity of the extraction well and an elongated zone of influence, oriented parallel with geologic strike, extending at least 900 ft to the east (downgradient) and 600 ft to the west (upgradient) of the extraction well, which closely approximates the hydrologic influence observed during the long-term aquifer pumping test (DOE 2002).

5.4 GROSS ALPHA ACTIVITY

One groundwater sample had gross alpha activity above the applicable MDA and corresponding CE and this result (3.1 pCi/L in July 2000) is less than the MCL for gross alpha activity (15 pCi/L) and is probably an analytical artifact.

5.5 GROSS BETA ACTIVITY

Eight groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (43.5 pCi/L in May 2001) being slightly below the SDWA screening level for gross beta activity (50 pCi/L). This result, however, appears to be an outlier (all the other gross beta results are less than 12 pCi/L) and is probably an analytical artifact.

WELL GW-722
Sampling Port 14

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1991, completed with an open-hole interval from 74 to 644 ft bgs, constructed with nominal 4.5-inch diameter steel (SF25) riser casing, and equipped with a multiport monitoring system (Westbay™) that enables collection of groundwater samples from multiple discreet depth intervals within the open-hole interval. The well is located in Bear Creek Valley near the east end of Y-12, about 350 ft west of the ORR boundary along Scarboro Road.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 14 being 425 ft bgs (Figure 1). A total of 26 samples were collected from the sampling port between July 1997 and October 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 14 yields groundwater from the Conasauga Group (Maynardville Limestone).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 14 yields calcium-magnesium bicarbonate groundwater generally characterized by:

- TDS of 185 – 590 mg/L;
- pH (field measurements) of 6.6 – 8.6;
- chloride and sodium concentrations near 100 mg/L and sulfate levels above 50 mg/L;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Twenty-five groundwater samples contained nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (3.09 mg/L in February 1998) being substantially below the MCL for nitrate (10 mg/L). Although below the MCL, these nitrate results exceed the range of background levels in the Maynardville Limestone (<1 mg/L). The source of the nitrate in the groundwater from this sampling port has not been confirmed, but may be the contaminant plume emplaced in the western part of Y-12 during operation of the former S-3 Ponds and the S-2 Site (DOE 1998). Nitrate leached from a stockpile of urea that was located in the eastern part of Y-12 also may be a potential source of nitrate in the groundwater.

In any case, the nitrate results reflect a decreasing concentration trend, with the lowest concentrations evident after the hydrologic testing and subsequent operation a groundwater extraction well (GW-845) installed about 600 ft east of well GW-722 as part of the contaminant plume capture system required under a CERCLA Action Memorandum (DOE 1999). Based on results of a long-term aquifer pumping test (and dye trace study) performed in July 1998, full-time operation of the system began in October 2000 and has involved pumping groundwater from the extraction well at a rate of 25 gpm (the pump intake is about 300 ft bgs) and treating the groundwater to remove VOCs, particulates, iron, and manganese. Operation of the system has produced 15 to 17 ft of drawdown in the immediate vicinity of the extraction well and an elongated zone of influence, oriented parallel with geologic strike, extending least 900 ft to the east (downgradient) and 600 ft to the west (upgradient) of the extraction well, which closely approximates the hydrologic influence observed during the long-term aquifer pumping test (DOE 2002).

5.2 URANIUM

Two groundwater samples had uranium concentrations above the applicable analytical reporting limit and both results (0.004 mg/L in November 2000 and 0.000536 mg/L in July 2002) are substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

One or more of the following VOCs were detected in all but one of the groundwater samples: PCE, TCE, c12DCE, 11 DCE, 111TCA, 11DCA, CTET, chloroform, acetone, and TCFM. The highest concentrations were reported for CTET (>500 μg/L), chloroform (>50 μg/L), PCE (>50 μg/L), and TCFM (>10 μg/L). This sampling port yields groundwater from migration pathways for the CTET-dominated plume of dissolved VOCs in the Maynardville Limestone that originates from multiple sources in Y-12 and extends eastward (along strike) beneath New Hope Pond into Union Valley east of the ORR boundary along Scarboro Road (DOE 1998); sampling ports 14, 17, 20, and 22 are believed to monitor the center of mass of the plume (DOE 2002). Available data for port 14 show clearly decreasing VOC concentration trends, with the lowest concentrations evident following the hydrologic testing and subsequent full-time operation of groundwater extraction well GW-845 (Figure 2).

5.4 GROSS ALPHA ACTIVITY

Seven groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (8 pCi/L in September 2000) being less than the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Seven groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (23 pCi/L in March 1999) being less than the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-722
Sampling Port 17

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1991, completed with an open-hole interval from 74 to 644 ft bgs, constructed with nominal 4.5-inch diameter steel (SF25) riser casing, and equipped with a multiport monitoring system (Westbay™) that enables collection of groundwater samples from multiple discreet depth intervals within the open-hole interval. The well is located in Bear Creek Valley near the east end of Y-12, about 350 ft west of the ORR boundary along Scarboro Road.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 17 being 385 ft bgs (Figure 1). A total of 27 samples were collected from the sampling port between February 1996 and October 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 17 yields groundwater from the Conasauga Group (Maynardville Limestone).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 17 yields chloride-, sodium-, and sulfate-enriched calcium-magnesium bicarbonate groundwater generally characterized by:

- TDS of 251 – 354 mg/L, excluding an outlier (34 mg/L) in September 2000;
- pH (field measurements) of 6.9 – 8.3;
- chloride, sodium, and sulfate concentrations above 30 mg/L;
- low molar proportions potassium (<10% of total anions); and
- *total (unfiltered sample) concentrations of trace metals that are either below respective* analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Each groundwater sample contained nitrate above the applicable analytical reporting limit, with the highest concentration (3.67 mg/L in July 1997) being substantially below the MCL for nitrate (10 mg/L). Although below the MCL, these nitrate results exceed the range of background levels in the Maynardville Limestone (<1 mg/L). The source of the nitrate in the groundwater from this sampling port has not been confirmed, but may be the contaminant plume emplaced in the western part of Y-12 during operation of the former S-3 Ponds and the S-2 Site (DOE 1998). Nitrate leached from a stockpile of urea that was located in the eastern part of Y-12 also may be a potential source of nitrate in the groundwater. In any case, these nitrate results reflect a decreasing concentration trend with the lowest concentrations evident after the hydrologic testing and subsequent operation of a groundwater extraction well (GW-845) installed about 600 ft east of well GW-722 as part of the contaminant plume capture system required under a CERCLA Action Memorandum (DOE 1999). Based on results of a long-term aquifer pumping test (and dye trace study) performed in July 1998, full-time operation of the system began in October 2000 and has involved pumping groundwater from the extraction well at a rate of 25 gpm (the pump intake is about 300 ft bgs) and treating the groundwater to remove VOCs, particulates, iron, and manganese. Operation of the system has produced 15 to 17 ft of drawdown in the immediate vicinity of the extraction well and an elongated zone of influence, oriented parallel with geologic strike, extending least 900 ft to the east (downgradient) and 600 ft to the west (upgradient) of the extraction well, which closely approximates the hydrologic influence observed during the long-term aquifer pumping test (DOE 2002).

5.2 URANIUM

One groundwater sample had a uranium concentration above the applicable analytical reporting limit and this result (0.004 mg/L in November 2000) is substantially below the MCL for uranium (0.03 mg/L) and is probably an analytical artifact.

5.3 VOLATILE ORGANIC COMPOUNDS

One or more of the following VOCs were detected in all but one of the groundwater samples: PCE, TCE, c12DCE, 11 DCE, 111TCA, 11DCA, CTET, chloroform, acetone, and TCFM. The highest concentrations were reported for CTET (>500 μg/L), chloroform (>50 μg/L), PCE (>50 μg/L), and TCFM (>10 μg/L). This sampling port yields groundwater from migration pathways for the CTET-dominated plume of dissolved VOCs in the Maynardville Limestone that originates from multiple sources in Y-12 and extends eastward (along strike) beneath New Hope Pond into Union Valley east of the ORR boundary along Scarboro Road (DOE 1998); sampling ports 14, 17, 20, and 22 are believed to monitor the center of mass of the plume (DOE 2002). Available data for port 17 show widely variable but clearly decreasing VOC concentration trends (Figure 2), with the lowest concentrations evident following the hydrologic testing and subsequent full-time operation of groundwater extraction well GW-845.

5.4 GROSS ALPHA ACTIVITY

Two groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, and this result (2.6 pCi/L in September 2000) is less than the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Six groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (8.9 pCi/L in February 2001) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-722
Sampling Port 20

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1991, completed with an open-hole interval from 74 to 644 ft bgs, constructed with nominal 4.5-inch diameter steel (SF25) riser casing, and equipped with a multiport monitoring system (Westbay™) that enables collection of groundwater samples from multiple discreet depth intervals within the open-hole interval. The well is located in Bear Creek Valley near the east end of Y-12, about 350 ft west of the ORR boundary along Scarboro Road.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 20 being 333 ft bgs (Figure 1). A total of 26 samples were collected from the sampling port between July 1997 and October 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 20 yields groundwater from the Conasauga Group (Maynardville Limestone).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 20 yields sulfate-enriched calcium-magnesium bicarbonate groundwater generally characterized by:

- TDS of 253 – 940 mg/L;
- pH (field measurements) of 6.6 – 800;
- sulfate concentrations near 30 mg/L;
- low molar proportions chloride, potassium, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Each groundwater sample contained nitrate above the applicable analytical reporting limit, with the highest concentration (2.73 mg/L in December 1997) being substantially below the MCL for nitrate (10 mg/L). Although below the MCL, these nitrate results exceed the range of background levels in the Maynardville Limestone (<1 mg/L). The source of the nitrate in the groundwater from this sampling port has not been confirmed, but may be the contaminant plume emplaced in the western part of Y-12 during operation of the former S-3 Ponds and the S-2 Site (DOE 1998). Nitrate leached from a stockpile of urea that was located in the eastern part of Y-12 also may be a potential source of nitrate in the groundwater. In any case, these nitrate results reflect a decreasing concentration trend with the lowest concentrations evident after the hydrologic testing and subsequent operation of a groundwater extraction well (GW-845) installed about 600 ft east of well GW-722 as part of the contaminant plume capture system required under a CERCLA Action Memorandum (DOE 1999). Based on results of a long-term aquifer pumping test (and dye trace study) performed in July 1998, full-time operation of the system began in October 2000 and has involved pumping groundwater from the extraction well at a rate of 25 gpm (the pump intake is about 300 ft bgs) and treating the groundwater to remove VOCs, particulates, iron, and manganese. Operation of the system has produced 15 to 17 ft of drawdown in the immediate vicinity of the extraction well and an elongated zone of influence, oriented parallel with geologic strike, extending least 900 ft to the east (downgradient) and 600 ft to the west (upgradient) of the extraction well, which closely approximates the hydrologic influence observed during the long-term aquifer pumping test (DOE 2002).

5.2 URANIUM

One groundwater sample had a uranium concentration above the applicable analytical reporting limit and this result (0.00087 mg/L in July 1997) is substantially below the MCL for uranium (0.03 mg/L) and is probably an analytical artifact.

5.3 VOLATILE ORGANIC COMPOUNDS

One or more of the following VOCs were detected in all of the groundwater samples: PCE, TCE, c12DCE, 11 DCE, 111TCA, 11DCA, CTET, chloroform, methylene chloride, chloromethane, acetone, and TCFM. The highest concentrations were reported for CTET (>500 μg/L), chloroform (>50 μg/L), PCE (>50 μg/L), and TCFM (>10 μg/L). This sampling port yields groundwater from migration pathways for the CTET-dominated plume of dissolved VOCs in the Maynardville Limestone that originates from multiple sources in Y-12 and extends eastward (along strike) beneath New Hope Pond into Union Valley east of the ORR boundary along Scarboro Road (DOE 1998); sampling ports 14, 17, 20, and 22 are believed to monitor the center of mass of the plume (DOE 2002). Available data for port 22 show widely variable but clearly decreasing VOC concentration trends (Figure 2), with the lowest concentrations evident following the hydrologic testing and subsequent full-time operation of groundwater extraction well GW-845.

5.4 GROSS ALPHA ACTIVITY

Four groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (2.6 pCi/L in September 2000) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Four groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (8.16 pCi/L in May 2003) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-722
Sampling Port 22

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1991, completed with an open-hole interval from 74 to 644 ft bgs, constructed with nominal 4.5-inch diameter steel (SF25) riser casing, and equipped with a multiport monitoring system (Westbay™) that enables collection of groundwater samples from multiple discreet depth intervals within the open-hole interval. The well is located in Bear Creek Valley near the east end of Y-12, about 350 ft west of the ORR boundary along Scarboro Road.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 22 being 313 ft bgs (Figure 1). A total of 26 samples were collected from the sampling port between July 1997 and October 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 22 yields groundwater from the Conasauga Group (Maynardville Limestone).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 22 yields calcium-magnesium bicarbonate groundwater generally characterized by:

- TDS of 222 – 360 mg/L, excluding an outlier (35 mg/L) in December 1997;
- pH (field measurements) of 6.6 – 8.2;
- low molar proportions chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Each groundwater sample contained nitrate above the applicable analytical reporting limit, with the highest concentration (3.26 mg/L in July 1997) being substantially below the MCL for nitrate (10 mg/L). Although below the MCL, these nitrate results exceed the range of background levels in the Maynardville Limestone (<1 mg/L). The source of the nitrate in the groundwater from this sampling port has not been confirmed, but may be the contaminant plume emplaced in the western part of Y-12 during operation of the former S-3 Ponds and the S-2 Site (DOE 1998). Nitrate leached from a stockpile of urea that was located in the eastern part of Y-12 also may be a potential source of nitrate in the groundwater. In any case, these nitrate results reflect a decreasing concentration trend with the lowest concentrations evident after the hydrologic testing and subsequent operation of a groundwater extraction well (GW-845) installed about 600 ft east of well GW-722 as part of the contaminant plume capture system required under a CERCLA Action Memorandum (DOE 1999). Based on results of a long-term aquifer pumping test (and dye trace study) performed in July 1998, full-time operation of the system began in October 2000 and has involved pumping groundwater from the extraction well at a rate of 25 gpm (the pump intake is about 300 ft bgs) and treating the groundwater to remove VOCs, particulates, iron, and manganese. Operation of the system has produced 15 to 17 ft of drawdown in the immediate vicinity of the extraction well and an elongated zone of influence, oriented parallel with geologic strike, extending least 900 ft to the east (downgradient) and 600 ft to the west (upgradient) of the extraction well, which closely approximates the hydrologic influence observed during the long-term aquifer pumping test (DOE 2002).

5.2 URANIUM

Three groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest value (0.00069 mg/L in July 1997) being substantially below the MCL for uranium (0.03 mg/L). These results are probably analytical artifacts.

5.3 VOLATILE ORGANIC COMPOUNDS

One or more of the following VOCs were detected in 26 of the groundwater samples: PCE, TCE, c12DCE, 11DCE, 111TCA, 11DCA, CTET, chloroform, and TCFM. The highest concentrations were reported for CTET (>500 μg/L), chloroform (>50 μg/L), and PCE (>40 μg/L). This sampling port yields groundwater from migration pathways for the CTET-dominated plume of dissolved VOCs in the Maynardville Limestone that originates from multiple sources in Y-12 and extends eastward (along strike) beneath New Hope Pond into Union Valley east of the ORR boundary along Scarboro Road (DOE 1998); sampling ports 14, 17, 20, and 22 are believed to monitor the center of mass of the plume (DOE 2002). Available data for port 22 show widely variable but clearly decreasing VOC concentration trends (Figure 2), with the lowest concentrations evident following the hydrologic testing and subsequent full-time operation of groundwater extraction well GW-845.

5.4 GROSS ALPHA ACTIVITY

Four groundwater samples had gross alpha activity above the applicable MDA and corresponding CE and both results (4.8 pCi/L in August 1998 and 2.62 pCi/L in May 2002) are substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Five groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (9.7 pCi/L in August 1998) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-722
Sampling Port 26

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1991, completed with an open-hole interval from 74 to 644 ft bgs, constructed with nominal 4.5-inch diameter steel (SF25) riser casing, and equipped with a multiport monitoring system (Westbay™) that enables collection of groundwater samples from multiple discreet depth intervals within the open-hole interval. The well is located in Bear Creek Valley near the east end of Y-12, about 350 ft west of the ORR boundary along Scarboro Road.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 26 being 216 ft bgs (Figure 1). A total of 28 samples were collected from the sampling port between August 1997 and October 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 26 yields groundwater from the Conasauga Group (Maynardville Limestone).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 26 yields calcium-magnesium bicarbonate groundwater generally characterized by:

- TDS of 154 – 280 mg/L;
- pH (field measurements) of 6.7 – 8.1;
- low molar proportions chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals (except strontium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Four groundwater samples contained nitrate above the applicable analytical reporting limit, with the highest concentration (0.17 mg/L in November 2002) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

None of the groundwater samples had uranium concentrations above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Significant concentrations (15 – 32 μg/L) of acrylonitrile were detected in each groundwater sample collected between August 1997 and March 2000. The Westbay™ monitoring system contains several components made with acrylonitrile and detection of this compound is often an artifact from sampling ports in low permeability zones (Westbay Instruments, Inc. 1999).

In contrast to the deeper sampling ports in well GW-722, only a few groundwater samples from port 26 contained the primary components of the dissolved VOC plume in the Maynardville Limestone (CTET, chloroform, and PCE) that originates from multiple sources in Y-12 and extends eastward (along geologic strike) under New Hope Pond into Union Valley east of the ORR boundary along Scarboro Road; PCE was detected in one sample (1 μg/L in December 1997), chloroform was detected in one sample (1 μg/L in September 2000), and CTET was detected in three samples (1 μg/L in December 1997, 5 μg/L in September 2000, and 2 μg/L in December 2000).

One or more petroleum hydrocarbons (benzene, ethylbenzene, toluene, and xylene [BTEX]) and a related degradation compound (styrene) were detected at low concentrations (<10 μg/L) in all but two of the groundwater samples (one of the samples was not analyzed for VOCs). The concentrations of these compounds exhibit an indeterminate long-term trend, as illustrated by the ethylbenzene results reported for the groundwater samples collected in August 1997 (3 μg/L), July 1999 (3 μg/L), August 2001 (3 μg/L), and July 2003 (2 μg/L). Moreover, the indeterminate concentration trends do not show any clear response to the hydrologic testing and subsequent operation of a groundwater extraction well (GW-845) installed about 600 ft east of well GW-722 as part of the contaminant plume capture system required under a CERCLA Action Memorandum (DOE 1999). Based on results of a long-term aquifer pumping test (and dye trace study) performed in July 1998, full-time operation of the system began in October 2000 and has involved pumping groundwater from the extraction well at a rate of 25 gpm (the pump intake is about 300 ft bgs) and treating the groundwater to remove VOCs, particulates, iron, and manganese. Operation of the system has produced 15 to 17 ft of drawdown in the immediate vicinity of the extraction well and an elongated zone of influence, oriented parallel with geologic strike, extending least 900 ft to the east (downgradient) and 600 ft to the west (upgradient) of the extraction well, which closely approximates the hydrologic influence observed during the long-term aquifer pumping test (DOE 2002).

There are several potential sources of the petroleum hydrocarbons in the groundwater samples from this well/sampling port: (1) downgradient transport from a groundwater contaminant plume originating from one or more potential sources within Y-12, including leaks and spills during historical operation of former petroleum fuel underground storage tanks (USTs); (2) residual contamination from installation of the well; (3) contamination from components of the Westbay sampling equipment that are made of or contain petroleum-based materials; (4) contamination of the samples during sampling or handling; and (5) traces of natural hydrocarbons in the low-permeability bedrock.

Migration from an upgradient source area(s) in Y-12 seems an unlikely source of the hydrocarbons considering the depth of the sampling port (>200 ft bgs), the extremely low hydraulic conductivity of the groundwater flowpaths intercepted by the monitored interval, the substantial distance (>5,000 ft) to the nearest potential source area (Tank 2331-U near Building 9201-1), and the various natural attenuation processes (including biologically mediated degradation) operative during transport to the well.

Residual contamination from installation/construction of the well also seems an unlikely source of the hydrocarbons in light of the age of the well (>12 years). Moreover, well installation and construction was closely supervised and controlled to exclude usage of petroleum-based drilling equipment lubricants. Additionally, well installation/ construction records do not note any accidental spills/leaks of petroleum-based fluids from the drilling rig or support equipment during installation of the well.

Contamination from components of the Westbay sampling equipment in the well is possible, as several components of the sampling apparatus contain petroleum hydrocarbons. However, it is not known if the hydrocarbons are leachable from these components and repeated sampling since installation of the equipment would be expected to "flush" any leached constituents from the sampling port. Also, such systemic contamination from components of the Westbay sampling equipment would be expected to result in consistent contamination of samples from multiple if not all sampling ports. However, only some of the other ports repeatedly yield samples that contain petroleum hydrocarbons. Indeed, these compounds have not been detected consistently in any of the samples collected to date from eight of the sampling ports in the well. In addition, these hydrocarbons have been observed in groundwater samples from some deeper wells that are not instrumented with Westbay sampling equipment.

Contamination of the samples during collection or handling also may be possible, but is not indicated by results for associated quality assurance samples (i.e., petroleum hydrocarbons are not detected in the field or trip blanks). Similarly, data for laboratory blank samples do not support contamination during storage and/or analysis in the laboratory. Also, contamination of the samples during collection at the well head seems very unlikely again because such systemic contamination would result in the detection of petroleum hydrocarbons in the samples collected from other ports in the well.

5.4 GROSS ALPHA ACTIVITY

Ten groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (4.2 pCi/L in August 1997) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Eight groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (14.9 pCi/L in May 2003) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-722
Sampling Port 30

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1991, completed with an open-hole interval from 74 to 644 ft bgs, constructed with nominal 4.5-inch diameter steel (SF25) riser casing, and equipped with a multiport monitoring system (Westbay™) that enables collection of groundwater samples from multiple discreet depth intervals within the open-hole interval. The well is located in Bear Creek Valley near the east end of Y-12, about 350 ft west of the ORR boundary along Scarboro Road.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 30 being 151 ft bgs (Figure 1). A total of 29 samples were collected from the sampling port between March 1996 and October 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 30 yields groundwater from the Conasauga Group (Maynardville Limestone).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 30 yields calcium-magnesium bicarbonate groundwater generally characterized by:

- TDS of 150 – 201 mg/L, excluding an outlier (82 mg/L) in November 2002;
- pH (field measurements) of 6.6 – 9.1;
- low molar proportions chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Fifteen groundwater samples contained nitrate above the applicable analytical reporting limit, with the highest concentration (0.65 mg/L in February 1998) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Six groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest value (0.000603 mg/L in July 2001) being substantially below the MCL for uranium (0.03 mg/L). These results are probably analytical artifacts.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, very low levels (<5 μg/L) of VOCs were detected in only five groundwater samples from the well: acrylonitrile was detected in three samples (August 1997, February 1999, and March 2000); ethylbenzene was detected in one sample (December 2002); and acetone was detected in one sample (October 2004).

5.4 GROSS ALPHA ACTIVITY

Five groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (1.96 pCi/L in May 2002) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Eight groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (59 pCi/L in May 2003) being slightly above the SDWA screening level for gross beta activity (50 pCi/L). However, this result appears to be an outlier (only two other results exceed 10 pCi/L).

WELL GW-722
Sampling Port 32

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1991, completed with an open-hole interval from 74 to 644 ft bgs, constructed with nominal 4.5-inch diameter steel (SF25) riser casing, and equipped with a multiport monitoring system (Westbay™) that enables collection of groundwater samples from multiple discreet depth intervals within the open-hole interval. The well is located in Bear Creek Valley near the east end of Y-12, about 350 ft west of the ORR boundary along Scarboro Road.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 32 being 107 ft bgs (Figure 1). A total of 28 samples were collected from the sampling port between August 1997 and October 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 32 yields groundwater from the Conasauga Group (Maynardville Limestone).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 32 yields calcium-magnesium bicarbonate groundwater generally characterized by:

- TDS of 150 – 324 mg/L;
- pH (field measurements) of 5.4 – 8.4;
- low molar proportions chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

All but two groundwater samples contained nitrate above the applicable analytical reporting limit, with the highest concentration (1 mg/L in October 2001) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Two groundwater samples had uranium concentrations above the applicable analytical reporting limit, and both results (0.0006 mg/L in September 1998 and 0.0212 mg/L in January 2003) are below the MCL for uranium (0.03 mg/L). Both results are considered to be outliers.

5.3 VOLATILE ORGANIC COMPOUNDS

Aside from trace levels of chloroform (<3 µg/L) detected in ten groundwater samples, non-detect values or false positive results were reported for VOCs that are confirmed groundwater contaminants in the East Fork Regime.

5.4 GROSS ALPHA ACTIVITY

Six groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (44.16 pCi/L in November 2002) being substantially above the MCL for gross alpha activity (15 pCi/L). However, this result appears to be an outlier (none of the other gross alpha results exceed 10 pCi/L).

5.5 GROSS BETA ACTIVITY

Six groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (39.82 pCi/L in May 2003) being slightly below the SDWA screening level for gross beta activity (50 pCi/L). However, this result appears to be an outlier (only one other result exceeds 10 pCi/L) and is probably an analytical artifact.

WELL GW-722
Sampling Port 33

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1991, completed with an open-hole interval from 74 to 644 ft bgs, constructed with nominal 4.5-inch diameter steel (SF25) riser casing, and equipped with a multiport monitoring system (Westbay™) that enables collection of groundwater samples from multiple discreet depth intervals within the open-hole interval. The well is located in Bear Creek Valley near the east end of Y-12, about 350 ft west of the ORR boundary along Scarboro Road.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 33 being 87 ft bgs (Figure 1). A total of 28 samples were collected from the sampling port between August 1997 and October 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 33 yields groundwater from the Conasauga Group (Maynardville Limestone).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 33 yields calcium-magnesium bicarbonate groundwater generally characterized by:

- TDS of 196 – 350 mg/L;
- pH (field measurements) of 4.6 – 8.3;
- low molar proportions chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

All but two groundwater samples contained nitrate above the applicable analytical reporting limit, with the highest concentration (0.98 mg/L in November 2001) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Three groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest value (0.00136 mg/L in March 2000) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Trace levels of chloroform (<3 µg/L) were detected in 12 groundwater samples, with CTET and benzene detected in the sample collected in November 2002; all other VOC results show non-detect values or false positive results were reported for VOCs that are confirmed groundwater contaminants in the East Fork Regime.

5.4 GROSS ALPHA ACTIVITY

Six groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (3.24 pCi/L in November 2002) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Six groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (20.14 pCi/L in October 2003) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-723

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1991, completed with an open-hole monitored interval from 340.6 to 444.5 ft bgs, and constructed with nominal 7-inch diameter steel (SF25) riser casing. The well is located in Bear Creek Valley (BCV) west of Y-12 and is a component of Exit Pathway Picket C, which consists of a series of wells (GW-736, GW-737, GW-738, GW-739, and GW-740) completed at different depths (and hydrostratigraphic zones) along a strike-normal transect across the Maynardville Limestone (Figure 1). The Maynardville Limestone underlies Bear Creek throughout BCV and the hydrologic interaction between the creek and the shallow karst network in the Maynardville Limestone provide the primary exit-pathways for groundwater and surface water contaminants.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Seventeen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 13 samples between May 1992 and August 1996, and the low-flow sampling method used to obtain four samples between March 2002 and July 2005.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the deep (>300 ft bgs) bedrock interval in the Maynardville Limestone (Conasauga Group), which exhibits the hydrologic characteristics typical of karst aquifers. Most groundwater flow in the Maynardville Limestone, which subcrops along the axis of BCV and underlies the main channel of Bear Creek, occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Hydrologic interaction between the creek and the shallow karst network provides the principal exit-pathway for contaminants released from source areas within the Bear Creek watershed west of Y-12. Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 69 ft bgs and exhibits seasonal fluctuation of about 10 ft. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV and on Chestnut Ridge, groundwater elevation isopleths in the vicinity of Exit-Pathway Picket C indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the unfiltered groundwater samples collected to date indicate that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 155 – 376 mg/L (low for a deep well, suggests lower residence time and higher permeability);
- pH (field measurements) of 6.7 – 9;
- low molar proportions of chloride, potassium, and sodium (<10% of total anions/cations);
- low calcium concentration (<15 mg/L) compared to other wells at Exit Pathway Picket C; and

- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

All but four of the groundwater samples collected to date had nitrate concentrations above the analytical reporting limit (Table 1), including six samples with concentrations that exceed the MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds, which are RCRA-regulated, unlined surface impoundments that were closed in 1988 and covered with a multilayer low-permeability cap in 1989. Located about 7,200 ft east-northeast (hydraulically upgradient) of the Exit Pathway Picket B, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984. The groundwater contaminant plume originating from the site contains a heterogeneous mixture of inorganic, organic, and radiological contaminants. Nitrate, a principal component of the plume, enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale and recharge of nitrate-contaminated surface water in Bear Creek (DOE 1997). Nitrate is chemically stable and highly mobile in groundwater and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells, the extent of nitrate contamination in the Maynardville Limestone in BCV west of Y-12, as defined by concentrations above 10 mg/L, is generally characterized by: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for about 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) and is significantly influenced by hydrologic interactions with surface water in Bear Creek.

As noted previously, six groundwater samples had nitrate concentrations above the MCL, with a historical maximum concentration of 20 mg/L (August 1992 and February 1993). All samples collected since February 1995 had nitrate concentrations below the MCL (10 mg/L), and none of the samples collected after August 1996 had concentrations above the analytical reporting limit (0.028 mg/L). The decrease in nitrate concentrations probably reflects the substantially reduced flux of nitrate following closure of the former S-3 Ponds and installation of the low-permeability cap. Note, however, that all of the groundwater samples with nitrate concentrations below the analytical reporting limit were obtained using the low-flow sampling method; all previous samples were collected using the conventional sampling method. Thus, the nitrate concentrations may be at least partially attributable to the manner in which each sampling method induces flow of groundwater into the well. Low-flow sampling involves purging the well at flow rate low enough (<300 milliliters per minute) to ensure minimal water-level drawdown in the well (<1 ft per quarter hour), which induces groundwater flow from the water-producing features more proximal to the well. In contrast, conventional sampling involves aggressively purging the well (1-2 gallons per minute), which may substantially lower the water level in the well and induce inflow from water-producing features (e.g., conduits or fractures) that may not be proximal to the well.

5.2 URANIUM

Twelve of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.0033 mg/L in December 1994) being an order-of-magnitude below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected to date: TCE, 12DCE, CTET, and 2-butanone. These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. In the Bear Creek watershed west of the flow divide, the VOC plume in the Maynardville Limestone appears to originate near Spoil Area I and to extend several thousand feet westward (parallel with geologic strike) down the axis of BCV, with influx of various VOCs from several different downgradient source areas. The distribution of VOCs within the plume reflects the relative contributions from the source areas and commingling during downgradient transport. Plume constituents in the upper part of BCV are TCE, c12DCE, and PCE; source areas include Spoil Area I and the former S-3 Ponds. Farther downstream (west), major inputs of VOCs occur from the Rust Spoil Area or a nearby source in the Bear Creek floodplain; the Oil Landfarm waste management area (WMA), including the former Boneyard/Burnyard (BYBY), Hazardous Chemical Disposal Area (HCDA), and Sanitary Landfill I; and inflow of VOC-contaminated groundwater and surface water that discharges from a northern tributary of Bear Creek (NT-7) that traverses the Bear Creek Burial Grounds WMA. The highest VOC concentrations within the Maynardville Limestone exceed 300 µg/L and occur in the deeper groundwater south (down dip) of the HCDA, about 1,500 ft west-southwest (hydraulically downgradient) of Exit Pathway Picket C. These high concentrations coincide with downward vertical hydraulic gradients in the Maynardville Limestone in this area and a major losing reach of the main channel of Bear Creek (DOE 1997).

The primary VOC in the groundwater samples is TCE (Table 1), which is the only VOC detected in every sample collected to date, including ten samples with TCE concentrations that exceed the drinking water MCL (5 µg/L). The highest TCE concentrations were detected in samples collected in May 1992 (22 µg/L), February 1993 (21 µg/L), and August 1992 (15 µg/L), with the most recent results showing TCE concentrations at the MCL in March 2005 (5 µg/L) and slightly below the MCL in July 2005 (4 µg/L). Low concentrations of CTET (1 µg/L) and 12DCE (2 µg/L) were detected in the sample collected in February 1993 and 2-butanone (4 µg/L) was detected in the sample collected in December 1994.

As indicated by the data in Table 1 and illustrated by the corresponding time-series plot (Figure 1), TCE concentrations detected in the groundwater samples shows an indeterminate long-term concentration trend dominated by apparent “peak” concentrations in May 1992 (22 µg/L) and February 1993 (21 µg/L). Aside from these results, however, there is little overall difference in the relative concentration of TCE over time, as illustrated by the equal concentrations reported for the groundwater samples collected in October 1992 (5 µg/L) and March 2005 (5 µg/L), although the concentrations evident in August 1996 (8 µg/L) and July 2005 (4 µg/L) suggest a slightly decreasing tend. In any case, the long-term concentration trend suggests minimal overall changes in the relative flux of TCE via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

Five groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (6.3 pCi/L in July 2002) being less than the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Eleven groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, with the highest value (37.5 pCi/L in December 1994) being less than the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-724

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1991, completed with an open-hole monitored interval from about 289.6 to 301.6 ft bgs, and constructed with nominal 7-inch diameter steel (SF25) riser casing. The well is located in Bear Creek Valley (BCV) west of Y-12 and is a component of Exit Pathway Picket C, which consists of a series of wells (GW-724, GW-725, GW-736, GW-737, GW-738, GW-739, and GW-740) completed at different depths (and hydrostratigraphic zones) along a strike-normal transect across the Maynardville Limestone (Figure 1). The Maynardville Limestone subcrops along the axis of BCV and underlies the main channel of Bear Creek.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-nine groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 15 samples between May 1992 and September 1997, and the low-flow sampling method used to obtain 14 samples between March 1998 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the deep bedrock interval in the Maynardville Limestone (Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 28 ft bgs and exhibits seasonal fluctuations up to about 10 ft. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV and on Chestnut Ridge, groundwater elevation isopleths in the vicinity of Exit-Pathway Picket C indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields chloride- and sodium-enriched, nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 330 – 660 mg/L;
- pH of 6.3 – 8 (field measurements);
- elevated concentrations of chloride (>70 mg/L), total iron (>2 mg/L), sodium (>25 mg/L), and strontium (>1 mg/L) relative to other wells completed at shallower depths in the Maynardville Limestone;
- low molar proportions of potassium and sulfate (<10% of total anions/cations); and

- total concentrations of trace metals (except iron and strontium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

It is not clear if the elevated chloride and sodium concentrations typical of the groundwater samples reflect localized geochemical characteristics, or if the elevated concentrations are the result of contamination from one or more sources upgradient of the well.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, nitrate and VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected to date had nitrate concentrations above the analytical reporting limit (Table 1), and all but one of these results exceed the drinking water MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds, which are unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988. Located about 3,500 ft east-northeast of the Exit Pathway Picket C, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984. The groundwater contaminant plume originating from the site contains a heterogeneous mixture of inorganic, organic, and radiological contaminants. Nitrate, a principal component of the plume, enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale and recharge of nitrate-contaminated surface water in Bear Creek (DOE 1997). Nitrate is chemically stable and highly mobile in groundwater and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells, the extent of nitrate contamination in the Maynardville Limestone in BCV west of Y-12, as defined by concentrations above 10 mg/L, is generally characterized by: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for about 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) and is significantly influenced by hydrologic interactions with surface water in Bear Creek.

As noted previously, all but one of the groundwater samples had nitrate concentrations above the MCL, with all but four of these results being 25 mg/L or higher (Table 1). The nitrate concentrations exhibit apparently seasonal fluctuations, with the highest concentrations, including the historical maximum (62 mg/L in February 1993), typically evident in samples obtained during seasonally high flow conditions (winter and spring), and the lowest concentrations, including the historical minimum (7.73 mg/L in September 1998), typically reported for samples obtained during seasonally low flow conditions (summer and fall). This relationship suggests seasonal (and episodic) fluctuations in the relative flux of nitrate via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

A time-series plot of nitrate concentrations in the groundwater samples shows a generally decreasing long-term trend dominated by wide temporal (seasonal) fluctuations (Figure 2). The overall decrease in nitrate concentrations, with the most recent sampling result (19.5 mg/L in July 2004) being 60 - 70% lower than evident in the early 1990s (e.g., 54 mg/L in August 1992), is attributable to the reduced flux of nitrate from the former S-3 Ponds following closure of the site and installation of the low-permeability cap.

5.2 URANIUM

Fifteen groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.00128 mg/L in August 1999) being an order-of-magnitude below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample collected to date (Table 2): CTET, chloroform, PCE, TCE, toluene, and 12DCE (isomers). These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. In the Bear Creek watershed west of the flow divide, the VOC plume in the Maynardville Limestone appears to originate near Spoil Area I and to extend several thousand feet westward (parallel with geologic strike) down the axis of BCV, with influx of various VOCs from several different downgradient source areas. The distribution of VOCs within the plume reflects the relative contributions from the source areas and commingling during downgradient transport. Plume constituents in the upper part of BCV are TCE, c12DCE, and PCE; source areas include Spoil Area I and the former S-3 Ponds. Farther downstream (west), major inputs of VOCs occur from the Rust Spoil Area or a nearby source in the Bear Creek floodplain; the Oil Landfarm waste management area (WMA), including the former Boneyard/Burnyard (BYBY), Hazardous Chemical Disposal Area (HCDA), and Sanitary Landfill I; and inflow of VOC-contaminated groundwater and surface water that discharges from a northern tributary of Bear Creek (NT-7) that traverses the Bear Creek Burial Grounds WMA. The highest VOC concentrations within the Maynardville Limestone exceed 300 µg/L and occur in the deeper groundwater south (down dip) of the HCDA, about 1,500 ft west-southwest (hydraulically downgradient) of Exit Pathway Picket C. These high concentrations coincide with downward vertical hydraulic gradients in the Maynardville Limestone in this area and a major losing reach of the main channel of Bear Creek (DOE 1997).

The primary VOC in the groundwater samples is TCE (Table 2), which was detected in every sample, with the historical maximum concentration of 160 µg/L in March 1996 and the most recent sampling results (February and July 2004) showing concentrations remain above 75 µg/L and substantially exceed the drinking water MCL (5 µg/L). Secondary compounds in the samples are PCE and 12DCE, which were detected in all but three of the samples, although all of the results for both compounds are estimated values below 5 µg/L. Also, the most recent sampling results also show that PCE and c12DCE concentrations remain below the respective MCLs (5 µg/L and 70 µg/L). Similarly low concentrations (estimated values below 5 µg/L) of CTET, chloroform, and toluene were detected in a total of nine samples, most of which were collected between January 1991 and March 1996 (Table 2).

A time-series plot of TCE concentrations in the groundwater samples shows an indeterminate long-term concentration trend (Figure 3) characterized by three distinct segments: (1) a generally increasing trend between May 1992 (54 µg/L) and March 1996 (160 µg/L), (2) a series of unusually low concentrations in August 1996 (40 µg/L), February 1997 (35 µg/L), and

September 1997 (45 µg/L), and (3) a slightly decreasing trend between March 1998 (130 µg/L) and July 2004 (77 µg/L). Additionally, the temporal "peak" concentrations of TCE are most frequently indicated by results for samples obtained during seasonally high groundwater flow conditions (winter and spring). These temporal fluctuations potentially correspond with changes in the relative flux of TCE along the groundwater flow/transport pathways intercepted by the monitored interval in the well.

Unlike TCE, the concentrations of the other VOCs detected in the groundwater samples do not exhibit any discernable long-term trend or significant temporal concentration fluctuations (Table 1), as illustrated by the PCE concentrations reported for the samples collected in December 1993 (3 µg/L), September 1998 (3 µg/L), and July 2004 (4 µg/L). Assuming the groundwater contaminant plume in the Maynardville Limestone contains a heterogeneous mixture of dissolved VOCs, it is not clear from the available data why the concentrations of individual compounds exhibit divergent long-term trends and temporal variations, or if such variations are significant with respect to the relative flux of VOCs in the groundwater.

5.4 GROSS ALPHA ACTIVITY

Four groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (4.97 pCi/L in February 1993) being less than the drinking water MCL for gross alpha activity (15 pCi/L). Also, the groundwater samples collected in January and July 2001 were analyzed for U-234 and U-238, which are the alpha-emitting radionuclides that are most likely to be present in the groundwater, and the respective results for each isotope that exceed the applicable MDA are less than 0.5 pCi/L.

5.5 GROSS BETA ACTIVITY

Twenty-five groundwater samples had gross beta activity above the applicable MDA and corresponding CE (Table 1), but only the result for one sample (60 pCi/L in February 2000) exceeds the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). The source of the gross beta activity in the groundwater at this well is believed to be Tc-99 based on the detection (i.e., >MDA and CE) of this beta-emitting radionuclide in the samples collected in January (48 pCi/L) and July 2001 (43 pCi/L). Note that both results are substantially below the SDWA screening level (3,790 pCi/L) for a 4 mrem/yr dose equivalent from Tc-99. This radionuclide is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, the only site at Y-12 which received wastes that contained Tc-99 (DOE 1998). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the groundwater transport of Tc-99 in the Maynardville Limestone closely mirrors that of nitrate.

A time-series plot of gross beta activity reported for the groundwater samples shows an indeterminate long-term trend dominated by wide temporal fluctuations (Figure 4). The indeterminate trend suggests minimal overall change in the relative flux of Tc-99 via the groundwater flow/transport pathways intercepted by the monitored interval in the well. Also, unlike the nitrate concentrations, temporal "peak" levels of gross beta activity do not exhibit a clear and consistent correlation with seasonal groundwater flow conditions, although five of the seven highest gross beta values were reported for samples obtained during seasonally high flow conditions (winter and spring).

WELL GW-725

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1991, completed with an open-hole monitored interval from about 132.5 to 142.5 ft bgs, and constructed with nominal 7-inch diameter steel (SF25) riser casing. The well is located in Bear Creek Valley (BCV) west of Y-12 and is a component of Exit Pathway Picket C, which consists of a series of wells (GW-724, GW-725, GW-736, GW-737, GW-738, GW-739, and GW-740) completed at different depths (and hydrostratigraphic zones) along a strike-normal transect across the Maynardville Limestone (Figure 1). The Maynardville Limestone subcrops along the axis of BCV and underlies the main channel of Bear Creek.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-one groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 17 samples between May 1992 and August 2000, and the low-flow sampling method used to obtain 14 samples between March 1998 and July 2004.

An evaluation of the monitoring data available through August 2000 indicated potential bias related to the groundwater sampling method: samples obtained with the conventional sampling method had substantially higher contaminant (VOC) concentrations than samples obtained with the low-flow sampling method (AJA 2001). Results of "paired sampling" performed during February and August 2000, when groundwater samples were collected with the low-flow sampling method one day and the conventional sampling method the next day, confirm the apparent sampling-method bias. As shown by the data summarized in Table 1, groundwater samples obtained with the low-flow method had at least 50% lower summed VOC concentrations than the samples obtained with the conventional sampling method. Interestingly, some of the inorganic analytes, notably nitrate and iron (total), also exhibit substantial difference between the low-flow and conventional sampling results, whereas other inorganic analytes (e.g., calcium and barium) do not.

Inherent differences in the manner in which each sampling method induces flow of groundwater into the well may explain the disparity between the conventional and low-flow sampling results. Conventional sampling involves aggressively purging the well (1-2 gallons per minute), which may substantially lower the water level in the well and induce inflow from water-producing features that may not be near the well. In contrast, low-flow sampling involves purging the well at flow rate low enough (<300 milliliters per minute) to ensure minimal water-level drawdown in the well (<1 ft per quarter hour), which induces groundwater flow from the water-producing features near the well. Thus, the conventional sampling method has much greater local hydrologic influence (particularly in directions parallel with geologic strike) and substantially increases the relative inflow of contaminated groundwater into the well.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the intermediate bedrock interval in the Maynardville Limestone (Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 9 ft bgs and exhibits seasonal fluctuations up to about 10 ft. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV and on Chestnut Ridge, groundwater elevation isopleths in the vicinity of Exit-Pathway Picket C indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields chloride- and sodium-enriched, nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 500 – 1,125 mg/L;
- pH of 6.33 – 7.2 (field measurements);
- elevated concentrations of chloride (>80 mg/L) and sodium (>30 mg/L) relative to other wells completed at shallower depths in the Maynardville Limestone;
- low molar proportions of potassium and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

It is not clear if the chloride and sodium concentrations typical of the groundwater samples reflect localized geochemical characteristics, or if the elevated concentrations are the result of contamination from one or more sources upgradient of the well.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, nitrate and VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected to date had nitrate concentrations above the analytical reporting limit (Table 1), and all of these results exceed the drinking water MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds, which are unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988. Located about 3,500 ft east-northeast of the Exit Pathway Picket C, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984. The groundwater contaminant plume originating from the site contains a heterogeneous mixture of inorganic, organic, and radiological contaminants. Nitrate, a principal component of the plume, enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale and recharge of nitrate-contaminated surface water in Bear Creek (DOE 1997). Nitrate is chemically stable and highly mobile in groundwater and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells, the extent of nitrate contamination in the Maynardville Limestone in BCV west of Y-12, as defined by concentrations above 10 mg/L, is generally characterized by: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for about 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) and is significantly influenced by hydrologic interactions with surface water in Bear Creek.

As noted previously, all of the groundwater samples had nitrate concentrations above the MCL, with higher concentrations, including the historical maximum value (106 mg/L in March 1994), reported for samples obtained using the conventional sampling method, and the lower concentrations, including the historical minimum value (13.8 mg/L in July 2004), reported for samples obtained the low-flow sampling method (Table 1). Also, the conventional sampling results exhibit greater concentrations fluctuations, with peak concentrations evident in February 1993 (61 mg/L), March 1994 (106 mg/L), March 1996 (67.9 mg/L), and February 1997 (76 mg/L). These results suggest seasonally increased flux of nitrate via the groundwater flow/transport pathways intercepted by the monitored interval in the well. In contrast, the low-flow sampling results show much less temporal variability, with the highest concentrations (48.2 mg/L in January 2002 and 56 mg/L in February 2004) appearing to be outliers compared to the other low-flow sampling results, most of which are all less than 25 mg/L.

A combined time-series plot of nitrate concentrations in the groundwater samples obtained with the conventional and low-flow sampling methods shows a generally indeterminate long-term trend (Figure 2). Although the results of "paired" conventional and low-flow sampling in May and August 2000 show significant differences between respective nitrate concentrations, the conventional sampling results also suggest a significant (30 – 50%) decrease from the concentrations evident in the early and mid-1990s. The long-term decrease in nitrate concentrations is attributable to the reduced flux of nitrate from the former S-3 Ponds following closure of the site and installation of the low-permeability cap (DOE 1997).

5.2 URANIUM

All of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.012 mg/L in July 2004) being less than the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample collected to date (Table 3): benzene, CTET, chloroform (CLF), methylene chloride, PCE, TCE, toluene, 11DCE, 12DCE (isomers), and 111TCA. These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. In the Bear Creek watershed west of the flow divide, the VOC plume in the Maynardville Limestone appears to originate near Spoil Area I and to extend several thousand feet westward (parallel with geologic strike) down the axis of BCV, with influx of various VOCs from several different downgradient source areas. The distribution of VOCs within the plume reflects the relative contributions from the source areas and commingling during downgradient transport. Plume constituents in the upper part of BCV are TCE, c12DCE, and PCE; source areas include Spoil Area I and the former S-3 Ponds. Farther downstream (west), major inputs of VOCs occur from the Rust Spoil Area or a nearby source in the Bear Creek floodplain; the Oil Landfarm waste management area (WMA), including the former Boneyard/Burnyard (BYBY), Hazardous Chemical Disposal Area (HCDA), and Sanitary Landfill I; and inflow of VOC-contaminated groundwater and surface water that discharges from a northern tributary of Bear Creek (NT-7) that traverses the Bear Creek Burial Grounds WMA. The highest VOC concentrations within the Maynardville Limestone exceed 300 μg/L and occur in the deeper groundwater south (down dip) of the HCDA, about 1,500 ft west-southwest (hydraulically downgradient) of Exit Pathway Picket C. These high concentrations coincide with downward vertical hydraulic gradients in the Maynardville Limestone in this area and a major losing reach of the main channel of Bear Creek (DOE 1997).

The primary VOC in the groundwater samples is TCE (Table 3), which was detected in every sample at concentrations ranging between 7 (February 1997 and July 2004) and 310 μg/L (February 2004), all of which exceed the drinking water MCL (5 μg/L). Secondary compounds in the samples are PCE and 12DCE (isomers), one or both of which were detected in all but six of the samples, although all of the results for both compounds are estimated values below 5 μg/L. The most recent sampling results also show that PCE and c12DCE concentrations remain below the respective MCLs (5 μg/L and 70 μg/L). Similarly low concentrations (most being estimated values below 5 μg/L) of benzene, CTET, chloroform, toluene, 11DCE, and 111TCA were detected in a total of nine samples, most of which were collected between December 1993 and February 1997 (Table 3).

As noted in Section 2.0, summed concentrations of VOCs detected in the groundwater samples obtained with the conventional sampling method are much higher than evident for samples obtained with the low-flow sampling method. As illustrated by the data summarized below, this is attributable to significantly higher TCE concentrations in samples obtained with the conventional sampling method.

VOC	Concentration (μg/L)			
	February 7-8, 2000		August 8-9, 2000	
	Low-Flow Sampling	Conventional Sampling	Low-Flow Sampling	Conventional Sampling
PCE	3 J	.	.	.
TCE	12	55	13	90
c12DCE	.	.	.	3 J

This suggests that the conventional sampling method induces greater inflow of TCE-contaminated groundwater into the well, possibly because this method promotes inflow from flowpaths that are not proximal to the well, whereas the low-flow sampling method induces inflow (of TCE-contaminated groundwater) from the flowpaths located near the well (see Section 2.0).

Combined time-series plots of respective TCE concentrations reported for the groundwater samples collected with the conventional and low-flow sampling methods shows an indeterminate long-term concentration trend (Figure 3), dominated by temporal "peak" concentrations evident in February 1995 (130 μg/L), January 2002 (200 μg/L), and February 2004 (310 μg/L). Aside from these results, however, there is little overall difference in the relative concentration of TCE over time, as illustrated by the similar concentrations reported for the groundwater samples collected in March 1992 (82 μg/L) and July 2004 (77 μg/L). This suggests minimal changes in the overall flux of TCE along the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

Fifteen groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, including six of the samples obtained with the conventional sampling method and nine samples obtained with the low-flow sampling method. The historical maximum gross alpha value (21.2 pCi/L in August 1992) exceeds the MCL for gross alpha activity (15 pCi/L), but this result appears to be an outlier (all but two of the remaining results are less than

10 pCi/L). Also, the groundwater samples collected in January and July 2001 were analyzed for U-234 and U-238, which are the alpha-emitting radionuclides that are most likely to be present in the groundwater, and the respective results for each isotope are 3 pCi/L or less.

5.5 GROSS BETA ACTIVITY

All of the groundwater samples had gross beta activity above the applicable MDA and corresponding CE (Table 2), but only the result for one sample (53.7 pCi/L in December 2000) exceeds the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the MCL for gross beta activity). The source of the gross beta activity in the groundwater at this well is believed to be Tc-99 based on the detection (i.e., >MDA and CE) of this beta-emitting radionuclide in the samples collected in January (22 pCi/L) and July 2001 (36 pCi/L). Note that both results are substantially below the SDWA screening level (3,790 pCi/L) for a 4 mrem/yr dose equivalent from Tc-99. This radionuclide is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, the only site at Y-12 which received wastes that contained Tc-99 (DOE 1998). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the groundwater transport of Tc-99 in the Maynardville Limestone closely mirrors that of nitrate.

Gross beta activity levels reported for the groundwater samples typically range between 25 and 50 pCi/L (Table 2), with the highest levels, including the historical maximum value (53.7 pCi/L in December 1993) reported for samples obtained using the conventional sampling method. Conversely, lower levels of gross beta activity, including the historical minimum value (11 pCi/L in July 2004), were reported for samples obtained using the low-flow sampling method. Interestingly, the gross beta results obtained with either sampling method show the highest values for samples collected during seasonally high flow conditions. Also, a combined time-series plot of gross beta results reported for samples obtained with conventional and low-flow sampling methods shows an indeterminate long-term trend (Figure 4), as illustrated by the close similarity between the gross beta results reported for samples collected in August 1992 (28.6 pCi/L), March 1998 (29 pCi/L), and July 2004 (34 pCi/L). This indeterminate long-term trend indicated by the sampling results for gross beta activity suggest minimal change in the relative flux of Tc-99 via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

WELL GW-731

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in September 1991, completed with a screened monitored interval from 164 to 178.7 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located on the crest of Chestnut Ridge southeast of Y-12, about 50 ft southeast (hydraulically downgradient) of the Chestnut Ridge Sediment Disposal Basin (CRSDB). The CRSDB is a former sinkhole filled with contaminated sediments generated from remedial actions at Y-12 and covered with a low-permeability, multilayer cap during RCRA closure of the site in 1989. Semiannual statistical evaluations performed for RCRA detection monitoring purposes has not indicated a contaminant release to groundwater at the site.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Seventy groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 31 samples between September 1991 and April 1997, and the low-flow sampling method used to obtain 39 samples between October 1997 and October 2004. Many of these samples were collected in accordance with the replicate sampling protocol associated with RCRA post-closure detection monitoring performed between October 1995 and April 2001, when four samples were collected over consecutive days during each semiannual sampling event.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the Knox Group (Copper Ridge Dolomite). The average static groundwater level in the well is 121 ft below ground surface. Presampling depth-to-water measurements for the well indicate moderate fluctuations (<5 ft) in seasonal groundwater surface elevations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 98 – 238 mg/L;
- pH (field measurements) of 7.3 – 10.1;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Thirty-three groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.67 mg/L in January 1995) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Ten groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.01 mg/L in February 1995) being below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Seventeen groundwater samples collected between September 1991 and July 1995 were analyzed for VOCs and the analytical results for each sample show non-detect values or false positive results for all of the VOCs that are confirmed groundwater contaminants in the Chestnut Ridge Regime. Acetone (77 µg/L in September 1991) and 4-methyl-2-pentanone (6 µg/L in May 1992) were each detected in only one sample from the well, and both results are considered to be outliers.

5.4 GROSS ALPHA ACTIVITY

Seven groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the results that exceed the MCL for gross alpha activity (15 pCi/L) reported for the samples collected in May 1992 (17.3 pCi/L) and February 1993 (18.8 pCi/L). Both results are suspected outliers because the other gross alpha results are all less than 5 pCi/L.

5.5 GROSS BETA ACTIVITY

Fifteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (27.3 pCi/L) being below the SDWA for gross beta activity (50 pCi/L).

WELL GW-732

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in September 1991, completed with a screened monitored interval from 178.3 to 190 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located on the crest of Chestnut Ridge southeast of Y-12 at the Chestnut Ridge Sediment Disposal Basin (CRSDB). The CRSDB is a former sinkhole filled with contaminated sediments generated from remedial actions at Y-12 and covered with a low-permeability, multilayer cap during RCRA closure of the site in 1989. Semiannual statistical evaluations performed for RCRA detection monitoring purposes has not indicated a contaminant release to groundwater at the site.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Seventy-one groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 32 samples between September 1991 and April 1997, and the low-flow sampling method used to obtain 39 samples between October 1997 and October 2004. Many of these samples were collected in accordance with the replicate sampling protocol associated with RCRA post-closure detection monitoring performed between October 1995 and April 2001, when four samples were collected over consecutive days during each semiannual sampling event.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the bedrock interval in the Knox Group. The average static groundwater level in the well is 153 ft below ground surface. Presampling depth-to-water measurements for the well indicate substantial (> 25 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 100 – 526 mg/L;
- pH (field measurements) of 7.1 – 11.2;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Thirty-five groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (1 mg/L in August 1995) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Twenty groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.016 mg/L in April 1995) being below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Seventeen groundwater samples collected between September 1991 and July 1995 were analyzed for VOCs and the analytical results for each sample show non-detect values or false positive results for all of the VOCs that are confirmed groundwater contaminants in the Chestnut Ridge Regime.

5.4 GROSS ALPHA ACTIVITY

Fifteen groundwater samples had gross alpha activity above the applicable MDA and corresponding CE. All but three of these results are less than the MCL for gross alpha activity (15 pCi/L); 19.3 pCi/L in November 1993, 34.1 pCi/L in January 1995, and 91 pCi/L in April 1995.

5.5 GROSS BETA ACTIVITY

Seventeen groundwater samples had gross beta activity above the applicable MDA and corresponding CE. Five of these results exceed 15 pCi/L: 27.4 pCi/L in January 1995; 59.8 pCi/L in January 1995, which exceeds the SDWA screening level for gross beta activity (50 pCi/L); and 17.5 pCi/L, 25.1 pCi/L, and 28.4 pCi/L for samples collected on successive days in October 1995.

WELL GW-733

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1991, completed with an open-hole monitored interval from 240.1 to 256.5 ft bgs, and constructed with nominal 7-inch diameter steel (SF25) riser casing. The well is located in Bear Creek Valley near the east end of Y-12, about 300 ft east (hydraulically downgradient) of New Hope Pond (NHP)/Lake Reality. Closed in 1988 and covered with a multi-layer low-permeability cap in 1989, NHP was an unlined surface impoundment constructed in 1963 to regulate the quantity and quality of surface water exiting Y-12 via UEFPC. Lake Reality is a lined surface impoundment that was built in 1988 to replace NHP. During normal operations, flow in of the Upper East Fork Poplar Creek (UEFPC) bypasses Lake Reality and is directed through the concrete-lined distribution channel, which borders the south and east sides of NHP/Lake Reality.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-eight groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 21 samples between April 1992 and July 1997, and the low-flow sampling method used to obtain 17 samples between March 1998 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the intermediate bedrock interval in the Maynardville Limestone (upper Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 53 ft bgs and exhibits seasonal fluctuations of about 9 ft. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-733 indicate components of flow to the north toward the UEFPC drainage system and to the east parallel with geologic strike in the Maynardville Limestone. Additionally, local groundwater flow patterns near NHP are influenced by the full-time operation of a groundwater extraction and treatment system intended to intercept and contain the VOC-contaminated groundwater in the Maynardville Limestone near the east end of Y-12, as required by the CERCLA Action Memorandum (DOE 1999). Beginning in October 2001, groundwater has been pumped from a well (GW-845) located about 700 ft west-northwest (hydraulically upgradient) of well GW-733 and is treated on-site to remove VOCs, particulates, iron, and manganese. Long-term operation of the system has generally maintained 15 to 17 ft of drawdown in the immediate vicinity of well GW-845 and has established an elongated zone of influence that extends parallel with geologic strike for at least 900 ft to the east (downgradient) and 600 ft to the west (upgradient) of the pumping well (DOE 2002).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 156 – 260 mg/L;
- pH (field measurements) of 7.1 – 8.8;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Twenty-seven groundwater samples had nitrate concentrations above the analytical reporting limit, with the highest value (2.5 mg/L in July 2000) being less than the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Thirteen groundwater samples had uranium concentrations at the applicable analytical reporting limit, with the highest value (0.001 mg/L in February 1993, August 1993, and January 1994) being an order-of-magnitude below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample (Table 1): acetone, benzene, CTET, chloroform, PCE, and TCE. These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and UEFPC watersheds. In the UEFPC watershed east of the flow divide, which occurs near the west end of Y-12, the VOC plume in the Maynardville Limestone appears to originate near the Fire Training Facility in the southwestern section of Y-12, extends eastward (parallel with geologic strike) and mixes with VOCs released from several sources in the central and eastern Y-12 areas, and enters Union Valley east of the ORR boundary along Scarboro Road (DOE 1998). In October 2000, full-time operation of a groundwater remediation system began to help intercept and contain the (CTET-dominated) portion of the VOC plume in the eastern Y-12 area, as required by the CERCLA Action Memorandum (DOE 1999). Operation of the system involves pumping groundwater from an extraction well (GW-845) completed in the Maynardville Limestone about 700 ft west-northwest (across geologic strike) of well GW-733; treating the groundwater on-site to remove particulates, iron, manganese, and VOCs; and discharging the effluent into UEFPC.

The primary VOCs in the groundwater samples are CTET and chloroform (Table 1), which were detected in each groundwater sample, with respective historical maximum concentrations evident in November 1993 (87 μg/L) and April 1992 (27 μg/L). Acetone, benzene, PCE, and TCE have been detected much less frequently and at substantially lower concentrations, with the bulk of the results for each compound being estimated values below 5 μg/L.

A time-series plot of the summed concentrations of VOCs detected in each groundwater sample (Figure 1) shows a steadily decreasing trend between November 1993 (98 µg/L) and July 1998 (5 µg/L), followed by an indeterminate trend through July 2004 (8 µg/L). Note that the decreasing concentration trend predates the full-time operation of groundwater extraction well GW-845, and the indeterminate trend generally corresponds with the change from conventional sampling to low-flow sampling. Also, the VOC results obtained from conventional sampling before March 1998 show cyclic temporal concentration fluctuations, with the highest concentrations typically detected in samples collected during seasonally low groundwater flow conditions (summer and fall). However, proportionally similar temporal concentration fluctuations are less evident from the VOC low-flow sampling results obtained since March 1998. Moreover, the VOC concentrations in the well do not yet reflect any discernable response to operation of groundwater extraction well GW-845 (DOE 2002).

5.4 GROSS ALPHA ACTIVITY

Ten groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (6.5 pCi/L in February 1999) being less than the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Seventeen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (9.9 pCi/L in February 1999) being less than the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-735

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1991, completed with a screened monitored interval from 67.5 to 79.2 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley east of Y-12, about 400 ft west of the ORR boundary along Scarboro Road.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-seven groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 20 samples between April 1992 and April 1997, and the low-flow sampling method used to obtain 17 samples between December 1997 and November 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the shallow bedrock interval in the Maynardville Limestone. The average static groundwater level in the well is 19.5 ft bgs. Excluding the unusually low groundwater elevation evident in December 1997 (Figure 1), presampling depth-to-water measurements for the well indicate moderate (<10 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 283 – 486 mg/L;
- pH (field measurements) of 5.7 – 7.9;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Nineteen groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (2.9 mg/L in August 2000) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Only the uranium concentration reported for the groundwater sample collected in March 1996 (0.0054 mg/L) exceeds the analytical reporting limit. This result is substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected at very low levels in two groundwater samples: methylene chloride (0.8 μg/L) in May 1993 and chloroform (2 μg/L) in April 1997. These results are probably sampling or analytical artifacts and are considered to be outliers.

5.4 GROSS ALPHA ACTIVITY

Seven groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (9.2 pCi/L in June 1999) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Thirteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (14.7 pCi/L in December 1994) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-736

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1991, completed with a screened monitored interval from 92 to 105 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire wound). The well is located in Bear Creek Valley (BCV) west of Y-12, on the north side of Bear Creek Road and directly south of the main channel of Bear Creek, approximately 300 ft downstream of the confluence between the main channel and a northern tributary (NT-2) of the creek. The well is a component of Exit Pathway Picket C, which consists of a series of wells (GW-724, GW-725, GW-736, GW-737, GW-738, GW-739, and GW-740) completed at different depths (and hydrostratigraphic zones) along a north-south transect approximately 3,300 ft (Figure 1).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fifteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 11 samples between May 1992 and September 1995, and the low-flow sampling method used to obtain four samples between March 2002 and August 2005. The sampling history includes quarterly sampling between May 1992 and December 1993, with semiannual sampling in 1994 and 1995, a nearly seven-year period (September 1995 – March 2002) when no samples were collected from the well, and semiannual sampling in 2002 and 2005.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maynardville Limestone (Conasauga Group), which exhibits the hydrologic characteristics typical of karst aquifers. Most groundwater flow in the Maynardville Limestone, which subcrops along the axis of BCV and underlies the main channel of Bear Creek, occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Hydrologic interaction between the creek and the shallow karst network provides the principal exit-pathway for contaminants released from source areas within the Bear Creek watershed west of Y-12. Below the shallow karst network, fractures provide the primary groundwater flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 9 ft bgs and exhibits seasonal fluctuations of about 6 ft. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV and on Chestnut Ridge, groundwater elevation isopleths in the vicinity of Exit-Pathway Picket C indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples collected to date show that the well yields nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 598 – 956 mg/L;
- pH of 6.72 – 7.12 (field measurements);

- nitrate concentrations above 10 mg/L;
- elevated concentrations of sodium (>25 mg/L), chloride (>50 mg/L), and sulfate (>40 mg/L) relative to other wells completed at similar depth in the Maynardville Limestone; and
- unusually high concentrations of some trace metals that indicate a correlation with the levels of suspended solids in the samples (see Section 5.6), total concentrations of other trace metals being either below respective analytical reporting limits or within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Dissolution of locally disseminated sulfides in the Maynardville Limestone may account for the elevated levels of sulfate in the groundwater at this well, and the elevated concentrations of sodium and chloride (and high TDS) potentially indicate that the well does not intercept highly permeable groundwater flowpaths. Instead, the well may be completed in a relatively low-yield interval where the groundwater geochemistry resembles that of the sodium-bicarbonate groundwater typically encountered at a depth of approximately 100 ft bgs in the Nolichucky Shale (and other low-permeability formations of the Conasauga Group). The sodium-bicarbonate geochemistry of the groundwater, which is accompanied by a general increase in chloride levels and TDS, is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture or increased fracture spacing (Solomon et al. 1992). Thus, the elevated levels of sodium and chloride (and TDS) may indicate that the well yields groundwater with higher residence time than typical of the more permeable intervals at shallow depths in the Maynardville Limestone. Also, considering that the monitored interval intercepts groundwater flowpaths within the lower part of the Maynardville Limestone (Figure 1), the atypical sodium and chloride levels the groundwater in the well potentially indicates hydraulic connection with the sodium-bicarbonate groundwater from the Nolichucky Shale.

As illustrated by the selected data summarized below, sodium and chloride concentrations appear to have increased (nearly doubled) during the prolonged gap in the sampling history for the well. Although the higher sodium and chloride levels appear to coincide with the change from conventional sampling to low-flow sampling, the concentrations of other major ions (e.g., potassium and sulfate) exhibit no apparent change coincident with the sampling method. Thus, the elevated sodium and chloride concentration do not appear to be artifacts related to the sampling method, but instead seem to define the passing of a temporal "slug" of sodium- and chloride-enriched groundwater via the flowpaths intercepted by the monitored interval in the well.

Sampling Method and Date		**Concentration (mg/L)**

	03/03/05	29.7	64.7	43.6
	08/02/05	29.4	59.5	44.5

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12, all of which are present in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected to date had nitrate concentrations above the analytical reporting limit (Table 1), and all of these results exceed the drinking water MCL for nitrate (10 mg/L). Elevated nitrate concentrations in the samples indicate that the monitored interval for the well intercepts groundwater flow/transport pathways for nitrate (and other contaminants) released from the former S-3 Ponds, which are RCRA-regulated, unlined surface impoundments that were closed in 1988 and covered with a multilayer low-permeability cap in 1989. Located approximately 3,500 ft east-northeast (hydraulically upgradient) of Exit Pathway Picket C, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984, which emplaced a heterogeneous plume of inorganic, organic, and radiological contaminants in the groundwater. Nitrate, a principal component of the plume, enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale, which underlies the former S-3 Ponds, and recharge of nitrate-contaminated surface water in Bear Creek (DOE 1997). Because nitrate is chemically stable and highly mobile in groundwater, the elevated concentrations of nitrate (>10 mg/L) effectively trace the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells, the extent of elevated nitrate concentrations in the Maynardville Limestone west of Y-12 reflects: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for approximately 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) and is significantly influenced by hydrologic communication with surface water in Bear Creek.

As noted previously, all of the nitrate results detected in the groundwater samples collected to date exceed 10 mg/L drinking water MCL (Table 1), although nitrate concentrations reported for the samples collected most recently (March and August 2005) are just slightly above the MCL and are the lowest levels reported for the well. Unlike the nitrate concentrations evident in the groundwater at other Maynardville Limestone wells west of Y-12, including several Exit Pathway Picket C wells, the nitrate results for this well do not indicate wide temporal (seasonal) concentration fluctuations, as illustrated by the most recent sampling results noted above. This also supports the possibility, as noted in Section 4.0 regarding the unusual geochemistry of the groundwater samples, that the monitored interval in the well may not intercept the more permeable flowpaths at shallow depths in the Maynardville Limestone, where nitrate concentrations typically exhibit pronounced fluctuations in response to seasonal (and episodic) recharge/discharge cycles.

As shown on Figure 2, a time-series plot of the nitrate concentrations detected in the groundwater samples collected to date shows a short-term increase between May 1992 (37.8 mg/L) and February 1993 (61 mg/L), with subsequent sampling results defining a long-term deceasing trend (spanning the gap in the sampling history for the well) though August 2005 (10.5 mg/L). The overall decrease in nitrate concentrations primarily reflects the substantially reduced flux of nitrate in the Maynardville Limestone following the closure/capping of the former S-3 Ponds, and indicates that the most highly contaminated groundwater has been flushed form the shallow karst network.

5.2 URANIUM

All of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with values slightly above the drinking water MCL (0.03 mg/L) reported for the samples collected in March and August 2005 (Table 1). Note, however, that none of the other Exit Pathway Picket C wells yield groundwater samples with uranium concentrations that exceed the MCL. Nevertheless, the elevated concentrations of uranium indicate that the monitored interval in the well intercepts groundwater flow/transport pathways for uranium from the contaminant plume emplaced during historical operation of the former S-3 Ponds, which is the only confirmed source of uranium located hydraulically upgradient of Exit Pathway Picket C. Additionally, a time-series plot of the uranium results shows a clearly increasing long-term concentration trend (Figure 3), as illustrated by the uranium concentrations reported for the samples collected in May 1992 (0.006 mg/L), December 1994 (0.0088 mg/L), March 2002 (0.0298 mg/L), and March 2005 (0.0309 mg/L). As with nitrate, the long-term uranium concentration trend spans a significant gap in the sampling history and the change in the groundwater sampling procedure. Nevertheless, this increasing concentration trend potentially reflects a corresponding increase in the relative flux of uranium via the groundwater flow/transport pathways intercepted by the monitored interval in the well. However, increase flux of uranium seems conspicuous considering that the disposal of wastewater at the former S-3 Ponds ceased more than 20 years ago and that similarly increasing flux of other contaminants from the site, particularly nitrate, is not indicated by the data for the well.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected to date (Table 2): benzene, ethylbenzene, carbon disulfide, CTET, chloroform, styrene, PCE, TCE, xylenes, 11DCA, 11DCE, and 112DCA. The presence of VOCs in the samples indicates that the monitored interval in the well intercepts groundwater flow/transport pathways for VOCs released from one or more upgradient sources that contribute to an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. Available data for the network of wells completed in the Maynardville Limestone west of the flow divide indicate that VOC-contaminated groundwater, as defined by individual or summed VOC concentrations above 5 µg/L, appears to originate near Spoil Area I and to extend hydraulically downgradient for several thousand feet westward (parallel with geologic strike) down the axis of BCV. The apparent distribution of VOCs within the plume reflects the relative influx from multiple source areas, commingling during downgradient groundwater transport, and hydraulic communication with Bear Creek (DOE 1997). In the upper part of BCV, hydraulically upgradient of the Exit Pathway Picket C wells, the primary VOCs are TCE, c12DCE, and PCE and the confirmed or suspected source areas include Spoil Area I, the contaminant plume emplaced during historical operation of the former S-3 Ponds, and the Rust Spoil Area (or nearby source within the Bear Creek floodplain), the latter site considered a primary source of TCE. Hydraulically downgradient (west) of Exit Pathway Picket C, additional influx of VOCs (primarily PCE) occurs from several sources within the Oil Landfarm waste management area (WMA) and the Bear Creek Burial Grounds WMA. Individual and summed VOC concentrations are highest (>300 µg/L) in the deeper groundwater flow/transport pathways (>200 ft bgs) in the Maynardville Limestone directly south (down dip) of the Oil Landfarm WMA, where the main channel of Bear Creek loses substantial flow to the groundwater (karst) system and where groundwater elevations in clustered monitoring wells indicate strongly downward vertical hydraulic gradients in the Maynardville Limestone (DOE 1997).

Based on frequency of detection and concentration magnitude, the primary VOCs in the groundwater samples collected to date are PCE, TCE, and 12DCE (Table 2). The dominant compound is TCE, which was detected in every sample, with the historical maximum concentration of 21 µg/L in May 1992. Also, the most recent sampling results (March and August 2005) show that the TCE concentrations remain slightly above the drinking water MCL (5 µg/L). All but one of the samples also contained 12DCE (c12DCE), although all of these results are less than 10 µg/L, with most being estimated concentrations below 5 µg/L. Similarly low concentrations of PCE have been detected in all but four of the samples collected to date, with the historical maximum concentration (7 µg/L in February 2003) being the only result above the MCL (5 µg/L). The remaining compounds were detected at concentrations of 5 µg/L or less and only in samples collected in May 1992, August 1992, and February 1993.

A time-series plot of TCE concentrations detected in the groundwater samples collected to date shows a steadily decreasing long-term concentration trend that is dominated by the nearly seven-year gap in the sampling history (Figure 4). Also, as illustrated by the TCE results for the samples collected in September 1995 (10 µg/L), July 2002 (9 µg/L) and August 2005 (7 µg/L), the rate of concentration decrease appears to have slowed considerably. The overall decrease in TCE levels probably reflects the reduced flux of VOCs following the closure/capping of the former S-3 Ponds and long-term natural attenuation of the VOC sources at Spoil Area I and the Rust Spoil Area, both of which were closed without further remedial action (e.g., waste removal or installation of low-permeability cap). Note also that the concentrations of other VOCs do not exhibit similarly decreasing long-term trends (Table 2), as illustrated by the PCE results reported for the samples collected in October 1992 (2 µg/L) September 1993 (1 µg/L), July 2002 (2 µg/L), and August 2005 (1 µg/L). Assuming a heterogeneous mixture of dissolved VOCs in the karst network at shallow depths in the Maynardville Limestone, it is unclear why the TCE and PCE concentrations exhibit such divergent trends or if such differences are significant with respect to the relative flux of dissolved VOCs. Perhaps the TCE and PCE (and other VOCs) are not well mixed in the groundwater system, but instead occur within separate, discreet transport pathways that are intercepted by the monitored interval in the well. The divergent concentration trends also may reflect differential transport from separate source areas, with decreased flux from the source of TCE (Rust Spoil Area) and comparably more consistent flux of PCE from another upgradient source (e.g., Spoil Area I).

5.4 GROSS ALPHA ACTIVITY

Ten groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE (Table 1), although only the historical maximum value (24 pCi/L in March 2002) exceeds the drinking water MCL for gross alpha activity (15 pCi/L). However, this result may be an outlier because all other results for gross alpha activity are less than 15 pCi/L. Note also that the highest levels of gross alpha activity have all been reported for the samples collected after the transition to the low-flow groundwater sampling method in 1998 and the nearly seven-year gap in the groundwater sampling history for the well. Nevertheless, uranium isotopes (and alpha-emitting daughters) in the groundwater are the likely source of the gross alpha activity, as indicated by the low levels of U-234 and U-238 detected in the groundwater samples collected in March and August 2005 (Table 1). Upgradient sources of the uranium isotopes are the same as noted for total uranium in Section 5.2 and, as with total uranium, U-234 and U-238 ions leached from the source area(s) probably combined with carbonate dissolved from the (limestone) bedrock, which greatly increased their relatively limited mobility in the neutral pH groundwater in the Maynardville Limestone (DOE 1997).

5.5 GROSS BETA ACTIVITY

All but one of the groundwater samples collect to date had gross beta activity above the applicable MDA and corresponding CE (Table 1), and results reported for the samples collected in September 1993 (57.9 pCi/L), December 1993 (52 pCi/L), and March 2002 (68 pCi/L) exceed the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). Uranium isotopes (and beta-emitting daughters) in the groundwater (see Section 5.4) may be a source of the gross beta activity. However, the detection of Tc-99 in the samples collected in March (13 pCi/L) and August 2005 (23 pCi/L) indicate that this beta-emitting radionuclide may be the primary source of the gross beta activity in the groundwater from this well. Note that both Tc-99 results are substantially below the SDWA screening level (900 pCi/L) for a 4 mrem/yr dose equivalent. Nevertheless, Tc-99 is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, which is the only site at Y-12 that received wastes containing this radionuclide (DOE 1997). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the transport of Tc-99 in the Maynardville Limestone closely mirrors that of nitrate, which reflects their common source and their similar transport characteristics in the groundwater.

A time-series plot of gross beta activity values reported for the groundwater samples collected to date shows an indeterminate long-term trend dominated by "peak" values in September 1993 (57.9 pCi/L) and March 2002 (68 pCi/L) and the nearly seven-year gap in the sampling history (Figure 5). Aside from these peaks, the results suggest a widely variably but slightly decreasing trend, as indicated by the results reported for the samples collected in May 1994 (49.5 pCi/L), September 1995 (38.7 pCi/L), and August 2005 (30 pCi/L). This potentially reflects a corresponding overall decrease in the relative flux of Tc-99 in response to the closure/capping of the former S-3 Ponds.

5.6 OTHER

As noted in Section 4.0, unusually high aluminum and iron concentrations were detected in (unfiltered) groundwater samples collected using the low-flow method during seasonally high flow directions (March 2002 and March 2005) and appear related to elevated total suspended solids (TSS). This correlation potentially indicates colloidal co-transport of aluminum and iron complexes in the groundwater. Although these samples also had elevated concentrations of several other metals (e.g., beryllium, copper, vanadium, and zinc), these results most likely reflect analytical interferences associated with the high levels of aluminum and iron. As illustrated by the data included in the following summary, the aluminum and iron concentrations appear to fluctuate concurrently with TSS levels, whereas similar correlations are not evident between TSS and the concentrations of other trace metals (barium, strontium, and uranium) detected in the samples (and not influenced by analytical interferences).

Date Sampled	Concentration (mg/L)					
	TSS	Aluminum	Iron	Barium	Strontium	Uranium

WELL GW-737

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in November 1991, completed with a screened monitored interval from 79 to 89.5 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire wound). The well is located in Bear Creek Valley (BCV) west of Y-12, on the north side of Bear Creek Road and directly south of the main channel of Bear Creek, approximately 300 ft downstream of confluence between the main channel and a northern tributary (NT-2) of the creek. This wells is a component of Exit Pathway Picket C, which consists of a series of wells (GW-724, GW-725, GW-736, GW-737, GW-738, GW-739, and GW-740) completed at different depths (and hydrostratigraphic zones) along a north-south transect approximately 3,000 ft west of Y-12 (Figure 1).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fifteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain eleven samples between May 1992 and September 1995, and the low-flow sampling method used to obtain four samples between March 2002 and August 2005. The sampling history includes quarterly sampling between May 1992 and December 1993, with semiannual sampling in 1994 and 1995, a nearly seven-year period (September 1995 – March 2002) when no samples were collected from the well, and semiannual sampling in 2002 and 2005.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maynardville Limestone (Conasauga Group), which exhibits the hydrologic characteristics typical of karst aquifers. Most groundwater flow in the Maynardville Limestone, which subcrops along the axis of BCV and underlies the main channel of Bear Creek, occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Hydrologic interaction between the creek and the shallow karst network provides the principal exit-pathway for contaminants released from source areas within the Bear Creek watershed west of Y-12. Below the shallow karst network, fractures provide the primary groundwater flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of approximately 9 ft bgs and exhibits seasonal fluctuations of approximately 7 ft. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV and on Chestnut Ridge, groundwater elevation isopleths in the vicinity of Exit-Pathway Picket C indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples collected to date show that the well yields nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 522 – 876 mg/L;
- pH of 6.5 – 7.29 (field measurements);

- elevated concentrations of sodium (>25 mg/L), chloride (>50 mg/L), and sulfate (>40 mg/L) relative to other wells completed at similar depth in the Maynardville Limestone; and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Dissolution of locally disseminated sulfides in the Maynardville Limestone may account for the elevated levels of sulfate in the groundwater at this well, and the elevated concentrations of sodium and chloride potentially indicate that the well does not intercept highly permeable groundwater flowpaths. Instead, the well may be completed in a relatively low-yield interval where the groundwater geochemistry resembles that of the sodium-bicarbonate groundwater typically encountered at a depth of approximately 100 ft bgs in the Nolichucky Shale (and other low-permeability formations of the Conasauga Group). The sodium-bicarbonate geochemistry of the groundwater, which is accompanied by a general increase in chloride levels and TDS, is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture or increased fracture spacing (Solomon et al. 1992). Thus, the elevated levels of sodium and chloride (and TDS) may indicate that the well yields groundwater with higher residence time than typical of the more permeable intervals at shallow depths in the Maynardville Limestone. Also, considering that the monitored interval intercepts groundwater flowpaths within the lower part of the Maynardville Limestone (Figure 1), the atypical sodium and chloride levels the groundwater in the well potentially indicates hydraulic connection with the sodium-bicarbonate groundwater from the Nolichucky Shale.

As illustrated by the selected data summarized below, sodium and chloride concentrations appear to have increased (nearly doubled) during the prolonged gap in the sampling history for the well. Although the higher sodium and chloride levels appear to coincide with the change from conventional sampling to low-flow sampling, the concentrations of other major ions (e.g., potassium and sulfate) exhibit no apparent change coincident with the sampling method. Thus, the elevated sodium and chloride concentration do not appear to be artifacts related to the sampling method, but instead seem to define the passing of a temporal "slug" of sodium- and chloride-enriched groundwater via the flowpaths intercepted by the monitored interval in the well.

Sampling Method and Date		**Concentration (mg/L)**			
		Sodium	**Chloride**	**Potassium**	**Sulfate**

	08/02/05	28.3	48.2	2.94	39.5

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show nitrate, VOCs, and gross beta activity are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected to date had nitrate concentrations above the analytical reporting limit, and only the results for the samples collected most recently (March and August 2005) are below the 10 mg/L drinking water MCL for nitrate (Table 1). Elevated nitrate concentrations in the samples indicate that the monitored interval for the well intercepts groundwater flow/transport pathways for nitrate (and other contaminants) released from the former S-3 Ponds, which are RCRA-regulated, unlined surface impoundments that were closed in 1988 and covered with a multilayer low-permeability cap in 1989. Located approximately 3,500 ft east-northeast (hydraulically upgradient) of Exit Pathway Picket C, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984, which emplaced a heterogeneous plume of inorganic, organic, and radiological contaminants in the groundwater. Nitrate, a principal component of the plume, enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale, which underlies the former S-3 Ponds, and recharge of nitrate-contaminated surface water in Bear Creek (DOE 1997). Because nitrate is chemically stable and highly mobile in groundwater, the elevated concentrations of nitrate (>10 mg/L) effectively trace the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells, the extent of elevated nitrate concentrations in the Maynardville Limestone west of Y-12 reflects: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for approximately 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) and is significantly influenced by hydrologic communication with surface water in Bear Creek.

As noted previously and shown by data summarized in Table 1, nitrate concentrations above 10 mg/L were detected in all of the groundwater samples except those collected in March (5.4 mg/L) and August 2005 (6.65 mg/l), with a historical maximum concentration of 61 mg/L in October 1992. Unlike the nitrate concentrations evident in the groundwater at other Maynardville Limestone wells west of Y-12, including several Exit Pathway Picket C wells, the nitrate results for this well do not indicate wide temporal (seasonal) concentration fluctuations, as illustrated by the most recent sampling results noted above. This too supports the possibility, as noted in Section 4.0 regarding the unusual geochemistry of the groundwater samples, that the monitored interval in the well may not intercept the more permeably flowpaths at shallow depths in the Maynardville Limestone, where nitrate concentrations typically exhibit pronounced temporal fluctuations in response to seasonal (and episodic) recharge/discharge cycles.

As shown on Figure 2, a time-series plot of nitrate concentrations detected in the groundwater samples collected to date shows a short-term increase between May 1992 (43.9 mg/L) and October 1992 (61 mg/L), with subsequent sampling results defining a long-term decreasing trend, (spanning the gaps in the sampling history for the well) through the historical minimum value in March 2005 (5.4 mg/L). The overall decrease in nitrate concentrations primarily reflects the substantially reduced flux of nitrate in the Maynardville Limestone following the closure/capping of the former S-3 Ponds, and indicates that the most highly contaminated groundwater has been flushed from the shallow karst network.

5.2 URANIUM

All of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit (Table 1), with the highest value (0.017 mg/L in March 2005) being below the drinking water MCL for uranium (0.03 mg/L). Note, however, that the concentrations reported for the samples collected since March 2002 substantially exceed all previous results. These results, although below the MCL, suggest an increasing long-term concentration trend, as illustrated by a time-series plot of the uranium results reported for the samples collected to date (Figure 3).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample collected to date (Table 2): CTET, chloroform, PCE, TCE, 12DCE, 111TCA, 11DCA, and vinyl acetate. The presence of VOCs in the samples indicates that the monitored interval in the well intercepts groundwater flow/transport pathways for VOCs released from one or more upgradient sources that contribute to an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. Available data for the network of wells completed in the Maynardville Limestone west of the flow divide indicate that VOC-contaminated groundwater, as defined by individual or summed VOC concentrations above 5 µg/L, appears to originate near Spoil Area I and to extend hydraulically downgradient for several thousand feet westward (parallel with geologic strike) down the axis of BCV. The apparent distribution of VOCs within the plume reflects the relative influx from multiple source areas, commingling during downgradient groundwater transport, and hydraulic communication with Bear Creek (DOE 1997). In the upper part of BCV, hydraulically upgradient of the Exit Pathway Picket C wells, the primary VOCs are TCE, c12DCE, and PCE and the confirmed or suspected source areas include Spoil Area I, the contaminant plume emplaced during historical operation of the former S-3 Ponds, and the Rust Spoil Area (or nearby source within the Bear Creek floodplain), the latter site considered a primary source of TCE. Hydraulically downgradient (west) of Exit Pathway Picket C, additional influx of VOCs (primarily PCE) occurs from several sources within the Oil Landfarm waste management area (WMA) and the Bear Creek Burial Grounds WMA. Individual and summed VOC concentrations are highest (>300 µg/L) in the deeper groundwater flow/transport pathways (>200 ft bgs) in the Maynardville Limestone directly south (down dip) of the Oil Landfarm WMA, where the main channel of Bear Creek loses substantial flow to the groundwater (karst) system and where groundwater elevations in clustered monitoring wells indicate strongly downward vertical hydraulic gradients in the Maynardville Limestone (DOE 1997).

Based on frequency of detection and concentration magnitude, the primary VOCs in the groundwater samples are PCE, TCE, and 12DCE (Table 2). The dominant compound is TCE, which was detected in every sample collected to date, with the historical maximum concentration of 21 µg/L in August 1992, and the most recent sampling results (March and August 2005) showing TCE concentrations at or slightly above the drinking water MCL (5 µg/L). Most of the samples also contained PCE and 12DCE (c12DCE), with all the results for PCE and all but three of the results for 12DCE being estimated values below 5 µg/L, and the most recent results showing concentrations below the respective MCL for each compound (Table 2). The remaining compounds were detected infrequently, with chloroform detected most often (six samples), and all these results are estimated values of 1 or 2 µg/L. Additionally, like the nitrate levels, none of the VOCs appear to exhibit wide concentration fluctuations, as illustrated by the TCE concentrations detected in the samples collected in March (6 µg/L) and August 2005 (5 µg/L).

A time-series plot of TCE concentrations detected in the groundwater samples collected to date shows a generally decreasing long-term concentration trend (Figure 4). The overall decrease in TCE levels probably reflects the reduced flux of TCE (and other VOCs) following the closure/capping of the former S-3 Ponds and the long-term natural attenuation of the VOC sources at Spoil Area I and the Rust Spoil Area, both of which were closed without further remedial action (e.g., waste removal or installation of low-permeability cap). Note, however, that the concentrations of other VOCs detected in the samples collected to date do not exhibit similarly decreasing long-term trends, as illustrated by the PCE results for reported for the samples collected in May 1993 (3 µg/L), March 1995 (4 µg/L), March 2002 (3 µg/L), and March 2005 (3 µg/L). Assuming a heterogeneous mixture of dissolved VOCs in the karst network at shallow depths in the Maynardville Limestone, it is unclear why the TCE and PCE concentrations exhibit such divergent temporal trends or if such differences are significant with respect to the relative flux of dissolved VOCs. Perhaps the TCE and PCE (and other VOCs) are not well mixed in the groundwater system, but instead occur within separate, discreet transport pathways that are intercepted by the monitored interval in the well. The divergent concentration trends also may reflect differential transport from separate source areas, with decreased flux from the source of TCE (Rust Spoil Area) and comparably more consistent flux of PCE from another upgradient source (e.g., Spoil Area I).

5.4 GROSS ALPHA ACTIVITY

Nine groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE (Table 1), with the highest value (23.8 pCi/L in August 1992) exceeding the drinking water MCL for gross alpha activity (15 pCi/L). However, this result is a suspected outlier because all other gross alpha results are less than 10 pCi/L.

5.5 GROSS BETA ACTIVITY

All of the groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE (Table 1), including results for two samples (52.8 pCi/L in September 1993 and 60.8 pCi/L in December 1993) that exceed the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). Although most of the gross beta results are less than the SWDA screening level, they exceed background levels and are probably attributable to Tc-99, a beta-emitting radionuclide that is considered a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds. Also, the lack of elevated gross alpha activity (and relatively low total uranium concentrations) suggests that uranium isotopes (and beta-emitting decay products) are not present in the groundwater at this well. Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on results of radiological analyses for Tc-99 and the distribution of elevated gross beta activity indicated by the network of wells in BCV west of Y-12, the transport of Tc-99 in the Maynardville Limestone closely mirrors that of nitrate (see Section 5.1), which reflects their common source and their similar transport characteristics in the groundwater.

Excluding the historical minimum value (4.85 pCi/L in October 1992) as a suspected outlier compared to previous and subsequent results, gross beta activity above 40 pCi/L was reported for all the samples collected between May 1992 and September 1995 (Table 1). Also, considering the analytical variability inherent to the laboratory analyses for gross beta activity, the results do not indicate significant temporal fluctuations, as noted in the previous discussions of nitrate and VOC concentrations and illustrated by the gross beta activity reported for the samples collected in March (15 pCi/L) and August 2005 (21 pCi/L). The apparent lack of significant temporal variability in gross beta activity (and nitrate and VOC concentrations) supports the possibility that the monitored interval in the well may not intercept the more permeable flowpaths at shallow depths in the Maynardville Limestone, where gross beta activity (i.e., Tc-99 concentrations) typically exhibit pronounced temporal fluctuations in response to seasonal (and episodic) recharge/discharge cycles.

A time-series plot of gross beta activity (excluding the suspected outlier noted above) reported for the groundwater samples collected to date shows an indeterminate trend between May 1992 (44 pCi/L) and September 1995 (47 pCi/L), with subsequent results showing a decreasing long-term trend, spanning the gaps in the sampling history, through March 2005 (15 pCi/L) (Figure 5).

WELL GW-738

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in November 1991, completed with a screened monitored interval from 63.5 to 88 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire wound). The well is located in Bear Creek Valley (BCV) west of Y-12 and is a component of Exit Pathway Picket C, which consists of a series of wells (GW-724, GW-725, GW-736, GW-737, GW-738, GW-739, and GW-740) completed at different depths (and hydrostratigraphic zones) along a strike-normal transect across the Maynardville Limestone (Figure 1). The Maynardville Limestone subcrops along the axis of BCV and underlies the main channel of Bear Creek.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 15 samples between May 1992 and September 1997, and the low-flow sampling method used to obtain 15 samples between March 1998 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maynardville Limestone (Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 26 ft bgs and exhibits seasonal fluctuations up to about 8 ft. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV and on Chestnut Ridge, groundwater elevation isopleths in the vicinity of Exit-Pathway Picket C indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 425 – 650 mg/L;
- pH of 6.2 – 7.8 (field measurements);
- elevated concentrations of sulfate (>30 mg/L) relative to other wells completed at similar depths in the Maynardville Limestone;
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and

- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

It is not clear if the elevated sulfate concentrations typical of the groundwater samples reflect localized geochemical characteristics, such as dissolution of locally disseminated sulfide minerals, or if the elevated concentrations are the result of contamination from one or more sources upgradient of the well.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, nitrate and VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Twenty-nine of the groundwater samples collected to date had nitrate concentrations above the analytical reporting limit (one sample was not analyzed for nitrate), and all but two of these results exceed the MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds, which are unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988. Located about 3,500 ft east-northeast of the Exit Pathway Picket C, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984. The groundwater contaminant plume originating from the site contains a heterogeneous mixture of inorganic, organic, and radiological contaminants. Nitrate, a principal component of the plume, enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale and recharge of nitrate-contaminated surface water in Bear Creek (DOE 1997). Nitrate is chemically stable and highly mobile in groundwater and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells, the extent of nitrate contamination in the Maynardville Limestone in BCV west of Y-12, as defined by concentrations above 10 mg/L, is generally characterized by: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for about 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) and is significantly influenced by hydrologic interactions with surface water in Bear Creek.

Aside from the historical maximum nitrate concentration (40.5 mg/L in September 1993) and the historical minimum nitrate concentration (1.5 mg/L in May 1992), the remaining nitrate results generally range between 5 - 25 mg/L (Table 1). Also, the nitrate concentrations clearly exhibit significant temporal (seasonal) fluctuations, with the lowest levels (including the historical minimum) typically reported for samples collected during seasonally high groundwater flow (winter and spring), and the highest concentrations (including the historical maximum) typically reported for samples collected during seasonally low flow conditions (summer and fall). This relationship suggests seasonal (or episodic) "dilution" from recharge of uncontaminated (or less nitrate-contaminated) groundwater via the flow/transport pathways intercepted by the monitored interval in the well. Dilution associated with presampling recharge to the shallow flow system may explain the conspicuously low nitrate concentration reported for the sample collected in May 1992, which appears to be an outlier compared to the other nitrate results (Table 1).

A time-series plot of nitrate concentrations in the groundwater samples (excluding the suspected outlier result noted above) shows a generally decreasing long-term trend dominated by wide temporal (seasonal) fluctuations (Figure 2). The overall decrease in nitrate concentrations is attributable to the reduced flux of nitrate from the former S-3 Ponds following closure of the site and installation of the low-permeability cap. Also, the nitrate results obtained with the low-flow sampling method seemingly exhibit greater temporal variability than the conventional sampling results. This may be an artifact of the semiannual sampling frequency used for low-flow sampling (the bulk of the conventional sampling events were performed quarterly), but also may be related to inherent differences in the manner in which each sampling method induces inflow of groundwater into the well. Conventional sampling involves aggressively purging the well (1-2 gallons per minute), which may substantially lower the water level in the well and induce inflow from water-producing features that may not be proximal to the monitored interval. In contrast, low-flow sampling involves purging the well at a flow rate low enough (<300 milliliters per minute) to ensure minimal water-level drawdown in the well (<1 ft per quarter hour), which induces groundwater flow from the water-producing features near the well.

5.2 URANIUM

Twenty-eight groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit (one sample was not analyzed for uranium), with the highest value (0.0031 mg/L in January 2003) being an order-of-magnitude below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample collected to date (Table 2): acetone, CTET, chloroform, PCE, TCE, xylenes, 12DCE (isomers), and 111TCA. These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. In the Bear Creek watershed west of the flow divide, the VOC plume in the Maynardville Limestone appears to originate near Spoil Area I and to extend several thousand feet westward (parallel with geologic strike) down the axis of BCV, with influx of various VOCs from several different downgradient source areas. The distribution of VOCs within the plume reflects the relative contributions from the source areas and commingling during downgradient transport. Plume constituents in the upper part of BCV are TCE, c12DCE, and PCE; source areas include Spoil Area I and the former S-3 Ponds. Farther downstream (west), major inputs of VOCs occur from the Rust Spoil Area or a nearby source in the Bear Creek floodplain; the Oil Landfarm waste management area (WMA), including the former Boneyard/Burnyard (BYBY), Hazardous Chemical Disposal Area (HCDA), and Sanitary Landfill I; and inflow of VOC-contaminated groundwater and surface water that discharges from a northern tributary of Bear Creek (NT-7) that traverses the Bear Creek Burial Grounds WMA. The highest VOC concentrations within the Maynardville Limestone exceed 300 μg/L and occur in the deeper groundwater south (down dip) of the HCDA, about 1,500 ft west-southwest (hydraulically downgradient) of Exit Pathway Picket C. These high concentrations coincide with downward vertical hydraulic gradients in the Maynardville Limestone in this area and a major losing reach of the main channel of Bear Creek (DOE 1997).

The primary VOCs in the groundwater samples are TCE and 12DCE (Table 2). The dominant compound is TCE, which was detected in every sample, with the historical maximum concentration of 96 μg/L in May 1992. Also, the most recent sampling results (February and July 2004) show that the TCE concentrations remain substantially above the drinking water MCL (5 μg/L). Many of the samples also contained 12DCE (c12DCE), but at substantially lower concentrations than evident for TCE, with all of the results being estimated values (<5 μg/L) substantially below the MCL (70 μg/L). Twelve of the 15 samples collected between May 1992 and July 1997 contained low concentrations (estimated values below 5 μg/L) of chloroform, CTET, PCE, or 111TCA; only chloroform was detected in any of the samples collected since then (3 μg/L in July 2004). Acetone and xylene were detected in one sample each and both results may be analytical artifacts.

A time-series plot of TCE concentrations in the groundwater samples shows a steadily decreasing long-term concentration trend (Figure 3), with the most recent TCE concentration (20 μg/L in July 2004) being more than 50% lower than evident during the early and mid-1990s. The overall decrease in TCE levels probably results from corrective actions at the primary sources of VOCs in BCV west of Y-12, including the closure of the Oil Landfarm and BCBG WMAs and the installation of low-permeability caps at each site and the CERCLA remedial actions at the BYBY/HCDA, which involved the excavation and removal of contaminated soils above and below the saturated zone (BJC 2003). Additionally, the TCE results show significant temporal variation, with cyclical "peak" concentrations typically reported for samples obtained during seasonally high groundwater flow conditions (winter and spring). These temporal fluctuations potentially correspond with changes in the relative flux of TCE along the groundwater flow/transport pathways intercepted by the monitored interval in the well. Also, the temporal changes in TCE concentrations show an inverse relationship with the corresponding fluctuations in nitrate concentrations and gross beta activity, whereby the respective levels of these contaminants are typically lowest in samples obtained during seasonally high groundwater flow conditions. This suggests the seasonal (or episodic) inflow/recharge of TCE-contaminated groundwater along the flowpaths intercepted monitored by well GW-738, and that the source(s) of TCE in groundwater at the well differ from that of nitrate (S-3 Site).

The concentrations of other VOCs detected in the groundwater samples do not exhibit the temporal fluctuations evident for TCE (Table 2). For instance, the 12DCE was detected at an estimated concentration of 2 μg/L in each of the six consecutive samples collected between August 1996 and February 1999. Assuming the plume of dissolved VOCs in the Maynardville Limestone contains a heterogeneous mixture of compounds, it is not clear from the available data why the concentrations of individual compounds exhibit such divergent temporal variations or if such variations are significant with respect to the relative flux of dissolved VOCs via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

Eight groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (33.7 pCi/L in October 1992) exceeding the drinking water MCL for gross alpha activity (15 pCi/L). However, the historical maximum appears to be an outlier compared to the other results for gross alpha activity, which are all less than 10 pCi/L.

5.5 GROSS BETA ACTIVITY

Twenty-eight groundwater samples had gross beta activity above the applicable MDA and corresponding CE, including results for seven samples that exceed the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity), with the historical maximum value reported for the sample collected in October 1991 (159 pCi/L). The source of the gross beta activity in the groundwater at this well is believed to be Tc-99 based on the detection of this radionuclide (i.e., >MDA and CE) in the samples collected in

January (81 pCi/L) and July 2001 (65 pCi/L). Both results are substantially below the SDWA screening level (3,790 pCi/L) for a 4 mrem/yr dose from Tc-99. This beta-emitting radionuclide is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, which is the only site at Y-12 that received wastes that contained Tc-99 (DOE 1998). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the transport of Tc-99 in the Maynardville Limestone closely mirrors that of nitrate.

A time-series plot of gross beta activity reported for the groundwater samples shows an indeterminate or slightly increasing long-term trend dominated by wide temporal (seasonal) fluctuations (Figure 4). The indeterminate trend suggests minimal overall change in the relative flux of beta-emitting radionuclides via the groundwater flow/transport pathways intercepted by the monitored interval in the well. As with nitrate concentrations, the wide temporal changes in gross beta activity levels show cyclical "peak" values reported for samples obtained during seasonally low groundwater flow conditions (summer and fall), which suggests "dilution" from seasonal (and episodic) recharge of groundwater that does not contain beta-emitting radionuclides. Also, the gross beta activity reported for samples obtained with the low-flow sampling method seemingly exhibit greater temporal variability than the conventional sampling results for gross beta activity, but this may be an artifact of the semiannual sampling frequency (the bulk of the conventional sampling events were performed quarterly).

WELL GW-739

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in November 1991, completed with an open-hole monitored interval from 289.2 to 320 ft bgs, and constructed with nominal 7-inch diameter steel (SF25) riser casing. The well is located in Bear Creek Valley (BCV) west of Y-12 and is a component of Exit Pathway Picket C, which consists of a series of wells (GW-736, GW-737, GW-738, GW-739, and GW-740) completed at different depths (and hydrostratigraphic zones) along a north-south transect approximately 3,000 ft west of Y-12 (Figure 1).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fifteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 11 samples between May 1992 and September 1995, and the low-flow sampling method used to obtain four samples between March 2002 and July 2005. The sampling history includes quarterly sampling between May 1992 and December 1993, with semiannual sampling in 1994 and 1995, a nearly 7-year period (September 1995 – March 2002) when no samples were collected from the well, and semiannual sampling in 2002 and 2005.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the deep (>300 ft bgs) bedrock interval in the Maynardville Limestone (Conasauga Group), which exhibits the hydrologic characteristics typical of karst aquifers. Most groundwater flow in the Maynardville Limestone, which subcrops along the axis of BCV and underlies the main channel of Bear Creek, occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Hydrologic interaction between the creek and the shallow karst network providing the principal exit-pathway for contaminants released from source areas within the Bear Creek watershed west of Y-12. Below the shallow karst network, fractures provide the primary groundwater flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 72 ft bgs and exhibits moderate (<10 ft) seasonal fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of Exit-Pathway Picket C indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples collected to date show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 259 – 358 mg/L;
- pH (field measurements) of 7.2 – 7.8;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and

- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected to date had nitrate concentrations above the analytical reporting limit, with the highest value (8.76 mg/L in December 1993) being below the drinking water MCL for nitrate (10 mg/L) and the lowest concentrations (<2 mg/L) reported for samples collected since March 2002.

5.2 URANIUM

All but one of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.002 mg/L in October 1992 and September 1993) being an order-of-magnitude below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample collected to date (Table 1): CTET, chloroform, TCE, 12DCE (c12DCE), 111TCA, and vinyl acetate. The presence of VOCs in the samples indicates that the monitored interval in the well intercepts groundwater flow/transport pathways for VOCs released from one or more upgradient sources that contribute to an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. Available data for the network of wells completed in the Maynardville Limestone west of the flow divide indicate that VOC-contaminated groundwater, as defined by individual or summed VOC concentrations above 5 µg/L, appears to originate near Spoil Area I and to extend hydraulically downgradient for several thousand feet westward (parallel with geologic strike) down the axis of BCV. The apparent distribution of VOCs within the plume reflects the relative influx from multiple source areas, commingling during downgradient groundwater transport, and hydraulic communication with Bear Creek (DOE 1997). In the upper part of BCV, hydraulically upgradient of the Exit Pathway Picket C wells, the primary VOCs are TCE, c12DCE, and PCE and the confirmed or suspected source areas include Spoil Area I, the contaminant plume emplaced during historical operation of the former S-3 Ponds, and the Rust Spoil Area (or nearby source within the Bear Creek floodplain), which is believed to be a primary source of TCE. Hydraulically downgradient (west) of Exit Pathway Picket C, additional influx of VOCs (primarily PCE) occurs from several sources within the Oil Landfarm waste management area (WMA) and the Bear Creek Burial Grounds WMA. Individual and summed VOC concentrations are highest (>300 µg/L) in the deeper groundwater flow/transport pathways (>200 ft bgs) in the Maynardville Limestone directly south (down dip) of the Oil Landfarm WMA, where the main channel of Bear Creek loses substantial flow to the groundwater (karst) system and where groundwater elevations in clustered monitoring wells indicate strongly downward vertical hydraulic gradients (DOE 1997).

Based on frequency of detection and concentration magnitude, the primary VOC in the groundwater samples is TCE (Table 1), which is the only compound detected in all of the samples and, as noted above, is believed to reflect transport/migration from the Rust Spoil Area or from a nearby source in the Bear Creek floodplain. The first sample collected from the well had the historical maximum TCE concentration (58 µg/L in May 1992) and the most recent TCE results from March (33 µg/L) and July 2005 (31 µg/L) show that concentrations remain substantially above the drinking water MCL for TCE (5 µg/L). Aside from TCE, many of the samples contained trace levels of CTET and/or 12DCE, with all results for both compounds being estimated concentrations of 1 or 2 µg/L. A few samples collected between February 1993 and February 1995 had similarly low levels of chloroform, vinyl acetate, and 111TCA (Table 1); results for these compounds, particularly vinyl acetate, are probably analytical artifacts.

A time-series plot of TCE concentrations detected in the groundwater samples collected to date shows a slightly decreasing long-term concentration trend (Figure 2). The overall decrease in TCE levels probably reflects the somewhat reduced flux of TCE from long-term natural attenuation of the suspected VOC sources at Spoil Area I and the Rust Spoil Area, both of which were closed without further remedial action (e.g., waste removal or installation of low-permeability cap).

5.4 GROSS ALPHA ACTIVITY

Two groundwater samples had gross alpha activity above the MDA and corresponding CE, with the highest value (3.94 pCi/L in August 1992) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Eleven groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (14.2 pCi/L in September 1993) being below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-740

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in December 1991, completed with an open-hole monitored interval from 165.6 to 190 ft bgs, and constructed with nominal 7-inch diameter steel (SF25) riser casing. The well is located in Bear Creek Valley (BCV) west of Y-12 and is a component of Exit Pathway Picket C, which consists of a series of wells (GW-736, GW-737, GW-738, GW-739, and GW-740) completed at different depths (and hydrostratigraphic zones) along a strike-normal transect across the Maynardville Limestone (Figure 1). The Maynardville Limestone underlies Bear Creek throughout BCV and the hydrologic interaction between the creek and the shallow karst network in the Maynardville Limestone provide the primary exit-pathways for groundwater and surface water contaminants.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 15 samples between June 1992 and September 1997, and the low-flow sampling method used to obtain 15 samples between March 1998 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the intermediate bedrock interval in the Conasauga Group (Maynardville Limestone). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 67 ft bgs and exhibits moderate (>10 ft) seasonal fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of Exit-Pathway Picket C indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the two samples collected from the well indicate that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 244 – 360 mg/L;
- pH (field measurements) of 5.6 – 7.8;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Twenty-nine of the groundwater samples had nitrate concentrations above the analytical reporting limit (one sample was not analyzed for nitrate), with the highest concentration (4.8 mg/L in September 1993) being below the drinking water MCL for nitrate (10 mg/L). Although the nitrate concentrations do not exceed the MCL, they are higher than the applicable UTL (2.7 mg/L) and probably reflect the transport of nitrate from the intermingled contaminant plumes in the Maynardville Limestone hydraulically upgradient (east) of the well. The source of the nitrate is the former S-3 Ponds, which are unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988. Several million gallons of nitric acid wastes from Y-12 were disposed during historical operation of the site (1951–1984), which emplaced a heterogeneous mixture of inorganic, organic, and radiological contaminants in the Nolichucky Shale beneath the site. Nitrate is one of the principal components of the plume and it enters the Maynardville Limestone via several pathways hydraulically downgradient of the former S-3 Ponds, including direct inflow from the Nolichucky Shale and hydraulic communication with nitrate-contaminated surface water in Bear Creek. Contaminated surface water is primarily from the northern tributaries of Bear Creek (NT-1 and NT-2) that are the principal discharge areas for nitrate-contaminated groundwater exiting the shallow flow system in the Nolichucky Shale west of the former S-3 Ponds (DOE 1997). Nitrate is chemically stable and highly mobile in groundwater and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (notably Tc-99) and elsewhere in BCV.

5.2 URANIUM

Seven groundwater samples had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.001 mg/L in June 1992, August 1992, and December 1993) being an order-of-magnitude below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in 29 groundwater samples collected from the well: acetone, CTET, chloroform, PCE, TCE, 12DCE (isomers), 11DCE, 11DCA, and 111TCA. These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. In the Bear Creek watershed west of the flow divide, which occurs near the west end of Y-12, the VOC plume in the Maynardville Limestone appears to originate near Spoil Area I and extends several thousand feet westward (parallel with geologic strike) down the axis of BCV, with influx of various VOCs from several different downgradient source areas. The distribution of VOCs within the plume reflects the relative contributions from the source areas and commingling during downgradient transport. Plume constituents in the upper part of BCV are TCE, c12DCE, and PCE; source areas include Spoil Area I and the former S-3 Ponds. Farther downgradient (west), major inputs of VOCs occur from the Rust Spoil Area or a nearby source in the Bear Creek floodplain; the Oil Landfarm waste management area (WMA), including the former Hazardous Chemical Disposal Area (HCDA) and Sanitary Landfill I; and inflow of VOC-contaminated groundwater and surface water that discharges from a northern tributary of Bear Creek (NT-7) that traverses the Bear Creek Burial Grounds WMA. The highest

VOC concentrations within the plume exceed 300 µg/L and occur in the deeper groundwater south (down dip) of the HCDA. These high concentrations coincide with downward vertical hydraulic gradients in the Maynardville Limestone in this area and a major losing reach of the main channel of Bear Creek south-southwest of Sanitary Landfill I (DOE 1997).

The primary VOC in the groundwater samples is TCE (Table 1); this compound was detected in every sample, with the historical maximum concentration of 77 µg/L in August 1992. Also, the most recent sampling results show that the TCE concentrations remain substantially above the drinking water MCL (5 µg/L). Secondary compounds in the samples are 12DCE (c12DCE), with trace levels (all estimated values below 5 µg/L) detected in all but two of the samples, and CTET, which was detected at similarly low levels (2 µg/L) in about half of the samples. Acetone, chloroform, 11DCE, 11DCA, and 111TCA have been detected much more infrequently and the respective results are all estimated values below analytical reporting limits.

The concentrations of VOCs in the groundwater at this well, as illustrated by the sampling results for TCE (Figure 2), show: (1) a sharply decreasing trend between December 1992 (77 µg/L) and June 1995 (28 µg/L); (2) an abrupt rebound above 70 µg/L through September 1995; and (3) a generally decreasing concentration trend through July 2004 (48 µg/L). These temporal changes in TCE concentrations potentially correspond with long-term changes in the relative flux of TCE along the groundwater flow/transport pathways intercepted by the monitored interval in the well. However, the other VOCs in the well do not exhibit similar concentration fluctuations, as illustrated by the results for 12DCE (Table 1). It is not clear from the available data why the concentrations of individual compounds exhibit such divergent temporal variations or if such variations are significant with respect to the relative flux of dissolved VOCs.

5.4 GROSS ALPHA ACTIVITY

Four groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (9.7 pCi/L in July 2003) being less than the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Fifteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (16.9 pCi/L in September 1993) being less than the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-742

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in December 1991, completed with an open-hole monitored interval from 350 to 420 ft bgs, and constructed nominal 7-inch diameter steel (SF25) riser casing. The well is paired with well GW-743 and is located near the crest of Chestnut Ridge directly south of Y-12, approximately 400 ft south of the eastern part of the Chestnut Ridge Security Pits (CRSP). The CRSP include two contiguous former waste disposal areas, each consisting of a series of unlined, east-west oriented trenches that were about 8 to 10 ft wide, 10 to 18 ft deep, and 700 to 800 ft long. Beginning in 1973, the disposal trenches at the site received a variety of hazardous waste until December 1984 and nonhazardous wastes until November 1988. All the disposal trenches are covered by a multi-layer low-permeability cap installed during RCRA closure of the site in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Eighteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 16 samples between April 1992 and February 1996, and the low-flow sampling method used to obtain samples in April and October 2004.

Presampling depth-to-water measurements show that the static water level in the well exhibits substantial (>40 ft) temporal (seasonal) fluctuations (Figure 1). Similarly distinctive groundwater elevation fluctuations also are evident in other wells completed in the Knox Group on Chestnut Ridge (including well GW-743), particularly wells located at or near the crest of the ridge, which is both a recharge area and a groundwater flow divide (Solomon et al. 1992). Wide temporal fluctuations in the groundwater elevations suggest that the monitored interval for the well intercepts highly permeable flowpaths in the Knox Group. This interpretation is supported by the relatively low TDS of the groundwater samples collected to date (see Section 4.0), which indicates fairly short residence time for groundwater in the well and potentially indicates that the monitored interval intercepts "quickflow" conduits in the bedrock (Shevenell 1994).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the lower Knox Group (Copper Ridge Dolomite), which underlies the steep northern flank of Chestnut Ridge. The Knox Group formations, along with the uppermost formation (Maynardville Limestone) of the underlying Conasauga Group, comprise an aquifer consisting of three vertically gradational subsystems distinguished by groundwater flux, which decreases with depth: (1) the stormflow zone, (2) the vadose zone, and (3) the groundwater zone (Solomon et al. 1992). The stormflow and vadose zones occur at shallow depths within the thick (>100 ft) residuum that has developed on Chestnut Ridge. In the bedrock zone, orthogonal sets of permeable, planar fractures form water-producing zones within an essentially impermeable matrix, and dissolution of carbonates has enlarged fractures and produced an interconnected conduit-flow system characteristic of karst aquifers. Because the occurrence of solution features and the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity of the groundwater zone is vertically gradational. Most groundwater flux occurs within the transitional horizon between residuum and unweathered bedrock (water table interval); lower flux (and longer solute residence times) occurs at successively greater depths in the bedrock (Solomon et al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 145 ft bgs and exhibits substantial seasonal fluctuations, as noted in Section 2.0. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-742 indicate radial flow directions, with components of flow to the north into BCV, to the east along the axis of the ridge (parallel with geologic strike), and south toward drainage features that traverse the broad southern flank of the ridge. Also, measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in well GW-742 are typically lower than evident in well GW-743, which is completed at a shallower depth (about 160 ft bgs) in the Knox Group. Based on the distance between the monitored interval midpoint (elevation) in each well (about 230 ft), the contemporaneous groundwater elevations indicate downward vertical hydraulic gradients (0.007 – 0.061) from well GW-743 to GW-742 during seasonally high and low flow conditions.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date indicate that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 136 – 208 mg/L;
- pH of 6.9 – 8.1 (field measurements);
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite);
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations);
- unusually high total (unfiltered sample) iron concentrations (e.g., 2.69 mg/L in April 2004); and
- total concentrations of trace metals (except iron) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, none of these contaminants are generally present in the groundwater at this well.

5.1 NITRATE

None of the groundwater samples collected to date had nitrate concentrations at or above the applicable analytical reporting limit.

5.2 URANIUM

Six of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest concentration (0.007 mg/L in October 1992) being an order-of-magnitude lower than the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were not detected in the groundwater samples collected to date.

5.4 GROSS ALPHA ACTIVITY

Twelve groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (9.09 pCi/L in February 1994) being below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Six groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, with the highest value (5.12 pCi/L in November 1994) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-743

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in December 1991, completed with a screened monitored interval from 150 to 161 ft bgs, and constructed nominal 4-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is paired with well GW-742 and is located near the crest of Chestnut Ridge directly south of Y-12, approximately 400 ft south of the eastern part of the Chestnut Ridge Security Pits (CRSP). The CRSP include two contiguous former waste disposal areas, each consisting of a series of unlined, east-west oriented trenches that were about 8 to 10 ft wide, 10 to 18 ft deep, and 700 to 800 ft long. Beginning in 1973, the disposal trenches at the site received a variety of hazardous waste until December 1984 and nonhazardous wastes until November 1988. All the disposal trenches are covered by a multi-layer low-permeability cap installed during RCRA closure of the site in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Eighteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 16 samples between April 1992 and February 1996, and the low-flow sampling method used to obtain samples in April and October 2004.

Presampling depth-to-water measurements show that the static water level in the well exhibits substantial (>50 ft) temporal (seasonal) fluctuations (Figure 1). Similarly distinctive groundwater elevation fluctuations also are evident in other wells completed in the Knox Group on Chestnut Ridge (including well GW-742), particularly wells located at or near the crest of the ridge, which is both a recharge area and a groundwater flow divide (Solomon et al. 1992). Wide temporal fluctuations in the groundwater elevations suggest that the monitored interval for the well intercepts highly permeable flowpaths in the Knox Group. This interpretation is supported by the relatively low TDS of the groundwater samples collected to date (see Section 4.0), which indicates fairly short residence time for groundwater in the well and potentially indicates that the monitored interval intercepts "quickflow" conduits in the bedrock (Shevenell 1994).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the lower Knox Group (Copper Ridge Dolomite), which underlies the steep northern flank of Chestnut Ridge. The Knox Group formations, along with the uppermost formation (Maynardville Limestone) of the underlying Conasauga Group, comprise an aquifer consisting of three vertically gradational subsystems distinguished by groundwater flux, which decreases with depth: (1) the stormflow zone, (2) the vadose zone, and (3) the groundwater zone (Solomon et al. 1992). The stormflow and vadose zones occur at shallow depths within the thick (>100 ft) residuum that has developed on Chestnut Ridge. In the bedrock zone, orthogonal sets of permeable, planar fractures form water-producing zones within an essentially impermeable matrix, and dissolution of carbonates has enlarged fractures and produced an interconnected conduit-flow system characteristic of karst aquifers. Because the occurrence of solution features and the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity of the groundwater zone is vertically gradational. Most groundwater flux occurs within the transitional horizon between residuum and unweathered bedrock (water table interval); lower flux (and longer solute residence times) occurs at successively greater depths in the bedrock (Solomon et al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 121 ft bgs and exhibits substantial seasonal fluctuations, as noted in Section 2.0. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-743 indicate radial flow directions, with components of flow to the north into BCV, to the east along the axis of the ridge (parallel with geologic strike), and south toward drainage features that traverse the broad southern flank of the ridge. Also, measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in well GW-743 are typically higher than evident in well GW-742, which is completed at a greater depth (420 ft bgs) in the Knox Group. Based on the distance between the monitored interval midpoint (elevation) in each well (about 230 ft), the contemporaneous groundwater elevations indicate downward vertical hydraulic gradients (0.007 – 0.061) from well GW-743 to GW-742 during seasonally high and low flow conditions.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date indicate that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 106 – 186 mg/L;
- pH of 6.7 – 8.7 (field measurements);
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite);
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, none of these contaminants are generally present in the groundwater at this well.

5.1 NITRATE

Twelve of the groundwater samples collected to date had nitrate concentrations at or above the applicable analytical reporting limit, with the highest concentration (1.4 mg/L in February 1994) being substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Only one of the groundwater samples collected to date had a total uranium concentration at or above the applicable analytical reporting limit, and this result (0.00061 mg/L in February 1996) is orders-of-magnitude lower than the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Two of the groundwater samples collected to date contained VOCs: methylene chloride was detected in the sample collected in October 1992, but the result is a false positive, and a low level of acetone (8 µg/L) was detected in the sample collected in November 1995. The latter result also is a likely analytical artifact.

5.4 GROSS ALPHA ACTIVITY

Five of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (3.84 pCi/L in May 1995) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Four groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, with the highest value (13.4 pCi/L in November 1995) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-744

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in January 1992, completed with a screened monitored interval from 55 to 69.5 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with wells GW-745 and GW-746 and is located in Bear Creek Valley east of Y-12, near the intersection of Bear Creek Road and Scarboro Road.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-five groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 20 samples between April 1992 and April 1997, and the low-flow sampling method used to obtain 15 samples between December 1997 and November 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the shallow bedrock interval in the Conasauga Group (Pumpkin Valley Shale). The average static groundwater level in the well is about 4 ft bgs. Presampling depth-to-water measurements for the well indicate moderate fluctuations (<4 ft) in seasonal groundwater surface elevations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 184 – 323 mg/L;
- pH (field measurements) of 7.0 – 8.4;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Three groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (2.2 mg/L in January 1994) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Three groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.004 mg/L in May 1994) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, methylene chloride (0.6 μg/L) was detected in the sample collected in January 1993. This result is probably an artifact.

5.4 GROSS ALPHA ACTIVITY

Six groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (4.9 pCi/L in May 2002) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Eleven groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (7.45 pCi/L in October 1994) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-747

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in January 1992, completed with a screened monitored interval from 67.4 to 79.6 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with wells GW-748 and GW-749 and is located in Bear Creek Valley east of Y-12, adjacent to Scarboro Road about 800 ft east of Lake Reality.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-four groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 19 samples between August 1992 and April 1997, and the low-flow sampling method used to obtain 15 samples between December 1997 and November 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the shallow bedrock interval in the Conasauga Group (Maryville Limestone). The average static groundwater level in the well is 2.7 ft bgs. Presampling depth-to-water measurements for the well indicate moderate fluctuations (<7 ft) in seasonal groundwater surface elevations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 225 – 314 mg/L;
- pH (field measurements) of 6.8 – 7.9;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Two groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.17 mg/L in December 1997) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Only the uranium concentration reported for the groundwater sample collected in April 2000 (0.000879 mg/L) exceeds the analytical reporting limit. This result is substantially below the MCL for uranium (0.03 mg/L) and is probably an analytical artifact.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, 2-butanone was detected (13 μg/L) in the sample collected in November 1995. This result is a suspected sampling or analytical artifact and is considered to be an outlier.

5.4 GROSS ALPHA ACTIVITY

Only one groundwater sample had gross alpha activity above the applicable MDA and corresponding CE (1.2 pCi/L in May 2002) which was substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Seven groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (9.74 pCi/L in August 1993) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-750

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in February 1992, completed with a screened monitored interval from 61.2 to 72.7 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley east of Y-12, about 300 ft west of Scarboro Road and 800 ft east (hydraulically downgradient) of New Hope Pond (NHP). NHP is a closed surface water impoundment formerly used to regulate flow in Upper East Fork Poplar Creek, and is covered with a low-permeability multilayer cap installed during RCRA closure of the site in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-four groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 19 samples between August 1992 and April 1997, and the low-flow sampling method used to obtain 15 samples between December 1997 and November 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the shallow bedrock interval in the Conasauga Group (Maynardville Limestone). The average static groundwater level in the well is 9 ft bgs. Presampling depth-to-water measurements for the well indicate moderate (<10 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 270 – 331 mg/L;
- pH (field measurements) of 6.6 – 7.7;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Only the nitrate concentration reported for the groundwater sample collected in May 2004 (0.0294 mg/L) exceeds the applicable analytical reporting limit. This result is substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Only the uranium concentration reported for the groundwater sample collected in October 2003 (0.002 mg/L) exceeds the applicable analytical reporting limit. This result is substantially below the MCL for uranium (0.03 mg/L) and is probably an analytical artifact.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected in only two groundwater samples. The single detection of acetone (12 µg/L in June 1998) and carbon disulfide (3 µg/L in June 1999) are suspected sampling or analytical artifacts and considered to be outliers.

5.4 GROSS ALPHA ACTIVITY

Only the gross alpha activity reported for the groundwater sample collected in August 1992 (2.41 pCi/L) exceeds the MDA and corresponding CE. This result is substantially below the MCL for gross alpha activity (15 pCi/L) and is probably an analytical artifact.

5.5 GROSS BETA ACTIVITY

Twelve groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (8.8 pCi/L in June 1998) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-757

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in April 1992, completed with a screened monitored interval from 134 to 166.5 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located on the southern flank of Chestnut Ridge directly south of Y-12, about 100 ft south-southeast (hydraulically downgradient) of the Industrial Landfill II, which is a closed landfill which operated between 1983 and 1996 for the disposal of combustible and decomposable nonhazardous solid waste, construction spoil, and special wastes (e.g., asbestos and beryllium oxide) generated from DOE operations at Y-12 and elsewhere on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-three groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 18 samples between June 1992 and April 1997, and the low-flow sampling method used to obtain 15 samples between October 1997 and July 2004.

Groundwater samples from the well exhibit conspicuous geochemical characteristics (see Section 4.0) attributable to contamination from the cement (grout) lost into the surrounding bedrock during installation of the well. To ensure collection of representative groundwater samples, the conventional sampling method should be used; redevelopment of the well before sampling also may be necessary.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the bedrock interval in the Knox Group (Copper Ridge Dolomite). The average static groundwater level in the well is 82 ft below ground surface. Presampling depth-to-water measurements for the well indicate substantial (10 - 25 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

Groundwater samples from this well exhibit atypical levels of carbonate and bicarbonate, high pH (>9), elevated potassium (>10 mg/L) and sodium (>30 mg/L) concentrations, and substantially lower concentrations (<5 mg/L) of calcium and magnesium compared to other wells in the Chestnut Ridge Regime. As noted in Section 2.0, this atypical groundwater geochemistry probably is a consequence of localized grout contamination. Of particular interest is the apparent correlation between the sharp increases in pH levels and potassium and sodium concentrations (and gross beta activity) following the change from conventional sampling to low-flow sampling (Figure 1). This suggests that the conventional sampling method induces greater inflow of "fresh" groundwater into the well, which effectively dilutes the grout-contaminated groundwater entering the well; thus buffering the pH and lowering the concentrations of potassium and sodium. Nevertheless, considering that the well was installed in 1992, the persistent grout contamination in the well is a chronic problem with respect to obtaining representative groundwater samples.

Aside from the geochemical indicators of grout contamination, the (unfiltered) groundwater samples from the well typically have total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Nineteen groundwater samples had nitrate concentrations above the analytical reporting limit, with the highest concentration (0.66 mg/L in August 2000) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Twenty-one groundwater samples had uranium concentrations above the analytical reporting limit, with the highest concentration (0.0069 mg/L in October 1998) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected in only five of the groundwater samples from the well. A low (estimated) concentration of 111TCA (4 µg/L) was detected in the sample collected in April 1999. Acetone has been detected in three samples (110 µg/L in April 1998, 2 µg/L in October 1998, and 1.8 µg/L in July 2001) and 2-butanone has been detected once (9 µg/L in October 1995). Acetone and 2-butanone are common laboratory reagents, and the results for these VOCs may be analytical artifacts.

5.4 GROSS ALPHA ACTIVITY

Eighteen groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (6.73 pCi/L in January 1994) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Twenty groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (18.9 pCi/L in July 2001) being substantially below the SDWA screening level for gross beta activity (50 pCi/L). Although gross beta activity in the groundwater at this well is less than the SDWA screening level, a time-series plot of the beta activities shows a generally increasing trend (Figure 2). Assuming that Industrial Landfill II received only the nonhazardous wastes for which it was permitted, there is not a confirmed source of radiological contaminants hydraulically upgradient of the well. Alternatively, the elevated gross beta activity may be a consequence of the elevated potassium concentrations in the grout-contaminated groundwater samples form the well. Potassium concentrations show a generally increasing trend that is similar to the gross beta trend (Figure 2). Potassium-40 (K-40) is a beta-emitting isotope and, based on the natural ratio of K-40 to total potassium (K-40 = 0.0119% of total potassium; Brownlow 1979), 14 of the samples contained at least 0.05 mg/L K-40, with the highest levels evident in January 2003 (0.23 mg/L), January 2002 (0.21), and January 2001 (0.2 mg/L). Thus, elevated gross beta activity may be an artifact of the grout contamination in well.

WELL GW-760

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in May 1992, completed with a screened monitored interval from 48.3 to 60.1 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-761 and is located in Bear Creek Valley in the east-central section of Y-12, about 250 ft north of Bldg. 9202.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Seventeen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 14 samples between July 1992 and November 1995, and the low-flow sampling method used to obtain three samples between June 2003 and April 2004.

A conspicuous characteristic of the groundwater samples from this well are elevated concentrations of chromium (maximum = 0.39 mg/L in November 1994) and nickel (maximum = 0.34 mg/L in May 1995) that are most likely attributable to chemical and/or microbiologically-induced corrosion (MIC) of the stainless steel well casing and/or screen. Corrosion of stainless steel may be caused by many different species of bacteria, including iron-related and sulfate-reducing organisms that typically attack the area near welds. Once a colony attaches to the metal it forms a nodule in which to live. The micro-environment within the nodule creates conditions (e.g., acidic pH) that enable the colony to expand and deepen the nodule, which eventually creates a pit or crevice in the metal and facilitates corrosion per the mechanisms described by Driscoll (1986). The following considerations suggest that elevated concentrations of nickel and chromium in the groundwater samples from this well are most likely attributable to corrosion of the stainless steel (Type 304) well screen: (1) there are no known sources of these metals near the well; (2) mobile species of these metals are not typically present in groundwater with the neutral pH evident in the well; (3) Type 304 stainless steel contains 18-20% chromium and 8-12% nickel and is prone to crevice corrosion (Oakley and Korte 1996); (4) indicator parameters (e.g., dissolved oxygen >1 mg/L and pH between 5.5 and 9) are in the optimum range for MIC by iron-related bacteria (Sarouhan et al. 1998); and (5) elevated chloride levels in the groundwater (see Section 4.0) may play a role in maintaining the elevated chromium and nickel concentrations in the samples from the well because chloride may combine with available metal cations to form soluble complexes that do not readily adsorb to mineral surfaces in the filter pack material and surrounding bedrock (McLean and Bledsoe 1992)

The Y-12 GWPP requested biological testing to assess microbial activity in groundwater at this well in April 2004. The results (shown below) are qualitative bacterial counts of four specific bacteria types that are estimates based on the appearance of the sample after an eight- to ten-day growth period.

Well	**Date Sampled**	**Metals (mg/L)**		**Bacteria Activity (colony forming units/milliliter)**			
		Chromium	Nickel	Heterotrophic Aerobic	Iron-Related	Slime Forming	Sulfate-Reducing
GW-760	04/27/04	0.0614	0.248	<100	>100	>100	100

The low bacterial count in this sample suggests that the elevated chromium and nickel concentrations probably reflect chemical corrosion of the stainless steel, and these metal ions may be kept in solution by the elevated chloride concentration.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the shallow bedrock interval in the Conasauga Group (Maryville Limestone). The average static groundwater level in the well is 7.7 ft bgs. Presampling depth-to-water measurements for the well indicate moderate fluctuations (<5 ft) in seasonal groundwater surface elevations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 440 – 774 mg/L, excluding an outlier (1,030 mg/L) in June 2003;
- pH (field measurements) of 7.0 – 8.0;
- very high (>200 mg/L) chloride concentrations;
- low molar proportions of potassium, sulfate, and nitrate (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals, excluding chromium and nickel, that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Fourteen groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (1.55 mg/L in October 2003) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Three groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.0023 mg/L in November 1995) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, 2-hexanone was detected (1 µg/L) in the groundwater sample collected from the well in October 1992. This result is a suspected sampling or analytical artifact and is considered to be an outlier.

5.4 GROSS ALPHA ACTIVITY

Three groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (4.53 pCi/L in April 1993) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Five groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (24 pCi/L in June 2003) being below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-761

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in May 1992, completed with a screened monitored interval from 3.6 to 15.3 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-760 and is located in Bear Creek Valley in the east-central section of Y-12, about 250 ft north of Bldg. 9202.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Sixteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 14 samples between July 1992 and November 1995, and the low-flow sampling method used to obtain samples in June and October 2003.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Maryville Limestone). Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 7 ft bgs and exhibit moderate seasonal fluctuations (<6 ft). The well forms a cluster with well GW-760.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- low TDS (<150 mg/L), which suggests short groundwater residence time and indicates that the monitored interval in the well intercepts hydraulically active flowpaths;
- pH (field measurements) of 6.1 – 7.3;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Ten groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.46 mg/L in February 2005) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Two groundwater samples had uranium concentrations above the applicable analytical reporting limit and both results (0.001 mg/L in July 1992 and August 1994) are substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for 15 groundwater samples show non-detect values or false positive results for all of the VOCs that are confirmed groundwater contaminants in the East Fork Regime. A low (estimated) concentration of methylene chloride (1 μg/L) was detected in the sample collected in July 1992. This result is probably a sampling or analytical artifact.

5.4 GROSS ALPHA ACTIVITY

Four groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (3.34 pCi/L in January 1993) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Three groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (5.26 pCi/L in November 1993) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-762

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in May 1992, completed with a screened monitored interval from 46.4 to 58.7 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (type 304) riser casing and well screen (0.01 slot wire-wound). The well is clustered with well GW-763 and is located in Bear Creek Valley at Comprehensive Monitoring Plan Grid J3, which is in the eastern Y-12 area near the northeast corner of Bldg. 9720-6 and about 500 ft west-southwest (hydraulically upgradient) of Lake Reality. Lake Reality is a lined surface impoundment used to regulate the quantity and quality of surface water exiting Y-12 via Upper East Fork Poplar Creek (UEFPC). Lake Reality replaced New Hope Pond (NHP), which was an unlined surface impoundment constructed in 1963, closed in 1988, and covered with a multi-layer low-permeability cap in 1989. During normal operations, flow in UEFPC bypasses Lake Reality and is directed through a concrete-lined distribution channel that borders the south and east sides of NHP/Lake Reality.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-five groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 13 samples between August 1992 and May 1995, and the low-flow sampling method used to obtain 12 samples between February 1999 and August 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Nolichucky Shale (Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within a highly permeable zone (the water table interval) that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into the buried northern tributaries of UEFPC and other components of the subsurface drainage system within the highly industrialized areas of Y-12 (DOE 1998). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that stratigraphically overlies the Nolichucky Shale and subcrops along the axis of BCV and the original main channel of UEFPC.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 10 ft bgs and exhibits seasonal fluctuations of about 10 ft. Also, presampling groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are typically at least 3 ft higher in well GW-762 that in well GW-763, which is completed at a shallower depth (19 ft bgs) in the Nolichucky Shale. Based on the distance (42 ft) between the monitored interval midpoint (elevation) in each well, the contemporaneous presampling groundwater elevations indicate consistently upward vertical hydraulic gradients (0.05 to 0.14) during seasonally high and seasonally low flow conditions.

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-762 indicate south and southeasterly flow toward the Maynardville Limestone and the UEFPC drainage system. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and original main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, groundwater flow in the Nolichucky Shale is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields chloride-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 309 – 470 mg/L;
- pH (field measurements) of 6.7 – 7.3;
- chloride concentrations above 30 mg/L;
- low molar proportions of potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The unusually high chloride concentrations in the groundwater samples may reflect local geochemical conditions or contamination from one or more sources within Y-12, including numerous potential non-specific sources such as leaking industrial process lines, sanitary sewers, or storm drains. Additionally, the elevated chloride levels may be a consequence of the biologically mediated degradation (dechlorination) of the chlorinated hydrocarbons in the groundwater (Hinchee et al. 1995). However, as illustrated by the most recent monitoring data summarized in Table 1, several indicator parameters suggest that the geochemical conditions in groundwater at this well (particularly the REDOX) are not especially conducive to the biotic degradation of chlorinated hydrocarbons.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Eight groundwater samples collected to date had nitrate concentrations at or above the applicable analytical reporting limit, with the highest value (2.8 mg/L in August 2000) being substantially below the drinking water MCL (10 mg/L)

5.2 URANIUM

None of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected 24 of the groundwater samples collected to date (Table 2): methylene chloride, PCE, TCE, VC, 12DCE (isomers), 11DCA, 11DCE, and 111TCA. Methylene chloride was detected in only two samples which are considered to be outliers. Based on the very high concentrations of PCE in the groundwater at this well, which exceed 1% of pure-phase solubility for PCE (1,500 μg/L), the source of the dissolved VOCs may be DNAPL in the subsurface near Building 9720-6 (DOE 1998). Biologically mediated degradation (dechlorination) of PCE and TCE may account for the presence of 11DCE, 12DCE isomers, and VC in the groundwater, but as noted in Section 4.0, results for several geochemical indicator parameters (e.g., REDOX) lie outside the respective optimum range for biotic degradation of chlorinated hydrocarbons. Considering the upward hydraulic gradient indicated by presampling groundwater elevations (see Section 3.0), perhaps the monitored interval in the well intercepts groundwater flow/transport pathways for dissolved VOCs moving upward from DNAPL deeper in the bedrock where conditions are better suited for biodegradation.

The principal VOC in the groundwater samples is PCE, which has been detected in every sample, with concentrations of 1,000 μg/L or more reported for all but six of the samples (Table 2). Secondary VOCs in the samples are TCE and 12DCE; one or both compounds were detected in all but three of the samples, with historical maximum concentrations of 180 μg/L and 85 μg/L, respectively. Also, analytical results for samples collected since February 1999 show that c12DCE is the principal 12DCE isomer in the samples. The most recent sampling results show that PCE and TCE concentrations remain several orders-of-magnitude higher than the respective drinking water MCLs (5 μg/L), with concentrations of c12DCE at or below the MCL (70 μg/L). Historical maximum concentrations exceed 50 μg/L for 11DCE, but the highest concentrations of VC, 11DCA, and 111TCA are less than 20 μg/L, with the most recent sampling results showing concentrations of 11DCE and VC above respective MCLs (Table 2).

A time-series plot of summed VOC concentrations for each groundwater sample (Figure 1) shows an increasing long-term trend (Figure 1). Nevertheless, results for individual compounds show divergent temporal trends, including strongly increasing trends for PCE and TCE, indeterminate trends for VC and 111TCA, and a generally decreasing trend for (total) 12DCE (see data in Table 2). The significance of these divergent concentration trends with respect to the relative flux of VOCs along the flowpaths intercepted by the well is not clear from the available data.

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity above the applicable MDA and corresponding CE was reported for the groundwater samples collected in August 1992 (2.8 pCi/L), January 1996 (1.96 pCi/L), July 2001 (2.57 pCi/L), and February 2004 (1.82 pCi/L). Each result is substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Eighteen groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, with the highest value (7.89 pCi/L in February 2003) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-763

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in May 1992, completed with a screened monitored interval from 4 to 16 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (type 304) riser casing and well screen (0.01 slot wire-wound). The well is clustered with well GW-762 and is located in Bear Creek Valley at Comprehensive Monitoring Plan Grid J3, which is in the eastern Y-12 area near the northeast corner of Bldg. 9720-6 and about 500 ft west-southwest (hydraulically upgradient) of Lake Reality. Lake Reality is a lined surface impoundment used to regulate the quantity and quality of surface water exiting Y-12 via Upper East Fork Poplar Creek (UEFPC). Lake Reality replaced New Hope Pond (NHP), which was an unlined surface impoundment constructed in 1963, closed in 1988, and covered with a multi-layer low-permeability cap in 1989. During normal operations, flow in UEFPC bypasses Lake Reality and is directed through a concrete-lined diversion channel that borders the south and east sides of NHP/Lake Reality.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-seven groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 21 samples between August 1992 and October 2000, and the low-flow sampling method used to obtain 16 samples between December 1997 and November 2004.

An evaluation of the monitoring data available through August 2000 indicated potential bias related to the groundwater sampling method: (unfiltered) samples obtained with the conventional sampling method had substantially lower contaminant (VOC) concentrations than samples obtained with the low-flow sampling method (AJA 2001). Results of "paired" sampling performed during May and October 2000, when groundwater samples were collected with the low-flow sampling method one day and the conventional sampling method the next day, confirm the sampling-method bias. As shown by the data summarized in Table 1, the groundwater samples obtained with the conventional sampling method have significantly higher dissolved oxygen, negative rather than positive oxidation-reduction potential (REDOX), and about 30 to 50% more suspended solids. Both sampling methods provide similar results for major ions and trace metals, whereas the low-flow sampling method seems to obtain samples with significantly lower VOC concentrations.

Inherent differences in the manner in which each sampling method induces inflow of groundwater into the well may explain the disparity between the conventional and low-flow sampling results for VOCs. Conventional sampling involves purging up to three well volumes of groundwater from the well at about 1-2 gallons per minute, which may substantially lower the water level in the well and induce inflow from water-producing features (i.e., fractures, cavities, conduits) that may not contribute to well recharge under normal conditions. In contrast, low-flow sampling involves purging the well at a flow rate low enough (<300 milliliters per minute) to ensure minimal water-level drawdown in the well (<1 ft per quarter hour), which induces groundwater inflow only from the water-producing feature(s) proximal to the monitored interval. Thus, the conventional sampling method has much greater local hydrologic influence (particularly in directions parallel with geologic strike) and substantially increases the relative inflow of clean groundwater into the well, and effectively dilutes the VOC concentrations.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Nolichucky Shale (Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within this highly permeable zone, which occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into the buried northern tributaries of UEFPC and other components of the subsurface drainage system within the highly industrialized areas of Y-12 (DOE 1998). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs *in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike* fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that stratigraphically overlies the Nolichucky Shale and subcrops along the axis of BCV and the original main channel of UEFPC.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 6 ft bgs and exhibits seasonal fluctuations of about 3 ft. Also, presampling groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are typically at least 3 ft lower in well GW-763 than in well GW-762, which is completed deeper (60 ft bgs) in the Nolichucky Shale. Based on the distance (42 ft) between the monitored interval midpoint (elevation) in each well, the contemporaneous presampling groundwater elevations indicate consistently upward vertical hydraulic gradients (0.05 to 0.14) during seasonally high and seasonally low flow conditions.

Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-763 indicate easterly flow toward the UEFPC drainage system. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and original main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred flow in directions that parallel geologic strike (i.e., bedding-plane fractures), which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that this well yields chloride-enriched calcium-magnesium bicarbonate groundwater generally characterized by:

- TDS of 286 – 448 mg/L;
- pH (field measurements) of 6.3 – 7.6;
- unusually high chloride concentrations (>50 mg/L);
- low molar proportions of potassium, sodium, and sulfate (<10% of total anions/cations);
- very high total iron concentrations (>20 mg/L); and
- total concentrations of trace metals (except iron) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The unusually high chloride concentrations in the groundwater samples may reflect local geochemical conditions or contamination from one or more sources within Y-12, including numerous potential non-specific sources such as leaking industrial process lines, sanitary sewers, or storm drains. Additionally, the elevated chloride levels may be a consequence of the biologically mediated degradation (dechlorination) of the chlorinated hydrocarbons in the groundwater (Hinchee et al. 1995). As illustrated by the most recent monitoring data summarized in Table 2, several indicator parameters, including the strongly negative REDOX and very high iron concentrations, suggest the geochemical conditions in groundwater at this well are conducive to the biotic degradation of chlorinated hydrocarbons.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Only the nitrate concentration reported for the groundwater sample collected in November 1994 (0.42 mg/L) exceeds the applicable analytical reporting limit and this result is substantially below the drinking water MCL (10 mg/L).

5.2 URANIUM

Uranium concentrations at or above the applicable analytical reporting limit were reported for groundwater samples collected in March 1996 (0.0015 mg/L) and May 2000 (0.00129 mg/L); both values are an order-of-magnitude below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in 34 of the groundwater samples collected to date (Table 3): acetone, bromomethane, 1,1,2-trichloro-1,2,2-trifluoroethane (freon-113), PCE, TCE, VC, 12DCE (isomers), 11DCA, 11DCE, and 111TCA. The suspected source of the dissolved VOCs in the groundwater at this well (and paired well GW-762) is DNAPL believed to be present in the subsurface near Building 9720-6 (DOE 1998). Also, biologically mediated degradation (dechlorination) of PCE and TCE may account for the presence of 11DCE, 12DCE isomers, and VC in the groundwater and, as noted in Section 4.0, geochemical conditions in the well appear to be conducive to biodegradation of these chlorinated hydrocarbons. Moreover, the low levels of dissolved oxygen in the well (Table 2) combined with the high concentrations of VC (Table 3), suggest the strongly reducing (methanogenic) geochemical conditions necessary to transform 12DCE isomers to VC (Chapelle. 1996). Also, in light of the upward vertical hydraulic gradients indicated by presampling groundwater elevations (see Section 3.0), the presence of VOCs in the shallow groundwater at this well potentially result from upward migration from the suspected DNAPL deeper in the bedrock.

The primary VOCs in the groundwater samples are PCE, TCE, c12DCE, and VC; one or more of these compounds were detected in the groundwater samples (Table 3). The highest concentrations are evident for c12DCE (350 μg/L), VC (92 μg/L), and PCE (65 μg/L), with the most recent monitoring results showing that the concentrations of these VOCs (and TCE) remain above respective drinking water MCLs (Table 3). Secondary VOCs in the samples are 11DCE and 11DCA, which have been detected less consistently and at substantially lower concentrations (almost all are estimated values below 5 μg/L), although the 11DCE concentration evident in March 2003 (13 μg/L) exceeds the historical maximum concentration (5 μg/L in May 2000) and the MCL (7 μg/L). Acetone, bromomethane, and freon-113 each were detected only in one sample.

As noted in Section 2.0, the groundwater sampling method appears to influence the concentrations of VOCs in the groundwater samples, as illustrated by the results of consecutive daily sampling in May and October 2000 (Table 4). In May 2000, VOCs were not detected in the sample collected using the low-flow sampling method, but several compounds dominated by PCE and c12DCE were detected in the sample obtained with the conventional sampling method the next day. Each of these same VOCs except 11DCA were detected in the groundwater samples obtained with each sampling method in October 2000, and there is not any significant difference between the respective concentrations of VOCs reported for either of these groundwater samples.

Respective time-series plots of summed concentrations of VOCs detected in the groundwater samples obtained with the conventional and low-flow sampling methods show two different long-term trends (Figure 1). The conventional sampling data show a widely fluctuating and indeterminate trend, as illustrated by the summed VOC concentrations evident in October 1992 (171 μg/L), November 1996 (102 μg/L) and October 2000 (125 μg/L). In contrast, the low-flow sampling results show a similarly fluctuating but clearly increasing trend, with the highest summed VOC concentration evident in June 2003 (476 μg/L). This increasing trend is primarily attributable to higher relative concentrations of c12DCE (Table 3), which increased more than 1,000% between June 1999 (29 μg/L) and June 2003 (350 μg/L), followed by lower concentrations in 2004 (7-142 μg/L). Increasing trends are evident for each compound, which suggests a corresponding increase in the overall flux of dissolved VOCs along the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity above the applicable MDA and corresponding CE was reported for the groundwater samples collected in August 1992 (2.86 pCi/L), October 1993 (3.94 pCi/L), and October 2001 (27 pCi/L). The latter result exceeds the drinking water MCL for gross alpha activity (15 pCi/L), but appears to be an outlier compared to the other results.

5.5 GROSS BETA ACTIVITY

Gross beta activity above the applicable MDA and corresponding CE was reported for the groundwater sample collected in October 1993 (4.1 pCi/L) and this result is substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-764

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in May 1992, completed with a screened monitored interval from 53.9 to 65 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-765 and is located in Bear Creek Valley in the east-central section of Y-12, about 200 ft south of Bear Creek Road.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Sixteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 14 samples between July 1992 and November 1995, and the low-flow sampling method used to obtain samples in June and October 2003.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the shallow bedrock interval in the Conasauga Group (Rogersville Shale). Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 17 ft bgs and exhibits minor seasonal fluctuations (<3 ft).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- moderate TDS (>150 mg/L<800 mg/L);
- pH (field measurements) of 7.2 – 7.9;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

None of the groundwater samples had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

One groundwater sample had a uranium concentration above the applicable analytical reporting limit and this result (0.001 mg/L in November 1993) is substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for 16 groundwater samples show non-detect values or false positive results for all of the VOCs that are confirmed groundwater contaminants in the East Fork Regime. The single detections at low concentrations (estimated values) of methylene chloride (1 μg/L in July 1992) and 12DCE (4 μg/L in November 1995) are suspected outliers.

5.4 GROSS ALPHA ACTIVITY

Three groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (8.35 pCi/L in April 1993) being below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Eight groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (9.71 pCi/L in November 1994) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-765

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in May 1992, completed with a screened monitored interval from 19.9 to 32.4 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-764 and is located in Bear Creek Valley in the east-central section of Y-12, about 200 ft south of Bear Creek Road.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Eighteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 15 samples between July 1992 and February 1996, and the low-flow sampling method used to obtain 3 samples between June 2003 and April 2004.

The Y-12 GWPP requested biological testing to assess microbial activity in groundwater at this well in April 2004. The results (shown below) are qualitative bacterial counts of four specific bacteria types that are estimates based on the appearance of the sample after an eight- to ten-day growth period.

Well	Date Sampled	Bacteria Activity (colony forming units/milliliter)			
		Heterotrophic Aerobic	Iron Related	Slime Forming	Sulfate Reducing
GW-765	04/27/04	1,000	>100	>100	<100

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Rogersville Shale). Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 17 ft bgs and exhibits minor seasonal fluctuations (<3 ft).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 304 – 460 mg/L;
- pH (field measurements) of 6.5 – 7.3;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

None of the groundwater samples had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

Two groundwater samples had uranium concentrations above the applicable analytical reporting limit and both results (0.001 mg/L in July and October 1992) are substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for each groundwater sample show non-detect values or false positive results for all of the VOCs that are confirmed groundwater contaminants in the East Fork Regime. Carbon disulfide was detected (4 µg/L) in one sample (November 2003), but this result is a probable artifact and considered to be an outlier.

5.4 GROSS ALPHA ACTIVITY

Eight groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the results for the samples collected in July 1992 (43.3 pCi/L) and September 1993 (17.5 pCi/L) exceeding the MCL for gross alpha activity (15 pCi/L). Both results may be outliers because all the other gross alpha results are less than 6 pCi/L.

5.5 GROSS BETA ACTIVITY

Seven groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (47.9 pCi/L in July 1992) being slightly below the SDWA screening level for gross beta activity (50 pCi/L). This result is clearly an outlier compared to the other gross beta results, which are all below 10 pCi/L.

WELL GW-769

1.0 *INSTALLATION, CONSTRUCTION, AND LOCATION*

This well was installed in June 1992, completed with a screened monitored interval from 48.2 to 60.3 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (type 304) riser casing and well screen (0.01 slot wire-wound). The well is clustered with well GW-770 and is located in Bear Creek Valley at Comprehensive Monitoring Plan Grid G3, which is in the east-central part of Y-12, directly across Second Street (north) from Bldg. 9201-2.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-one groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 16 samples between January 1993 and May 1997, and the low-flow sampling method used to obtain 15 samples between November 1997 and October 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Nolichucky Shale (Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within a highly permeable zone (the water table interval) that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into the buried northern tributaries of Upper East Fork Poplar Creek (UEFPC) and other subsurface components of the subsurface drainage system within the highly industrialized areas of Y-12 (DOE 1998). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that stratigraphically overlies the Nolichucky Shale and subcrops along the axis of BCV and the original main channel of UEFPC.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 8 ft bgs and exhibits seasonal fluctuations of less than 5 ft. Also, results of contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in the well are usually 2 to 3 ft higher than the presampling groundwater elevations in well GW-770, which is completed at a shallower depth (19 ft bgs) in the Nolichucky Shale. Based on the difference between the midpoint elevation of the monitored interval in each well (41.1 ft), the presampling groundwater elevations indicate consistently upward vertical hydraulic gradients (0.05 – 0.1).

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-769 indicate south and southeasterly flow toward the Maynardville Limestone and the Upper East Fork Poplar Creek (UEFPC) drainage system. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and original main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred flow in directions that parallel geologic strike (i.e., bedding-plane fractures), which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields sulfate-enriched calcium-magnesium bicarbonate groundwater generally characterized by:

- TDS of 258 – 334 mg/L, excluding an outlier (36 mg/L) in November 1995;
- pH (field measurements) of 7.0 – 7.6;
- sulfate concentrations above 20 mg/L;
- low molar proportions of chloride, potassium, and sodium (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The elevated sulfate concentrations in the groundwater samples may reflect local geochemical conditions or contamination from one or more sources within Y-12, including numerous potential non-specific sources such as leaking industrial process lines, sanitary sewers, or storm drains.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the contaminants present in the groundwater at this well.

5.1 NITRATE

Twenty-two groundwater samples collected to date had nitrate concentrations at or above the applicable analytical reporting limit, with each concentration being less than 1 mg/L and substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Uranium concentrations at or above the applicable analytical reporting limit were reported for the groundwater samples collected in September 1993 (0.001 mg/L), August 1994 (0.001 mg/L), and February 1995 (0.00052 mg/L); each result is at least an order-of-magnitude below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample collected to date (Table 1): CTET, chloroform, methylene chloride, PCE, TCE, 12DCE (c12DCE), 11DCA, 11DCE, 111TCA, and 1,1,2-trichloro-1,2,2-trifluoroethane (freon-113). The source(s) of the VOCs in the groundwater at this well has not been conclusively identified. However, because basement sumps in Bldg. 9201-2 strongly influence local groundwater flow and contaminant transport patterns, the source(s) may be north of the well, possibly Buildings 9202, 9203, and 9205 where large amounts of CTET were used to convert uranium trioxide to uranium tetrachloride (DOE 1998). Also, considering the upward vertical hydraulic gradient noted in Section 3.0, the VOCs transported via the groundwater flowpaths intercepted by the monitored interval in the well would be expected to move upward into the shallow flow system. Indeed, operation of the basement sumps in Bldg. 9201-2 may induce or increase the upward flow of contaminated groundwater from deeper in the bedrock.

The primary VOCs in the groundwater samples are CTET and PCE, both of which were detected in all but one of the samples, with historical maximum concentrations 160 μg/L and 22 μg/L, respectively (Table 1). The most recent sampling results show that the concentrations of CTET and PCE remain above respective drinking water MCLs of 5 μg/L. Secondary compounds in the samples are chloroform and TCE, which were detected in all but 11 of the samples, with the bulk of the results being estimated values below 5 μg/L. Other compounds (11DCE, 12DCE, 11DCA, 111TCA, and freon-113) have been detected less frequently, with almost all the concentrations are estimated values below 5 μg/L. Additionally, methylene chloride was only detected in one sample and the result is considered to be an outlier.

A time-series plot of summed VOC concentrations for each groundwater sample (Figure 1) shows an indeterminate trend between January 1993 (18 μg/L) and October 1999 (11 μg/L), followed by a widely fluctuating but clearly increasing trend through October 2004 (131 μg/L). Also, the VOC results obtained since October 1999 show temporal concentration fluctuations that appear to correlate with seasonal groundwater flow conditions, with the highest VOC concentration typically evident in samples collected during seasonally low flow conditions (summer and fall). This relationship suggests dilution-related concentration fluctuations, with greater relative inflow of "clean" groundwater into the well effectively lowering the VOC concentrations in the samples collected during seasonally (and episodically) high flow conditions. Also, increasing summed VOC concentrations are primarily attributable to CTET and PCE, the concentrations of which increased significantly between January 1993 (CTET = 9 μg/L; PCE = 4 μg/L) and October 2004 (CTET = 100 μg/L; PCE = 16 μg/L). However, similar concentration increases are less evident for the other VOCs (Table 1).

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity above the applicable MDA and corresponding CE was reported for the groundwater sample collected in April 2002 (2.9 pCi/L) and this result is substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Five groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, with the highest value (10 pCi/L in October 1999) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-770

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in June 1992, completed with a screened monitored interval from 7.5 to 19 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (type 304) riser casing and well screen (0.01 slot wire-wound). The well is clustered with well GW-769 and is located in Bear Creek Valley at Comprehensive Monitoring Plan Grid G3, which is in the east-central part of Y-12, directly across Second Street (north) from Bldg. 9201-2.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-one groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 16 samples between January 1993 and May 1997, and the low-flow sampling method used to obtain 15 samples between November 1997 and October 2004.

The Y-12 GWPP requested biological testing to assess microbial activity in groundwater at this well in April 2004. The results (shown below) are qualitative bacterial counts of four specific bacteria types that are estimates based on the appearance of the sample after an eight- to ten-day growth period.

Well	Date Sampled	Bacteria Activity (colony forming units/milliliter)			
		Heterotrophic Aerobic	Iron Related	Slime Forming	Sulfate Reducing
GW-770	04/28/04	500,000	5,000	1,000	100

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Nolichucky Shale (Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within this highly permeable zone, which occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into the buried northern tributaries of Upper East Fork Poplar Creek (UEFPC) and other subsurface components of the subsurface drainage system within the highly industrialized areas of Y-12 (DOE 1998). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that stratigraphically overlies the Nolichucky Shale and subcrops along the axis of BCV and the original main channel of UEFPC.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 10 ft bgs and exhibits seasonal fluctuations of about 5 ft. Also, results of contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in the well are usually 2 to 3 ft lower than the presampling groundwater elevations in well GW-769, which is completed at a greater depth (60.3 ft bgs) in the Nolichucky Shale. Based on the difference between the midpoint elevation of the monitored interval in each well (41.1 ft), the presampling groundwater elevations indicate consistently upward vertical hydraulic gradients (0.05-0.1).

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells the vicinity of well GW-770 indicate south and southeasterly flow toward the Maynardville Limestone and the Upper East Fork Poplar Creek (UEFPC) drainage system. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and original main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred flow in directions that parallel geologic strike (i.e., bedding-plane fractures), which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields sulfate-enriched calcium-magnesium bicarbonate groundwater generally characterized by:

- TDS of 154 – 266 mg/L;
- pH (field measurements) of 6.0 – 7.4;
- sulfate concentrations above 20 mg/L;
- low molar proportions of chloride, potassium, and sodium (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The elevated sulfate concentrations in the groundwater samples may reflect local geochemical conditions or contamination from one or more sources within Y-12, including numerous potential non-specific sources such as leaking industrial process lines, sanitary sewers, or storm drains.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Nitrate concentrations at or above the applicable analytical reporting limit were reported for each groundwater sample collected to date, with each concentration being less than 1 mg/L and substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Twenty-one groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.0018 mg/L in November 1997) being substantially below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in 30 of the groundwater samples collected to date (Table 1): acetone, CTET, chloroform, and PCE. The source(s) of the VOCs in the groundwater at this well has not been conclusively identified.

However, because basement sumps in Bldg. 9201-2 strongly influence local groundwater flow and contaminant transport patterns, the source(s) may be north of the well, possibly Buildings 9202, 9203, and 9205 where large amounts of CTET were used to convert uranium trioxide to uranium tetrachloride (DOE 1998). Also, considering the upward vertical hydraulic gradient noted in Section 3.0, the VOCs transported via the groundwater flowpaths intercepted by the monitored interval in the well would be expected to move upward into the shallow flow system. Indeed, operation of the basement sumps in Bldg. 9201-2 may induce or increase the upward flow of contaminated groundwater from deeper in the bedrock.

The primary VOCs in the groundwater samples are CTET and chloroform, with one or both compounds detected in each sample (Table 1). Historical maximum concentrations of these compounds are slightly above (CTET) and below (chloroform) 10 µg/L, with the bulk of the concentrations being estimated values below 5 µg/L. Nevertheless, the most recent monitoring data show that CTET concentrations exceed the drinking water MCL (Table 1). In contrast, acetone and PCE were detected in one sample each, and both of these results are considered to be outliers.

A time-series plot of summed VOC (CTET and chloroform) concentrations for each groundwater sample (excluding the outliers mentioned above, see Table 1) shows a widely fluctuating and generally increasing trend (Figure 1). Also, the VOC concentration fluctuations often correlate with seasonal groundwater flow conditions, with the highest concentrations typically reported for samples collected during seasonally low groundwater flow conditions (summer and fall). This relationship suggests that greater relative inflow of clean groundwater into the well effectively dilutes the VOC concentrations in the samples collected during seasonally (and episodically) high flow conditions.

5.4 GROSS ALPHA ACTIVITY

Eight groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (3.96 pCi/L in April 1993) being less than the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Six groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, with the highest value (5.38 pCi/L in August 1994) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-775

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in July 1992, completed with a screened monitored interval from 45 to 56 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is clustered with well GW-776 and is located in Bear Creek Valley in the east-central section of Y-12, about 150 ft northeast of the intersection of Second Street and "B" Road, approximately 500 ft north of the exposed section of Upper East Fork Poplar Creek (UEFPC).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-four groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 16 samples between February 1993 and May 1997, and the low-flow sampling method used to obtain 8 samples between November 1997 and April 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Nolichucky Shale (Conasauga Group) near the geologic contact with the overlying Maynardville Limestone. The bulk of the groundwater flow in the Nolichucky Shale occurs within a highly permeable zone (the water table interval) that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into the buried northern tributaries of UEFPC and other subsurface components of the subsurface drainage system within the highly industrialized areas of Y-12 (DOE 1998). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that subcrops along the axis of BCV and the original main channel of UEFPC.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 14 ft bgs and exhibits moderate seasonal fluctuations (<10 ft). Also, measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in well GW-775 are typically higher than evident in well GW-776, which is completed at a shallower depth (24 ft bgs) in the Nolichucky Shale. Based on the distance between the monitored interval midpoint (elevation) in each well (33.9 ft), the contemporaneous groundwater elevations indicate upward vertical hydraulic gradients (0.005 to 0.131) from the shallow bedrock interval (GW-775) to the water table interval (GW-776).

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-775 indicate south and southeasterly flow toward the Maynardville Limestone and the UEFPC drainage system. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and original main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred flow in directions that parallel geologic strike (i.e., bedding-plane fractures), which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields chloride- and sulfate-enriched calcium-magnesium bicarbonate groundwater generally characterized by:

- TDS of 178 – 343 mg/L, excluding an apparent outlier (36 mg/L) reported for the sample collected in November 1995;
- pH (field measurements) of 6.9 – 7.6;
- chloride and sulfate concentrations above 30 mg/L;
- low molar proportions of nitrate, potassium, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The elevated sulfate and chloride concentrations in the groundwater samples may reflect local geochemical conditions or contamination from one or more sources within Y-12, including numerous potential non-specific sources such as leaking sanitary sewers or storm drains.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the primary contaminants present in the groundwater at this well.

5.1 NITRATE

Twenty-three groundwater samples collected to date had nitrate concentrations at or above the applicable analytical reporting limit, and the maximum value (1.2 mg/L in July 1995) is substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Three groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, and the maximum result (0.001 mg/L in August 1994) is substantially below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in all but one of the groundwater samples collected to date (Table 1): CTET, chloroform, methylene chloride (MC), acetone, PCE, and TCE. The source(s) of the VOCs in the groundwater at this well has not been conclusively identified. However, because basement sumps in Bldg. 9201-2 strongly influence local groundwater flow and contaminant transport patterns, the source(s) may be north of the well, possibly Buildings 9202, 9203, and 9205 where large amounts of CTET were used to convert uranium trioxide to uranium tetrachloride (DOE 1998). Also, considering the upward vertical hydraulic gradient noted in Section 3.0, the VOCs transported via the groundwater flowpaths intercepted by the monitored interval in the well would be expected to move upward into the shallow flow system. Indeed, operation of the basement sumps in Bldg. 9201-2 may induce or increase the upward flow of contaminated groundwater from deeper in the bedrock.

As shown by the data in Table 1, TCE was detected in all but one of the groundwater samples, whereas the other compounds were detected infrequently, with acetone, CTET and PCE each detected in one sample, MC detected in two samples, and chloroform detected in four samples. The bulk of the VOC results are estimated values below 5 μg/L, with the highest concentration reported for acetone (17 μg/L in January 1994). Excluding false positive results, TCE is the only compound detected in any of the samples collected since November 1997, with the most recent analytical results (April and October 2002) showing concentrations just below (4 μg/L) and above (6 μg/L) the drinking water MCL (5 μg/L).

A time-series plot of TCE concentrations for each groundwater sample (Figure 1) shows a generally indeterminate long-term trend (Figure 1), as illustrated by the TCE results reported for the samples collected in October 1993 (5 μg/L), June 1998 (6 μg/L), and October 2002 (6 μg/L). Also, the TCE results show temporal concentration fluctuations that appear to correlate with seasonal groundwater flow conditions, with temporal "peak" concentrations typically evident in samples collected during seasonally low flow conditions (summer and fall). This relationship suggests dilution-related concentration fluctuations, with greater relative inflow of "clean" groundwater into the well slightly lowering the TCE concentrations in the samples collected during seasonally (and episodically) high flow conditions.

Minimal biotic degradation of the TCE in the groundwater at this well is indicated by the relatively unchanged long-term concentration trend and the consistent lack of TCE degradation products (e.g., c12DCE) in the groundwater samples. A groundwater sample was collected (as a control sample) in April 2004 to assess microbiologically-induced corrosion of stainless steel casing and screens and, based on the appearance of the sample after an 8-10 day growth period, qualitative bacterial counts for specific bacteria types, summarized below, confirm the presence of a fairly low level of microbial activity in the well.

Date Sampled	**Bacteria Activity (colony forming units/milliliter)**			
	Heterotrophic Aerobic	Iron Related	Slime Forming	Sulfate Reducing
04/28/04	100	5,000	1,000	1,000

As shown in the following data summary, results for selected indicator parameters reported for samples collected in April and October 2002 indicate that the geochemical characteristics of the groundwater are only marginally favorable for biologically mediated degradation of chlorinated hydrocarbons.

Geochemical Parameter/Optimum Range (Wilson et al. 1996)	April 2002	October 2002
Nitrate < 1 mg/L	0.383	0.657
Iron (II) > 1 mg/L	<0.05*	<0.05*
Sulfate < 20 mg/L	30.4	33.8
Dissolved Oxygen < 0.5 ppm	0.2**	0.56**
REDOX < 50 mV	49**	119**
pH >5 and < 9 st. units	7.44**	6.9**
Note: *Result is for total iron; **Field measurement.		

The limited microbial activity, the marginal geochemical conditions, and the absence of degradation products support the lack of biotic degradation of TCE in the groundwater near well GW-775.

5.4 GROSS ALPHA ACTIVITY

One groundwater sample collected to date had gross alpha activity above the applicable MDA and corresponding CE, and this result (6.4 mg/L in October 1999) is substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Five groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, with the highest value (4.17 pCi/L in January 1995) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-782

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1992, completed with a screened monitored interval from about 23.8 to 35.9 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with wells GW-781 and GW-783 and is located in Bear Creek Valley (BCV) at Comprehensive Monitoring Plan Grid E3, which is in the south-central section of Y-12 at the intersection of Second Street and D Road, just west of Bldg. 9731. These wells are on the west side of the concrete foundation for the former Development Incinerator, which was used from 1981 to 1992 for test burns of small quantities of various wastes generated at Y-12, including uranium-contaminated trash and mercury-contaminated soils (DOE 1998).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-nine groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 13 samples in between June 1994 and November 2003, and the low-flow sampling method used to obtain 16 samples between November 1997 and October 2004.

An evaluation of the monitoring data available through August 2000 indicated potential bias related to the groundwater sampling method: samples obtained with the conventional sampling method had substantially lower gross alpha activity than samples obtained with the low-flow sampling method (AJA 2001). However, the results of "paired sampling" performed during May and November 2003, when groundwater samples were collected with the low-flow sampling method one day and the conventional sampling method the next day, show little if any difference between the results for most analytes, including gross alpha activity (Table 1). Thus, sampling bias does not appear to explain the higher levels of gross alpha activity evident since the change from conventional sampling to low-flow sampling. Instead, the higher gross alpha activity may reflect a coincident increase in the relative flux of alpha-emitting radionuclides via the groundwater flow/transport pathways intercepted by the well (see Section 5.4).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Nolichucky Shale (Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within a highly permeable zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 6 ft bgs and exhibits seasonal fluctuations up to about 4 ft. Also, measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in well GW-782 are typically lower than evident in well GW-781, which is completed deeper (69 ft bgs) in the Nolichucky Shale, but are usually higher than evident in well GW-783, which is completed at a much shallower depth (16 ft bgs). Based on the distance between the monitored interval midpoint (elevation) in well GW-782 and well GW-781 (21.2 ft) and well GW-783 (32.6 ft), the contemporaneous groundwater elevations indicate upward vertical hydraulic gradients of 0.01 to 0.046 from the deeper flowpaths (GW-781) and 0.006 to 0.06 from the shallow bedrock interval (GW-782) to the water table interval (GW-783).

Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-782 indicate flow primarily to the east-southeast (across geologic strike) toward Maynardville Limestone and an exposed section of the main channel of UEFPC. However, the Nolichucky shale exhibits strongly anisotropic flow in directions that parallel geologic strike and which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Moreover, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local groundwater flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 295 – 375 mg/L;
- pH (field measurements) of 7 – 7.8;
- total iron and total strontium concentrations above 1 mg/L;
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations);
- total concentrations of trace metals (except iron and strontium) that are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, VOCs and gross alpha activity are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Eighteen of the groundwater samples collected to date had nitrate (as N) concentrations above the analytical reporting limit, with the highest value (1.2 mg/L in March 1995) being substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Twenty-seven of the groundwater samples collected to date had uranium concentrations above the analytical reporting limit, with the historical maximum concentration (0.0045 mg/L in February 1996) being almost an order-of-magnitude below the drinking water MCL for total uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample collected to date (Table 2): benzene, CTET, chloroform (CLF), chloromethane (CLM), PCE, toluene, TCE, VC, 11DCA, 111TCA, and 12DCE (c12DCE and t12DCE). These compounds are components of a plume of dissolved VOCs in the groundwater that is believed to originate from one or more source areas, possibly including DNAPL in the subsurface near Bldg. 9204-2, which is about 600 ft directly west of well GW-782, and potential sources associated with operations at Bldg. 9731 and the Development Incinerator (DOE 1998).

The primary VOCs in the groundwater samples are PCE and 11DCA (Table 2), both of which were detected at the highest concentrations (>100 µg/L), including the samples collected most recently (May and October 2004), with the PCE values being substantially above the drinking water MCL (5 µg/L). Secondary compounds are TCE and 11DCE, each having historical maximum concentrations above 50 µg/L and the most recent results showing concentrations substantially above respective MCLs (5 µg/L and 7 µg/L). Tertiary compounds are CLM, 111TCA, and 12DCE, with the latter two compounds detected in all but three of the samples (excluding false positive results for 111TCA), and each compound having a historical maximum concentration above 25 µg/L. Also, the most recent sampling results show that the concentrations of 111TCA and c12DCE remain below respective MCLs (200 µg/L and 70 µg/L). Trace compounds detected in the samples are CTET, CLF, and VC, at least one of which was detected in 25 of the samples, although neither CTET nor CLF have been detected in any of the samples collected since November 1997. Although the bulk of the results are estimated values below 5 µg/L, the most recent sampling results show VC slightly above the MCL (2 µg/L). Acetone, benzene, and toluene were detected in a total of four samples, most recently the sample collected with the low-flow sampling method in May 2003.

As shown by the data summarized in Table 3, contemporaneous monitoring results show that VOC concentrations in the groundwater samples from well GW-782 are an order-of-magnitude higher than the VOC concentrations in the groundwater samples from the wells with which it is clustered (GW-781 and GW-783). This suggests that the respective monitored interval in each well intercepts somewhat stratabound groundwater flow/ transport pathways, which is consistent with the characteristically strike-parallel anisotropy of flow in the Nolichucky Shale. Additionally, the upward hydraulic gradients indicated by contemporaneous presampling groundwater elevations in these wells (see Section 2.0) suggest vertically upward VOC transport/migration patterns.

Several of the VOCs in the groundwater samples are probably present as a result of the biotic and/or abiotic degradation of related parent compounds. For instance, chemical (abiotic) degradation of 111TCA, which is the only major chlorinated solvent that can be transformed chemically in groundwater under all likely conditions (McCarty 1996), might at least partially account for the preponderance of 11DCA and 11DCE in the samples. Similarly, biologically mediated sequential dechlorination of PCE and TCE by anaerobic (methanotropic) organisms in the groundwater may explain the presence of c12DCE, t12DCE, and VC in the samples. This interpretation is generally supported by monitoring results for several indicator parameters, which show that geochemical conditions in the well are within the optimum range for biotic degradation of chlorinated hydrocarbons (Table 4). However, the REDOX conditions do not indicate the strongly reducing (methanogenic) conditions necessary to transform 12DCE isomers to VC (Chapelle 1996). Considering the upward vertical hydraulic gradients noted previously, perhaps the monitored interval in well GW-782 intercepts groundwater flow/transport pathways for dissolved VOCs moving upward from a source (DNAPL) deeper in the bedrock where conditions are better suited for reductive dechlorination of the VOCs. Results of microbiological sampling performed in CY 2000 (summarized below) suggest limited biotic activity at well GW-782, but much greater biotic activity (particularly iron-related bacteria) in the shallower groundwater flow/transport pathways intercepted by the monitored interval in well GW-783 (AJA 2000).

Well Number	Date Sampled	Bacteria counts (CFU/mL)		
		Iron-Related Bacteria	Sulfate-Reducing Bacteria	Slime-Forming Bacteria
GW-782	05/01/00	100	1000	<100
	05/01/00 D	100	<100	<100
GW-783	05/01/00	5000	100	1000
	05/01/00 D	5000	<100	<100
Note: D = Duplicate sample				

A time-series plot of the summed concentrations of VOCs detected in each groundwater sample shows a generally indeterminate long-term trend dominated by wide temporal fluctuations (Figure 1), with the highest concentrations typically reported for samples collected during seasonally low groundwater flow conditions. The indeterminate long term trend, illustrated by the nearly equal concentrations of PCE detected in samples collected in June 1994 (140 µg/L) and May 2004 (160 µg/L), suggest minimal overall change in the relative flux of dissolved VOCs along the groundwater flow/transport pathways intercepted by the monitored interval in the well. The temporal changes in VOC concentrations suggest inflow of uncontaminated (or less VOC contaminated) groundwater during seasonally (or episodically) high flow conditions. However, the seasonal fluctuations are not always evident and are not always consistent with seasonal flow conditions, as illustrated by the highest and lowest summed VOC concentration being reported for samples collected during seasonally low flow conditions (632 µg/L in June 1996 and 261 µg/L in November 2003). Also, several of the compounds, notably 12DCE isomers and VC, show little if any temporal fluctuation, with equal or nearly equal concentrations reported for samples obtained during both seasonally high and low groundwater flow conditions.

5.4 GROSS ALPHA ACTIVITY

Twenty-seven of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE (Table 5), with all but two of these results exceeding the drinking water MCL for gross alpha activity (15 pCi/L), including the historical maximum value (64 pCi/L in May 1998 and April 2001). Elevated levels of gross alpha activity are supported by the analytical results for uranium isotopes (Table 3), with relatively high levels of U-234 (36 – 57 pCi/L), but substantially lower levels of U-238 (0.38 – 0.56 pCi/L), reported for the series of five samples collected between April 2001 and November 2002 (the only samples that were analyzed for uranium isotopes). The uranium isotopes are probably present as uranyl cations that, considering the neutral pH of the groundwater in the well, are probably complexed with dissolved anions (e.g., carbonate) in the groundwater (Fetter 1993). The source of the uranium isotopes in the groundwater at this well has not been identified (DOE 1998).

A time-series plot of the gross alpha activity reported for each groundwater sample shows (Figure 2): (1) a relatively indeterminate trend between June 1994 (24.6 pCi/L) and November 1996 (26.2 pCi/L, (2) a sharply increasing trend through Mar 1998 (64 pCi/L), (3) a widely fluctuating but generally indeterminate trend through April 2001 (64 pCi/L), and (4) a steadily decreasing trend through October 2004 (20 pCi/L). The latter trend coincides with an overall decrease in the levels of in U-234 in the groundwater samples (Table 5). This suggests that the temporal trends for gross alpha activity are attributable to corresponding changes in the relative flux of U-234 via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.5 GROSS BETA ACTIVITY

Twenty-two of the groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, with the highest value (18 pCi/L in July 1998) being less than the SDWA screening level (50 pCi/L) for a 4 millirem dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-783

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1992, completed with a screened monitored interval from about 4 to 16 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with wells GW-781 and GW-782 and is located in Bear Creek Valley (BCV) at Comprehensive Monitoring Plan Grid E3, which is in the south-central section of Y-12 at the intersection of Second Street and D Road, just west of Bldg. 9731. These wells are on the west side of the concrete foundation for the former Development Incinerator, which was used from 1981 to 1992 for test burns of small quantities of various wastes generated at Y-12, including uranium-contaminated trash and mercury-contaminated soils (DOE 1998).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Eighteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 11 samples in between June 1994 and May 1997, and the low-flow sampling method used to obtain seven samples between November 1997 and April 2004.

Groundwater samples from this well are distinguished by elevated total (unfiltered sample) concentrations of chromium and nickel that are probably attributable to chemical and/or microbiologically-induced corrosion (MIC) of the stainless steel riser casing and/or well screen (see Section 5.6).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Nolichucky Shale (Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within this highly permeable zone developed near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 8 ft bgs and exhibits temporal (seasonal) fluctuations of 4 ft or less. Also, measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in well GW-783 are typically lower than evident in wells GW-782 and GW-781, which are completed deeper (36 and 69 ft bgs, respectively) in the Nolichucky Shale. Based on the distance between the monitored interval midpoint (elevation) in each well, the contemporaneous groundwater elevations indicate upward vertical hydraulic gradients of 0.01 to 0.046 from the deeper flowpaths (GW-781) to the shallow bedrock interval (well GW-782), and 0.006 to 0.06 from the shallow bedrock interval (GW-782) to the water table interval (GW-783).

Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-783 indicate flow primarily to the east-southeast (across geologic strike) toward Maynardville Limestone and an exposed section of the main channel of UEFPC. However, the Nolichucky shale exhibits strongly anisotropic flow in directions that parallel geologic strike and which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Moreover, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local groundwater flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples collected to date show that the well yields chloride- and sodium-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 282 – 444 mg/L;
- pH (field measurements) of 7 – 7.6;
- elevated concentrations of chloride (>40 mg/L) and sulfate (>20 mg/L) relative to other wells completed at similar depths in the water table interval of the Nolichucky Shale;
- low molar proportions of nitrate, potassium, and sulfate (<10% of total anions/cations);
- total concentrations of trace metals (except chromium and nickel) that are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee (HSW 1995).*

The elevated chloride and sulfate concentrations in the groundwater samples may reflect local geochemical conditions or contamination from one or more sources within Y-12, including numerous potential non-specific sources such as leaking industrial process lines, sanitary sewers, or storm drains.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Sixteen of the groundwater samples collected to date had nitrate (as N) concentrations above the analytical reporting limit, with the highest value (4.6 mg/L in March 1995) being below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Fifteen of the groundwater samples collected to date had uranium concentrations above the analytical reporting limit, with the historical maximum concentration (0.002 mg/L in June 1994) being substantially below the drinking water MCL for total uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample collected to date (Table 1): acetone, 2-butanone, CTET, chloroform (CLF), PCE, TCE, 11DCA, 11DCE, 12DCE (c12DCE), and 111TCA. These compounds are components of a plume of dissolved VOCs in the groundwater that is believed to originate from one or more source areas, possibly including DNAPL in the subsurface near Bldg. 9204-2, which is about 600 ft directly west of well GW-783, and potential sources associated with operations at Bldg. 9731 and the Development Incinerator (DOE 1998).

Based on frequency of detection and concentration magnitude, the primary VOCs in the groundwater samples are PCE, TCE, 12DCE, and 11DCA (Table 1), each of which were detected in all but two of the groundwater samples collected to date, with respective historical maximum concentrations of 59 μg/L, 23 μg/L, 35 μg/L, and 26 μg/L. Additionally, the most recent results for VOCs (October 1999) show PCE and TCE concentrations above the respective drinking water MCL (5 μg/L). Secondary compounds in the samples are CTET, 11DCE, and 11TCA, which have all been detected somewhat infrequently compared to the primary VOCs, with only three results (all for 11DCE) being above 5 μg/L. Acetone was detected in only one sample, 2-butanone was detected in two samples, and chloroform was detected in five samples, but none of these compounds have been detected in samples collected since November 1997 (Table 1).

As shown by the data summarized in Table 2, contemporaneous monitoring results show that VOC concentrations in the shallow groundwater at well GW-783 and deepest well GW-781 are an order-of-magnitude lower than the VOC concentrations in the intermediate depth groundwater from well GW-782. This suggests that the respective monitored interval in each well intercepts somewhat stratabound groundwater flow/ transport pathways, which is consistent with the characteristically strike-parallel anisotropy of flow in the Nolichucky Shale. Additionally, the upward hydraulic gradients indicated by contemporaneous presampling groundwater elevations in these wells (see Section 2.0) suggest vertically upward VOC transport/migration patterns.

Several of the VOCs in the groundwater at this well are probably present as a result of the biotic and/or abiotic degradation of related parent compounds. For instance, chemical (abiotic) degradation of 111TCA, which is the only major chlorinated solvent that can be transformed chemically in groundwater under all likely conditions (McCarty 1996), might at least partially account for the preponderance of 11DCA and 11DCE in the samples. Similarly, biologically mediated sequential dechlorination of PCE and TCE may explain the presence of c12DCE (and 11DCE) in the groundwater. Moreover, results of microbiological groundwater sampling performed in May 2000 and April 2004 (summarized below), which are based on qualitative bacterial counts estimated from the appearance of the groundwater sample after an eight- to ten-day growth period, confirm substantial and varied biotic activity in the shallower groundwater at well GW-783.

Date Sampled	Bacteria counts (CFU/mL)			
	Heterotropic Aerobic Bacteria	**Iron-Related Bacteria**	**Sulfate-Reducing Bacteria**	**Slime-Forming Bacteria**
05/01/00	NR	5,000	100	1,000
05/01/00 D	NR	5,000	<100	<100
04/27/04	500,000	100	100	50,000
Note: D = Duplicate sample; NR = Not reported				

A time-series plot of the summed concentrations of VOCs detected in each groundwater sample shows a decreasing long-term trend dominated by wide temporal fluctuations

(Figure 1), with the highest concentrations typically reported for samples collected during seasonally low groundwater flow conditions (summer and fall), as illustrated by the temporal "peak" concentrations evident in August 1995 (133 μg/L), November 1996 (147 μg/L), and November 1998 (75 μg/L). Conversely, the lowest summed concentrations are evident for samples collected during seasonally high groundwater flow conditions (winter and spring), as illustrated by the concentrations evident in March 1995 (36 μg/L), March 1996 (45 μg/L), and May 1998 (14 μg/L). Additionally, the concentrations of the primary compounds in the samples (PCE, TCE, 12DCE, and 11DCA) show concurrent temporal (seasonal) fluctuations. This suggests that samples collected during seasonally high flow conditions contain lower VOC concentrations because of the greater relative inflow of uncontaminated (or less VOC-contaminated) recharge via the groundwater flow/transport pathways intercepted by the monitored interval in the well. Considering the upward hydraulic gradients indicated by presampling groundwater elevations (see Section 3.0), VOC-contaminated groundwater upwelling from the groundwater flow system deeper in the Nolichucky Shale may comprise the bulk of the inflow (baseflow) into the well during seasonally low flow conditions.

5.4 GROSS ALPHA ACTIVITY

Six of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (7.57 pCi/L in November 1995) being less than the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Three of the groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, with the highest value (5.16 pCi/L in December 1994) being less than the SDWA screening level (50 pCi/L) for a 4 millirem dose equivalent (the drinking water MCL for gross beta activity).

5.6 OTHER

As noted in Section 2.0, the groundwater samples from this well typically contain elevated chromium and nickel concentrations; all but one of the samples had chromium and/or nickel concentrations above respective UTLs (Table 3). Ten of the samples, including the sample collected most recently (April 2004), had chromium concentrations above the federal drinking water MCL (0.1 mg/L). Similarly, 15 of the samples (including the sample collected in April 2004) had nickel concentrations above the state drinking water MCL (0.1 mg/L). Corrosion of the stainless steel well casing and screen in the well is the suspected source of the nickel (and chromium) in the samples (AJA 2000), primarily because: (1) mobile species of chromium and nickel are not typically present in groundwater with the neutral pH evident in the well; (2) Type 304 stainless steel contains 18-20% chromium and 8-12% nickel and is prone to crevice corrosion (Oakley and Korte 1996); and (3) microbiological sampling results (see Section 5.3) qualitatively confirm the presence of bacteria (e.g., slime-forming bacteria) in the groundwater that are known to cause MIC of stainless steel (Sarouhan et. al. 1998).

WELL GW-786

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1992, completed with a screened monitored interval from 52.9 to 64.9 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-787 and is located in Bear Creek Valley in the east-central section of Y-12, about 400 ft north of First Street and 150 ft northwest of Bldg. 9704-2.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twelve groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain ten samples between June 1994 and November 1996, and the low-flow sampling method used to obtain samples in June and October 2003.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the shallow bedrock interval (<100 ft bgs) in the Conasauga Group (Maryville Limestone). The average static groundwater level in the well is 7.2 ft bgs. Presampling depth-to-water measurements for the well indicate moderate fluctuations (<6 ft) in seasonal groundwater surface elevations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- moderate TDS (>150 mg/L<800 mg/L);
- pH (field measurements) of 7.0 – 7.8;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

One groundwater sample had a nitrate concentration above the applicable analytical reporting limit, and this result (0.04 mg/L in November 1996) is substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

None of the groundwater samples had uranium concentrations above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for each groundwater sample show non-detect values or false positive results for all of the VOCs that are confirmed groundwater contaminants in the East Fork Regime.

5.4 GROSS ALPHA ACTIVITY

One groundwater sample had gross alpha activity above the applicable MDA and corresponding CE, and this result (2.79 pCi/L in September 1994) is substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Three groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (5.21 pCi/L in September 1994) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-787

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in September 1992, completed with screened monitored interval from 5.3 to 18.1 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (type 304) riser casing and well screen (0.01 slot wire-wound). The well is clustered with well GW-786 and is located at Comprehensive Monitoring Plan Grid E2, which is in the north-central Y-12 area about 350 ft north of First Street and about 130 ft west of Bldg 9704-2.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twelve groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain ten samples between June 1994 and November 1996, and the low-flow sampling method used to obtain the samples in June and October 2003.

Groundwater samples from the well are conspicuous with regard to their unusual combination of low TDS and acidic pH (see Section 3.0).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Conasauga Group (Maryville Limestone). Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 13 ft bgs and exhibits seasonal fluctuations of about 5 ft.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields calcium-magnesium bicarbonate groundwater generally characterized by:

- extremely low TDS (<100 mg/L), which suggests short groundwater residence time and indicates that the monitored interval in the well intercepts hydraulically active flowpaths;
- pH (field measurements) of 4.8 – 5.7;
- unusually low (<5 mg/L) calcium and magnesium concentrations;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Nitrate concentrations at or above the applicable analytical reporting limit were reported for all but one of the groundwater samples, with each concentration being less than 1 mg/L and substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

None of the groundwater samples had uranium concentrations at or above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, none of the VOCs that are known to be groundwater contaminants at Y-12 were detected in the groundwater samples.

5.4 GROSS ALPHA ACTIVITY

Four groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (8.1 pCi/L in October 2003) being less than the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Gross beta activity above the applicable MDA and corresponding CE was reported for the groundwater samples collected in June 1994 (7.94 pCi/L), August 1995 (3.56 pCi/L), and June 2003 (6.7 pCi/L); each result being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-791

1.0 *INSTALLATION, CONSTRUCTION, AND LOCATION*

This well was installed in September 1992, completed with screened monitored interval from 57.5 to 70.6 ft bgs, and constructed with nominal 4.5-inch diameter steel stainless steel (type 304) riser casing and well screen (0.01 slot wire-wound). The well is clustered with well GW-792 and is located in the northern section of the central Y-12 area, about 170 ft directly south of Bldg. 9212

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-eight groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 13 samples between June 1994 and October 2000, and the low-flow sampling method used to obtain 15 samples between November 1997 and October 2004.

An evaluation of the monitoring data available through August 2000 indicated potential bias related to the groundwater sampling method: (unfiltered) samples obtained with the conventional sampling method had substantially higher contaminant (VOC) concentrations than samples obtained with the low-flow sampling method (AJA 2001). Results of "paired" sampling performed during May and October 2000, when groundwater samples were collected with the low-flow sampling method one day and the conventional sampling method the next day, confirm the apparent sampling-method bias. As shown by the data summarized in Table 1, although both methods yield groundwater samples with similar geochemical characteristics (aside from the higher dissolved oxygen and REDOX for samples obtained with the conventional method), the samples obtained with the low-flow sampling method have significantly lower VOC concentrations than the samples obtained with the conventional sampling method.

Inherent differences in the manner in which each sampling method induces inflow of groundwater into the well may explain the disparity between the conventional and low-flow sampling results for VOCs. Conventional sampling involves purging up to three well volumes of groundwater from the well at about 1-2 gallons per minute, which may substantially lower the water level in the well and induce inflow from water-producing features (i.e., fractures, cavities, conduits) that may not contribute to well recharge under normal conditions. In contrast, low-flow sampling involves purging the well at flow rate low enough (<300 milliliters per minute) to ensure minimal water-level drawdown in the well (<1 ft per quarter hour), which induces groundwater inflow only from the water-producing feature(s) proximal to the monitored interval. Thus, the conventional sampling method has much greater local hydrologic influence (particularly in directions parallel with geologic strike) and substantially increases the relative inflow of VOC-contaminated groundwater into the well.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Maryville Limestone (Conasauga Group). The bulk of the groundwater flow in the Maryville Limestone occurs within this highly permeable zone, which occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into the buried northern tributaries of Upper East Fork Poplar Creek (UEFPC) and other subsurface components of the subsurface drainage system within the highly industrialized areas of Y-12 (DOE 1998). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that stratigraphically overlies the Nolichucky Shale and subcrops along the axis of BCV and the original main channel of UEFPC.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 20 ft bgs and exhibits seasonal fluctuations of about 3 ft. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells the vicinity of well GW-791 indicate south and southeasterly flow toward the Maynardville Limestone and the UEFPC drainage system. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and original main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred flow in directions that parallel geologic strike (i.e., bedding-plane fractures), which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields calcium-magnesium bicarbonate groundwater generally characterized by:

- TDS of 236 – 324 mg/L, excluding suspected outliers in November 1995 (482 mg/L) and April 1996 (108 mg/L);
- pH (field measurements) of 7.1 – 7.9;
- average water temperature (field measurements) above 20 degrees Centigrade, reflects steam condensate discharge points located about 70 ft north (upgradient) of the well;
- low molar proportions chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

The nitrate concentration reported for the groundwater sample collected in September 1994 (0.5 mg/L) exceeds the analytical reporting limit but is an order-of-magnitude below the drinking water MCL for nitrate (10 mg/L) and is probably an analytical artifact.

5.2 URANIUM

None of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

At least one of the following three VOCs was detected in at least one of the groundwater samples collected to date: PCE, TCE, and c12DCE (Table 2). The primary VOC in the samples is PCE, which was detected in each sample, whereas TCE was detected in about half of the samples and c12DCE was detected only in recent samples (June 2003, October 2003, and October 2004). Additionally, several of the PCE results, particularly the results reported for the samples collected during the mid-1990s (Table 2), show that the concentrations exceed 1% of pure-phase solubility for PCE (1,500 μg/L). This suggests that that the PCE may be present as DNAPL in the subsurface near the production complex in the vicinity of Building 9212 (DOE 1998). Conversely, almost all of the TCE and c12DCE concentrations are below 10 μg/L, and many of these results are estimated values below 5 μg/L (Table 2). This suggests little if any natural biodegradation (dechlorination) of the PCE in the groundwater, an interpretation supported by microbiologic sampling results, which indicate minimal microbial activity in the groundwater at this well (AJA 2001). Moreover, as noted in Section 2.0, the VOC concentrations are strongly influenced by the method used to collect the samples. This is illustrated by the "paired" sampling results, which show substantially higher PCE concentrations in the groundwater samples obtained with the conventional sampling method (Table 1).

A time-series plot of the PCE results reported for the groundwater samples obtained with the conventional sampling method shows a generally decreasing concentration trend (Figure 1), with the concentration evident in October 2000 (730 μg/L) being about 80% lower than the concentration evident in September 1994 (3,500 μg/L). A similar plot of the low-flow sampling results for PCE shows an indeterminate or slightly decreasing concentration trend through October 2000 followed by a generally increasing trend (Figure 1), with the PCE concentration reported for the sample collected in May 2003 (1,400 μg/L) being the highest detected in the well since April 1997 (2,100 μg/L).

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity above the applicable MDA and corresponding CE was reported for he groundwater samples collected in September 1994 (1.79 pCi/L), November 1995 (1.73 pCi/L), and May 2000 (2 pCi/L); each result is substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Gross beta activity above the applicable MDA and corresponding CE was reported for he groundwater samples collected in September 1994 (4.25 pCi/L), May 2000 (13 pCi/L), and October 2000 (8.6 pCi/L); each result is substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-795

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1992, completed with a screened monitored interval from approximately 7.5 to 20 ft bgs, and constructed with nominal 4.5-inch stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley (BCV) about one and one-half miles west of Y-12, adjacent to the main channel of Bear Creek just upstream (east) of the confluence with a northern tributary (NT) of the creek (NT-5) that drains the western sections of the Above Grade Low Level Storage Facility (AGLLSF). The AGLLSF is an operating facility used for storage of low-level radioactive wastes.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Seventeen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 15 samples between December 1992 and August 1996, and the low-flow sampling method used to obtain samples in February and August 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the uppermost part of the Nolichucky Shale (Conasauga Group) near the geologic contact with the overlying Maynardville Limestone. The water table interval is a highly permeable zone that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock and transmits the bulk of the groundwater in the Nolichucky Shale. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek, which traverse the Nolichucky Shale from northeast to southwest throughout BCV west of Y-12 and are numbered in ascending order downstream from the headwaters of the creek. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, which is a highly permeable (karst) formation that subcrops beneath the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 4 ft bgs and exhibits moderate (7 ft) seasonal fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-795 indicate flow to the west, parallel with geologic strike (i.e., bedding-plane fractures) in the Nolichucky Shale.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date indicate that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 216 – 316 mg/L;
- pH (field measurements) of 4.5 – 7.6;
- elevated sulfate concentrations (e.g., 19.3 mg/L in February 2004) compared to other wells that yield groundwater from similarly shallow depths in the Nolichucky Shale;

- low molar proportions of chloride, potassium, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date indicate that none of these contaminants are present in the groundwater at this well.

5.1 NITRATE

Four of the groundwater samples collected to date had nitrate concentrations above the analytical reporting limit, with the highest value (5.2 mg/L in October 1993) being below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

All but two of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.004 mg/L in October 1995) being an order-of-magnitude below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, only one of the groundwater samples collected to date contained VOCs: a trace of acetone (1 µg/L) was detected in the sample collected in March 1993. This result is may be an analytical artifact and is considered to be an outlier.

5.4 GROSS ALPHA ACTIVITY

Two of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, and both results (3.24 pCi/L in October 1993 and 1.74 pCi/L in August 1994) are substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Eight of the groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, with the highest value (13.3 pCi/L in October 1995) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-796

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in March 1993, completed with a screened monitored interval from 122.9 to 136.5 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located on the southern flank of Chestnut Ridge directly south of Y-12, about 600 ft northwest (hydraulically upgradient) of Industrial Landfill V, which is an operating disposal facility for nonhazardous solid waste generated from DOE operations on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-eight groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 14 samples between May 1993 and July 1997, and the low-flow sampling method used to obtain 14 samples between January 1998 and July 2004.

The well yields groundwater samples with low TDS (see Section 4.0), which suggests short groundwater residence time and indicates that the monitored interval in the well intercepts hydraulically active flowpaths.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the bedrock interval in the Knox Group. The average static groundwater level in the well is 69 ft below ground surface. Presampling depth-to-water measurements for the well indicate unusually wide (>50 ft) fluctuations in seasonal groundwater surface elevations (Figure 1). The average result of several falling head permeability tests performed in well GW-796 (Jones 2004) indicates that the hydraulic conductivity of the bedrock near the well is about 9.85×10^{-4} cm/s (2.79 ft/day).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 77 – 150 mg/L, excluding a suspected outlier (212 mg/L) in October 1996;
- pH (field measurements) of 6.4 – 9.3;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Eighteen groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.52 mg/L) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Two groundwater samples had uranium concentrations above the applicable analytical reporting limit, and both results (0.001 mg/L in May 1993 and April 1994) are substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Traces of 111TCA (<1 μg/L) have been detected in 21 of the groundwater samples collected from the well. Although the concentrations are very low, the consistent detection of 111TCA suggests that this compound is present in the groundwater at the well and is not an artifact of sample collection, handling, storage, or analysis in the laboratory. Also, the results suggest an indeterminate long-term trend, as illustrated by the 111TCA concentrations evident in March 1994 (1 μg/L), January 1998 (1 μg/L), January 2001 (0.65 μg/L), and January 2004 (0.77 μg/L). The presence of 111TCA in the groundwater at this well most likely reflects transport from the Chestnut Ridge Security Pits (CRSP), which are the only known source of 111TCA and other VOCs hydraulically upgradient of the well, which is about 500 ft directly south of the site. Historical operation of the former waste disposal trenches at the CRSP emplaced an elongated plume of dissolved VOCs in the groundwater that extends more than 2,500 ft east-northeast (parallel with geologic strike), with less extensive transport to the north and south down the flanks of Chestnut Ridge. The elongated geometry of the VOC plume suggests preferred groundwater flow along strike-parallel flowpaths in the Knox Group (e.g., bedding-plane fractures), which may or may not coincide with the direction of maximum hydraulic gradient inferred from groundwater elevation isopleths. Because well GW-796 is hydraulically downgradient of the CRSP across geologic strike, the presence of dissolved VOCs in the well may reflect transport via cross-strike "quickflow" conduits in the Knox Group (Shevenell 1994). This interpretation is supported by the characteristically low levels of dissolved solids in the groundwater from the well (see Section 4) and the results of falling head permeability tests for the well which indicate that the monitored interval for the well intercepts highly permeable groundwater flowpaths (see Section 3). Note that acetone was detected in the samples collected from the well in July 1998 (17 μg/L), January 2000 (8.6 μg/L), and January 2003 (4.3 μg/L); however these results are suspected outliers.

5.4 GROSS ALPHA ACTIVITY

Four groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (3.3 pCi/L in July 2002) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Five groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (22.4 pCi/L January 2001) being below the SDWA screening level for gross beta activity (50 pCi/L). Moreover, the unusually high gross beta activity evident in the sample collected in January 2001 is probably an analytical artifact considering that all the other gross beta results that exceed the MDA are below 3 pCi/L.

WELL GW-797

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in March 1993, completed with a screened monitored interval from 118 to 134.1 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located on the southern flank of Chestnut Ridge directly south of Y-12, about 200 ft directly west (hydraulically downgradient) of Industrial Landfill V, a landfill operated since 1994 and used for disposal of nonhazardous and nonradioactive combustible and decomposable solid waste generated from DOE operations on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-nine groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 14 samples between May 1993 and July 1997, and the low-flow sampling method used to obtain 15 samples between January 1998 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the bedrock interval in the Knox Group (Copper Ridge Dolomite). The average static groundwater level in the well is about 65 ft bgs. Presampling depth-to-water measurements for the well indicate substantial (10 - 25 ft) water-level fluctuations, which is typical of many wells in the Knox Group on Chestnut Ridge. The average result of several falling head permeability tests performed in well GW-797 (Jones 2004) indicates that the hydraulic conductivity of the bedrock near the well is about 2.9×10^{-5} cm/s (0.08 ft/day).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 146 – 300 mg/L;
- pH (field measurements) of 6.5 – 9.0;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Nineteen groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (1.4 mg/L in July 2004) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

One groundwater sample had a uranium concentration above the applicable analytical reporting limit, and this result (0.001 mg/L in July 1994) is substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected in five groundwater samples: carbon disulfide in August 1993 (1 μg/L) and July 2004 (0.33 μg/L); acetone in April 1995 (21 μg/L), February 2000 (9.3 μg/L), and July 2001 (2 μg/L); and chloromethane in July 2001 (0.41 μg/L). These sporadic detections are considered sampling or analytical artifacts.

5.4 GROSS ALPHA ACTIVITY

Three groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (2.65 pCi/L in March 1994) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Two groundwater samples had gross beta activity above the applicable MDA and corresponding CE, and both results (4.17 pCi/L in March 1994 and 2.74 pCi/L in October 1994) are substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-798

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in March 1993, completed with a screened monitored interval from 122 to 135.4 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located on the southern flank of Chestnut Ridge directly south of Y-12, about 100 ft northeast (hydraulically upgradient) of Construction/Demolition Landfill VII, is an operating disposal facility for nonhazardous solid waste generated from DOE operations on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-eight groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 13 samples between June 1993 and July 1997, and the low-flow sampling method used to obtain 25 samples between January 1998 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the bedrock interval in the Knox Group (Chepultepec Dolomite). The average static groundwater level in the well is 72 ft below ground surface. Presampling depth-to-water measurements for the well indicate unusually wide (>40 ft) water level fluctuations (Figure 1). However, excluding the unusually high groundwater elevations evident in March 1994 (957 ft above msl) and April 1994 (962 ft above msl), water levels fluctuations are typically less than 20 ft. In either case, large seasonal and episodic groundwater elevation fluctuations are characteristic of many wells in karst aquifers such as the Knox Group. The average result of several falling head permeability tests performed in well GW-798 (Jones 2004) indicates that the hydraulic conductivity of the bedrock near the well is about 1.19×10^{-3} cm/s (3.38 ft/day).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 92 – 330 mg/L;
- pH (field measurements) of 6.4 – 8.2;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Twenty-eight groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (1 mg/L) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

One groundwater samples had a uranium concentration above the applicable analytical reporting limit, and this result (0.001 mg/L) is substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

One or more of the following VOCs were detected in 20 of the groundwater samples collected from the well since January 2000: PCE, TCE, c12DCE, 11DCE, 111TCA, 11DCA, CTET, chloromethane, and TCFM. Historical data show that individual VOC concentrations are relatively low, ranging from less than 1 µg/L (CTET and chloromethane) to more than 10 µg/L (PCE and TCFM), with PCE concentrations at or above the MCL (5 µg/L) reported for each groundwater sample collected from January 2002 to January 2004. As illustrated by the data for PCE (Figure 2), 111TCA (Figure 3), and TCFM (Figure 4), VOC concentrations have steadily increased following their initial detection, with the historical peak summed VOC concentrations evident in January 2003 (58 µg/L). Note that the concentrations of each compound show a decreasing trend since January 2003, possibly suggesting that a "pulse" of dissolved VOCs has been transported along the groundwater flowpaths intercepted by the monitored interval in the well. The Chestnut Ridge Security Pits (CRSP) are the only known source of VOCs hydraulically upgradient of the well, which is about 1,500 ft east-southeast of the site, and VOC concentrations in each well located near the CRSP have decreased substantially since closure of the site. Historical operation of the former waste disposal trenches at the CRSP emplaced an elongated plume of dissolved VOCs in the groundwater that extends more than 2,500 ft east-northeast (parallel with geologic strike), but only about 500 ft to the north and south down the flanks of Chestnut Ridge. The geometry of the VOC plume suggests preferred groundwater flow along strike-parallel flowpaths in the Knox Group (e.g., bedding-plane fractures), which may or may not coincide with the direction of maximum hydraulic gradient inferred from groundwater elevation isopleths. Because well GW-798 is hydraulically downgradient of the CRSP across geologic strike, the presence of dissolved VOCs in the well may reflect transport via cross-strike "quickflow" conduits in the Knox Group (Shevenell 1994).

5.4 GROSS ALPHA ACTIVITY

Four groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (3.76 pCi/L in March 1994) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Eleven groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (6.41 pCi/L in January 2003) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-799

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in March 1993, completed with a screened monitored interval from 78.7 to 92 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located on the southern flank of Chestnut Ridge directly south of Y-12, about 200 ft southeast (hydraulically downgradient) of Industrial Landfill V, a landfill operated since 1994 and used for disposal of nonhazardous and nonradioactive combustible and decomposable solid waste generated from DOE operations on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-eight groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 14 samples between May 1993 and July 1997, and the low-flow sampling method used to obtain 14 samples between January 1998 and July 2004.

This well yields groundwater samples with low TDS (see Section 4.0), which suggests short groundwater residence time and indicates that the monitored interval in the well intercepts hydraulically active flowpaths.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the bedrock interval in the Knox Group (Chepultepec Dolomite). The average static groundwater level in the well is about 9 ft bgs. Presampling depth-to-water measurements for the well indicate substantial (10 - 25 ft) water-level fluctuations, which is typical of many Knox Group wells on Chestnut Ridge. The average result of several falling head permeability tests performed in well GW-799 (Jones 2004) indicates that the hydraulic conductivity of the bedrock near the well is about 1.56×10^{-4} cm/s (0.44 ft/day).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 118 – 184 mg/L;
- pH (field measurements) of 6.6 – 8.5;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Twenty-seven groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (2.885 mg/L in July 1999) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Six groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.002 mg/L in April 1994) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected in five groundwater samples: acetone in July 1997 (23 µg/L), July 1998 (2 µg/L), January 2000 (31 µg/L), January 2003 (3.6 µg/L), and January 2004 (9.5 µg/L). Additionally, very low levels of 2-butanone (2 µg/L in July 1998) and chloromethane (0.26 µg/L in January 2003) have been reported for two of these samples. Acetone and 2-butanone are common laboratory reagents, and these results may be sampling or analytical artifacts.

5.4 GROSS ALPHA ACTIVITY

Two groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, and both results (3.4 pCi/L in July 1999 and 1.6 pCi/L in January 2002) are substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

None of the groundwater samples had gross beta activity above the applicable MDA and corresponding CE.

WELL GW-801

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in July 1993, completed with a screened monitored interval from 175.8 to 188.9 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located on the southern flank of Chestnut Ridge directly south of Y-12, about 200 ft southwest (hydraulically downgradient) of Industrial Landfill V, a landfill operated since 1994 and used for disposal of nonhazardous and nonradioactive combustible and decomposable solid waste generated from DOE operations on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-eight groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 13 samples between July 1993 and July 1997, and the low-flow sampling method used to obtain 15 samples between January 1998 and July 2004.

This well yields groundwater samples with low TDS (see Section 4.0), which suggests short groundwater residence time and indicates that the monitored interval in the well intercepts hydraulically active flowpaths.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the bedrock interval in the Knox Group (Chepultepec Dolomite). The average static groundwater level in the well is about 102 ft bgs, and presampling depth-to-water measurements for the well suggest wide (>30 ft) water-level fluctuations (Figure 1). The average result of several falling head permeability tests performed in well GW-801 (Jones 2004) indicates that the hydraulic conductivity of the bedrock near the well is about 1.77×10^{-4} cm/s (0.5 ft/day).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 78 – 170 mg/L;
- pH (field measurements) of 7.4 – 8.4;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Eighteen groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (1.6 mg/L in January 2003) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

None of the groundwater samples had uranium concentrations above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected at low (estimated) levels in three groundwater samples: 111TCA (4 μg/L) in January 1998; 2-butanone (2 μg/L) in July 1998; and carbon disulfide (0.25 μg/L) in July 2004. These single detections may be sampling or analytical artifacts and are considered to be outliers.

5.4 GROSS ALPHA ACTIVITY

Three groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, and the highest result (2.3 pCi/L in March 1994) is substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Three groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (13.5 pCi/L in April 1996) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-802

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in June 1993, completed with a screened monitored interval from 13.3 to 26.5 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and PVC (#40) well screen (0.01 slot). The well is in Bear Creek Valley near the east end of Y-12, about 200 ft south-southeast (hydraulically downgradient across geologic strike) of the Bldg. 9754-2 Fuel Facility, and is flush-mounted in the asphalt pavement near the intersection of First Street and Agate Drive.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Five groundwater samples were collected from the well between March 1997 and May 2004 using the conventional sampling method and a peristaltic pump.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Nolichucky Shale). The average static groundwater level in the well is 6 ft bgs. Presampling depth-to-water measurements for the well indicate minimal (<1 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

Data regarding the geochemical characteristics of the groundwater in the well are not available (groundwater samples from the well have not been analyzed for the primary anions and cations). Also, the required analyses have not been performed to determine if the trace metals concentrations in the well are below respective analytical reporting limits or within the range of background levels in groundwater at Y-12.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Groundwater samples from this well have not been analyzed for nitrate.

5.2 URANIUM

Only one groundwater sample (March 1997) was analyzed for uranium and the concentration did not exceed the analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Of the five groundwater samples analyzed for VOCs, only acetone was detected (8 μg/L) in the sample collected in July 1998. This result is considered to be an outlier.

5.4 GROSS ALPHA ACTIVITY

One groundwater sample was analyzed for gross alpha activity (March 1997), and the result for this sample (117 pCi/L) is substantially higher than the MCL for gross alpha activity (15 pCi/L). However, the high gross alpha value is not supported by the U-234 (1.13 pCi/L) and U-238 (0.65 pCi/L) activities reported for this groundwater sample (uranium isotopes are the most likely radiological contaminants in the well).

5.5 GROSS BETA ACTIVITY

One groundwater sample was analyzed for gross beta activity (March 1997), and the result for this sample (47.2 pCi/L) is just below the SWDA screening level for gross beta activity (50 pCi/L). Notably, this sample also was analyzed for technetium-99 activity and the result was less than the MDA.

WELL GW-816

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in June 1994, completed with a screened monitored interval from 2.9 to 15.8 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with wells GW-207 and GW-208 and is located near Scarboro Road about 50 ft east of the section of Upper East Fork Poplar Creek that passes through a gap in Pine Ridge directly northeast of Y-12.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-six groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 11 samples between September 1994 and April 1997, and the low-flow sampling method used to obtain 15 samples between December 1997 and November 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Rome Formation. The average static groundwater level in the well is about 9 ft bgs. Presampling depth-to-water measurements for the well indicate moderate fluctuations (<4 ft) in seasonal groundwater surface elevations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 156 – 306 mg/L, excluding an outlier (128 mg/L) in September 1996;
- pH (field measurements) of 6.3 – 7.0;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Three groundwater samples had nitrate concentrations above the analytical reporting limit, with the highest concentration (0.52 mg/L in November 1994) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Two groundwater samples had uranium concentrations above the analytical reporting limit, with the highest concentration (0.00124 mg/L in May 2001) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, acetone was detected in one sample (5 µg/L in June 1995) and the result is a suspected analytical artifact.

5.4 GROSS ALPHA ACTIVITY

Six of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest activity (5.34 pCi/L in September 1994) being below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Twelve of the groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest activity (16.1 pCi/L in September 1994) being below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-818

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

The date for installation of this well is not known, but available information show that the well was completed with a screened monitored interval to a total depth of about 12 ft bgs, and is constructed with nominal 4.5-inch diameter PVC riser casing. The well is located in Bear Creek Valley (BCV) in the east-central section of Y-12, on the north side of the main channel of Upper East Fork Poplar Creek (UEFPC) near the southeast corner of Building 9201-2. This well was plugged and abandoned in April 2004.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Two groundwater samples have been collected from the well to date, with the low-flow sampling method used to obtain samples in March 1998 and February 2004.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Maynardville Limestone (upper Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 8 ft bgs. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-818 indicate flow primarily to the east, parallel with geologic strike in the Maynardville Limestone and the exposed portion of the UEFPC channel. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local groundwater flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998).

4.0 GEOCHEMCICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date indicate that the well yields sulfate-enriched, calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 337 – 387 mg/L;
- pH of 6.7 – 7.1 (field measurements);
- negative oxidation-reduction potential (REDOX) and low dissolved oxygen (DO) indicative of reducing conditions (REDOX = -72mV and DO = 0.09 ppm in February 2004);
- elevated concentrations (>75 mg/L) of sulfate relative to other wells of similar depth in the Maynardville Limestone;
- low molar proportions of chloride, potassium, and sodium (<10% of total anions/cations);
- unusually high total (unfiltered concentrations) of iron (>9 mg/L) and manganese (>1 mg/L); and

- total concentrations of other trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, none of the principal contaminants are generally present in the groundwater at this well.

5.1 NITRATE

One of the groundwater samples collected to date had nitrate concentrations at or above the analytical reporting limit, and this result (0.481 mg/L in March 1998) is an order-of-magnitude below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Both groundwater samples collected to date had total uranium concentrations above the applicable analytical reporting limit, with the highest value (0.005 mg/L in March 1998) being an order-of-magnitude below the drinking water MCL for total uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

The groundwater sample collected in March 1998 contained low concentrations of TCE (6 μg/L) and c12DCE (1 μg/L); no VOCs were detected in the groundwater sample collected in February 2004.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA.

WELL GW-820

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

Documentation regarding the installation date and construction details for this well is not available; the well has nominal 4.5-inch PVC (#40) riser casing and is completed at a depth of 17.3 ft bgs. The well is located in the eastern part of Y-12 near the southwest corner of Bldg. 9201-2.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Six groundwater samples were collected from the well between March 1998 and October 2003, all of which were obtained using the low-flow sampling method.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Conasauga Group (Maynardville Limestone). Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 10 ft bgs and exhibits minimal (<1 ft) seasonal fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields chloride- and sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- moderate TDS (>300 mg/L);
- pH (field measurements) of 7.1 – 7.5;
- unusually high concentrations of chloride (>20 mg/L) and sulfate (>30 mg/L) compared to other wells that yield groundwater from similar depths in the Maynardville Limestone;
- low molar proportions of potassium and sodium (<10% of total anions/cations); and
- total concentrations of trace metals (except iron and manganese) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The unusually high chloride and sulfate concentrations in the groundwater samples may reflect local geochemical conditions or contamination from one or more sources within Y-12, including numerous potential non-specific sources such as leaking industrial process lines, sanitary sewers, or storm drains. Additionally, the elevated chloride levels may be a consequence of the biologically mediated degradation (dechlorination) of the chlorinated hydrocarbons in the groundwater (Hinchee et al. 1995). As shown by the data summarized in Table 1, the groundwater in the well exhibits geochemical conditions (aside from the elevated sulfate levels) that are favorable to the biotic degradation of chlorinated hydrocarbons.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Nitrate was not detected in the groundwater samples.

5.2 URANIUM

Uranium was not detected in the groundwater samples.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample (Table 2): PCE, TCE, 11DCA, 11DCE, c12DCE, and VC. The source of these VOCs has not been confirmed, but the concentrations of PCE exceed 1% of pure-phase solubility (1,500 μg/L), which suggests that PCE may be present as DNAPL in the subsurface near the western (upgradient) end of Bldg. 9201-2 (DOE 1998). Additionally, the high concentrations of c12DCE potentially result from the biotic degradation of the PCE and TCE, with very low dissolved oxygen and strongly negative REDOX (see Table 1) suggesting the strongly reducing (methanogenic) conditions necessary to transform 12DCE isomers to VC (Chapelle 1996), which may account for the high VC concentrations in the groundwater.

The primary VOCs in the groundwater samples are PCE and c12DCE, which have been detected in each sample and have historical maximum concentrations above 5,000 μg/L and 2,500 μg/L, respectively (Table 2). Also, the most recent sampling results show that the concentrations of both compounds remain several orders-of-magnitude higher than respective MCLs. Secondary VOCs in the samples are TCE and VC, which also were detected in each sample, with the highest concentrations of both compounds reported for the samples collected in June 2003 (TCE = 1,100 μg/L) and October 2003 (VC = 220 μg/L). Other compounds have been detected at substantially lower concentrations (Table 2), the highest being reported for t12DCE (16 μg/L), although the most recent results show concentrations of 11DCE at or slightly above the MCL (7 μg/L).

A time-series plot of the summed concentrations of VOCs detected in each groundwater sample shows a generally indeterminate long-term trend that is probably an artifact of the relatively limited sampling history for the well, which encompasses a total of six samples collected between March 1998 and October 2003 (Figure 1). Also, the concentrations of individual compounds show divergent temporal changes. For example, the concentration of PCE evident in June 2003 (6,500 μg/L) is about 30% higher than the PCE concentration in October 2003 (5,000 μg/L), whereas the concentration of c12DCE in June 2003 (1,900 μg/L) is about 50% lower than the c12DCE concentration in October 2003 (2,800 μg/L). Additionally, the results for several compounds, particularly c12DCE and VC, suggest clearly increasing long-term concentration trends (Table 2). In general, the PCE concentration trend is similar to the TCE trend, and the c12DCE concentration trend is similar to the VC trend (Figure 2). The mechanism(s) governing wide temporal concentration fluctuations and the significance of the long-term concentration trends, considering the limited sampling history for the well, are not characterized by available data.

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity above the applicable MDA and corresponding CE was reported for the groundwater sample collected in June 2000 (2 pCi/L); this result is substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Gross beta activity above the applicable MDA and corresponding CE was reported for the groundwater sample collected in June 2000 (8.2 pCi/L); this result is substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-827

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in January 1995, completed with a screened monitored interval from 122.1 to 134.8 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located on the southern flank of Chestnut Ridge directly south of Y-12 (unless noted otherwise, directions are in reference to the Y-12 grid system), about 200 ft north (hydraulically upgradient) of Construction/Demolition Landfill VI. This closed landfill operated from 1994 to 2003 and received nonhazardous and nonradioactive solid wastes, including construction spoil (concrete, wood, metal, plastic, and roofing material) and soil wastes, generated from DOE operations on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-two groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain six samples between April 1995 and April 1997, and the low-flow sampling method used to obtain 16 samples between October 1997 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the bedrock interval in the Knox Group (Chepultepec Dolomite). The average static groundwater level in the well is 38 ft bgs. Presampling depth-to-water measurements for the well indicate substantial (17 ft) water-level fluctuations, which is typical of many Knox Group wells on Chestnut Ridge. The result of a falling head permeability test performed in well GW-827 (Jones 2004) indicates that the hydraulic conductivity of the bedrock near the well is about 5.91×10^{-4} cm/s (1.7 ft/day).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 130 – 192 mg/L;
- pH (field measurements) of 6.9 – 8;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Seventeen groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.67 mg/L in April 1998) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Five groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.000764 mg/L in October 1999) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, a trace of toluene was detected in one sample (1.4 µg/L in February 2000) and the result is a suspected analytical artifact.

5.4 GROSS ALPHA ACTIVITY

One groundwater sample had gross alpha activity above the applicable MDA and corresponding CE, and this result (0.962 pCi/L in July 2000) is substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Three groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (4.4 pCi/L in January 2002) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-831

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in July 1996, completed with a screened monitored interval from 182 to 199.6 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well serves RCRA plume delineation monitoring purposes and is located on the southern flank of Chestnut Ridge, about 2000 ft southwest of the Chestnut Ridge Security Pits (CRSP). The CRSP include two contiguous former waste disposal areas, each consisting of a series of unlined, east-west oriented trenches that were about 8 to 10 ft wide, 10 to 18 ft deep, and 700 to 800 ft long. Beginning in 1973, the disposal trenches at the site received a variety of hazardous waste until December 1984 and nonhazardous wastes until November 1988. All the disposal trenches are covered by a multi-layer low-permeability cap installed during RCRA closure of the site in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Eighteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain four samples between August 1996 and July 1997, and the low-flow sampling method used to obtain 14 samples between January 1998 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the bedrock interval in the Knox Group (Kingsport Formation/Longview Dolomite). The average static groundwater level in the well is 125 ft bgs. Presampling depth-to-water measurements for the well indicate substantial (10 - 25 ft) water-level fluctuations, which is typical of many Knox Group wells on Chestnut Ridge.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 139 – 230 mg/L;
- pH (field measurements) of 6.9 – 8.8;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Four groundwater samples (between August 1996 and January 1999) had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.072 mg/L in January 1997) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Four groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.0021 mg/L in July 1998) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, a trace of acetone was reported for one sample (2 µg/L in July 1998), and the result is a suspected analytical artifact.

5.4 GROSS ALPHA ACTIVITY

Seven groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (4.31 pCi/L in January 2001) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Seven groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (16.9 pCi/L in July 2001) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-832

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in May 1996, completed with a screened monitored interval from 4 to 11.8 ft bgs, and constructed with nominal 6.5-inch diameter PVC (#40) riser casing and well screen (0.02 slot). The well is in Bear Creek Valley near the east end of Y-12 and intercepts the gravel underdrain Upper East Fork Poplar Creek (UEFPC) distribution channel at the southeast corner of Lake Reality. Lake Reality is a lined surface impoundment that was built in 1988 to replace New Hope Pond, an unlined surface impoundment built in 1963 to help regulate the quantity and quality of surface water exiting Y-12 via UEFPC.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Seventeen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain samples in May 1996, April 1997, and August 1997 and the low-flow sampling method used to obtain 14 samples between February 1998 and August 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from a gravel underdrain beneath the UEFPC distribution channel. The underdain appears to function as a highly permeable groundwater flowpath and a constant head recharge boundary and strongly influences local groundwater flow patterns (SAIC 1998). Presampling depth-to-water measurements for the well show that the average static groundwater level is about 8 ft below ground surface and exhibits minor water-level fluctuations (<2 ft). This well served as the pumping well for a short-term aquifer pumping test performed in May 1995, the results of which demonstrated a direct hydraulic connection between the well and the Lake Reality Sump (SAIC 1998).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- pH (field measurements) of 6.7 – 8.1;
- low molar proportions of potassium and sodium (<10% of total anions/cations);
- unusually high concentrations of chloride (>20 mg/L) and sulfate (>30 mg/L); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Seventeen groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (4.4 mg/L in August 2000) being below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Ten groundwater samples were analyzed for uranium and concentrations above the applicable analytical reporting limit were reported for seven samples, with the highest concentration (0.0166 mg/L in July 2001) being below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

One or more of the following VOCs confirmed as groundwater contaminants in the East Fork Regime were detected in all but one of the groundwater samples from this well: CTET, chloroform, PCE, and TCE. Of these, CTET is the dominant compound, with concentrations ranging from 6 µg/L in August 2002 to 44 µg/L in February and August 1999. Concentrations of the other compounds are all below 10 µg/L, although the PCE concentrations evident in May 1996 (6 µg/L), February 1998 (7 µg/L), February 1999 (6 µg/L), August 1999 (6 µg/L), July 2001 (6 µg/L), and February 2004 (6 µg/L) slightly exceed the MCL (5 µg/L). These PCE results also reflect an indeterminate long-term concentration trend, as illustrated by the summed concentrations of VOCs detected in each sample from the well (Figure 1). The indeterminate concentration trend suggests that the CERCLA East End VOC Plume Intercept Action has not yet influenced the migration/transport of contaminants in the UEFPC distribution channel underdrain (DOE 2002).

5.4 GROSS ALPHA ACTIVITY

Fifteen groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (11.67 pCi/L in February 2003) being slightly below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Fourteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (11.49 pCi/L in July 1998) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-835

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in July 1996, completed with a screened monitored interval from 16.2 to 19.2 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and well screen. The well is located in Bear Creek Valley west of Y-12, on the north side of Bear Creek about 800 ft southeast (hydraulically downgradient) of the former S-3 Ponds, which are a major source of groundwater contamination in Bear Creek Valley. Located at the headwaters of Bear Creek, the S-3 Ponds consisted of four unlined surface impoundments, each with a 2.5 million gallon capacity, that were used between 1951 and 1984 for the disposal of acidic, radioactive liquid wastes generated primarily at Y-12. The S-3 Ponds were covered with a multi-layer, low permeability cap (including asphalt paving) during RCRA closure of the site in 1988.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-one groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain the initial sample from the well in April 1997 and 20 samples obtained with the low-flow sampling method between October 1997 and August 2003.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Maynardville Limestone). The Maynardville Limestone underlies Bear Creek throughout the Bear Creek Regime and most groundwater flow in the formation occurs at shallow depths (<100 ft bgs) in an extensively interconnected network of solution conduits and cavities (shallow karst network). Hydraulic interactions between Bear Creek and the shallow karst network provide the primary exit-pathways for groundwater and surface water contaminants originating from source areas in Bear Creek Valley west of Y-12. The average static groundwater level in the well is about 12 ft below ground surface. Presampling depth-to-water measurements for the well indicate moderate water-level fluctuations (<10 ft).

An aquifer pumping test performed in November 1996 involved pumping groundwater from well GW-835 and monitoring the water level in nine nearby piezometers (LMES 1997). A constant water level drawdown (about 4 ft below static level) was achieved in well GW-835 at a pumping rate of about 6 liters per minute. The pumping test continued for about nine hours and little response was noted in the observation piezometers.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- pH (field measurements) of 6.1 – 6.8;
- low molar proportions of potassium and sodium (<10% of total anions/cations);
- unusually high concentrations of chloride (>20 mg/L) and sulfate (>100 mg/L); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Groundwater at this well is contaminated by nitrate that originates from the contaminant plume emplaced during operation of the former S-3 Ponds. Available data for the well show a wide range of nitrate concentrations, with a minimum value of 0.621 mg/L in January 1998 and a maximum value of 128 mg/L in April 1997. Nitrate concentrations in the well appear to fluctuate seasonally (Figure 1), with higher nitrate levels typically evident during seasonally low flow conditions (summer and fall). Although skewed by the highest and lowest values, the nitrate data for the well suggest a decreasing long-term concentration trend, punctuated by a sharp concentration "spike" in August 1998 (97.2 mg/L), with relatively stable concentrations just above and below the MCL (10 mg/L) evident since May 2002 (Figure 1).

5.2 URANIUM

Groundwater at this well is contaminated by uranium that originates from the contaminant plume emplaced during operation of the former S-3 Ponds. Available data for the well show (total) uranium concentrations ranging from 0.62 mg/L in January 1998 to 1.92 mg/L in May 2001; all of these results exceed the MCL for uranium (0.03 mg/L). As shown on Figure 2, the uranium concentrations in the well do not appear to fluctuate and the long-term concentration trend is dominated by a series of concentration "spikes" evident in October 1997 (1.22 mg/L), June 2000 (1.07 mg/L), and May 2001 (1.92 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Groundwater at this well is contaminated by a mixture of dissolved VOCs that originate from the contaminant plume emplaced during operation of the former S-3 Ponds. Compounds detected in the groundwater samples from the well include acetone, benzene, PCE, TCE, and c12DCE. Acetone has been detected at the highest concentration (68 μg/L), but PCE has been detected the most frequently (16 of 21 samples), with PCE concentrations at or above the MCL (5 μg/L) reported for the samples collected in October 1997 (9.6 μg/L), November 2000 (5 μg/L), and May 2001 (5 μg/L). As illustrated by summed VOC concentrations (Figure 3), the available data suggest an indeterminate long-term trend near 5 μg/L that is punctuated by sharp "spikes" attributable to high concentrations of acetone detected in the samples collected by December 1997 (68 μg/L), January 1998 (29 μg/L), and June 2003 (20 μg/L).

5.4 GROSS ALPHA ACTIVITY

Groundwater at this well is contaminated by alpha-emitting radioisotopes that originate from the contaminant plume emplaced during operation of the former S-3 Ponds. Six of the groundwater samples from this well were analyzed for gross alpha activity and the results for these samples show gross alpha levels that substantially exceed the MCL (15 pCi/L), with the lowest level reported for the sample collected in February 1998 (51 pCi/L) and the highest level reported for the sample collected in April 1997 (315 pCi/L). In addition to or in lieu of gross alpha activity, 16 of the groundwater samples collected from the well were analyzed for uranium isotopes. Analytical results for these samples show U-234 and U-238 levels above the applicable MDA and corresponding CE, with U-234 values of 37 to 177 pCi/L and the U-238 values of 91 to 472 pCi/L. Also, data for both isotopes suggest increasing long-term concentration trends (Figure 4), which is somewhat surprising in light of the decreasing long-term trend evident for nitrate.

5.5 GROSS BETA ACTIVITY

Six of the groundwater samples from this well were analyzed for gross beta activity and the results for these samples show gross beta levels that substantially exceed the SDWA screening level (50 pCi/L), with the lowest level reported for the sample collected in January 1998 (108 pCi/L) and the highest level reported for the sample collected in April 1997 (315 pCi/L). The primary beta-emitting radioisotope in the groundwater at the well is probably Tc-99, which is a principal component of the contaminant plume emplaced during operation of the former S-3 Ponds and is highly mobile in groundwater. However, none of the groundwater samples collected from the well to date have been analyzed for Tc-99. Gross beta activity in the groundwater at the well also reflects contributions from applicable related daughter products (e.g., Th-234) of U-238 in the groundwater.

WELL GW-916

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in January 2001, completed with a screened monitored interval from 13 to 36 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located in Bear Creek Valley on the northeast side of the Environmental Management Waste Management Facility (EMWMF). Located about 1.5 miles west of Y-12, the EMWMF is a hazardous and mixed-waste landfill that began operation in June 2002 as a disposal site for wastes generated from CERCLA remedial actions on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fourteen groundwater samples were collected from the well to date, all of which were obtained with the low-flow sampling method between April 2001 and November 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the lower Conasauga Group (undifferentiated). The average static groundwater level in the well is about 6 ft below the top of the well casing. Presampling depth-to-water measurements for the well indicate moderate fluctuations (<10 ft) in seasonal groundwater surface elevations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- pH (field measurements) of 6.7 – 7.7;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Four groundwater samples were analyzed for nitrate (between April and December 2001). Results that exceed the analytical reporting limit were reported for each of these samples, with the highest concentration (0.19 mg/L in April 2001) being below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Five groundwater samples were analyzed for uranium and the uranium results for these samples do not exceed the corresponding analytical reporting limits.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected in two groundwater samples. The sample collected in September 2003 had low levels of PCE (2 μg/L) and TCE (10 μg/L), and the sample collected in September 2004 had a trace of TCE (0.2 μg/L).

5.4 GROSS ALPHA ACTIVITY

Each groundwater sample was analyzed for alpha-emitting radionuclides, including U-234 and U-238. Twelve of the samples had U-234 or U-238 activity above the MDA and corresponding CE, with the highest activity for either isotope (U-234 = 1.57 pCi/L in April 2001) being within the range of background levels in Bear Creek Valley.

5.5 GROSS BETA ACTIVITY

Each groundwater sample was analyzed for beta-emitting radionuclides, including Tc-99. The Tc-99 activity reported for each sample does not exceed the MDA and corresponding CE.

WELL GW-917

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in January 2001, completed with a screened monitored interval from 18 to 51 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located in Bear Creek Valley, about 200 ft east of the Environmental Management Waste Management Facility. Located about 1.5 miles west of Y-12, the EMWMF is a hazardous and mixed-waste landfill that began operation in June 2002 as a disposal site for wastes generated from CERCLA remedial actions on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fourteen groundwater samples have been collected from the well since April 2001, all of which were obtained with the low-flow sampling.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Maryville Limestone). The average static groundwater level in the well is about 21 ft below the top of the well casing. Presampling depth-to-water measurements for the well indicate moderate fluctuations (<6 ft) in seasonal groundwater surface elevations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- pH (field measurements) of 5.9 – 7.5;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Four of the groundwater samples were analyzed for nitrate. Results that exceed the analytical reporting limit were reported for three samples, with the highest concentration (0.99 mg/L in August 2001) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Five of the groundwater samples were analyzed for uranium and the uranium results for these samples do not exceed the corresponding analytical reporting limits.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, a trace of acetone (0.4 µg/L) was detected in one groundwater sample (September 2003). This result is probably a sampling or analytical artifact.

5.4 GROSS ALPHA ACTIVITY

Each groundwater sample was analyzed for alpha-emitting radionuclides, including U-234 and U-238. Ten samples had U-234 or U-238 activity above the MDA and corresponding CE, with the highest activity for either isotope (U-234 = 1.16 pCi/L in February 2003) being within the range of background levels in Bear Creek Valley.

5.5 GROSS BETA ACTIVITY

Each groundwater sample was analyzed for beta-emitting radionuclides, including Tc-99. The Tc-99 activity reported for each sample does not exceed the MDA and/or CE.

WELL GW-918

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in February 2001, completed with a screened monitored interval from 18 to 33 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located in Bear Creek Valley, about 300 ft north (hydraulically upgradient) of the Environmental Management Waste Management Facility. Located about 1.5 miles west of Y-12, the EMWMF is a hazardous and mixed-waste landfill that began operating in June 2002 as a disposal site for wastes generated from CERCLA remedial actions on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fourteen groundwater samples have been collected from the well since April 2001, all of which were obtained with the low-flow sampling.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the lower Conasauga Group (undifferentiated). The average static groundwater level in the well is about 6 ft 21 ft below the top of the well casing. Presampling depth-to-water measurements for the well indicate minor water-level fluctuations (<2 ft).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- pH (field measurements) of 5.6 – 6.7;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Four groundwater samples were analyzed for nitrate. Results that exceed the analytical reporting limit were reported for one sample (0.17 mg/L in December 2001) and this result is substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Five of the groundwater samples were analyzed for uranium and the uranium results for these samples do not exceed the corresponding analytical reporting limits.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, trace levels of TCE (0.4 μg/L) and toluene (0.3 μg/L) were detected in one groundwater sample (September 2004). This significance of these results is questionable because neither compound was detected in the subsequent quarterly sample (November 2004).

5.4 GROSS ALPHA ACTIVITY

Each groundwater sample was analyzed for alpha-emitting radionuclides, including U-234 and U-235. Seven samples had U-234 or U-235 activity above the MDA and corresponding CE, with the highest activity for either isotope (0.96 pCi/L in December 2001) being less than 1 pCi/L.

5.5 GROSS BETA ACTIVITY

Each groundwater sample was analyzed for beta-emitting radionuclides, including Tc-99. The Tc-99 activity reported for each sample does not exceed the MDA and corresponding CE.

WELL GW-919

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 2001, completed with a screened monitored interval from 11.6 to 32 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located in Bear Creek Valley on the east side (hydraulically downgradient) of the Environmental Management Waste Management Facility. Located about 1.5 miles west of Y-12, the EMWMF is a hazardous and mixed-waste landfill that began operating in June 2002 as a disposal site for wastes generated from CERCLA remedial actions on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Seven groundwater samples have been collected from the well since December 2001, all of which were obtained with the low-flow sampling method.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Maryville Limestone). The average static groundwater level in the well is –0.3 ft above the ground surface, indicating artesian conditions. Presampling depth-to-water measurements for the well indicate minor water-level fluctuations (<3 ft).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- moderate TDS (>150 mg/L<800 mg/L);
- pH (field measurements) of 6.8 – 7.4;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Only one of the groundwater samples was analyzed for nitrate, and the nitrate result for this sample did not exceed the analytical reporting limit.

5.2 URANIUM

Only two of the groundwater samples were analyzed for uranium, and neither of these uranium results exceeds the analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for six groundwater samples show non-detect values or false positive results for all of the VOCs that are confirmed groundwater contaminants in the Bear Creek Regime. A sample collected in September 2003 had a trace of acetone (0.5 μg/L), which is probably a sampling or analytical artifact.

5.4 GROSS ALPHA ACTIVITY

Each groundwater sample was analyzed for alpha-emitting radionuclides, including U-234 and U-235. Six samples had U-234 or U-235 activity above the MDA and corresponding CE, with the highest activity for either isotope (2.14 pCi/L in December 2001) being within the range of background levels in Bear Creek Valley.

5.5 GROSS BETA ACTIVITY

Each groundwater sample was analyzed for beta-emitting radionuclides, including Tc-99. The Tc-99 activity reported for each sample does not exceed the MDA and/or CE.

WELL GW-920

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in January 2001, completed with a screened monitored interval from 22 to 55 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is in Bear Creek Valley about 300 ft south (hydraulically downgradient) of the Environmental Management Waste Management Facility (EMWMF). Located about 1.5 miles west of Y-12, the EMWMF is a hazardous and mixed-waste landfill that began operating in June 2002 as a disposal site for wastes generated from CERCLA remedial actions on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fourteen groundwater samples have been collected from the well since April 2001, all of which were obtained with the low-flow sampling.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the shallow bedrock interval in the Conasauga Group (Nolichucky Shale). The average static groundwater level in the well is 8 ft below the top of the well casing. Presampling depth-to-water measurements for the well indicate minor water-level fluctuations (<5 ft).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- pH (field measurements) of 5.9 – 8.1;
- low molar proportions of potassium and sodium; and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Four of the groundwater samples were analyzed for nitrate. Results that exceed the analytical reporting limit were reported for two samples, and both results (2 mg/L June 2001 and 0.025 mg/L in December 2001) are substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Five of the groundwater samples were analyzed for uranium; none of the uranium results exceed the corresponding analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for each groundwater sample showed non-detect values or false positive results for all of the VOCs analyzed.

5.4 GROSS ALPHA ACTIVITY

Four groundwater samples were analyzed for gross alpha activity (between June 2001 and May 2003), and none of the results were above the MDA. Each groundwater sample was analyzed for alpha-emitting radionuclides, including U-234 and U-238. Six samples had U-234 or U-238 activity above the MDA and corresponding CE, with the highest activity for either isotope (U-234 = 0.93 pCi/L in November 2004) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Each groundwater sample collected from this well to date was analyzed for beta-emitting radionuclides, including Tc-99. Only the sample collected in August 2002 had Tc-99 activity above the applicable MDA and corresponding CE, and this result (7.42 pCi/L) is very low. Gross beta activity was analyzed in four of the samples from the well, and only one result was above the applicable MDA and corresponding CE (60.74 pCi/L in June 2001), which also exceeded the SWDA screening level for gross beta (50 pCi/L). However, this result is a suspected outlier.

WELL GW-921

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in January 2001, completed with a screened monitored interval from 16 to 50 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well forms a cluster with well GW-925 and is located in Bear Creek Valley adjacent to the south side (hydraulically downgradient) of the Environmental Management Waste Management Facility (EMWMF). Located about 1.5 miles west of Y-12, the EMWMF is a hazardous and mixed-waste landfill that began operating in June 2002 as a disposal site for wastes generated from CERCLA remedial actions on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fourteen groundwater samples have been collected from the well since April 2001, all of which were obtained with the low-flow sampling.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the shallow bedrock interval in the Conasauga Group (Nolichucky Shale). The average static groundwater level in the well is 7 ft below the top of the well casing. Presampling depth-to-water measurements for the well indicate moderate fluctuations (<10 ft) in seasonal groundwater surface elevations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- pH (field measurements) of 6.7 – 7.7;
- low molar proportions of potassium and sodium; and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Four of the groundwater samples were analyzed for nitrate. Nitrate above the analytical reporting limit was detected only in the sample collected in August 2001 and this result (0.18 mg/L) is substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Five of the groundwater samples were analyzed for uranium (between April 2001 and May 2003); none of these results exceed the corresponding analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for the groundwater samples show non-detect values or false positive results for all of the VOCs analyzed, except for a trace of TCE (0.1 μg/L) in the September 2004 sample. The significance of this result is questionable because TCE was not detected in the subsequent sample (November 2004).

5.4 GROSS ALPHA ACTIVITY

Each groundwater sample was analyzed for alpha-emitting radionuclides, including U-234 and U-238. Six samples had U-234 or U-238 activity above the MDA and corresponding CE, with the highest activity for either isotope (U-234 = 0.66 pCi/L in May 2001) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Each groundwater sample was analyzed for beta-emitting radionuclides, including Tc-99. Only the sample collected in December 2002 had Tc-99 activity above the applicable MDA and corresponding CE, and this result (8.27 pCi/L) is substantially below the SDWA screening level of gross beta activity (50 pCi/L).

WELL GW-922

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in January 2001, completed with a screened monitored interval from 23 to 46 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located in Bear Creek Valley, about 500 ft south (hydraulically downgradient) of the Environmental Management Waste Management Facility (EMWMF). Located about 1.5 miles west of Y-12, the EMWMF is a hazardous and mixed-waste landfill that began operating in June 2002 as a disposal site for wastes generated from CERCLA remedial actions on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fourteen groundwater samples have been collected from the well since April 2001, all of which were obtained with the low-flow sampling.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the shallow bedrock interval in the Conasauga Group (Nolichucky Shale). The average static groundwater level in the well is 5 ft below below the top of the well casing. Presampling depth-to-water measurements for the well indicate minor (<5 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- pH (field measurements) of 6.4 – 7.9;
- low molar proportions of potassium and sodium; and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Four of the groundwater samples (between April and December 2001) were analyzed for nitrate. Only the nitrate concentration detected in the sample collected in August 2001 exceeds the analytical reporting limit and this result (0.06 mg/L) is substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Five of the groundwater samples were analyzed for uranium (between April 2001 and May 2003); none of the results exceed the corresponding analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results the groundwater samples to date show non-detect values or false positive results for all of the VOCs analyzed, except for a trace of toluene (0.1 µg/L) reported for the September 2004 sample. This result may be a sampling or analytical artifact.

5.4 GROSS ALPHA ACTIVITY

Each groundwater sample was analyzed for alpha-emitting radionuclides, including U-234 and U-238. Eight of the samples had U-234 or U-238 activity above the MDA and corresponding CE, with the highest activity for either isotope (U-234 = 1.06 pCi/L in April 2001) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Each groundwater sample was analyzed for beta-emitting radionuclides, including Tc-99. The Tc-99 activity reported for each sample does not exceed the MDA and/or CE.

WELL GW-923

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in February 2001, completed with a screened monitored interval from 36 to 75 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is in Bear Creek Valley about 100 ft directly east (hydraulically downgradient) of the Environmental Management Waste Management Facility (EMWMF). Located about 1.5 miles west of Y-12, the EMWMF is a hazardous and mixed-waste landfill that began operating in June 2002 as a disposal site for wastes generated from CERCLA remedial actions on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fifteen groundwater samples have been collected from the well since April 2001, all of which were obtained with the low-flow sampling.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Maryville Limestone). The average static groundwater level in the well is 34 ft below below the top of the well casing. Presampling depth-to-water measurements for the well indicate unusually wide (>25 ft) fluctuations in seasonal groundwater surface elevations. A time-series plot of the water levels (Figure 1) shows that the initial water level in the well was about 30 ft lower than currently observed, and that the water levels measured since August 2001 have shown moderate (<10 ft) fluctuation.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- pH (field measurements) of 6.7 – 7.5;
- low molar proportions of potassium and sodium; and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Four of the groundwater samples (between April and December 2001) were analyzed for nitrate. Nitrate results that exceed the analytical reporting limit were reported for each sample, with the highest concentration (0.62 mg/L in April 2001) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Five of the groundwater samples were analyzed for uranium (between April 2001 and May 2003). Uranium results that exceed the analytical reporting limit were reported for three samples collected in 2001, with the highest concentration (0.012 mg/L in August 2001) being below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for the groundwater samples to date show non-detect values or false positive results for all of the VOCs analyzed, except for a trace of benzene (0.1 μg/L) reported for the December 2001 sample. This result may be a sampling or analytical artifact and is considered to be an outlier.

5.4 GROSS ALPHA ACTIVITY

Ten of the groundwater samples were analyzed for alpha-emitting radionuclides, including U-234 and U-238. All the samples had U-234 or U-238 activity above the MDA and corresponding CE, with the highest activity for either isotope (U-234 = 2.99 pCi/L in April 2001) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Ten of the groundwater samples were analyzed for beta-emitting radionuclides, including Tc-99. Only one sample had Tc-99 activity above the applicable MDA and corresponding CE, and this result (11.42 pCi/L in December 2001) is substantially below the SDWA screening level of gross beta activity (50 pCi/L) and is probably an analytical artifact.

WELL GW-924

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in January 2001, completed with a screened monitored interval from 21 to 54 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well forms a cluster with well GW-926 and is located in Bear Creek Valley directly south (hydraulically downgradient) of the Environmental Management Waste Management Facility (EMWMF). Located about 1.5 miles west of Y-12, the EMWMF is a hazardous and mixed-waste landfill that began operating in June 2002 as a disposal site for wastes generated from CERCLA remedial actions on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirteen groundwater samples have been collected from the well since June 2001, all of which were obtained with the low-flow sampling.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Nolichucky Shale). The average static groundwater level in the well is 11 ft below below the top of the well casing. Presampling depth-to-water measurements for the well indicate moderate fluctuations (<10 ft) in seasonal groundwater surface elevations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- pH (field measurements) of 6.3 – 7.6;
- low molar proportions of potassium and sodium; and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Three of the groundwater samples were analyzed for nitrate. Nitrate concentrations above the analytical reporting limit were reported for each sample, with the highest concentration (0.051 mg/L in December 2001) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Four of the groundwater samples were analyzed for uranium and none of these results exceed the analytical reporting limits.

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for the groundwater samples to date show non-detect values or false positive results for all of the VOCs analyzed, except for a trace of chloroform (0.1 μg/L) reported for the sample collected in March 2004. This result may be a sampling or analytical artifact and is considered to be an outlier.

5.4 GROSS ALPHA ACTIVITY

Each groundwater sample was analyzed for alpha-emitting radionuclides, including U-234 and U-238. Six samples had U-234 or U-238 activity above the MDA and corresponding CE, with the highest activity for either isotope (U-234 = 0.84 pCi/L in November 2004) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Each groundwater sample was analyzed for beta-emitting radionuclides, including Tc-99. The Tc-99 activity reported for each sample does not exceed the MDA and corresponding CE.

WELL GW-925

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in February 2001, completed with a screened monitored interval from 92 to 148 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well forms a cluster with well GW-921 and is located in Bear Creek Valley adjacent to the south side (hydraulically downgradient) of the Environmental Management Waste Management Facility (EMWMF). Located about 1.5 miles west of Y-12, the EMWMF is a hazardous and mixed-waste landfill that began operating in June 2002 as a disposal site for wastes generated from CERCLA remedial actions on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fourteen groundwater samples have been collected from the well since April 2001, all of which were obtained with the low-flow sampling.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the intermediate bedrock interval in the Conasauga Group (Maryville Limestone). The average static groundwater level in the well is 4 ft below below the top of the well casing. Presampling depth-to-water measurements for the well indicate substantial fluctuations (15-20 ft) in seasonal groundwater surface elevations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields sodium-bicarbonate groundwater generally characterized by:

- pH (field measurements) of 7.7 – 9.4;
- high sodium concentrations (>100 mg/L);
- low molar proportions of calcium, magnesium, and potassium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The sodium-enriched geochemistry of the groundwater from this well is observed elsewhere in Bear Creek Valley and reflects a fairly abrupt change from the calcium-magnesium-bicarbonate groundwater encountered at shallower depths in the Conasauga Group. The sharp transition to the sodium-bicarbonate groundwater is believed to be a function of the more poorly connected flowpaths with longer groundwater residence time as a consequence of reduced fracture aperture and/or increased fracture spacing at depth (Solomon et. al. 1992).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Four of the groundwater samples were analyzed for nitrate (between April and November 2001). Nitrate results that exceed the analytical reporting limit were reported for each of these samples, with the highest concentration (0.03 mg/L in April 2001) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Five of the groundwater samples were analyzed for uranium (between April 2001 and May 2003), and uranium concentrations above the analytical reporting limits were reported for three samples, with the highest concentration (0.0166 mg/L in August 2001) being less than the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for the groundwater samples show non-detect values or false positive results for all of the VOCs analyzed except for trace levels of acetone (0.8 μg/L in November 2003) and TCE (0.2 μg/L in September 2004). The significance of these results is questionable because each compound was detected only once.

5.4 GROSS ALPHA ACTIVITY

Each groundwater sample was analyzed for alpha-emitting radionuclides, including U-234 and U-238. Seven samples had U-234 or U-238 activity above the MDA and corresponding CE, with the highest activity for either isotope (U-234 = 4.47 pCi/L in April 2001) being below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Each groundwater sample was analyzed for beta-emitting radionuclides, including Tc-99. Only one sample had Tc-99 activity above the applicable MDA and corresponding CE, and this result (12.8 pCi/L in November 2001) is substantially below the SDWA screening level of gross beta activity (50 pCi/L) and is probably an analytical artifact.

WELL GW-926

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in February 2001, completed with a screened monitored interval from 103 to 145 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well forms a cluster with well GW-924 and is in Bear Creek Valley directly south (hydraulically downgradient) of the Environmental Management Waste Management Facility (EMWMF). Located about 1.5 miles west of Y-12, the EMWMF is a hazardous and mixed-waste landfill that began operating in June 2002 as a disposal site for wastes generated from CERCLA remedial actions on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fourteen groundwater samples have been collected from the well since April 2001, all of which were obtained with the low-flow sampling.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the intermediate bedrock interval in the Conasauga Group (Nolichucky Shale). The average static groundwater level in the well is 9 ft below below the top of the well casing. Presampling depth-to-water measurements for the well indicate moderate fluctuations (<10 ft) in seasonal groundwater surface elevations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields sodium-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- pH (field measurements) of 7.0 – 8.1;
- low molar proportions of potassium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The sodium-enriched geochemistry of the groundwater from this well is observed elsewhere in Bear Creek Valley and reflects a fairly abrupt change from the calcium-magnesium-bicarbonate groundwater encountered at shallower depths in the Conasauga Group. The sharp transition to the sodium-bicarbonate groundwater is believed to be a function of the more poorly connected flowpaths with longer-groundwater residence time as a consequence of reduced fracture aperture and/or increased fracture spacing at depth (Solomon et. al. 1992).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Four of the groundwater samples were analyzed for nitrate (between April and November 2001). Nitrate results that exceed the analytical reporting limit were reported for each of these samples, with the highest concentration (0.32 mg/L in November 2001) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Five of the groundwater samples were analyzed for uranium (between April 2001 and May 2003) and none of these results exceed the analytical reporting limits.

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for the groundwater samples show non-detect values or false positive results for all of the VOCs analyzed except for trace levels of benzene (1 µg/L) in November 2001, acetone (0.3 µg/L) in November 2003, and toluene (0.2 µg/L) and PCE (0.1 µg/L) in June 2004. The significance of these results is questionable because each compound was detected only once.

5.4 GROSS ALPHA ACTIVITY

Each groundwater sample was analyzed for alpha-emitting radionuclides, including U-234 and U-238. Five samples had U-234 and/or U-238 activity above the MDA and corresponding CE, with the highest activity for either isotope (U-234 = 0.75 pCi/L in June 2004) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Each groundwater sample was analyzed for beta-emitting radionuclides, including Tc-99. Only the sample collected in August 2003 had Tc-99 activity above the applicable MDA and corresponding CE, and this result (11.6 pCi/L) is substantially below the SDWA screening level of gross beta activity (50 pCi/L) and is probably an analytical artifact.

WELL GW-927

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in February 2001, completed with a screened monitored interval from 57 to 92 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well forms a cluster with well GW-917 and is located in Bear Creek Valley about 200 ft south-southeast (hydraulically downgradient) of the Environmental Management Waste Management Facility (EMWMF). Located about 1.5 miles west of Y-12, the EMWMF is a hazardous and mixed-waste landfill that began operating in June 2002 as a disposal site for wastes generated from CERCLA remedial actions on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fifteen groundwater samples have been collected from the well since April 2001, all of which were obtained with the low-flow sampling.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the shallow bedrock interval in the Conasauga Group (Maryville Limestone). The average static groundwater level in the well is 17 ft below below the top of the well casing. Presampling depth-to-water measurements for the well indicate moderate fluctuations (<10 ft) in seasonal groundwater surface elevations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- pH (field measurements) of 5.8 – 8.0;
- low molar proportions of potassium and sodium; and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Four of the groundwater samples were analyzed for nitrate (between April and December 2001). Nitrate results that exceed the analytical reporting limit were reported for one sample and the nitrate concentration for this sample (1.6 mg/L in April 2001) is substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Five of the groundwater samples were analyzed for uranium (between April 2001 and May 2003) and none of these results exceed the analytical reporting limits.

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for the groundwater samples show non-detect values or false positive results for all of the VOCs analyzed except for a trace level of acetone (0.3 μg/L) reported for a sample collected in November 2003. Acetone is a common laboratory contaminant and may be an analytical artifact.

5.4 GROSS ALPHA ACTIVITY

Each groundwater sample was analyzed for alpha-emitting radionuclides, including U-234 and U-238. Five samples had U-234 and/or U-238 activity above the MDA and corresponding CE, with the highest activity for either isotope (U-234 = 1.53 pCi/L in November 2004) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Each groundwater sample was analyzed for beta-emitting radionuclides, including Tc-99. Only the sample collected in November 2003 had Tc-99 activity above the applicable MDA and corresponding CE, and this result (4.42 pCi/L) is substantially below the SDWA screening level of gross beta activity (50 pCi/L) and is probably an analytical artifact.

WELL GW-959

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in March 2005, completed with a screened monitored interval from 2.4 to 9 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). Installed to replace well 60-2A, which was plugged and abandoned in April 2004 to accommodate construction of the Big Spring Mercury Treatment Facility, this well is located in the central Y-12 area at the southeast corner of Bldg. 9201-2, approximately 100 ft north of the main channel of UEFPC. Additionally, the location of the well was selected so as to intercept the buried original (pre-construction) streambed of the UEFPC. The lithologic log prepared during drilling shows that the monitored interval is in a primarily clay zone with bedrock (auger refusal) encountered at 9 ft, which may be shallower than the presumed depth to the original streambed.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Groundwater samples were collected from the well in March, June, August, and October 2005 using the low-flow sampling method.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval of the Maynardville Limestone (Conasauga Group), which trends northeast-southwest along the axis of BCV, dips southeast at an angle of 45º - 55º, and underlies the main channel of UEFPC. The water-table interval is a highly permeable zone that often occurs within the unconsolidated material overlying the Maynardville Limestone, which exhibits the hydrologic characteristics typical of karst aquifers, with most of the groundwater flow occurring at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (shallow karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

The static groundwater level in the well occurs at an average depth of approximately 3.5 ft bgs and exhibits seasonal fluctuations of about 1 ft. Directions of groundwater flow near the well, as indicated by groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for nearby monitoring wells, are primarily to the east, parallel with the geologic strike of bedding in the Maynardville Limestone. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface utilities (process lines and storm sewers), the buried northern tributaries and original main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, the elevations of the groundwater surface in the well are higher than the levels in nearby wells (e.g., well 60-1A located 100 ft north of the well), which suggests that the well may be completed in an area influenced by discharge from Big Spring.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the (unfiltered) groundwater samples collected to date show that the well yields sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 242 – 502 mg/L;
- pH of 7.13 – 7.28 (field measurements);
- low molar proportions of chloride, potassium, and nitrate (<5% of total anions/cations);
- conspicuously high concentrations sodium (>20 mg/L) and sulfate (>100 mg/L) concentrations compared to respective levels typically evident in groundwater from other wells completed at similarly shallow depths in the Maynardville Limestone;
- high concentrations (>1 mg/L) of aluminum, iron, and manganese in the initial three samples from the well, which are probably sampling artifacts related to elevated suspended solids (>30 mg/L); and
- total (unfiltered sample) concentrations of trace metals in the most recent sample that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. Based on the results reported for the groundwater samples collected to date, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected to date had nitrate concentrations at or above the applicable reporting limit, with the highest concentration (0.492 mg/L in March 2005) being substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

All of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.0027 mg/L in March 2005) being below than the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

At least one of the following VOCs was detected in each of the groundwater samples collected to date: TCE, c12DCE, t12DCE, VC, and chloroform (Table 1). The source of these VOCs is not confirmed, but extremely high concentrations (>2,000 µg/L) of PCE and c12DCE occur in the groundwater at well GW-820, which is located south of Building 9201-2, approximately 400 ft hydraulically upgradient to the west (parallel the geologic strike) of well GW-959.

The primary VOCs detected in the groundwater samples collected to date are c12DCE and VC, which have been detected in every sample, with respective maximum concentrations above 50 µg/L (Table 1). Also, the sampling results show that the concentrations of these compounds in the groundwater exceed the drinking water MCLs (70 µg/L and 2 µg/L, respectively). Other VOCs were detected at estimated concentrations of 3 µg/L or less, and all the results are below applicable MCLs.

Both c12DCE and VC are most likely present in the groundwater as a consequence of biologically-mediated degradation (sequential dechlorination) of related parent compounds (PCE and TCE). However, several of the geochemical characteristics of the groundwater in the well are not consistently conducive to anaerobic biotic degradation (Table 2). Perhaps the monitored interval in the well intercepts groundwater flowpaths that transport dissolved VOCs from the source area where biotic degradation primarily occurs. This may also explain why the parent compounds (PCE and TCE) are either not detected in the groundwater from the well or are present at concentrations substantially lower than either c12DCE or VC, which are more soluble and mobile in groundwater than either parent compound, and thus may be expected to be present at higher concentrations in the shallow groundwater from this well.

5.4 GROSS ALPHA ACTIVITY

One groundwater sample collected to date had gross alpha activity above the applicable MDA and corresponding CE, and this result (2.2 pCi/L in March 2005) is substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Two groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, with the highest value (11 pCi/L in August 2005) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

BUILDING SUMP SAMPLING STATION
9201-1K-22SU

1.0 LOCATION

This sampling station is located in a basement sump in the eastern portion of the Bldg. 9201-1, which is in the central area of the Y-12 National Security Complex. The sump was installed to dewater the basement after construction of the building was completed and it receives groundwater with possible potable water contributions. Construction of facilities at Y-12 substantially modified UEFPC, with the headwaters and several thousand feet of the main channel in the upper reach of the creek, including all the northern tributaries of the creek in the western and central sections of Y-12, filled and replaced with an extensive network of underground storm drains. About 70% of dry-weather flow in UEFPC is attributable to once-through non-contact cooling water, condensate, cooling tower blowdown, and potable water treated and discharged from wastewater treatment facilities and the remaining 30% is from groundwater discharge (DOE 1998).

2.0 SAMPLING HISTORY

Two (unfiltered) surface water samples collected in CY 2004 meet the surveillance monitoring objectives of the Y-12 GWPP (June 2004 and October 2004). The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 242 – 289 mg/L;
- TSS of 88 mg/L in the sample collected in June 2004 (<5 mg/L in the October 2004 sample);
- pH of 6.94 – 7.09 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with elevated molar proportions of chloride, sodium, and sulfate (>15% of total anions/cations); and
- total concentrations of trace metals (except aluminum, iron, manganese, and nickel in the June 2004 sample) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Both surface water samples had nitrate concentrations above the applicable analytical reporting limit, with the maximum value (0.556 mg/L in June 2004) being substantially less than the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

The surface water samples had (total) uranium concentrations above the applicable analytical reporting limit, with both of these results (0.00364 mg/L in June and 0.00128 mg/L in October 2004) being substantially below the drinking water MCL for uranium (0.03 mg/L).

4.3 MERCURY

The surface water sample collected in June 2004 had a mercury concentration (0.000221 mg/L) slightly above the analytical reporting limit (0.0002 mg/L), which is substantially less than the drinking water MCL for mercury (0.002 mg/L).

4.4 VOLATILE ORGANIC COMPOUNDS

The surface water sample collected in June 2004 had fairly low concentrations (<30 µg/L) of PCE, TCE, c12DCE, and chloroform. The PCE concentration (7 µg/L) exceeded the MCL for PCE (5 µg/L), but chloroform had the highest concentration (21 µg/L) and is the only compound that was also detected in the sample collected in October 2004 (3 µg/L). Trihalomethanes (chloroform, bromoform, bromodichloromethane, and dibromochloromethane) are included in a class of drinking water disinfection byproducts (DBPs) that form through chemical interactions between chlorine and natural organic matter (U.S. Environmental Protection Agency 2001). The dissolved chloroform in the samples from this location may reflect a nearby discharge of chlorinated (potable) water.

4.5 GROSS ALPHA ACTIVITY

Gross alpha activity was above the associated MDA and CE in the June 2004 sample (4.4 pCi/L). The significance of this result is questionable because the sample had elevated TSS (see Section 3.0) which can cause interferences in gross alpha activity analyses.

4.6 GROSS BETA ACTIVITY

Neither of the surface water samples had gross beta activity above the associated MDA.

SPRING SAMPLING STATION
9201-3C-4SP

1.0 LOCATION

This spring sampling station is located in the southeastern section of the basement of Bldg. 9201-3, which is in the central area of the Y-12 National Security Complex. The sampling location is at the confluence of three perennial springs before they discharge into a dewatering sump in the basement. Construction of facilities at Y-12 substantially modified UEFPC, with the headwaters and several thousand feet of the main channel in the upper reach of the creek, including all the northern tributaries of the creek in the western and central sections of Y-12, filled and replaced with an extensive network of underground storm drains.

2.0 SAMPLING HISTORY

Two (unfiltered) surface water samples collected in CY 2004 meet the surveillance monitoring objectives of the Y-12 GWPP (May 2004 and October 2004). The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 233 – 274 mg/L;
- pH of 7.65 – 7.47 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with elevated molar proportions of sodium, chloride, and sulfate (>15% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Both surface water samples had nitrate concentrations above the applicable analytical reporting limit, with the maximum value (0.398 mg/L in October 2004) being substantially less than the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

The samples had (total) uranium concentrations above the applicable analytical reporting limit, with both of these results (0.000847 mg/L in May and 0.00314 mg/L in October 2004) being substantially below the drinking water MCL for uranium (0.03 mg/L).

4.3 MERCURY

Mercury was not detected above the analytical reporting limit (0.0002 mg/L) in either sample.

4.4 VOLATILE ORGANIC COMPOUNDS

The surface water sample collected in October 2004 had moderately low concentrations (<50 µg/L) of PCE, TCE, c12DCE, bromoform, and chloroform. The PCE concentration (11 µg/L) exceeded the MCL for PCE (5 µg/L), but chloroform had the highest concentration (42 µg/L) and is the only compound that was also detected in the sample collected in May 2004 (9 µg/L). Trihalomethanes (chloroform, bromoform, bromodichloromethane, and dibromochloromethane) are included in a class of drinking water disinfection byproducts (DBPs) that form through chemical interactions between chlorine and natural organic matter (U.S. Environmental Protection Agency 2001). The chloroform and bromoform concentrations in the samples from this location are most likely DBPs from a nearby discharge of chlorinated (potable) water.

4.5 GROSS ALPHA ACTIVITY

Neither of the surface water samples had gross alpha activity above the associated MDA.

4.6 GROSS BETA ACTIVITY

Neither of the surface water samples had gross beta activity above the associated MDA.

SURFACE WATER SAMPLING STATION
BCK-00.63

1.0 LOCATION

This surface water sampling station is located on the main channel of Bear Creek, 0.63 kilometers upstream of the confluence between Bear Creek and East Fork Poplar Creek. From its headwaters near the west end of Y-12, Bear Creek flows southwest for approximately 4.5 miles, where it turns northward to flow into East Fork Poplar Creek. Monitoring locations along the main channel of Bear Creek are specified by the Bear Creek kilometer (BCK) value corresponding to the distance upstream from the confluence with East Fork Poplar Creek (e.g., BCK-00.63).

Approximately half of the annual precipitation in Bear Creek Valley (BCV) exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Springs located along the Maynardville Limestone/Copper Ridge Dolomite boundary on the north slope of Chestnut Ridge dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

A total of 17 (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in August 1996 and the most recent sample collected in July 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 107 – 384 mg/L;
- pH of 6.5 – 8.5 (field measurements);
- elevated concentrations of sulfate (>20 mg/L); and
- total concentrations of trace metals (except uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Nitrate concentrations above the applicable analytical reporting limit were reported for all of the groundwater samples (Table 1), with the results ranging between the historical minimum value of 0.176 mg/L in July 2002 and 2.78 mg/L in February 2000, which is substantially below the drinking water MCL for nitrate (10 mg/L). A time series plot of the nitrate results shows an indeterminate long-term concentration trend dominated by seasonal fluctuations (Figure 1), with the highest concentrations evident during seasonally high flow conditions (January and February).

4.2 URANIUM

All of the surface water samples had (total) uranium concentrations above the applicable analytical reporting limit (Table 1), with results for eight samples, including the maximum historical value (0.039 mg/L in February 2000), exceeding the drinking water MCL for uranium (0.03 mg/L). As with the nitrate concentration trend, a time-series plot of the uranium results shows a generally decreasing long-term concentration trend dominated by wide concentration fluctuations (Figure 2). Like nitrate results, the uranium concentrations are typically highest in samples collected during seasonally high flow conditions.

4.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were not detected in any of the surface water samples.

4.4 GROSS ALPHA ACTIVITY

Thirteen of the surface water samples had gross alpha activity above the applicable MDA and corresponding CE (Table 1), with results for three samples, including the historical maximum value (22 pCi/L in February 1999 and February 2000), exceeding the drinking water MCL for gross alpha activity (15 pCi/L). Like the uranium concentration trend, a time-series plot of the results for gross alpha activity shows a generally decreasing long-term concentration trend dominated by wide concentration fluctuations, with the highest values reported for samples collected during seasonally high flow conditions (Figure 3).

4.5 GROSS BETA ACTIVITY

Twelve of the surface water samples had gross beta activity above the applicable MDA and corresponding CE (Table 1), with the historical maximum value (18 pCi/L in January 2001) being less than the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

SURFACE WATER SAMPLING STATION BCK-03.30

1.0 LOCATION

This surface water sampling station is located on the main channel of Bear Creek, 3.3 kilometers upstream of the confluence between Bear Creek and Upper East Fork Poplar Creek. From its headwaters near the west end of Y-12, Bear Creek flows southwest for approximately 4.5 miles, where it turns northward to flow into East Fork Poplar Creek. Monitoring locations along the main channel of Bear Creek are specified by the Bear Creek kilometer (BCK) value corresponding to the distance upstream from the confluence with East Fork Poplar Creek (e.g., BCK-09.20). Each northern tributary (NT) of the creek is designated by a value representing the tributary number counted downstream from the headwaters (e.g., NT-1). Major springs along the south side (SS) of Bear Creek are numbered in ascending order downstream from the headwaters (e.g., SS-1).

Approximately half of the annual precipitation in Bear Creek Valley (BCV) exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Discharge from springs located along the Maynardville Limestone/Copper Ridge Dolomite boundary on the north slope of Chestnut Ridge dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Eight (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in March 2001 and the most recent sample collected in September 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 123 – 265 mg/L;
- pH of 7.4 – 8.6 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Eight of the surface water samples had nitrate concentrations above the applicable analytical reporting limit, with the historical maximum value (4.1 mg/L in March 2002) being less than the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

Eight of the surface water samples had (total) uranium concentrations above the applicable analytical reporting limit, including two results (0.0325 mg/L in March 2001 and 0.345 mg/L in March 2002) that exceed the drinking water MCL for uranium (0.03 mg/L).

4.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were not detected in any of the surface water samples.

4.4 GROSS ALPHA ACTIVITY

One of the surface water samples had gross alpha activity above the applicable MDA and corresponding CE, and this result (11.67 pCi/L in March 2001) is less than the drinking water MCL for gross alpha activity.

4.5 GROSS BETA ACTIVITY

Eight of the surface water samples had gross beta activity above the applicable MDA and corresponding CE, with the historical maximum value (15.96 pCi/L in March 2002) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

SURFACE WATER SAMPLING STATION
BCK-04.55

1.0 LOCATION

This surface water sampling station is located on the main channel of Bear Creek, 4.55 kilometers upstream of the confluence between Bear Creek and East Fork Poplar Creek. From its headwaters near the west end of Y-12, Bear Creek flows southwest for approximately 4.5 miles, where it turns northward to flow into East Fork Poplar Creek. Monitoring locations along the main channel of Bear Creek are specified by the Bear Creek kilometer (BCK) value corresponding to the distance upstream from the confluence with East Fork Poplar Creek (e.g., BCK-04.55).

Approximately half of the annual precipitation in Bear Creek Valley (BCV) exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Springs located along the Maynardville Limestone/Copper Ridge Dolomite boundary on the north slope of Chestnut Ridge dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Thirty-six (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in August 1990 and the most recent sample collected in July 2004. The grab sampling method was used to collect each surface water sample.

In addition to the sampling performed to meet the surveillance monitoring objectives Y-12 GWPP, surface water samples also have been collected to meet other monitoring requirements, including sampling that the Y-12 Surface Water Program performs as a best management practice and to meet the requirements of DOE Order 5400.5. Also, grab sampling and/or flow-proportionate composite sampling is performed for NPDES purposes.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 104 – 376 mg/L;
- pH of 6.6 – 8.4 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and

- total concentrations of trace metals (except uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Thirty-four of the surface water samples had nitrate concentrations above the applicable analytical reporting limit (Table 1), with the results ranging between the historical minimum value of 0.234 mg/L in July 2002 and 10.3 mg/L in November 1993, which is the only result that exceeds the drinking water MCL for nitrate (10 mg/L). A time series plot of the nitrate results shows a widely fluctuating but generally decreasing long-term concentration trend (Figure 1). Concentration fluctuations typically correlate with seasonal flow conditions, with higher nitrate concentrations evident for samples collected during winter and spring.

4.2 URANIUM

Thirty-three of the surface water samples had (total) uranium concentrations above the applicable analytical reporting limit (Table 1); the non-detect result reported for the sample collected in September 1992 is an outlier. Uranium concentrations reported for 15 samples, including the maximum historical value (0.0691 mg/L in February 2000), exceed the drinking water MCL for uranium (0.03 mg/L). A time-series plot of the uranium results shows an indeterminate long-term trend totally dominated by wide concentration fluctuations (Figure 2). Many of these "peak" uranium concentrations coincide with the nitrate levels and are evident for samples collected during seasonally high flow conditions (e.g., 0.0568 mg/L in January 2002).

4.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected in only one of the surface water samples (acetone = 1 μg/L in March 1993).

4.4 GROSS ALPHA ACTIVITY

Thirty-three of the surface water samples had gross alpha activity above the applicable MDA and corresponding CE (Table 1), with results for 13 samples, including the historical maximum value (35 pCi/L in February 2000), exceeding the drinking water MCL for gross alpha activity (15 pCi/L). Like the uranium concentration trend, a time-series plot of the results for gross alpha activity shows an indeterminate long-term concentration trend dominated by wide concentration fluctuations, with the highest values (e.g., 21 pCi/L in January 2002) reported for samples collected during winter and spring (Figure 3). Analytical results summarized below show that uranium isotopes are the source of the elevated gross alpha activity in the surface water samples.

Sampling Date	Concentration (pCi/L)	
	U-234	U-238
01/18/91	3.24	6.49
04/10/91	2.09	3.34
07/29/91	3.27	6.13
12/04/91	6.26	18.4
03/10/92	<CE	2.45
06/01/92	3.68	4.91
09/08/92	<CE	<CE
12/16/92	<CE	<CE
01/11/01	6.1	13
07/12/01	3.7	7.1
01/09/02	7.5	17
07/10/02	1.6	2.5

4.5 GROSS BETA ACTIVITY

Thirty of the surface water samples had gross beta activity above the applicable MDA and corresponding CE (Table 1), with the historical maximum value (37.28 pCi/L in July 1991) being less than the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). Uranium isotopes (and related beta-particle emitting daughter products) contribute to the level of gross beta activity in the surface water samples. Additionally, available analytical results, summarized below, are inconclusive with regard to the concentrations of Tc-99, a beta-emitting radionuclide and a known groundwater and surface water contaminant in BCV.

Sampling Date	Tc-99 (pCi/L)
03/10/92	9.79
06/01/92	3,710
09/08/92	4,780
12/16/92	<CE
01/11/01	28
07/12/01	<MDA
01/09/02	38
07/10/02	<MDA

This man-made radionuclide is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, which is the only site at Y-12 that received wastes that contained Tc-99 (DOE 1997). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile (Gee et al. 1983).

SURFACE WATER SAMPLING STATION
BCK-07.87

1.0 LOCATION

This surface water sampling station is located on the main channel of Bear Creek, 7.87 kilometers upstream of the confluence between Bear Creek and East Fork Poplar Creek. From its headwaters near the west end of Y-12, Bear Creek flows southwest for approximately 4.5 miles, where it turns northward to flow into East Fork Poplar Creek. Monitoring locations along the main channel of Bear Creek are specified by the Bear Creek kilometer (BCK) value corresponding to the distance upstream from the confluence with East Fork Poplar Creek (e.g., BCK-07.87). Each northern tributary (NT) of the creek is designated by a value representing the tributary number counted downstream from the headwaters (e.g., NT-1). Major springs along the south side (SS) of Bear Creek are numbered in ascending order downstream from the headwaters (e.g., SS-1).

Approximately half of the annual precipitation in Bear Creek Valley (BCV) exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Springs located along the Maynardville Limestone/Copper Ridge Dolomite boundary on the north slope of Chestnut Ridge dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Fifteen (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in August 1998 and the most recent sample collected in September 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 185 – 369 mg/L;
- pH of 7.0 – 8.4 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals (except uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Thirteen surface water samples had nitrate concentrations above the applicable analytical reporting limit (Table 1), with results for six samples, including the historical maximum value (18.8 mg/L in August 1998), exceeding the drinking water MCL for nitrate (10 mg/L). A time series plot of the nitrate results shows a widely fluctuating but generally decreasing long-term concentration trend (Figure 1). Concentration fluctuations typically correlate with seasonal flow conditions, with higher nitrate concentrations evident for samples collected during winter and spring.

4.2 URANIUM

Thirteen of the surface water samples had (total) uranium concentrations above the applicable analytical reporting limit (Table 1), with concentrations above the drinking water MCL for uranium (0.03 mg/L) reported for each sample, ranging between the historical minimum and maximum values of 0.048 mg/L (August 2003) and 0.155 mg/L (February 2000). As with the nitrate concentration trend, a time-series plot of the uranium results shows a generally decreasing long-term trend dominated by wide concentration fluctuations (Figure 2). Many of these "peak" uranium concentrations are evident for samples collected during winter and spring (e.g., 0.0568 mg/L in January 2002). Considering the neutral to slightly basic pH of the surface water samples (see Section 3.0), uranium (and uranium isotopes) probably occurs as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble complexes with a variety of inorganic anions (Fetter 1993). The decreasing uranium trend may be a consequence of the CERCLA remedial actions at the Boneyard/Burnyard, which were completed in March 2003. These remedial actions involved the construction of an upgradient subsurface drain to hydraulically isolate the buried wastes in June 2002; the excavation, consolidation, and disposal of about 64,000 yd^3 of wastes that were in contact with groundwater by December 2002; and the reconstruction of a section of the Bear Creek tributary (NT-3) that drains surface runoff from the site by March 2003 (BJC 2003).

4.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected in only one of the surface water samples (c12DCE = 1 μg/L in March 2003).

4.4 GROSS ALPHA ACTIVITY

Ten of the surface water samples had gross alpha activity above the applicable MDA and corresponding CE (Table 2), and all of these results, including the historical maximum value (72 pCi/L in February 2000), exceed the drinking water MCL for gross alpha activity (15 pCi/L). Like the uranium concentration trend, a time-series plot of the results for gross alpha activity shows a slightly decreasing long-term concentration trend dominated by wide fluctuations, with the highest values (e.g., 62 pCi/L in January 2002) reported for samples collected during winter and spring (Figure 3). As shown by the data summarized in Table 2, uranium isotopes are the source of the elevated gross alpha activity in the surface water samples. The source of the uranium isotopes is probably the Boneyard/Burnyard and/or the BCBG WMA.

4.5 GROSS BETA ACTIVITY

Thirteen of the surface water samples had gross beta activity above the applicable MDA and corresponding CE (Table 2), with results reported for four samples, including the historical maximum value (110 pCi/L in January 2002), exceeding the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). A time-series plot of the results show a generally decreasing long-term trend dominated by a conspicuous "peak" concentration in January 2002 (Figure 4). Uranium isotopes (and related beta-particle emitting daughter products) contribute to the level of gross beta activity in the surface water samples. Additionally, available analytical results, summarized below, suggest that the gross beta activity also may be attributable to Tc-99, a beta-emitting radionuclide and a known groundwater and surface water contaminant in BCV.

Sampling Date	Tc-99 (pCi/L)
02/03/99	14.39
08/10/99	21.69
02/09/00	<MDA
08/03/00	29.19
01/11/01	89.54
07/11/01	55.03
01/08/02	74.44
07/10/02	21.34
03/04/03	15.3
08/19/03	30.24
03/02/04	15.61
09/14/04	37.58

This man-made radionuclide is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, which is the only site at Y-12 that received wastes that contained Tc-99 (DOE 1997). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile (Gee et al. 1983).

SURFACE WATER SAMPLING STATION
BCK-09.20

1.0 LOCATION

This surface water sampling station is located on the main channel of Bear Creek, 9.2 kilometers upstream of the confluence between Bear Creek and East Fork Poplar Creek. From its headwaters near the west end of Y-12, Bear Creek flows southwest for approximately 4.5 miles, where it turns northward to flow into East Fork Poplar Creek. Monitoring locations along the main channel of Bear Creek are specified by the Bear Creek kilometer (BCK) value corresponding to the distance upstream from the confluence with East Fork Poplar Creek (e.g., BCK-09.20). Each northern tributary (NT) of the creek is designated by a value representing the tributary number counted downstream from the headwaters (e.g., NT-1). Major springs along the south side (SS) of Bear Creek are numbered in ascending order downstream from the headwaters (e.g., SS-1).

Approximately half of the annual precipitation in Bear Creek Valley (BCV) exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Springs located along the Maynardville Limestone/Copper Ridge Dolomite boundary on the north slope of Chestnut Ridge dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Eight (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in March 2001 and the most recent sample collected in September 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 188 – 390 mg/L;
- pH of 6.4 – 8.5 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals (except uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Eight surface water samples had nitrate concentrations above the applicable analytical reporting limit (Table 1), with results for three samples, including the historical maximum value (17.6 mg/L in August 2003), exceeding the drinking water MCL for nitrate (10 mg/L). A time-series plot of the nitrate results shows a widely fluctuating, indeterminate long-term concentration trend (Figure 1). Concentration fluctuations typically correlate with seasonal flow conditions, with higher nitrate concentrations evident for samples collected during winter and spring.

4.2 URANIUM

Eight surface water samples had (total) uranium concentrations above the applicable analytical reporting limit (Table 1), and all of these results, which range from 0.0522 mg/L (August 2003) to 0.121 mg/L (March 2002), exceed the drinking water MCL for uranium (0.03 mg/L). Considering the pH of the samples (see Section 3.0), uranium probably occurs in the surface water as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble, mobile complexes with a variety of inorganic anions in the groundwater, such as carbonate (Fetter 1993). Elevated uranium concentrations in the surface water at this Bear Creek sampling station primarily reflects a combination of: (1) downstream transport of uranium from the former Boneyard/Burnyard, which was identified as a primary source of elemental uranium in BCV; (2) inflow of uranium-contaminated surface water from the catchments of the tributaries (NT-7 an NT-8) that drain the Bear Creek Burial Grounds (BCBG) waste management area (WMA); and (3) recharge of uranium-contaminated groundwater discharged into the creek from springs SS-4 and SS-5 (DOE 1997).

Unlike the nitrate concentration trend, a time-series plot of the uranium results reported for the surface water samples shows a decreasing long-term trend (Figure 2). The decreasing trend may be a consequence of the CERCLA remedial actions at the Boneyard/Burnyard, which were completed in March 2003. These remedial actions involved the construction of an upgradient subsurface drain to hydraulically isolate the buried wastes in June 2002; the excavation, consolidation, and disposal of about 64,000 yd^3 of wastes that were in contact with groundwater by December 2002; and the reconstruction of a section of the Bear Creek tributary (NT-3) that drains surface runoff from the site by March 2003 (BJC 2003).

4.3 VOLATILE ORGANIC COMPOUNDS

Four of the surface water samples had low concentrations of VOCs: c12DCE was detected in March 2001 (5 μg/L), March 2002 (2 μg/L), March 2003 (5 μg/L), and March 2004 (6 μg/L). Trace levels of PCE (1 μg/L) and TCE (1 μg/L) were also detected in the sample collected in March 2004. There are multiple sources of VOCs in BCV, with the compounds present in this section of Bear Creek probably indicative of the inflow of VOC-contaminated surface water from the catchments of the Bear Creek tributaries (NT-7 and NT-8) that receive surface runoff (and groundwater discharge) from the BCBG WMA and enter the main channel of Bear Creek upstream of this sampling station.

4.4 GROSS ALPHA ACTIVITY

Only one of the surface water samples was analyzed for gross alpha activity (Table 1), and this result (29.92 pCi/L in March 2001) exceeds the drinking water MCL for gross alpha activity (15 pCi/L). Instead of gross alpha activity, the samples were analyzed for uranium isotopes; analytical results are summarized below.

Sampling Date	Concentration (pCi/L)	
	U-234	U-238
03/21/01	14.59	34.9
09/17/01	13.18	28.2
03/11/02	14.19	30.29
09/09/02	11.26	19.12
03/03/03	10.21	19.4
08/18/03	8.86	17.98
03/01/04	6.47	16.66
09/13/04	11.55	18.21

As with total uranium, the presence of uranium isotopes in the surface water at this sampling location in Bear Creek primarily reflects downstream transport from the former Boneyard/Burnyard combined with inflow of contaminated surface water from the catchments of the tributaries that drain the BCBG WMA and recharge of uranium-contaminated groundwater discharged into the creek from springs SS-4 and SS-5 (DOE 1997).

4.5 GROSS BETA ACTIVITY

All of the surface water samples had gross beta activity above the applicable MDA and corresponding CE (Table 1), with the historical maximum value (55.32 pCi/L in August 2003) being slightly above the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). A time-series plot of the results for gross beta activity shows an indeterminate long-term trend (Figure 3). Uranium isotopes (and related beta-particle emitting daughter products) contribute to the level of gross beta activity in the surface water samples. Additionally, available analytical results, summarized below, suggest that the gross beta activity also may be attributable to Tc-99, a beta-emitting radionuclide and a known groundwater and surface water contaminant in BCV.

Sampling Date	Tc-99 (pCi/L)
03/21/01	50.43
09/17/01	63.3
03/11/02	69.84
09/09/02	54.47
03/03/03	21.18
08/18/03	49.17
03/01/04	35.32
09/13/04	41.98

This man-made radionuclide is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, which is the only site at Y-12 that received wastes that contained Tc-99 (DOE 1997). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile (Gee et al. 1983).

SURFACE WATER SAMPLING STATION
BCK-09.40

1.0 LOCATION

This surface water sampling station is located on the main channel of Bear Creek, 9.40 kilometers upstream of the confluence between Bear Creek and East Fork Poplar Creek. From its headwaters near the west end of Y-12, Bear Creek flows southwest for approximately 4.5 miles, where it turns northward to flow into East Fork Poplar Creek. Monitoring locations along the main channel of Bear Creek are specified by the Bear Creek kilometer (BCK) value corresponding to the distance upstream from the confluence with East Fork Poplar Creek (e.g., BCK-09.40). Each northern tributary (NT) of the creek is designated by a value representing the tributary number counted downstream from the headwaters (e.g., NT-1). Major springs along the south side (SS) of Bear Creek are numbered in ascending order downstream from the headwaters (e.g., SS-1).

Approximately half of the annual precipitation in Bear Creek Valley (BCV) exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Springs located along the Maynardville Limestone/Copper Ridge Dolomite boundary on the north slope of Chestnut Ridge dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Thirty-four (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in August 1990 and the most recent sample collected in July 2003. The grab sampling method was used to collect each sample. Note that the sample collected on November 1993 may have been inadvertently misidentified as a sample that was collected the same day from spring SS-6, and vice versa. Misidentification of these samples in the field is suspected because the analytical results reported for the sample from BCK-09.40 are more consistent with the historical data for SS-6 and the analytical results reported for the sample from spring SS-6 are more consistent with the historical data for BCK-09.40. However, there are not any available records that prove the misidentification of these samples; consequently, the analytical results for both samples are considered unusable for the purposes of the Y-12 GWPP.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 168 – 492 mg/L;
- pH of 6.9 – 8.6 (field measurements);
- elevated concentrations of chloride (>20 mg/L); and

- total concentrations of trace metals (except uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

All the surface water samples had nitrate concentrations above the applicable analytical reporting limit (Table 1), with results for 18 samples, including the historical maximum value (36 mg/L in July 1991), exceeding the drinking water MCL for nitrate (10 mg/L). A time-series plot of the nitrate results shows a widely fluctuating, indeterminate long-term concentration trend (Figure 1). Concentration fluctuations typically correlate with seasonal flow conditions, with higher nitrate concentrations evident for samples collected during winter and spring.

4.2 URANIUM

All of the surface water samples had (total) uranium concentrations above the applicable analytical reporting limit (Table 1), and all but one of these results, which range from 0.023 mg/L (February 1998) to 0.259 mg/L (January 2001), exceed the drinking water MCL for uranium (0.03 mg/L). Considering the pH of the samples (see Section 3.0), uranium probably occurs in the surface water as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble, mobile complexes with a variety of inorganic anions in the groundwater, such as carbonate (Fetter 1993). Elevated uranium concentrations in the surface water at this Bear Creek sampling station primarily reflects a combination of: (1) downstream transport of uranium from the former Boneyard/Burnyard, which was identified as a primary source of elemental uranium in BCV; (2) inflow of uranium-contaminated surface water from the catchments of the tributaries (NT-7 an NT-8) that drain the Bear Creek Burial Grounds (BCBG) waste management area (WMA); and (3) recharge of uranium-contaminated groundwater discharged into the creek from spring SS-4 (DOE 1997).

A time-series plot of the uranium results reported for the surface water samples shows a generally increasing long-term trend that is skewed by results for a three-year period (February 1999-July 2002) when samples had much higher uranium concentrations (>0.15 mg/L) than all other samples (Figure 2). Recent samples show that uranium concentrations decreased by an order of magnitude from January 2001 (0.259 mg/L) to January 2003 (0.0316 mg/L). This decreasing trend may be a consequence of the CERCLA remedial actions at the Boneyard/Burnyard, which were completed in March 2003 and involved the construction of an upgradient subsurface drain to hydraulically isolate the buried wastes; the excavation, consolidation, and disposal of about 64,000 yd^3 of wastes that were in contact with groundwater; and the reconstruction of a section of the Bear Creek tributary (NT-3) that drains surface runoff from the site (BJC 2003).

4.3 VOLATILE ORGANIC COMPOUNDS

At least one of the following VOCs was detected in 28 of the surface water samples: PCE, TCE, 12DCE (c12DCE), 11DCA and 111TCA (Table 2). Based on the frequency of detection and the highest concentration, 12DCE (c12DCE) is the primary VOC in the samples and has been detected in 27 samples at concentrations ranging from 1 μg/L in August 1993 to 50 μg/L in January 2001. The other compounds were detected much more infrequently, with the bulk of the results being estimated values below 5 μg/L. There are multiple sources of VOCs in BCV, with the compounds present in this section of Bear Creek probably indicative of the inflow of VOC-contaminated surface water from the catchments of the Bear Creek tributaries (NT-7 and NT-8) that receive surface runoff (and groundwater discharge) from the BCBG WMA and enter the main channel of Bear Creek upstream of this sampling station.

A time-series plot of the summed concentration of VOCs detected (excluding false positive results) in each surface water sample shows a widely fluctuating, indeterminate long-term trend (Figure 2). Note that these "peak" concentrations occurred during the winter months suggesting greater inflow of VOC-contaminated surface water during periods of seasonally high flow conditions. The samples with the highest VOC concentrations (> 20 μg/L; January 1999-January 2002) were collected during the same three-year time period when there was a "pulse" of higher uranium concentrations (see Section 4.2).

4.4 GROSS ALPHA ACTIVITY

All of the surface water samples had gross alpha activity above the associated MDA and CE (Table 1), and all but one of these results exceed the drinking water MCL for gross alpha activity (15 pCi/L), including three results that exceed 100 pCi/L. Indeed, compared to the other results, the historical minimum value (6.8 pCi/L in February 1998), appears to be an outlier compared to the other results for gross alpha activity. A time-series plot of the results for gross alpha activity shows an indeterminate long-term concentration trend (Figure 4) that includes a three-year period (January 1999-July 2002) of elevated activity that coincides with the "pulse" of elevated uranium concentrations (see Section 4.2).

Analytical results for applicable surface water samples, summarized below, suggest that uranium isotopes are the source of the elevated gross alpha activity in the surface water at this sampling location.

Sampling Date	Concentration (pCi/L)	
	U-234	U-238
03/18/91	7.51	22.5
04/10/91	2.16	3.46
07/29/91	7.54	18
12/04/91	32.9	82.6
03/10/92	4.75	8.07
06/01/92	7.84	<CE
09/08/92	<CE	<CE
12/16/92	<CE	38

As with total uranium, the presence of uranium isotopes in the surface water at this sampling location in Bear Creek primarily reflects downstream transport from the former Boneyard/Burnyard combined with inflow of contaminated surface water from the catchments of the tributaries that drain the BCBG WMA and recharge of uranium-contaminated groundwater discharged into the creek from springs SS-4 and SS-5 (DOE 1997).

4.5 GROSS BETA ACTIVITY

All of the surface water samples had gross beta activity above the applicable MDA and corresponding CE (Table 1), with results for 15 samples exceeding the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity), including the historical maximum value (120 pCi/L in August 2000 and January 2002). A time-series plot of the results for gross beta activity shows an indeterminate long-term trend similar to the trend for gross alpha activity (Figure 4). Uranium isotopes (and related beta-particle emitting daughter products) contribute to the level of gross beta activity in the surface water samples.

Analytical results for applicable surface water samples, summarized below, are somewhat inconclusive with regard to the presence of Tc-99, a beta-emitting radionuclide and a known groundwater and surface water contaminant in BCV.

SURFACE WATER SAMPLING STATION
BCK-09.47

1.0 LOCATION

This surface water sampling station is located on the main channel of Bear Creek, 9.47 kilometers upstream of the confluence between Bear Creek and East Fork Poplar Creek. From its headwaters near the west end of Y-12, Bear Creek flows southwest for approximately 4.5 miles, where it turns northward to flow into East Fork Poplar Creek. Monitoring locations along the main channel of Bear Creek are specified by the Bear Creek kilometer (BCK) value corresponding to the distance upstream from the confluence with East Fork Poplar Creek (e.g., BCK-09.47). Each northern tributary (NT) of the creek is designated by a value representing the tributary number counted downstream from the headwaters (e.g., NT-1). Major springs along the south side (SS) of Bear Creek are numbered in ascending order downstream from the headwaters (e.g., SS-1).

Approximately half of the annual precipitation in Bear Creek Valley (BCV) exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Springs located along the Maynardville Limestone/Copper Ridge Dolomite boundary on the north slope of Chestnut Ridge dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Eleven (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in February 1999 and the most recent sample collected in September 2004. The grab sampling method was used to collect each sample.

In addition to sampling performed to meet the surveillance monitoring objectives of the Y-12 GWPP, numerous samples have been collected to date for the purposes of other monitoring programs, including flow proportionate composite sampling performed in accordance with the Phase I ROD for the Bear Creek watershed (DOE 2000).

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 180 – 453 mg/L;
- pH of 6.5 – 8.6 (field measurements);
- elevated concentrations of chloride (>25 mg/L) and sulfate (>20 mg/L); and

- total concentrations of trace metals (except uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Ten of the surface water samples had nitrate concentrations above the applicable analytical reporting limit (Table 1), with results for five samples exceeding the drinking water MCL for nitrate (10 mg/L). A time-series plot of the nitrate results shows a widely fluctuating, but generally increasing long-term concentration trend (Figure 1).

4.2 URANIUM

Nine surface water samples had (total) uranium concentrations above the applicable analytical reporting limit (Table 1), and all of these results, which range from 0.0757 mg/L (August 2003) to 0.304 mg/L (January 2001), exceed the drinking water MCL for uranium (0.03 mg/L). Considering the pH of the samples (see Section 3.0), uranium probably occurs in the surface water as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble, mobile complexes with a variety of inorganic anions in the groundwater, such as carbonate (Fetter 1993). Elevated uranium concentrations in the surface water at this Bear Creek sampling station primarily reflects a combination of: (1) downstream transport of uranium from the former Boneyard/Burnyard, which was identified as a primary source of elemental uranium in BCV; (2) inflow of uranium-contaminated surface water from the catchments of the tributaries (NT-7 an NT-8) that drain the Bear Creek Burial Grounds (BCBG) waste management area (WMA); and (3) recharge of uranium-contaminated groundwater discharged into the creek from spring SS-4 (DOE 1997).

A time-series plot of the uranium results reported for the surface water samples shows a clearly decreasing long-term trend (Figure 2). The decreasing trend may be a consequence of the CERCLA remedial actions at the Boneyard/Burnyard, which were completed in March 2003. These remedial actions involved the construction of an upgradient subsurface drain to hydraulically isolate the buried wastes in June 2002; the excavation, consolidation, and disposal of about 64,000 yd^3 of wastes that were in contact with groundwater by December 2002; and the reconstruction of a section of the Bear Creek tributary (NT-3) that drains surface runoff from the site by March 2003 (BJC 2003).

4.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, at least one of the following VOCs was detected in the surface water samples: PCE, TCE, c12DCE, 11DCA, and chloromethane (Table 2). The primary VOC in the samples is c12DCE, which was detected in ten samples, with a historical maximum concentration (32 µg/L in January 2001) being less than the drinking water MCL (70 µg/L). The other compounds were detected much more infrequently, with all of the results being less than or equal to 5 µg/L. There are multiple sources of VOCs in BCV, with the compounds present in this section of Bear Creek probably indicative of the inflow of VOC-contaminated surface water from the catchments of the Bear Creek tributaries (NT-7 and NT-8) that receive surface runoff (and groundwater discharge) from the BCBG WMA and enter the main channel of Bear Creek upstream of this sampling station.

4.4 GROSS ALPHA ACTIVITY

Three surface water samples were analyzed for gross alpha activity (Table 1), with all three results exceeding the drinking water MCL for gross alpha activity (15 pCi/L). However, all of the surface water samples were analyzed for uranium isotopes and, as shown in the following data summary, U-234 and U-238 were detected in each sample.

Sampling Date	Concentration (pCi/L)	
	U-234	U-238
02/03/99	18.64	48.24
07/29/99	31.27	69.06
01/25/00	37.48	96.52
08/16/00	29.48	86.36
03/21/01	18.44	70.05
09/17/01	16.75	57.75
03/11/02	16.76	44.46
03/03/03	16.33	29.83
08/18/03	10.04	21.19
03/01/04	9.16	23.34
09/13/04	19.56	38.99

As with total uranium, the presence of uranium isotopes in the surface water at this sampling location in Bear Creek primarily reflects downstream transport from the former Boneyard/Burnyard combined with inflow of contaminated surface water from the catchments of the tributaries that drain the BCBG WMA and recharge of uranium-contaminated groundwater discharged into the creek from springs SS-4 and SS-5 (DOE 1997).

4.5 GROSS BETA ACTIVITY

Ten of the surface water samples had gross beta activity above the applicable MDA and corresponding CE (Table 1), with results for five samples exceeding the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity), including the historical maximum value (93 pCi/L in August 2003). A time-series plot of the results for gross beta activity shows a generally increasing long-term trend (Figure 3). Uranium isotopes (and related beta-particle emitting daughter products) contribute to the level of gross beta activity in the surface water samples. Additionally, available analytical results, summarized below, suggest that the gross beta activity also is attributable to Tc-99, a beta-emitting radionuclide and a known groundwater and surface water contaminant in BCV.

Sampling Date	Tc-99 (pCi/L)
07/29/99	38.85
01/25/00	74.57
08/16/00	111.75
03/21/01	52.8
09/17/01	30.6
03/11/02	118.07
03/03/03	27.22
08/18/03	70.88
03/01/04	44.16
09/13/04	66.31

This man-made radionuclide is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, which is the only site at Y-12 that received wastes that contained Tc-99 (DOE 1997). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile (Gee et al. 1983).

SURFACE WATER SAMPLING STATION
BCK-11.54

1.0 LOCATION

This surface water sampling station is located on the main channel of Bear Creek, just downstream of the confluence between the creek channel and a northern tributary (NT) of the creek (NT-3), which are numbered in ascending order downstream from the headwaters of the creek near the west end of Y-12. From its headwaters, Bear Creek flows southwest for approximately 4.5 miles, where it turns northward through a gap in Pine Ridge and flows into East Fork Poplar Creek. Monitoring locations along the main channel of Bear Creek are specified by the Bear Creek kilometer (BCK) value corresponding to the distance upstream from the confluence with East Fork Poplar Creek (e.g., BCK-11.54).

Approximately half of the annual precipitation in Bear Creek Valley (BCV) exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Major springs along the south side (SS) of Bear Creek, which are numbered in ascending order downstream from the headwaters (e.g., SS-1) and occur along the Maynardville Limestone/Copper Ridge Dolomite boundary, dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main creek channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Seven (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in September 2001 and the most recent sample collected in September 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 212 – 713 mg/L;
- pH of 7.3 – 8.3 (field measurements);
- elevated concentrations of chloride (>30 mg/L) and sulfate (>30 mg/L); and
- total concentrations of trace metals (except uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

All the surface water samples had nitrate concentrations above the applicable analytical reporting limit (Table 1), and all but one of these results, including the historical maximum value (61.2 mg/L in March 2002), exceed the drinking water MCL for nitrate (10 mg/L). The historical minimum value (0.041 mg/L in September 2002) is an outlier when compared to the other results. A time series plot of the nitrate results shows a widely fluctuating and indeterminate trend (Figure 1). The source of the nitrate is the former S-3 Ponds, which are unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988. Located about 3,000 ft east-northeast of BCK-11.54, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984. The groundwater contaminant plume originating from the site contains a heterogeneous mixture of inorganic, organic, and radiological contaminants. Nitrate, a principal component of the plume, enters Bear Creek via discharge of nitrate-contaminated groundwater from the shallow karst network in the Maynardville Limestone and inflow of nitrate-contaminated surface water from two northern tributaries of Bear Creek (NT-1 and NT-2) that are primary discharge areas for nitrate-contaminated groundwater in the Nolichucky Shale west of the former S-3 Ponds (DOE 1997).

As noted in Section 1.0, the BCK-11.54 sampling station is on the main channel of Bear Creek immediately downstream of the confluence with NT-3, and the sampling results show that nitrate concentrations are typically about 50% lower than evident upstream at the BCK-11.84 sampling station. Lower levels of nitrate at BCK-11.54 are at least partially attributable to dilution from inflow of non-nitrate contaminated groundwater and surface water from the NT-3 catchment.

4.2 URANIUM

All the surface water samples had (total) uranium concentrations above the applicable analytical reporting limit (Table 1), and all but one of these results, including the historical maximum value (0.145 mg/L in March 2002 and September 2004), exceed the drinking water MCL for uranium (0.03 mg/L). Considering the pH of the samples (see Section 3.0), uranium probably occurs in the surface water as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble, mobile complexes with a variety of inorganic anions in the groundwater, such as carbonate (Fetter 1993). Although upstream contamination in Bear Creek from the contaminant plume emplaced during historical operation of the former S-3 Ponds is a likely source of the uranium (and uranium isotopes) in the samples, the primary source is probably the former Boneyard/Burnyard (BYBY). Located about 500 ft east-northeast of the BCK-11.54 sampling station, the BYBY was confirmed as the primary source of uranium (and uranium isotopes) in surface water in Bear Creek (and groundwater in the Maynardville Limestone) downstream of the confluence with NT-3 (DOE 1997).

A time series plot of the uranium results shows a widely fluctuating and indeterminate long term trend (Figure 2). The substantially lower uranium levels in September 2002 appear to be a direct consequence of the CERCLA remedial actions at the BYBY. Completed in March 2003, the CERCLA remedial action involved hydraulically isolating buried wastes in contact with groundwater; the excavation, consolidation, and disposal of about 64,000 yd^3 of these wastes; and the reconstruction of a section of NT-3 to promote better drainage from the site (BJC 2003). The uranium concentrations have increased since completion of the remedial actions, but this increase may reflect an upstream source of contamination (e.g., NT-1) rather than input from NT-3.

4.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were not detected in the surface water samples.

4.4 GROSS ALPHA ACTIVITY

Instead of gross alpha activity, the surface water samples were analyzed for uranium isotopes. Analytical results, summarized below, show that relatively low levels of U-234 and U-238 were detected in each sample.

Sampling Date	Concentration (pCi/L)	
	U-234	**U-238**
09/17/01	16.79	29.07
03/11/02	18.07	30.72
09/09/02	2.38	3.66
03/03/03	22	29.39
08/18/03	9.43	18.88
03/01/04	9.69	17
09/13/04	28.97	47.77

As with total uranium, the presence of uranium isotopes in the surface water at this sampling location in Bear Creek primarily reflects downstream transport from the contaminant plumes emplaced during historical operations of the former S-3 Ponds and Boneyard/Burnyard, the latter site being the most likely source (DOE 1997).

4.5 GROSS BETA ACTIVITY

All of the surface water samples had gross beta activity above the applicable MDA and corresponding CE (Table 1) and all but one of these results exceed the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). The historical minimum value (4.3 pCi/L in September 2002) is an outlier when compared to the other six results, four of which exceed 100 pCi/L. A time series plot of the results for gross beta activity shows a widely fluctuating and indeterminate long term trend (Figure 3). Uranium isotopes (and related beta-particle emitting daughter products) contribute to the level of gross beta activity in the surface water samples. Nevertheless, available analytical results, summarized below, show that the gross beta activity is mostly attributable to Tc-99, a beta-emitting radionuclide that is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, which is the only site at Y-12 that received wastes that contained Tc-99 (DOE 1997).

Sampling Date	Tc-99 (pCi/L)
09/17/01	288
03/11/02	235.57
09/09/02	<MDA
03/03/03	56.76
08/18/03	99.8
03/01/04	90.53
09/13/04	212.09

Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile (Gee et al. 1983). Based on the existing network of sampling locations (and springs) in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the transport of Tc-99 in Bear Creek (and the Maynardville Limestone) closely mirrors that of nitrate.

SURFACE WATER SAMPLING STATION
BCK-11.84

1.0 LOCATION

This surface water sampling station is located on the main channel of Bear Creek, about 500 ft downstream (west-southwest) of the confluence between the creek channel and a northern tributary (NT) of the creek (NT-2). These tributaries are numbered in ascending order downstream from the headwaters of the creek near the west end of Y-12. From its headwaters, Bear Creek flows southwest for approximately 4.5 miles, where it turns northward through a gap in Pine Ridge and flows into East Fork Poplar Creek. Monitoring locations along the main channel of Bear Creek are specified by the Bear Creek kilometer (BCK) value corresponding to the distance upstream from the confluence with East Fork Poplar Creek (e.g., BCK-11.84).

Approximately half of the annual precipitation in Bear Creek Valley (BCV) exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Major springs along the south side (SS) of Bear Creek, which are numbered in ascending order downstream from the headwaters (e.g., SS-1) and occur along the Maynardville Limestone/Copper Ridge Dolomite boundary, dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main creek channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Six (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in September 2001 and the most recent sample collected in September 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 428 – 1,380 mg/L;
- pH of 7.9 – 8.1 (field measurements);
- elevated concentrations of chloride (>60 mg/L) and sulfate (>40 mg/L); and
- total concentrations of trace metals (except uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

All the surface water samples had nitrate concentrations above the applicable analytical reporting limit (Table 1), and all these results exceed the drinking water MCL for nitrate (10 mg/L). A time series plot of nitrate results suggests a decreasing concentration trend (Figure 1). The source of the nitrate is the former S-3 Ponds, which are unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988. Located about 2,300 ft east-northeast of BCK-11-84, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984. The groundwater contaminant plume originating from the site contains a heterogeneous mixture of inorganic, organic, and radiological contaminants. Nitrate, a principal component of the plume, enters Bear Creek via discharge of nitrate-contaminated groundwater from the shallow karst network in the Maynardville Limestone and inflow of nitrate-contaminated surface water from two northern tributaries of Bear Creek (NT-1 and NT-2) that are primary discharge areas for nitrate-contaminated groundwater in the Nolichucky Shale west of the former S-3 Ponds (DOE 1997).

4.2 URANIUM

All the surface water samples had (total) uranium concentrations above the applicable analytical reporting limit (Table 1), and all but one of these results, including the historical maximum value (0.195 mg/L in September 2001), exceed the drinking water MCL for uranium (0.03 mg/L). A time series plot of uranium results shows a widely fluctuating indeterminate long term trend (Figure 2). Considering the pH of the samples (see Section 3.0), uranium probably occurs in the surface water as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble, mobile complexes with a variety of inorganic anions in the groundwater, such as carbonate (Fetter 1993). Uranium is one of the primary inorganic contaminants within the plume emplaced during historical operation of the former S-3 Ponds and, as with nitrate levels, the elevated uranium concentrations in Bear Creek at this surface water sampling station results from the upstream inflow of uranium-contaminated groundwater discharged from the Maynardville Limestone and uranium-contaminated surface water from the NT-1 catchment.

4.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were not detected in the surface water samples.

4.4 GROSS ALPHA ACTIVITY

Instead of gross alpha activity, the surface water samples were analyzed for uranium isotopes. Analytical results, summarized below, show relatively high levels of U-234 and U-238 were detected in each sample.

Sampling Date	Concentration (pCi/L)	
	U-234	U-238
09/17/01	29.75	49.24
03/11/02	19.38	30.11
03/03/03	26.46	36.26
08/18/03	10.85	18.93
03/01/04	24.17	34.78
09/13/04	36.72	66.65

As with total uranium, the presence of uranium isotopes in the surface water at this sampling location in Bear Creek primarily reflects the upstream inflow of U-234/U-238 contaminated groundwater from the Maynardville Limestone and U-234/U-238 contaminated surface water from the NT-1 catchment.

4.5 GROSS BETA ACTIVITY

All of the surface water samples had gross beta activity above the applicable MDA and corresponding CE (Table 1) and all of these results exceed the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). A time series plot of the results for gross beta activity shows a generally decreasing long term trend (Figure 3). Uranium isotopes (and related beta-particle emitting daughter products) contribute to the level of gross beta activity in the surface water samples. Nevertheless, available analytical results, summarized below, show that the gross beta activity is mostly attributable to Tc-99, a beta-emitting radionuclide that is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, which is the only site at Y-12 that received wastes that contained Tc-99 (DOE 1997).

Sampling Date	Tc-99 (pCi/L)
09/17/01	582
03/11/02	403.11
03/03/03	96.35
08/18/03	111.19
03/01/04	141.32
09/13/04	284.95

Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile (Gee et al. 1983). Based on the existing network of sampling locations (and springs) in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the transport of Tc-99 in Bear Creek (and the Maynardville Limestone) closely mirrors that of nitrate. Thus, the elevated gross beta activity in Bear Creek at this surface water sampling station is a combined result of the upstream inflow of Tc-99 contaminated groundwater from the Maynardville Limestone and Tc-99 contaminated surface water from NT-1.

SURFACE WATER SAMPLING STATION
BCK-11.97

1.0 LOCATION

This surface water sampling station is located on the main channel of Bear Creek, immediately downstream (west-southwest) of the confluence between the creek channel and a northern tributary (NT) of the creek (NT-2), which are numbered in ascending order downstream from the headwaters of the creek near the west end of Y-12. From its headwaters, Bear Creek flows southwest for approximately 4.5 miles, where it turns northward through a gap in Pine Ridge and flows into East Fork Poplar Creek. Monitoring locations along the main channel of Bear Creek are specified by the Bear Creek kilometer (BCK) value corresponding to the distance upstream from the confluence with East Fork Poplar Creek (e.g., BCK-11.97).

Approximately half of the annual precipitation in Bear Creek Valley (BCV) exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Major springs along the south side (SS) of Bear Creek, which are numbered in ascending order downstream from the headwaters (e.g., SS-1) and occur along the Maynardville Limestone/Copper Ridge Dolomite boundary, dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main creek channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Thirty-one (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in August 1990 and the most recent sample collected in July 2003. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 340 – 2,080 mg/L, excluding suspected outlier results reported for samples collected in August 1990 (22 mg/L) and January 2002 (6,380 mg/L);
- pH of 7.1 – 8.4 (field measurements);
- elevated concentrations of chloride (>100 mg/L), sodium (>60 mg/L), and sulfate (>30 mg/L); and
- total concentrations of trace metals (except uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

All the surface water samples had nitrate concentrations above the applicable analytical reporting limit (Table 1), and all these results exceed the drinking water MCL for nitrate (10 mg/L), ranging between the historical minimum and maximum values of 15.3 mg/L (August 1996) and 257 mg/L (July 2002). The source of the nitrate is the former S-3 Ponds, which are unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988. Located about 2,200 ft east-northeast of BCK-11.97, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984. The contaminant plume originating from the site contains a heterogeneous mixture of inorganic, organic, and radiological contaminants. Nitrate, a principal component of the plume, enters Bear Creek via discharge of nitrate-contaminated groundwater from the shallow karst network in the Maynardville Limestone and inflow of nitrate-contaminated surface water from two northern tributaries of Bear Creek (NT-1 and NT-2) that are primary discharge areas for nitrate-contaminated groundwater in the Nolichucky Shale west of the former S-3 Ponds (DOE 1997).

A time-series plot of the nitrate results reported for the surface water samples shows an indeterminate long-term concentration trend dominated by wide (seasonal) concentration fluctuations (Figure 1). Also, these "peak" nitrate concentrations often are evident for samples collected during summer or fall, which shows that nitrate-contaminated groundwater provides the bulk of the baseflow in the upper reach of Bear Creek.

4.2 URANIUM

All the surface water samples had (total) uranium concentrations above the applicable analytical reporting limit (Table 1) and all of these results meet or exceed the drinking water MCL for uranium (0.03 mg/L), with the highest concentrations reported for the samples collected in September 1992 (0.31 mg/L) and February 1994 (0.324 mg/L). Considering the pH of the samples (see Section 3.0), uranium probably occurs in the surface water as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble, mobile complexes with a variety of inorganic anions in the groundwater, such as carbonate (Fetter 1993). Uranium is a principal component of the contaminant plume emplaced during historical operation of the former S-3 Ponds and, as with nitrate levels, the elevated uranium concentrations at this surface water sampling station are the combined result of upstream inflow of uranium-contaminated groundwater from the Maynardville Limestone and uranium-contaminated surface water from the NT-1 and NT-2 catchments.

A time-series plot of the uranium results reported for the surface water samples shows an indeterminate long-term concentration trend dominated by wide (seasonal) concentration fluctuations (Figure 2). As with nitrate levels, the highest uranium concentrations were reported for samples collected during summer or fall, with conspicuous concentration "peaks" evident in

September 1992 (0.31 mg/L), September 1994 (0.324 mg/L), and August 2000 (0.207 mg/L). This too shows that contaminated groundwater baseflow provides the bulk of the flow in the upper reach of Bear Creek.

4.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, low concentrations of PCE were detected in samples collected in February 1998 (1 μg/L), January 2001 (3 μg/L), and January 2003 (2 μg/L). Also, a trace level of 111TCA (0.4 μg/L) was detected in the sample collected in January 1991 and TCFM (1 μg/L) was detected in the sample collected in August 1998. The sporadic detection and low concentration of these compounds suggests that these results may be sampling or analytical artifacts.

4.4 GROSS ALPHA ACTIVITY

All of the surface water samples had gross alpha activity above the applicable MDA and corresponding CE (Table 2), and all but one of these results exceed the drinking water MCL for gross alpha activity (15 pCi/L). Uranium isotopes are the source of the elevated gross alpha activity, which range between the historical minimum and maximum values of 12 pCi/L (February 1997) and 96 pCi/L (July 2001). Radiological analyses performed to data show uranium isotope concentrations ranging from 3.04 pCi/L (U-234) to 67 pCi/L (U-238). As with total uranium, the presence of uranium isotopes in the surface water at this sampling location in Bear Creek primarily reflects the upstream inflow of U-234/U-238 contaminated groundwater from the Maynardville Limestone and U-234/U-238 contaminated surface water from the NT-1.

A time-series plot of the gross alpha activity reported for the surface water samples shows an indeterminate long-term concentration trend dominated by wide (seasonal) concentration fluctuations (Figure 3). These "peak" levels of gross alpha activity are indicated by results for samples collected during seasonally high flow (e.g., 63.9 pCi/L in March 1996) and seasonally low flow (e.g., 96 pCi/L in July 2001) in Bear Creek.

4.5 GROSS BETA ACTIVITY

All of the surface water samples had gross beta activity above the applicable MDA and corresponding CE (Table 2) and all but one of these results substantially exceed the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). Uranium isotopes (and related beta-particle emitting daughter products) contribute to the level of gross beta activity in the surface water samples. Nevertheless, available analytical results show that the gross beta activity is mostly attributable to Tc-99 (Table 2), a beta-emitting radionuclide that is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, which is the only site at Y-12 that received wastes that contained Tc-99 (DOE 1997). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile (Gee et al. 1983). Based on the existing network of sampling locations (and springs) in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the transport of Tc-99 in Bear Creek (and the Maynardville Limestone) closely mirrors that of nitrate. Thus, the elevated gross beta activity in Bear Creek at this surface water sampling station is a combined result of the upstream inflow of Tc-99-contaminated groundwater from the Maynardville Limestone and Tc-99-contaminated surface water from NT-1.

A time-series plot of the gross beta activity reported for the surface water samples shows an indeterminate long-term concentration trend dominated by wide (seasonal) concentration fluctuations (Figure 4). As with nitrate levels, the highest gross beta activity values were reported for samples collected during summer or fall, with conspicuous concentration "peaks" evident in September 1992 (368 pCi/L), July 1995 (600 pCi/L), and July 2002 (780 pCi/L). These results likewise show that contaminated groundwater provides the baseflow in the upper reach of Bear Creek.

SURFACE WATER SAMPLING STATION
BCK-12.34

1.0 LOCATION

This surface water sampling station is located on the main channel of Bear Creek, just downstream (west-southwest) of the confluence between the creek channel and a northern tributary (NT) of the creek (NT-1). These tributaries are numbered in ascending order downstream from the headwaters of the creek near the west end of Y-12. From its headwaters, Bear Creek flows southwest for approximately 4.5 miles (7.2 km), where it turns northward through a gap in Pine Ridge and flows into East Fork Poplar Creek. Monitoring locations along the main channel of Bear Creek are specified by the Bear Creek kilometer (BCK) value corresponding to the distance upstream from the confluence with East Fork Poplar Creek (e.g., BCK-12.34).

Approximately half of the annual precipitation in Bear Creek Valley (BCV) exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Major springs along the south side (SS) of Bear Creek, which are numbered in ascending order downstream from the headwaters (e.g., SS-1) and occur along the Maynardville Limestone/Copper Ridge Dolomite boundary, dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main creek channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Six (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in March 2001 and the most recent sample collected in November 2004. This station is currently monitored as part of the remediation effectiveness evaluation under the BCV Phase I ROD, and the samples (collected quarterly) are analyzed only for total uranium. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on limited available data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- pH of 7.92 – 8.18 (field measurements);
- total concentrations of trace metals (except cadmium, manganese, and uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Nitrate was detected in the two samples analyzed for nitrate (collected in March and September 2001), and concentrations (59.3 mg/L and 141 mg/L, respectively) were above the drinking water MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds, which are unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988. Located about 1,700 ft east-northeast of BCK-12.34, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984. The groundwater contaminant plume originating from the site contains a heterogeneous mixture of inorganic, organic, and radiological contaminants. Nitrate, a principal component of the plume, enters Bear Creek upstream of BCK-12.34 via discharge of nitrate-contaminated groundwater from the shallow karst network in the Maynardville Limestone and inflow of nitrate-contaminated surface water from a northern tributary of Bear Creek (NT-1) that is a primary discharge area for nitrate-contaminated groundwater in the Nolichucky Shale west of the former S-3 Ponds (DOE 1997).

4.2 URANIUM

The surface water samples collected in CY 2004 were analyzed for (total) uranium, and the concentration in each sample exceeded the drinking water MCL (0.03 mg/L) for uranium (Table 1). Considering the pH of the samples (see Section 3.0), uranium probably occurs in the surface water as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble, mobile complexes with a variety of inorganic anions in the groundwater, such as carbonate (Fetter 1993). Uranium is one of the primary inorganic contaminants within the plume emplaced during historical operation of the former S-3 Ponds and, as with nitrate levels, the elevated uranium concentrations in Bear Creek at this surface water sampling station result from the upstream inflow of uranium-contaminated groundwater discharged from the Maynardville Limestone and contaminated surface water from the NT-1 catchment.

4.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, PCE was detected in the two surface water samples analyzed for VOCs, and the concentrations were slightly above and below the MCL (5 μg/L) for PCE (Table 1). As with nitrate and uranium, PCE is one of the contaminants within the plume emplaced during historical operation of the former S-3 Ponds and the elevated PCE concentrations in Bear Creek at this surface water sampling station result from the upstream inflow of contaminated groundwater discharged from the Maynardville Limestone and contaminated surface water from the NT-1 catchment.

4.4 GROSS ALPHA ACTIVITY

None of the six samples collected at this location were analyzed for gross alpha activity; however, two of the surface water samples were analyzed for uranium isotopes. Analytical results (Table 1) show that relatively high levels of U-234 and U-238 were detected in each sample. As with total uranium, the presence of uranium isotopes in the surface water at this sampling location in Bear Creek primarily reflects the upstream inflow of U-234/U-238 contaminated groundwater from the Maynardville Limestone and contaminated surface water from the NT-1 catchment.

4.5 GROSS BETA ACTIVITY

None of the six samples collected at this location were analyzed for gross beta activity. However, two of the surface water samples were analyzed for Tc-99, a beta-emitting radionuclide that is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds. Analytical results show that relatively high levels of Tc-99 were detected in each sample (Table 1).

Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile (Gee et al. 1983). Based on the existing network of sampling locations (and springs) in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the transport of Tc-99 in Bear Creek (and the Maynardville Limestone) closely mirrors that of nitrate. Thus, the elevated Tc-99 activity in Bear Creek at this surface water sampling station is a result of the upstream inflow of contaminated groundwater from the Maynardville Limestone and contaminated surface water from the NT-1 catchment.

SURFACE WATER SAMPLING STATION
BCK-12.47

1.0 LOCATION

This surface water sampling station is located on the main channel of Bear Creek, about 400 ft upstream (west-southwest) of the confluence between the creek channel and a northern tributary (NT) of the creek (NT-1). These tributaries are numbered in ascending order downstream from the headwaters of the creek near the west end of Y-12. From its headwaters, Bear Creek flows southwest for approximately 4.5 miles, where it turns northward through a gap in Pine Ridge and flows into East Fork Poplar Creek. Monitoring locations along the main channel of Bear Creek are specified by the Bear Creek kilometer (BCK) value corresponding to the distance upstream from the confluence with East Fork Poplar Creek (e.g., BCK-12.47).

Approximately half of the annual precipitation in Bear Creek Valley (BCV) exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Major springs along the south side (SS) of Bear Creek, which are numbered in ascending order downstream from the headwaters (e.g., SS-1) and occur along the Maynardville Limestone/Copper Ridge Dolomite boundary, dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main creek channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Four (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in January 2004 and the most recent sample collected in November 2004. This station is currently monitored as part of the remediation effectiveness evaluation under the BCV Phase I ROD, and the samples (collected quarterly) are analyzed only for total uranium. The grab sampling method was used to collect each sample. The grab sampling method was used to collect each sample.

3.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

The surface water samples collected at BCK-12.47 during CY 2004 were analyzed only for (total) uranium, and the concentration of each sample was more than an order-of-magnitude above the MCL for uranium (0.03 mg/L). The uranium concentrations ranged from 0.501 mg/L (November 2004) to 0.628 mg/L (June 2004). Although the pH of the water at this location is unknown, uranium probably occurs in the surface water as uranyl cations, which tend to form soluble, mobile complexes with a variety of inorganic anions in the groundwater, such as carbonate (Fetter 1993). Uranium is one of the primary inorganic contaminants within the plume emplaced during historical operation of the former S-3 Ponds and the elevated uranium concentrations in Bear Creek at this surface water sampling station result from the upstream inflow of uranium-contaminated groundwater discharged from the Maynardville Limestone.

SURFACE WATER SAMPLING STATION
EMWNT-03A

1.0 LOCATION

This surface water sampling station is located in the channel of a northern tributary (NT) of Bear Creek (NT-03), which are numbered in ascending order downstream of the creek headwaters, about 1,200 ft upstream of its confluence with the main creek channel. From the headwaters near the west end of Y-12, Bear Creek flows southwest for approximately 4.5 miles, where it turns northward to flow into East Fork Poplar Creek.

Approximately half of the annual precipitation in Bear Creek Valley (BCV) exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Discharge from springs located along the Maynardville Limestone/Copper Ridge Dolomite boundary on the north slope of Chestnut Ridge dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Six (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in September 2003 and the most recent sample collected in December 2004. The grab sampling method was used to collect each sample. Note that other samples have been collected at different frequencies and analyzed for different parameters to meet the requirements of the EMWMF Environmental Monitoring Plan (DOE 2001).

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- pH of 7.5 and 8.7 (field measurements) and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in

UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

The surface water samples were not analyzed for nitrate.

4.2 URANIUM

The surface water samples were not analyzed for uranium.

4.3 VOLATILE ORGANIC COMPOUNDS

Acetone was detected at low levels in two samples: 6 µg/L in September 2003 and 2 µg/L in June 2004. The significance of these results is questionable because acetone is a common laboratory reagent.

4.4 GROSS ALPHA ACTIVITY

The surface water samples were not analyzed for gross alpha activity.

4.5 GROSS BETA ACTIVITY

The surface water samples were not analyzed gross beta activity.

SURFACE WATER SAMPLING STATION
EMWNT-05

1.0 LOCATION

This surface water sampling station is located in the channel of a northern tributary (NT) of Bear Creek (NT-5), which are numbered in ascending order downstream from the creek headwaters near the west of Y-12, about 100 ft upstream of its confluence with the main channel of the creek. From the headwaters, Bear Creek flows southwest for approximately 4.5 miles, where it turns northward to flow into East Fork Poplar Creek.

Approximately half of the annual precipitation in Bear Creek Valley (BCV) exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Discharge from springs located along the Maynardville Limestone/Copper Ridge Dolomite boundary on the north slope of Chestnut Ridge dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Eight (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in February 2003 and the most recent sample collected in December 2004. The grab sampling method was used to collect each sample. Note that other samples have been collected at different frequencies and analyzed for different parameters to meet the requirements of the EMWMF Environmental Monitoring Plan (DOE 2001).

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- pH of 7.7 – 8.9 (field measurements) and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in

UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

The surface water samples were not analyzed for nitrate.

4.2 URANIUM

The surface water sample collected in May 2003 was analyzed for (total) uranium, and the result was below the applicable analytical reporting limit.

4.3 VOLATILE ORGANIC COMPOUNDS

VOCs were not detected in the surface water samples.

4.4 GROSS ALPHA ACTIVITY

The surface water sample collected in May 2003 was analyzed for gross alpha activity, and the result was below the applicable MDA.

4.5 GROSS BETA ACTIVITY

The surface water sample collected in May 2003 was analyzed for gross beta activity, and this result (2.6 pCi/L) was substantially below the SDWA screening level (50 pCi/L) for a 4 millirem dose equivalent (the drinking water MCL for gross beta activity).

SURFACE WATER SAMPLING STATION
EMW-VWEIR

1.0 LOCATION

This surface water sampling station is located at a weir installed at the outfall of a storm-water retention basin on the southeast side of the Environmental Management Waste Management Facility (EMWMF). The EMWMF is located in Bear Creek Valley about one mile west of Y-12 and is an operating facility used for disposal of hazardous and mixed waste generated from CERCLA remedial action activities at sites located on the DOE Oak Ridge Reservation.

2.0 SAMPLING HISTORY

Five (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in February 2003 and the most recent sample collected in December 2004. The grab sampling method was used to collect each sample. Note that other samples have been collected at different frequencies and analyzed for different parameters to meet the requirements of the EMWMF Environmental Monitoring Plan (DOE 2001).

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- pH of 7.4 – 8.6 (field measurements) and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

None of the surface water samples were analyzed for nitrate concentrations.

4.2 URANIUM

The surface water sample collected in May 2003 was analyzed for (total) uranium, and the result is below the applicable analytical reporting limit.

4.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, a low concentration of acetone (7.8 µg/L) was detected in the sample collected in May 2003; this result is probably a sampling or analytical artifact.

4.4 GROSS ALPHA ACTIVITY

The surface water sample collected in May 2003 was analyzed for gross alpha activity, and this result (4.23 pCi/L in May 2003) is substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

4.5 GROSS BETA ACTIVITY

The surface water sample collected in May 2003 was analyzed for gross beta activity, and this result (11.08 pCi/L) is substantially below the SDWA screening level (50 pCi/L) for a 4 millirem dose equivalent (the drinking water MCL for gross beta activity).

SURFACE WATER SAMPLING STATION
ET-4

1.0 LOCATION

This surface water sampling station is located on the channel of an unnamed eastern tributary (ET) of Bear Creek, about 2,000 ft upstream of its confluence with the main channel of the creek south of the White Wing Scrap Yard (WWSY). From the headwaters near the west end of Y-12, Bear Creek flows southwest for approximately 4.5 miles, where it turns northward to flow into East Fork Poplar Creek.

Approximately half of the annual precipitation in Bear Creek Valley (BCV) exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Discharge from springs located along the Maynardville Limestone/Copper Ridge Dolomite boundary on the north slope of Chestnut Ridge dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Three (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in January 2001 and the most recent sample collected in March 2003. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 44 – 104 mg/L;
- pH of 6.5 – 8.2 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Two surface water samples had nitrate concentrations above the applicable analytical reporting limit, and both results (0.36 mg/L in January 2001 and 0.1 mg/L in February 2001) are an order of magnitude below the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

One surface water sample had a (total) uranium concentration above the applicable analytical reporting limit, and this result (0.0088 mg/L in March 2003) is an order-of-magnitude below the drinking water MCL for uranium (0.03 mg/L).

4.3 VOLATILE ORGANIC COMPOUNDS

VOCs were not detected in the any of the surface water samples.

4.4 GROSS ALPHA ACTIVITY

Three surface water samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (7.81 pCi/L in March 2003) being less than the drinking water MCL for gross alpha activity (15 pCi/L).

4.5 GROSS BETA ACTIVITY

Three surface water samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (8.8 pCi/L in March 2003) substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

SURFACE WATER SAMPLING STATION
GHK2.51ESW

1.0 LOCATION

This surface water sampling station is located on the main channel of Gum Hollow Branch north of Pine Ridge on the DOE Oak Ridge Reservation (ORR) about two miles northwest of Y-12. Samples are collected from this location to provide data regarding the quality of surface water in Gum Hollow Branch where it exits the ORR and flows adjacent to the Country Club Estates community.

2.0 SAMPLING HISTORY

Ten (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in September 1999 and the most recent sample collected in December 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 95 – 226 mg/L;
- pH of 6.5 – 7.8 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Nine surface water samples had nitrate concentrations above the applicable analytical reporting limit, and all of these results are less than 1 mg/L and are at least an order-of-magnitude below the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

One surface water sample had (total) uranium concentrations above the applicable analytical reporting limit, and this result (0.000889 mg/L in May 2001) is substantially below the drinking water MCL for uranium (0.03 mg/L).

4.3 VOLATILE ORGANIC COMPOUNDS

A trace (2 μg/L) of carbon tetrachloride was detected in the surface water sample collected in September 1999; this result is probably a sampling or analytical artifact.

4.4 GROSS ALPHA ACTIVITY

One surface water sample had gross alpha activity above the applicable MDA and corresponding CE, and this result (2.6 pCi/L in May 2003) is substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

4.5 GROSS BETA ACTIVITY

Two surface water samples had gross beta activity above the applicable MDA and corresponding CE, and both of these results (6.7 pCi/L in May 2001 and 7.4 pCi/L in May 2002) are substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

SURFACE WATER SAMPLING STATION GHK2.51WSW

1.0 LOCATION

This surface water sampling station is located on the main channel of Gum Hollow Branch north of Pine Ridge on the DOE Oak Ridge Reservation (ORR) about two miles northwest of Y-12. Samples are collected from this location to provide data regarding the quality of surface water in Gum Hollow Branch where it exits the ORR and flows adjacent to the Country Club Estates community.

2.0 SAMPLING HISTORY

Eleven (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in September 1999 and the most recent sample collected in December 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 51 -153;
- pH of 6.3 – 7.8 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Eleven surface water samples had nitrate concentrations above the applicable analytical reporting limit, and all of these results are less than 1 mg/L and are at least an order-of-magnitude below the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

Three surface water samples had (total) uranium concentrations above the applicable analytical reporting limit:, with the highest value (0.0012 mg/L in May 2003) being an order-of-magnitude below the drinking water MCL for uranium (0.03 mg/L).

4.3 VOLATILE ORGANIC COMPOUNDS

VOCs were not detected in the any of the surface water samples.

4.4 GROSS ALPHA ACTIVITY

None of the surface water samples had gross alpha activity above the applicable MDA and corresponding CE.

4.5 GROSS BETA ACTIVITY

None of the surface water samples had gross beta activity above the applicable MDA and corresponding CE.

SURFACE WATER SAMPLING STATION
MCK 2.0

1.0 LOCATION

There are five primary tributary drainage basins on south Chestnut Ridge (SCR), informally numbered from west to east (SCR1 through SCR5): Dunaway Branch (SCR1) and SCR2 southwest of Y-12, McCoy Branch (SCR3) directly south of Y-12; and SCR4 and SCR5 in southeast of Y-12. Flow in each tributary is mainly intermittent at elevations higher than 900 ft above msl. Surface runoff, stormflow discharge, and groundwater baseflow contribute flow to each tributary, which increases with distance downstream and includes substantial contributions from springs. Each drainage feature conveys surface water south toward Bethel Valley and discharges into Melton Hill Reservoir (Clinch River). This surface water sampling station is located in the main channel of McCoy Branch, directly downstream of a wetland area constructed immediately south of the Filled Coal Ash Pond (FCAP).

The FCAP is a former settling basin formed by the construction of an earthen dam across the upper reach of McCoy Branch. Beginning in 1955, the basin received coal ash from the Y-12 Steam Plant that was pumped as slurry over the crest of Chestnut Ridge and gravity-drained into the basin. By 1967, the basin had filled with ash and the slurry was allowed to overtop the dam and flow down McCoy Branch into Rogers Quarry until 1989. Remedial action at the FCAP was completed in April 1997 in accordance with a CERCLA ROD approved in February 1996 (DOE 1996). As described in the remedial action report, CERCLA remedial actions at the FCAP included: (1) raising the crest of the dam, (2) removing large trees from and reinforcing the face of the dam; (3) installing a subsurface drain; (4) repairing the emergency spillway for the dam; (5) constructing a settling basin and oxygenation weir at the foot of the dam; and (6) replacing a small wetland area in McCoy Branch immediately downstream of the settling basin (DOE 1997). These remedial actions are intended to minimize the migration of contaminants into surface water, minimize direct contact of humans and animals with the ash, reduce the potential for failure of the dam, and preserve the local habitat over the long term (DOE 1996).

2.0 SAMPLING HISTORY

Twelve (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in February 1999 and the most recent sample collected in August 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 90 – 477 mg/L;
- pH of 6.1 – 8.5 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals (except arsenic) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

The surface water sample collected in February 1999 had nitrate above the applicable analytical reporting limit, and this result (0.6 mg/L) is an order-of-magnitude below the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

None of the surface water samples had (total) uranium concentrations above the applicable analytical reporting limit.

4.3 VOLATILE ORGANIC COMPOUNDS

None of the samples were analyzed for VOCs.

4.4 GROSS ALPHA ACTIVITY

One surface water sample had gross alpha activity above the applicable MDA and corresponding CE, and this result (1.6 pCi/L in February 2004) is substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

4.5 GROSS BETA ACTIVITY

All of the surface water samples had gross beta activity above the applicable MDA and corresponding CE, with the historical maximum value (115.02 pCi/L in February 2001) being substantially above the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). However, this result is an outlier when compared to the other results for gross beta activity, all of which are less than 10 pCi/L.

4.6 OTHER TRACE METALS

Analytical data for surface water samples collected in accordance with the ROD for the FCAP indicate that the wetlands constructed in McCoy Branch immediately upstream of this sampling station continue to be effective at reducing concentrations of arsenic, manganese, iron, and zinc in the influent to the wetlands, as indicated by analytical results for samples from MCK 2.05 (DOE 2004).

SURFACE WATER SAMPLING STATION
MCK 2.05

1.0 LOCATION

There are five primary tributary drainage basins on south Chestnut Ridge (SCR), informally numbered from west to east (SCR1 through SCR5): Dunaway Branch (SCR1) and SCR2 southwest of Y-12, McCoy Branch (SCR3) directly south of Y-12; and SCR4 and SCR5 in southeast of Y-12. Flow in each tributary is mainly intermittent at elevations higher than 900 ft above msl. Surface runoff, stormflow discharge, and groundwater baseflow contribute flow to each tributary, which increases with distance downstream and includes substantial contributions from springs. Each drainage feature conveys surface water south toward Bethel Valley and discharges into Melton Hill Reservoir (Clinch River). This surface water sampling station is located in the main channel of McCoy Branch, directly upstream of a wetland area constructed immediately south of the Filled Coal Ash Pond (FCAP).

The FCAP is a former settling basin formed by the construction of an earthen dam across the upper reach of McCoy Branch. Beginning in 1955, the basin received coal ash from the Y-12 Steam Plant that was pumped as slurry over the crest of Chestnut Ridge and gravity-drained into the basin. By 1967, the basin had filled with ash and the slurry was allowed to overtop the dam and flow down McCoy Branch into Rogers Quarry until 1989. Remedial action at the FCAP was completed in April 1997 in accordance with a CERCLA ROD approved in February 1996 (DOE 1996). As described in the remedial action report, CERCLA remedial actions at the FCAP included: (1) raising the crest of the dam, (2) removing large trees from and reinforcing the face of the dam;; (3) installing a subsurface drain; (4) repairing the emergency spillway for the dam; (5) constructing a settling basin and oxygenation weir at the foot of the dam; and (6) replacing a small wetland area in McCoy Branch immediately downstream of the settling basin (DOE 1997). These remedial actions are intended to minimize the migration of contaminants into surface water, minimize direct contact of humans and animals with the ash, reduce the potential for failure of the dam, and preserve the local habitat over the long term (DOE 1996).

2.0 SAMPLING HISTORY

Twelve (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in February 1999 and the most recent sample collected in August 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 190 – 322 mg/L;
- pH of 6.1 – 8.2 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals (except arsenic) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

The surface water sample collected in February 1999 had nitrate above the applicable analytical reporting limit, and this result (0.1 mg/L) is two orders-of-magnitude below the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

None of the surface water samples had (total) uranium concentrations above the applicable analytical reporting limit.

4.3 VOLATILE ORGANIC COMPOUNDS

None of the surface water samples were analyzed for VOCs.

4.4 GROSS ALPHA ACTIVITY

Five of the 12 surface water samples analyzed for gross alpha activity had results above the applicable MDA and corresponding CE, and two of these results were above the drinking water MCL for gross alpha activity (15 pCi/L). The highest value (112.59 pCi/L in February 2001) is an outlier when compared to other results for gross alpha activity, all of which are less than 6 pCi/L excluding the result for the sample collected in August 2004 (15.2 pCi/L), which probably reflects interferences from the high TSS (866 mg/L) reported for the sample.

4.5 GROSS BETA ACTIVITY

Twelve surface water samples had gross beta activity above the applicable MDA and corresponding CE, with the historical maximum value (273 pCi/L in February 2001) being substantially above the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). However, this result is an outlier when compared to other results for gross beta activity, all of which are less than 18 pCi/L.

4.6 OTHER TRACE METALS

Analytical data for surface water samples collected in accordance with the ROD for the FCAP indicate that the wetlands constructed in McCoy Branch immediately downstream of this sampling station continue to be effective at reducing concentrations of arsenic, manganese, iron, and zinc in the effluent from the wetlands, as indicated by analytical results for samples from MCK 2.0 (DOE 2004). The arsenic concentrations in surface water samples at this station are typically about equal to the drinking water MCL for arsenic (0.05 mg/L), but two samples had sharply higher concentrations: 0.339 mg/L in August 2003 and 7.8 mg/L in August 2004. The August 2004 result, as with gross alpha activity, probably reflects interference from high TSS (866 mg/L) in the sample.

SURFACE WATER SAMPLING STATION
NPR07.0SW

1.0 LOCATION

This surface water sampling station is on the main channel of an unnamed drainage feature located north of Pine Ridge, about 2,000 ft north of Y-12. Samples are collected from this location to provide data regarding the quality of surface water that drains from the north slope of Pine Ridge and flows into the Scarboro Community. The surface-water quality monitoring is performed by the Y-12 GWPP to provide data regarding potential health impacts from Y-12 operations.

2.0 SAMPLING HISTORY

Eleven (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in April 2000 and the most recent sample collected in December 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 42 – 135 mg/L;
- pH of 5.8 – 7.7 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

One surface water sample had a nitrate concentration above the applicable analytical reporting limit (0.04789 September 2004); this result is substantially below the MCL.

4.2 URANIUM

None of the surface water samples had (total) uranium concentrations above the applicable analytical reporting limit.

4.3 VOLATILE ORGANIC COMPOUNDS

VOCs were not detected in the any of the surface water samples.

4.4 GROSS ALPHA ACTIVITY

One surface water sample had gross alpha activity above the applicable MDA and corresponding CE, and this result (3.7 pCi/L in October 2002) is substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

4.5 GROSS BETA ACTIVITY

Two surface water samples had gross beta activity above the applicable MDA and corresponding CE, and both results (10 pCi/L in November 2001 and 9.8 pCi/L in October 2002) are substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

SURFACE WATER SAMPLING STATION
NPR12.0SW

1.0 LOCATION

This surface water sampling station is on the main channel of an unnamed drainage feature located in north of Pine Ridge, about 1,500 ft north of Y-12. Samples are collected from this location to provide data regarding the quality of surface water that drains from the north slope of Pine Ridge and flows into the Scarboro Community. The surface-water quality monitoring is performed by the Y-12 GWPP to provide data regarding potential health impacts from Y-12 operations.

2.0 SAMPLING HISTORY

Eleven (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in September 1999 and the most recent sample collected in December 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 42 – 121 mg/L;
- pH of 5.8 – 7.6 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

One surface water sample had nitrate concentrations above the applicable analytical reporting limit, and this result (0.056 mg/L in September 1999) is several orders-of-magnitude below the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

One surface water sample had (total) uranium concentrations above the applicable analytical reporting limit, and this result (0.000572 mg/L) is several orders-of-magnitude lower than the drinking water MCL for uranium (0.03 mg/L).

4.3 VOLATILE ORGANIC COMPOUNDS

VOCs were not detected in the any of the surface water samples.

4.4 GROSS ALPHA ACTIVITY

Two surface water samples had gross alpha activity above the applicable MDA and corresponding CE, and both results (3.5 pCi/L in November 2001 and 6.8 pCi/L in May 2002) are less than the drinking water MCL for gross alpha activity (15 pCi/L).

4.5 GROSS BETA ACTIVITY

Two surface water samples had gross beta activity above the applicable MDA and corresponding CE, and both results (11 pCi/L in May 2002 and 6.9 pCi/L in October 2002) are substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

SURFACE WATER SAMPLING STATION
NPR23.0SW

1.0 LOCATION

This surface water sampling station is on an upper reach of Mill Branch north of Pine Ridge, about one mile northwest of Y-12. Samples are collected from this location to provide data regarding the quality of surface water that drains from the north slope of Pine Ridge and flows into a residential area along Wiltshire Drive. The surface-water quality monitoring is performed by the Y-12 GWPP to provide data regarding potential off-site health impacts from Y-12 operations.

2.0 SAMPLING HISTORY

Eight (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in May 2001 and the most recent sample collected in December 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 41 – 138 mg/L;
- pH of 6.6 – 7.5 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

None of the surface water samples had nitrate concentrations above the applicable analytical reporting limit.

4.2 URANIUM

None of the surface water samples had (total) uranium concentrations above the applicable analytical reporting limit.

4.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were not detected in the any of the surface water samples.

4.4 GROSS ALPHA ACTIVITY

Three surface water samples had gross alpha activity above the applicable MDA and corresponding CE, and the highest result (4.4 pCi/L in April 2004) is substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

4.5 GROSS BETA ACTIVITY

One surface water samples had gross beta activity above the applicable MDA and corresponding CE, and this result (6.1 pCi/L in May 2003) are substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

SURFACE WATER SAMPLING STATION
NT-01

1.0 LOCATION

This surface water sampling station is in a northern tributary (NT) of Bear Creek (NT-1) immediately upstream of its confluence with the main creek channel. Numbered in ascending order downstream (west) of the Bear Creek headwaters near the west end of Y-12, the northern tributaries trend northeast-southwest across the southern flank of Pine Ridge and are believed to be the surface expression of large-scale fracture zones (or small faults) in the bedrock (Conasauga Group) underlying Bear Creek Valley (BCV) (Solomon et. al. 1992). Upstream of this sampling station, the channel of NT-1 traverses an undeveloped area about 1,200 ft west of the former S-3 Ponds.

Approximately half of the annual precipitation in BCV exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Major springs along the south side (SS) of Bear Creek, which are numbered in ascending order downstream from the headwaters (e.g., SS-1) and occur along the Maynardville Limestone/Copper Ridge Dolomite boundary, dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main creek channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Thirty-seven (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in March 1993 and the most recent sample collected in November 2004. The grab sampling method was used to collect each sample. Note that numerous surface water samples have been collected for other monitoring programs, including CERCLA monitoring performed at the former S-3 Ponds.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 290 – 7,540 mg/L;
- pH of 6.1 – 7.6 (field measurements);
- elevated concentrations of chloride (>200 mg/L), potassium (>10 mg/L), sodium (>60 mg/L), and sulfate (>20 mg/L); and
- total concentrations of several trace metals, including barium, cadmium, manganese, strontium, and uranium, that substantially exceed the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Thirty of the surface water samples had nitrate concentrations above the applicable analytical reporting limit (Table 1). The one non-detect value (<0.02 mg/L) reported for the sample collected in March 1996 is an outlier when compared to the other nitrate results, all of which exceed the drinking water MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds. Located at the headwaters of Bear Creek near the west end of Y-12, the S-3 Ponds were four contiguous, unlined surface impoundments used from 1951 to 1984 for the infiltration/evaporation of several million gallons of nitric acid wastes generated at Y-12. Now covered with a multilayer low-permeability cap constructed in 1988, the former S-3 Ponds emplaced a heterogeneous mixture of inorganic, organic, and radiological contamination in the underlying Nolichucky Shale. Nitrate is a primary component of the plume and is transported in the shallow groundwater system to the south toward Bear Creek and to the west, parallel with geologic strike, toward discharge areas in NT-1 and NT-2 (DOE 1997). Additionally, nitrate in the deeper (>150 ft bgs) groundwater flow/transport pathways in the Nolichucky Shale moves westward along strike and, under vertically upward hydraulic gradients, enters the shallow flow system and ultimately discharges into NT-1 and NT-2. Thus, elevated nitrate concentrations in the surface water at this sampling station result from the upstream discharge of nitrate-contaminated groundwater into NT-1.

Excluding the non-detect result noted above, the nitrate concentrations reported for the surface water samples show a wide range, with six results below 50 mg/L and three results above 500 mg/L, including the historical maximum value of 1,180 mg/L in July 2002 (Table 1). A time-series plot of these nitrate results shows a generally increasing long-term concentration trend dominated by wide seasonal concentration fluctuations (Figure 1). Also, these "peak" nitrate concentrations often are evident for samples collected during summer or fall, which shows that inflow of nitrate-contaminated groundwater from the Nolichucky Shale provides baseflow in NT-1.

4.2 URANIUM

Thirty-four of the surface water samples had (total) uranium concentrations above the applicable analytical reporting limit (Table 1), with 15 samples having concentrations above the drinking water MCL for uranium (0.03 mg/L). Considering the pH of the samples (see Section 3.0), uranium probably occurs in the surface water as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble, mobile complexes with a variety of inorganic anions in the groundwater, such as carbonate (Fetter 1993). Uranium is a principal component of the contaminant plume emplaced during historical operation of the former S-3 Ponds. As with nitrate levels, the elevated uranium concentrations in the surface water in NT-1 are attributable to the upstream inflow of uranium-contaminated groundwater from the Nolichucky Shale.

A time-series plot of the uranium results reported for the surface water samples shows an indeterminate long-term concentration trend dominated by wide seasonal concentration fluctuations (Figure 2). As with nitrate levels, the highest uranium concentrations were reported for samples collected during summer or fall (dry season), as illustrated by the conspicuous concentration "peaks" evident in October 1997 (0.32 mg/L), August 1998 (0.149 mg/L), and July 2002 (0.132 mg/L). This too shows that inflow of contaminated groundwater from the Nolichucky Shale provides baseflow in NT-1 and that the uranium concentrations evident in samples collected during winter and spring (wet season) reflect dilution from uncontaminated (or less contaminated) recharge.

4.3 VOLATILE ORGANIC COMPOUNDS

At least one of the following VOCs was detected in 28 of the surface water samples: acetone, chloroform, methylene chloride, PCE, TCE, and c12DCE (Table 2). Each compound is a confirmed component of the contaminant plume emplaced during historical operation of the former S-3 Ponds. Like nitrate and uranium, the presence of these compounds in the surface water in NT-1 (and NT-2) results from the discharge of VOC-contaminated groundwater in the Nolichucky Shale west of the site.

Based on the detection frequency and concentration, PCE is the primary VOC in the surface water samples (Table 2). This compound was detected in all but three of the samples, with concentrations above the drinking water MCL for PCE (5 μg/L) reported for 18 samples. A time-series plot of the PCE results shows a generally increasing concentration trend (Figure 3). The other compounds are detected much less frequently, with one or more of these VOCs detected (excluding false positive results) in only seven of the samples and all of the results being estimated values below 5 μg/L (Table 2).

4.4 GROSS ALPHA ACTIVITY

Twenty-seven of the surface water samples had gross alpha activity above the applicable MDA and corresponding CE (Table 1), and results for 17 of the samples exceed the drinking water MCL for gross alpha activity (15 pCi/L). The contaminant plume emplaced during historical operation of the former S-3 Ponds includes several alpha-particle emitting radionuclides, including uranium isotopes. Radiological analyses performed to date, summarized below, confirm the presence of U-234 and U-238 in the surface water samples.

Sampling Date	Concentration (pCi/L)	
	U-234	U-238
02/20/98	1.64	3.33
07/29/98	32.16	68.55
01/55/01	55	84
07/12/01	18	37

As with total uranium, the presence of uranium isotopes in the surface water at this sampling location in NT-1 reflects the upstream inflow of uranium-contaminated groundwater from the Nolichucky Shale.

A time-series plot of the gross alpha activity reported for the surface water samples shows a slightly increasing long-term concentration trend dominated by wide short-term concentration fluctuations (Figure 4). These "peak" levels of gross alpha activity are indicated by results for samples collected during seasonally low flow (e.g., 150 pCi/L in July 2002) and seasonally high flow (e.g., 120 pCi/L in January 2001). Thus, the short-term changes in gross alpha activity do not appear to be directly related to groundwater seasonal flow conditions.

4.5 GROSS BETA ACTIVITY

Thirty-one of the surface water samples had gross beta activity above the applicable MDA and corresponding CE (Table 1) and all but one of these results substantially exceed the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). Indeed, the one result below 50 pCi/L (18.1 pCi/L in March 1995) appears to be an outlier compared to the other results for gross beta activity. Although uranium isotopes (and related beta-particle emitting daughter products) contribute to the level of gross beta activity in the surface water samples, available analytical results, summarized below, show that the gross beta activity is mostly attributable to Tc-99, a beta-emitting radionuclide that is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds (DOE 1997).

Sampling Date	Tc-99 (pCi/L)
03/09/93	<CE
05/03/93	<CE
08/16/93	1,120
11/08/93	708
02/14/94	458
09/07/94	786
03/09/95	165
07/25/95	956
03/18/96	313
08/13/96	107
11/10/97	2,440
12/01/97	541
01/10/01	280
07/12/01	5,900

Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile (Gee et al. 1983). Thus, the elevated gross beta activity in the surface water samples from NT-01 reflect the upstream inflow of Tc-99 contaminated groundwater from the Nolichucky Shale.

A time-series plot of the gross beta activity reported for the surface water samples shows a generally increasing long-term concentration trend dominated by wide seasonal concentration fluctuations (Figure 5). As with nitrate levels, the highest gross beta activity values were reported for samples collected during summer or fall (dry season), as illustrated by the conspicuous concentration "peaks" evident in July 2001 (4,400 pCi/L), July 2002 (6,000 pCi/L; the historical maximum value for NT-01), and July 2002 (1,000 pCi/L). These results indicate that contaminated groundwater provides the baseflow in the upper reach of Bear Creek and that the gross beta activity reported for samples collected during winter and spring (wet season) reflect dilution from uncontaminated (or less contaminated) recharge.

SURFACE WATER SAMPLING STATION NT-03

1.0 LOCATION

This surface water sampling station is located in a northern tributary (NT) of Bear Creek (NT-3) immediately upstream of its confluence with the main creek channel. Numbered in ascending order downstream (west) of the Bear Creek headwaters near the west end of Y-12, the northern tributaries trend northeast-southwest across the southern flank of Pine Ridge and are believed to be the surface expression of large-scale fracture zones (or small faults) in the bedrock (Conasauga Group) underlying Bear Creek Valley (BCV) (Solomon et. al. 1992). Upstream of this sampling station, the channel of NT-3 traverses the east-central section of the Oil Landfarm waste management area. Additionally, a section of tributary channel upstream of the NT-03 sampling station was extensively modified and reconstructed during CERCLA remedial action at the Boneyard/Burnyard (BYBY) (see Section 4.2).

Approximately half of the annual precipitation in BCV exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Major springs along the south side (SS) of Bear Creek, which are numbered in ascending order downstream from the headwaters (e.g., SS-1) and occur along the Maynardville Limestone/Copper Ridge Dolomite boundary, dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main creek channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Nine (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in April 1997 and the most recent sample collected in September 2004. The grab sampling method was used to collect each sample.

In addition to sampling performed to meet the surveillance monitoring objectives of the Y-12 GWPP, samples have been collected to date for the purposes of other monitoring programs, including flow proportionate composite sampling performed in accordance with the Phase I ROD for the Bear Creek watershed (DOE 2000).

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- pH of 5.8 – 8.6 (field measurements) and

- total concentrations of several trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Four samples had nitrate concentrations above the applicable analytical reporting limit, with very low concentrations (<1 mg/L) that are an order-of-magnitude below the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

The surface water samples were not analyzed for total uranium.

4.3 VOLATILE ORGANIC COMPOUNDS

VOCs were not detected in the surface water samples.

4.4 GROSS ALPHA ACTIVITY

Two of the surface water samples were analyzed for gross alpha activity and both results (264 pCi/L in April 1997 and 445.99 pCi/L in June 1998) substantially exceed the drinking water MCL for gross alpha activity (15 pCi/L). Results of radiological analyses performed to date, summarized below, confirm the presence of U-234 and U-238 in the surface water samples.

Sampling Date	Concentration (pCi/L)	
	U-234	U-238
04/18/97	78	159
06/25/98	179.6	378.2
12/30/98	599.9	1,267
03/12/01	131.8	286.1

The source of the uranium isotopes is the former BYBY. A CERCLA remedial action at the site, completed in March 2003, involved the construction of an upgradient subsurface drain to hydraulically isolate the buried wastes in June 2002; the excavation, consolidation, and disposal of about 64,000 yd^3 of wastes that were in contact with groundwater by December 2002; and the reconstruction of a section of the Bear Creek tributary (NT-3) that drains surface runoff from the site by March 2003 (BJC 2003).

4.5 GROSS BETA ACTIVITY

Two of the surface water samples were analyzed for gross beta activity and both results (190 pCi/L in April 1997 and 200.05 pCi/L in June 1998) substantially exceed the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). Uranium isotopes (and related beta-particle emitting daughter products) are the primary source of the gross beta activity in the surface water samples. Additionally, available analytical results, summarized below, show that the gross beta activity is probably not attributable to Tc-99, a beta-emitting radionuclide that is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds (DOE 1997).

Sampling Date	Tc-99 (pCi/L)

SURFACE WATER SAMPLING STATION
NT-04

1.0 LOCATION

This surface water sampling station is located in a northern tributary (NT) of Bear Creek (NT-4) about 270 ft upstream of its confluence with the main creek channel. Numbered in ascending order downstream (west) of the Bear Creek headwaters near the west end of Y-12, the northern tributaries trend northeast-southwest across the southern flank of Pine Ridge and are believed to be the surface expression of large-scale fracture zones (or small faults) in the bedrock (Conasauga Group) underlying Bear Creek Valley (BCV) (Solomon et. al. 1992). Upstream of the NT-04 sampling station, the channel of NT-4 drains the EMWMF and meanders between the western side of the Oil Landfarm waste management area and the Above Ground Low Level Storage Facility. A French drain installed to bypass surface water drainage from Pine Ridge and to lower the water table beneath the EMWMF discharges groundwater into NT-4 upstream of the sampling location.

Approximately half of the annual precipitation in BCV exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Discharge from springs located along the Maynardville Limestone/Copper Ridge Dolomite boundary on the north slope of Chestnut Ridge dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Eight (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in February 2003 and the most recent sample collected in December 2004. The grab sampling method was used to collect each sample.

In addition to sampling performed to meet the surveillance monitoring objectives of the Y-12 GWPP, samples have been collected to date for the purposes of other monitoring programs, including flow proportionate composite sampling performed in accordance with the Phase I ROD for the Bear Creek watershed (DOE 2000).

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data for the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- pH of 7.0 – 8.2 (field measurements) and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

The surface water samples were not analyzed for nitrate.

4.2 URANIUM

One surface water sample was analyzed for (total) uranium concentrations, and this result (0.00781 mg/L in May 2003) is more than an order-of-magnitude lower than the drinking water MCL for uranium (0.03 mg/L).

4.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, a low concentration (5.5 μg/L) of c12DCE was detected in the surface water sample collected in May 2003.

4.4 GROSS ALPHA ACTIVITY

One surface water sample was analyzed for gross alpha activity, and this result (4.66 pCi/L in May 2003) is below the drinking water MCL for gross alpha activity (15 pCi/L).

4.5 GROSS BETA ACTIVITY

One surface water sample was analyzed for gross beta activity, and this result (5.23 pCi/L in May 2003) is substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

SURFACE WATER SAMPLING STATION
NT-07

1.0 LOCATION

This surface water sampling station is located in a northern tributary (NT) of Bear Creek (NT-7) immediately upstream of its confluence with the main creek channel. Numbered in ascending order downstream (west) of the Bear Creek headwaters near the west end of Y-12, the northern tributaries trend northeast-southwest across the southern flank of Pine Ridge and are believed to be the surface expression of large-scale fracture zones (or small faults) in the bedrock (Conasauga Group) underlying Bear Creek Valley (BCV) (Solomon et. al. 1992). Upstream of this sampling station, the channel of NT-7 traverses the west-central section of the Bear Creek Burial Grounds (BCBG) waste management area (WMA).

Approximately half of the annual precipitation in BCV exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Discharge from springs located along the Maynardville Limestone/Copper Ridge Dolomite contact on the north slope of Chestnut Ridge dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Sixteen (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in April 1997 and the most recent sample collected in September 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 146 – 470 mg/L;
- pH of 6.1 – 8.9 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals (except uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Seven surface water samples had nitrate concentrations above the applicable analytical reporting limit, with the historical maximum value (0.31 mg/L in January 2000) being an order-of-magnitude below the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

Ten surface water samples had (total) uranium concentrations above the applicable analytical reporting limit, with a historical maximum value of 0.0275 in September 2001. Although less than the drinking water MCL for uranium (0.03 mg/L), these uranium concentrations exceed the range of background levels in BCV. Wastes disposed at the BCBG are known sources of uranium and other inorganic (and organic) contaminants present in the surface water in the northern tributaries of Bear Creek (NT-6, NT-7, and NT-8) that drain the WMA (DOE 1997). Uranium leached from the wastes enters the shallow groundwater and is transported primarily in the direction of geologic strike toward discharge areas in nearby drainage features (e.g., NT-7). Thus, the uranium concentrations in the surface water at this sampling station reflect the upstream inflow of contaminated groundwater into NT-7.

4.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, at least one of the following VOCs were detected in 15 of the groundwater samples: chloroform, chloromethane, PCE, TCE, VC, 11DCA, 12DCA, 12DCE (c12DCE), and 111TCA (Table 1). These compounds are all components of the groundwater contaminant plume emplaced during historical operation of the BCBG WMA. Dissolved VOCs in the shallow groundwater are transported primarily in the direction of geologic strike toward discharge areas in nearby drainage features (e.g., NT-7). Thus, the presence of VOCs in the surface water at this sampling station is a result of the upstream inflow of VOC-contaminated groundwater into NT-7.

Based on the detection frequency, the primary VOCs in the surface water samples are PCE, TCE, 11DCA, and 12DCE (Table 1). These compounds were each detected in all but six of the samples, with respective historical maximum values of 99 µg/L, 74 µg/L, 25 µg/L, and 410 µg/L. The most recent sampling results (September 2004) show PCE and TCE concentrations below their respective 5 µg/L MCL for drinking water. Chloroform, chloromethane, VC, 11DCE, 12DCE, and 111TCA were detected less frequently; chloromethane and 12DCA were detected in only one sample (Table 1). Additionally, the bulk of the results for these compounds are estimated values below 5 µg/L, with concentrations above 10 µg/L reported only for VC (22 µg/L in January 2000).

A times-series plot of summed concentrations of VOCs detected (excluding false positive results) in each applicable surface water sample (some samples were not analyzed for VOCs) shows a generally decreasing long-term trend dominated by wide (seasonal) concentration fluctuations

(Figure 1). Note that these "peak" concentrations typically are represented by summed VOC concentrations determined for samples collected during winter and spring (wet season). Indeed, all of the summed VOC concentrations that are below 100 µg/L were determined for samples collected during summer and fall (dry season). This suggests greater inflow of VOC-contaminated groundwater into NT-7 during seasonally high flow conditions.

4.4 GROSS ALPHA ACTIVITY

Five of the surface water samples (collected April 1997 through March 1999) were analyzed for gross alpha activity, and all of these results are less than the drinking water MCL for gross alpha activity (15 pCi/L).

4.5 GROSS BETA ACTIVITY

Five of the surface water samples (collected April 1997 through March 1999) were analyzed for gross beta activity, and all of these results are less than the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the MCL for gross beta activity).

SURFACE WATER SAMPLING STATION NT-08

1.0 LOCATION

This surface water sampling station is located immediately upstream of the confluence of the main channel of Bear Creek and a the northern tributary (NT) of the creek (NT-8). Numbered in ascending order downstream (west) of the Bear Creek headwaters near the west end of Y-12, the northern tributaries trend northeast-southwest across the southern flank of Pine Ridge and are believed to be the surface expression of large-scale fracture zones (or small faults) in the bedrock (Conasauga Group) underlying Bear Creek Valley (BCV) (Solomon et. al. 1992). About 600 ft upstream of its confluence with Bear Creek, the main channel of NT-8 splits into eastern and western branches, both of which extend northeast toward the northwest section of the Bear Creek Burial Grounds (BCBG) waste management area (WMA).

Approximately half of the annual precipitation in BCV exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Discharge from springs located along the Maynardville Limestone/Copper Ridge Dolomite boundary on the north slope of Chestnut Ridge dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Sixteen (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in April 1997 and the most recent sample collected in September 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 109 – 560 mg/L;
- pH of 6.3 – 8.9 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals (except uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Nine surface water samples had nitrate concentrations above the applicable analytical reporting limit, with the historical maximum value (5.4 mg/L in August 2000) being below the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

Ten surface water samples had (total) uranium concentrations above the applicable analytical reporting limit (Table 1), and all of these results exceed the drinking water MCL for uranium (0.03 mg/L). Wastes disposed at the BCBG are known sources of uranium and other inorganic (and organic) contaminants present in the surface water in the northern tributaries of Bear Creek (NT-6, NT-7, and NT-8) that drain the WMA (DOE 1997). Uranium leached from the wastes enters the shallow groundwater and is transported primarily in the direction of geologic strike toward discharge areas in nearby drainage features. Because much of the main channel of NT-8 is more than 1,000 ft west of the waste disposal sites within the BCBG, the uranium probably enters the tributary via contaminated groundwater discharged into the headwaters of the tributary, which extend within a few hundred feet of the waste disposal areas within the northwest section of the BCBG. Moreover, the uranium concentrations reported for samples of surface water from the eastern branch of the tributary headwaters (sampling station NT-8-E) are higher than evident in samples of the surface water from the western branch of the tributary headwaters (sampling station NT-8-W). This suggests that inflow of uranium-contaminated groundwater into the eastern headwaters channel may be the principal source of the uranium evident downstream at the NT-08 surface water sampling station.

As shown by a time-series plot of available uranium concentrations (Figure 1), a generally decreasing concentration trend is indicated by the uranium results obtained to date. The uranium concentration reported for the sample collected in September 2004 (0.201 mg/L) is about 50 % lower than the concentration reported for the sample collected in January 2000 (0.442 mg/L; the historical maximum value).

4.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, at least one of the following VOCs were detected in each of the groundwater samples: benzene, chloroform, PCE, TCE, 12DCE, 11DCE, VC, 111TCA, 12DCA, and 11DCA (Table 1). These compounds are all components of the groundwater contaminant plume emplaced during historical operation of the BCBG WMA. Dissolved VOCs in the shallow groundwater are transported primarily in the direction of geologic strike toward discharge areas in nearby drainage features (e.g., NT-8). Thus, the presence of VOCs in the surface water at this sampling station is a result of the upstream inflow of VOC-contaminated groundwater into NT-8.

Based on the detection frequency and concentration levels, the primary VOCs in the surface water samples are PCE, TCE, 12DCE, and 11DCA (Table 2). These compounds were each detected in all but three of the samples, with respective historical maximum values of PCE (56 µg/L in July 1998), TCE (39 µg/L in July 1998), and c12DCE (200 µg/L in February 1999) exceeding respective drinking water MCLs. The most recent sampling results (September 2004) show concentrations of these compounds below their respective MCLs. Benzene, chloroform, 11DCE, VC, 11DCA, and 111TCA were detected less frequently, and the bulk of the results for these compounds are estimated values below 5 µg/L, with the highest concentration of 11DCE (7 µg/L) and VC (16 µg/L) exceeding respective MCLs (Table 2).

A time-series plot of the summed concentration of VOCs detected in surface water samples collected at NT-08 shows a generally decreasing long-term trend with a concentration "spike" (898 µg/L) in July 1998 and fairly steady concentrations since March 1999 (Figure 2).

4.4 GROSS ALPHA ACTIVITY

Five of the surface water samples (collected April 1997 through March 1999) were analyzed for gross alpha activity, and all but one of these results exceed the drinking water MCL for gross alpha activity (15 pCi/L), including the historical maximum value (140 pCi/L in March 1999). In addition to or in lieu of gross alpha activity, thirteen of the samples were analyzed for uranium isotopes and these analytical results, summarized below, confirm that the elevated gross alpha activity is attributable to U-234 and U-238.

Sampling Date	Concentration (pCi/L)	
	U-234	U-238
04/03/97	7.1	31
08/22/97	19.49	50.22
02/18/98	15.77	91
07/17/98	1.54	6.59
02/02/99	16.75	137.6
07/29/99	19.48	73.32
01/25/00	32.16	154.9
08/17/00	34.45	109.3
03/22/01	17.35	99.46
09/18/01	9.41	29.36
03/13/02	17.83	90.59
03/04/03	32.46	121.3
08/18/03	26.05	71.68
03/02/04	14.61	101.6
09/14/04	14.67	50.83

As with uranium and VOCs in the surface water, the uranium isotopes are leached from sources within the BCBG WMA and are transported in the shallow groundwater toward discharge areas in nearby surface drainage features (e.g., NT-8). Thus, the presence of uranium isotopes in the surface water at this sampling station reflects the upstream inflow of contaminated groundwater into NT-8. Moreover, based on sampling results for surface water sampling stations located in the eastern and western headwaters channel of NT-8, higher levels of U-234 and U-238 in the easternmost channel (sampling station NT-8-E) compared to the westernmost channel (sampling station NT-8-W) suggest greater relative discharge of radiologically-contaminated groundwater into the easternmost channel, which borders the northwest side of the BCBG WMA.

4.5 GROSS BETA ACTIVITY

Five of the surface water samples (collected April 1997 through March 1999) were analyzed for gross beta activity, and two of these results exceed the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the MCL for gross beta activity): 52.9 pCi/L in August 1997 and 60.22 pCi/L in February 1998. As with gross alpha activity, the elevated levels of gross beta activity are attributable to uranium isotopes (and beta-particle emitting daughter products).

SURFACE WATER SAMPLING STATION
NT-8-E

1.0 LOCATION

This surface water sampling station is located in the eastern headwaters channel of a northern tributary (NT) of Bear Creek (NT-8). Numbered in ascending order downstream (west) of the Bear Creek headwaters near the west end of Y-12, the northern tributaries traverse northeast-southwest across the southern flank of Pine Ridge and are believed to be the surface expression of large-scale fracture zones (or small faults) in the bedrock (Conasauga Group) underlying Bear Creek Valley (BCV) (Solomon et. al. 1992). About 600 ft upstream of its confluence with Bear Creek, the main channel of NT-8 splits into eastern and western branches, both of which extend northeast toward the northwest section of the Bear Creek Burial Grounds (BCBG) waste management area (WMA), with sampling station NT-8-E being about 500 ft upstream of the confluence of the western and eastern branches.

Approximately half of the annual precipitation in BCV exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Discharge from springs located along the Maynardville Limestone/Copper Ridge Dolomite boundary on the north slope of Chestnut Ridge dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Five (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in March 2001 and the most recent sample collected in August 2003. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 148 – 288 mg/L;
- pH of 7.5 – 8.3 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals (except uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Five surface water samples had nitrate concentrations above the applicable analytical reporting limit, with the historical maximum value (0.132 mg/L in March 2002) being substantially below the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

Five surface water samples had (total) uranium concentrations above the applicable analytical reporting limit and three results exceed the drinking water MCL for uranium (0.03 mg/L): 1.16 mg/L in March 2002, 2.2 mg/L in March 2003, and 0.543 mg/L in August 2003. Waste disposal areas within the BCBG are known sources of uranium and other inorganic (and organic) contaminants present in the surface water in the northern tributaries of Bear Creek that drain this WMA (DOE 1997). Uranium leached from the wastes enters the shallow groundwater and is transported primarily in the direction of geologic strike toward discharge areas in nearby drainage features. Because much of the main channel of NT-8 is more than 1,000 ft west of the waste disposal sites within the BCBG, the uranium probably enters the tributary via contaminated groundwater discharged into the headwaters of the tributary, which extend within a few hundred feet of the waste disposal areas within the northwest section of the BCBG. Moreover, the uranium concentrations reported for this sampling station are higher than reported for the samples of surface water collected from the western branch of the tributary headwaters (sampling station NT-8-W). This suggests greater inflow of uranium-contaminated groundwater into the eastern branch.

4.3 VOLATILE ORGANIC COMPOUNDS

Low concentrations of PCE (1 μg/L) and c12DCE (2 μg/L) were detected in the surface water sample collected in March 2001. Both VOCs are confirmed components of the groundwater contaminant plume emplaced during historical operation of the BCBG WMA. Dissolved VOCs in the shallow groundwater are transported primarily in the direction of geologic strike toward discharge areas in nearby drainage features (e.g., NT-8).

4.4 GROSS ALPHA ACTIVITY

Instead of gross alpha activity, the surface water samples collected to date were analyzed for uranium isotopes; analytical results are summarized below.

Sampling Date	Concentration (pCi/L)	
	U-234	U-238
03/22/01	1.71	6.14
09/18/01	2.64	16.47
03/13/02	50.25	223.2
03/04/03	134.9	625.8
08/19/03	35.65	185.8

As with uranium and VOCs in the surface water, the uranium isotopes are leached from sources within the BCBG WMA and are transported in the shallow groundwater toward discharge areas in nearby surface drainage features (e.g., NT-8). Interestingly, these U-234 and U-238 concentrations are substantially higher than evident in surface water samples collected from the surface water station (NT-8-W) in the western headwaters channel of NT-8. This suggests greater relative discharge of radiologically-contaminated groundwater into the reach of the tributary channel upstream of NT-8-E.

4.5 GROSS BETA ACTIVITY

The surface water samples were not analyzed for gross beta activity.

SURFACE WATER SAMPLING STATION
NT-8-W

1.0 LOCATION

This surface water sampling station is located in the western headwaters channel of a northern tributary (NT) of Bear Creek (NT-8). Numbered in ascending order downstream (west) of the Bear Creek headwaters near the west end of Y-12, the northern tributaries traverse northeast-southwest across the southern flank of Pine Ridge and are believed to be the surface expression of large-scale fracture zones (or small faults) in the bedrock (Conasauga Group) underlying Bear Creek Valley (BCV) (Solomon et. al. 1992). About 600 ft upstream of its confluence with Bear Creek, the main channel of NT-8 splits into eastern and western branches, both of which extend northeast toward the northwest section of the Bear Creek Burial Grounds (BCBG) waste management area (WMA), with sampling station NT-8-W being about 500 ft upstream of the confluence of the western and eastern branches.

Approximately half of the annual precipitation in BCV exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Discharge from springs located along the Maynardville Limestone/Copper Ridge Dolomite boundary on the north slope of Chestnut Ridge dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Five (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in March 2001 and the most recent sample collected in August 2003. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 57 - 187;
- pH of 7.4 – 8.9 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals (except uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Two surface water samples had nitrate concentrations above the applicable analytical reporting limit, and both results (0.033 mg/L in September 2001 and 0.029 mg/L in March 2002) are several orders-of-magnitude below the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

Five surface water samples had (total) uranium concentrations above the applicable analytical reporting limit, including two results that exceed the drinking water MCL for uranium (0.03 mg/L): 0.0465 mg/L in September 2001 and 0.487 mg/L in March 2003. Waste disposal areas within the Bear Creek Burial Grounds (BCBG) waste management area (WMA) are known sources of uranium and other inorganic (and organic) contaminants present in the surface water in the northern tributaries of Bear Creek that drain the WMA (DOE 1997). Uranium leached from the wastes enters the shallow groundwater and is transported primarily in the direction of geologic strike toward discharge areas in nearby drainage features. Because much of the main channel of NT-8 is more than 1,000 ft west of the waste disposal sites within the BCBG, the uranium probably enters the tributary via contaminated groundwater discharged into the headwaters of the tributary, which extend within a few hundred feet of the waste disposal areas within the northwest section of the BCBG. Moreover, the uranium concentrations reported for this sampling station are lower than reported for the samples of surface water collected from the eastern branch of the tributary headwaters (sampling station NT-8-E). This suggests greater inflow of uranium-contaminated groundwater into the eastern branch.

4.3 VOLATILE ORGANIC COMPOUNDS

Low concentrations of c12DCE (2 μg/L) and 11DCE (1 μg/L) were detected in the surface water sample collected in March 2003. Both VOCs are confirmed components of the groundwater contaminant plume emplaced during historical operation of the BCBG WMA. As with uranium in the surface water; dissolved VOCs in the shallow groundwater are transported primarily in the direction of geologic strike toward discharge areas in nearby drainage features (e.g., NT-8).

4.4 GROSS ALPHA ACTIVITY

Instead of gross alpha activity, the surface water samples collected to date were analyzed for uranium isotopes; analytical results are summarized below.

Sampling Date	Concentration (pCi/L)	
	U-234	U-238
03/22/01	2.69	3.27
09/18/01	2.4	11.03
03/13/02	1.3	4.03
03/04/03	4.65	17.13
08/19/03	1.41	7.44

As with uranium and VOCs in the surface water, the uranium isotopes are leached from sources within the BCBG WMA and are transported in the shallow groundwater toward discharge areas in nearby surface drainage features (e.g., NT-8). Interestingly, these U-234 and U-238 concentrations are substantially lower than evident in surface water samples collected from the surface water station (NT-8-E) in the eastern headwaters channel of NT-8. This suggests substantially less discharge of radiologically-contaminated groundwater into the reach of the tributary channel upstream of NT-8-W.

4.5 GROSS BETA ACTIVITY

The surface water samples were not analyzed for gross beta activity.

OUTFALL 51

1.0 LOCATION

Outfall 51 captures flow from a large spring (Big Spring) located the southeast corner of Bldg. 9201-2 and discharges into the exposed section of the main channel of Upper East Fork Poplar Creek (UEFPC) in south-central Y-12. The spring discharge was captured during construction of Bldg. 9201-2 in the early 1940's and measurements obtained over the past three years show average daily flow rates of 0.17 to 0.87 million gallons per day (mgd). Substantial sections of UEFPC also were modified during construction of other facilities at Y-12, with the headwaters and several thousand feet of the main channel in the upper reach of the creek, including all the northern tributaries of the creek in the western and central sections of Y-12, being filled and replaced with an extensive network of underground storm drains. Also, the section of the creek near the eastern end of Y-12 was extensively modified by construction of New Hope Pond (NHP) in 1963 and the closure of NHP in 1988. An unlined surface impoundment, NHP was used to regulate the quantity and quality of surface water exiting Y-12 until it was closed and replace by Lake Reality, a lined surface impoundment built in 1988.

About 80% of dry-weather flow in UEFPC is attributable to once-through non-contact cooling water, condensate, and cooling tower blowdown, and the remaining 20% is from groundwater discharge (DOE 1998). In accordance with a flow management program initiated in July 1996, untreated water from the Clinch River intake lines to the DOE water treatment plant that supplies potable water to Y-12 is discharged into the exposed section of the main channel of UEFPC in the south-central section of Y-12 near Bldg. 9201-1. Augmentation of flow in UEFPC is necessary because reduced operations at Y-12 have decreased flow from 10-15 mgd to about 2.5 mgd. Flow augmentation also is needed to: (1) achieve the National Pollution Discharge Elimination System (NPDES) minimum daily flow requirement of 7 mgd at Station 17, which is located immediately upstream of where UEFPC exits the DOE Oak Ridge Reservation northeast of Y-12; (2) maintain compliance with NPDES toxicity requirements; and (3) lower the otherwise elevated water temperature in UEFPC.

Discharge from Outfall 51 accounts for about 10% of the total annual flow at Station 17. Beginning in August 2005, discharge from the outfall is captured and treated at the Big Spring Treatment Facility in accordance with the Phase I ROD for UEFPC (DOE 1997). This facility captures and treats Outfall 51 discharge and groundwater from basement dewatering sumps in Building 9201-2. It is unknown if any residual discharge from Outfall 51 persists as a result of groundwater infiltration.

2.0 SAMPLING HISTORY

Twelve (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in February 1999 and the most recent sample collected in August 2004. The grab sampling method was used to collect each sample.

In addition to the sampling performed to meet the surveillance monitoring objectives Y-12 GWPP, surface water samples also have been collected to meet other monitoring requirements, including sampling that the Y-12 Surface Water Program performs as a best management practice and to meet the requirements of DOE Order 5400.5. Also, grab sampling and/or flow-proportionate composite sampling is performed for NPDES purposes and to meet the requirements of the Phase I ROD for UEFPC (DOE 1997).

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 139 – 300 mg/L;
- pH of 6.8 – 8.6 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals (except mercury) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

All of the surface water samples had nitrate concentrations above the applicable analytical reporting limit (Table 1), with the historical maximum value (5.5 mg/L in August 2001) being substantially below the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

Ten surface water samples had (total) uranium concentrations above the applicable analytical reporting limit (Table 1), with the historical maximum value (0.0116 mg/L in August 2001), being less than the drinking water MCL for uranium (0.03 mg/L).

4.3 MERCURY

Three surface water samples had (total) mercury concentrations above the applicable analytical reporting limit (Table 1), with the highest value (0.00096 mg/L in July 1999) being substantially below the drinking water MCL for mercury (0.002 mg/L). There are multiple sources of mercury within Y-12 upstream of this sampling station, including inflow of mercury-contaminated groundwater into UEFPC, and the remediation of these sources is the focus of the CERCLA Phase I ROD for mercury source areas in UEFPC (DOE 1997).

4.4 VOLATILE ORGANIC COMPOUNDS

Each surface water sample collected to date had low concentrations (most being estimated values below 5 μg/L) of one or more of the following VOCs (Table 2): bromodichloromethane (BDM), CTET, chloroform (CLF), PCE, TCE, c12DCE, 11DCA, and 111TCA. Based on concentration levels, the principal VOCs are PCE and TCE, with historical maximum concentrations that exceed the respective 5 μg/L drinking water MCL. The bulk of the results for the other compounds are estimated values below applicable analytical reporting limits. There are multiple sources of VOCs in Y-12 upstream of this sampling station, including the inflow of VOC-contaminated groundwater into UEFPC. Additionally, trihalomethanes (CLF and BDM) are included in a class of drinking water disinfection byproducts (DBPs) that form through chemical interactions between chlorine and natural organic matter (U.S. Environmental Protection Agency [EPA] 2001).

4.5 GROSS ALPHA ACTIVITY

Eleven surface water samples had gross alpha activity above the applicable MDA and corresponding CE (Table 1), with the historical maximum value (4.82 pCi/L in February 1999) being substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

4.6 GROSS BETA ACTIVITY

Ten surface water samples had gross beta activity above the applicable MDA and corresponding CE (Table 1), with historical maximum value (4.89 pCi/L in September 2002) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

OUTFALL 200

1.0 LOCATION

This surface water sampling station is located at the outfall of the North-South Pipe, a subsurface drain that discharges into the exposed section of the main channel of Upper East Fork Poplar Creek (UEFPC) in south-central Y-12, directly southwest of Bldg. 9204-1. Construction of facilities at Y-12 substantially modified UEFPC, with the headwaters and several thousand feet of the main channel in the upper reach of the creek, including all the northern tributaries of the creek in the western and central sections of Y-12, filled and replaced with an extensive network of underground storm drains. Also, the section of the creek near the eastern end of Y-12 was extensively modified by construction of New Hope Pond (NHP) in 1963 and the closure of NHP in 1988. An unlined surface impoundment, NHP was used to regulate the quantity and quality of surface water exiting Y-12 until it was closed and replace by Lake Reality, a lined surface impoundment built in 1988.

About 80% of dry-weather flow in UEFPC is attributable to once-through non-contact cooling water, condensate, cooling tower blowdown, and potable water treated and discharged from wastewater treatment facilities and the remaining 20% is from groundwater discharge (DOE 1998). In accordance with a flow management program initiated in July 1996, untreated water from the Clinch River intake lines to the DOE water treatment plant that supplies potable water to Y-12 is discharged near OF 200 to augment flow in UEFPC, which decreased from 10-15 million gallons per day (mgd) to about 2.5 mgd because of reduced operations at Y-12 in recent years. Flow management is needed to achieve the National Pollution Discharge Elimination System (NPDES) minimum daily flow requirement of 7 mgd at Station 17, which is located immediately upstream of where UEFPC exits the DOE Oak Ridge Reservation northeast of Y-12. Flow management also allows compliance with NPDES toxicity requirements and helps lower the otherwise elevated water temperature in UEFPC.

2.0 SAMPLING HISTORY

Twenty-one (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in July 1999 and the most recent sample collected in August 2004. The grab sampling method was used to collect each sample.

In addition to the sampling performed to meet the surveillance monitoring objectives Y-12 GWPP, surface water samples also have been collected to meet other monitoring requirements, including sampling that the Y-12 Surface Water Program performs as a best management practice and to meet the requirements of DOE Order 5400.5. Also, grab sampling and/or flow-proportionate composite sampling is performed for NPDES purposes and to meet the requirements of the Phase I ROD for UEFPC (DOE 1997).

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 120 – 316 mg/L;
- pH of 6.7 – 9.0 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals (except mercury and uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

The 17 surface water samples collected between July 1999 and August 2003 had nitrate concentrations above the applicable analytical reporting limit (Table 1), with the historical maximum value (8.7 mg/L in March 2000) being less than the drinking water MCL for nitrate (10 mg/L). Surface water samples collected from this station after August 2003 are not analyzed for nitrate.

4.2 URANIUM

Nineteen surface water samples had (total) uranium concentrations above the applicable analytical reporting limit (Table 1), and all but five of these results, including the historical maximum value (0.17 mg/L in March 2000), exceed the drinking water MCL for uranium (0.03 mg/L). There are multiple sources of uranium in the groundwater and surface water upgradient of Outfall 200.

4.3 MERCURY

Four surface water samples had (total) mercury concentrations above the applicable analytical reporting limit (Table 1), with the highest value (0.001 mg/L in March 2000) being less than the drinking water MCL for mercury (0.002 mg/L). There are multiple sources of mercury within Y-12 upstream of this sampling station, including inflow of mercury-contaminated groundwater into UEFPC, and the remediation of these sources is the focus of the Phase I ROD for mercury source areas in UEFPC (DOE 1997).

4.4 VOLATILE ORGANIC COMPOUNDS

Seventeen surface water samples collected between July 1999 and August 2003 had low concentrations of one or more of the following VOCs (Table 2): acetone, bromoform, bromodichloromethane (BDM), CTET, chloroform, dibromochloromethane (DBM), PCE, TCE, and c12DCE. Surface water samples collected from this station after August 2003 are not analyzed for VOCs. The bulk of the VOC results are estimated values below applicable analytical reporting limits; only results for acetone exceed 10 µg/L. There are multiple sources of VOCs in Y-12 upstream of this sampling station. Additionally, trihalomethanes (bromoform, BDM, chloroform, and DBM) are included in a class of drinking water disinfection byproducts (DBPs) that form through chemical interactions between chlorine and natural organic matter (U.S. Environmental Protection Agency 2001).

4.5 GROSS ALPHA ACTIVITY

The surface water samples collected to date were not analyzed for gross alpha activity.

4.6 GROSS BETA ACTIVITY

Surface water samples collected to date were not analyzed for gross beta activity.

SURFACE WATER SAMPLING STATION
S07

1.0 LOCATION

Samples of surface water in the channel of a northern tributary (NT) of Bear Creek (NT-2), which are numbered in ascending order downstream of the creek headwaters near the west end of Y-12, are obtained from this sampling station. The channel of NT-2 trends northeast-southwest across the southern flank of Pine Ridge about midway between the former S-3 Ponds and the Oil Landfarm waste management area (WMA), with sampling station S07 located just upstream of the confluence with the main channel of Bear Creek. The similar trend and pattern of the northern tributaries of Bear Creek suggest that they are the surface expression of large-scale fracture zones (or small faults) in the bedrock (Conasauga Group) underlying Bear Creek Valley (BCV) (Solomon et. al. 1992).

Approximately half of the annual precipitation in BCV exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Discharge from springs located along the Maynardville Limestone/Copper Ridge Dolomite boundary on the north slope of Chestnut Ridge dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Six (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in September 2001 and the most recent sample collected in September 2004. The grab sampling method was used to collect each sample.

In addition to the sampling performed to meet the surveillance monitoring objectives of the Y-12 GWPP, surface water samples also have been collected to meet other monitoring requirements, including sampling that the Y-12 Surface Water Program performs as a best management practice and to meet the requirements of DOE Order 5400.5. Also, grab sampling and/or flow-proportionate composite sampling is performed for NPDES purposes and to meet the requirements of the Phase I ROD for the Bear Creek watershed (DOE 2000).

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- pH of 7.3 – 8.4 (field measurements) and

- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Six of the surface water samples had nitrate concentrations above the applicable analytical reporting limit, and all of these results, including the historical maximum value (276 mg/L in September 2001), substantially exceed the drinking water MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds. Located at the headwaters of Bear Creek near the west end of Y-12, the S-3 Ponds were four contiguous, unlined surface impoundments used from 1951 to 1984 for the infiltration/evaporation of several million gallons of nitric acid wastes generated at Y-12. Now covered with a multilayer low-permeability cap constructed in 1988, the former S-3 Ponds emplaced a heterogeneous mixture of inorganic, organic, and radiological contamination in the underlying Nolichucky Shale. Nitrate is a primary component of the plume and is transported in the shallow groundwater system south toward Bear Creek and to the west, parallel with geologic strike, toward discharge areas in NT-1 and NT-2 (DOE 1997). Additionally, nitrate in the deeper (>150 ft bgs) groundwater flow/transport pathways in the Nolichucky Shale moves westward along strike and, under vertically upward hydraulic gradients, enters the shallow flow system and ultimately discharges into NT-1 and NT-2. Thus, elevated nitrate concentrations in the surface water at this sampling station result from the upstream discharge of nitrate-contaminated groundwater into NT-2.

4.2 URANIUM

The surface water samples were not analyzed for (total) uranium.

4.3 VOLATILE ORGANIC COMPOUNDS

VOCs were not detected in the surface water samples.

4.4 GROSS ALPHA ACTIVITY

None of the surface water samples were analyzed for gross alpha activity; however, the samples collected between September 2001 and August 2003 were analyzed for uranium isotopes. The analytical results, summarized below, do not indicate the presence of uranium isotopes above background levels in BCV.

Sampling Date	Concentration (pCi/L)	
	U-234	U-238
09/17/01	1.53	0.61
03/11/02	0.36	0.36
03/03/03	0.91	0.66
08/18/03	0.57	0.31

4.5 GROSS BETA ACTIVITY

None of the surface water samples were analyzed for gross beta activity however, the samples collected between September 2001 and August 2003 were analyzed for Tc-99. The analytical results, summarized below, show that Tc-99 is present in the surface water at this sampling location.

Sampling Date	Tc-99 (pCi/L)
09/17/01	487.22
03/11/02	94.14
03/03/03	36.94
08/18/03	47.15

This man-made radionuclide is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, which is the only site at Y-12 that received wastes that contained Tc-99 (DOE 1997). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the transport of Tc-99 in the Nolichucky Shale closely mirrors that of nitrate. Accordingly, Tc-99 in the shallow groundwater system is transported westward, parallel with geologic strike, toward discharge areas in NT-1 and NT-2 (DOE 1997). Thus, the repeated detection of Tc-99 in the surface water samples indicate the discharge of nitrate-contaminated groundwater into NT-2 upstream of this sampling station.

SURFACE WATER SAMPLING STATION
S17

1.0 LOCATION

There are five primary tributary drainage basins on south Chestnut Ridge (SCR), informally numbered from west to east (SCR1 through SCR5): Dunaway Branch (SCR1) and SCR2 southwest of Y-12, McCoy Branch (SCR3) directly south of Y-12; and SCR4 and SCR5 in southeast of Y-12. Flow in each tributary is mainly intermittent at elevations higher than 900 ft above msl. Surface runoff, stormflow discharge, and groundwater baseflow contribute flow to each tributary, which increases with distance downstream and includes substantial contributions from springs. Each tributary conveys surface water south toward Bethel Valley and discharges into Melton Hill Reservoir (Clinch River). This surface water sampling station is located in the main channel of SCR5 north of and adjacent to Bethel Valley Road. Flow in SCR5 includes discharge from the outfall for Kerr Hollow Quarry (KHQ), which is an abandoned water-filled quarry formerly used for the disposal of hazardous wastes from Y-12 and elsewhere on the DOE Oak Ridge Reservation. KHQ was closed in accordance with a RCRA closure plan in 1989. Requirements for RCRA post-closure care of the site, including groundwater quality monitoring, are specified in the RCRA post-closure permit for the Chestnut Ridge Hydrogeologic Regime (TDEC 1995).

2.0 SAMPLING HISTORY

Four (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in February 2003 and the most recent sample collected in July 2004. The grab sampling method was used to collect each sample.

In addition to the sampling performed to meet the surveillance monitoring objectives Y-12 GWPP, surface water samples also have been collected to meet other monitoring requirements, including sampling that the Y-12 Surface Water Program performs as a best management practice and to meet the requirements of DOE Order 5400.5. Also, grab sampling and/or flow-proportionate composite sampling is performed for NPDES purposes.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 130 – 199 mg/L;
- pH of 7.1 – 7.5 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

All of the surface water samples had nitrate concentrations above the applicable analytical reporting limit, with the highest result (2.99 in January 2004) being substantially below the drinking water MCL for nitrate (10 mg/L). The nitrate results are higher than background levels of nitrate in groundwater and surface water on Chestnut Ridge, which are typically less than 1 mg/L. The source of the nitrate in surface water at this location (as in the groundwater at wells located at Kerr Hollow Quarry) may be municipal sewage sludge that was applied to the land surface at nearby upgradient areas, the closest of which is located west of SCR5 about 600 ft upgradient of S17.

4.2 URANIUM

All of the surface water samples had (total) uranium concentrations above the applicable analytical reporting limit, with the highest result (0.00106 mg/L in August 2003) being substantially below the drinking water MCL for uranium (0.03 mg/L).

4.3 VOLATILE ORGANIC COMPOUNDS

VOCs were not detected in the surface water samples.

4.4 GROSS ALPHA ACTIVITY

One surface water sample had gross alpha activity above the applicable MDA and corresponding CE, and this result (3.5 pCi/L in August 2003) is substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

4.5 GROSS BETA ACTIVITY

None of the surface water samples had gross beta activity above the applicable MDA and corresponding CE.

SPRING SCR1.25SP

1.0 LOCATION

There are five primary tributary drainage basins on south Chestnut Ridge (SCR), informally numbered from west to east (SCR1 through SCR5): Dunaway Branch (SCR1) and SCR2 southwest of Y-12, McCoy Branch (SCR3) directly south of Y-12; and SCR4 and SCR5 in southeast of Y-12. Flow in each tributary is mainly intermittent at elevations higher than 900 ft above msl. Surface runoff, stormflow discharge, and groundwater baseflow contribute flow to each tributary, which increases with distance downstream and includes substantial contributions from springs. Each tributary conveys surface water south toward Bethel Valley and discharges into Melton Hill Reservoir (Clinch River). This spring discharges groundwater into the main channel of Dunaway Branch, hydraulically downgradient (south) of Industrial Landfill II.

2.0 SAMPLING HISTORY

Thirteen (unfiltered) groundwater samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in February 1999 and the most recent sample collected in August 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the groundwater samples is characterized by:

- TDS of 120 – 231 mg/L;
- pH of 5.6 – 8.9 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Five of the groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest value (0.088 mg/L in January and August 2003) being several orders-of-magnitude below the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

None of the groundwater samples had (total) uranium concentrations above the applicable analytical reporting limit.

4.3 VOLATILE ORGANIC COMPOUNDS

VOCs were not detected in the groundwater samples.

4.4 GROSS ALPHA ACTIVITY

Eleven groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the historical maximum value (33.27 pCi/L in February 2001) exceeding the drinking water MCL for gross alpha activity (15 pCi/L). However, this result is an outlier compared to the other results for gross alpha activity, which are all less than 5 pCi/L, and is probably a sampling or analytical artifact.

4.5 GROSS BETA ACTIVITY

Ten groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the historical maximum value (4.62 pCi/L in January 2003) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem dose equivalent (the drinking water MCL for gross beta activity).

SURFACE WATER SAMPLING STATION
SCR1.5SW

1.0 LOCATION

There are five primary tributary drainage basins on south Chestnut Ridge (SCR), informally numbered from west to east (SCR1 through SCR5): Dunaway Branch (SCR1) and SCR2 southwest of Y-12, McCoy Branch (SCR3) directly south of Y-12; and SCR4 and SCR5 in southeast of Y-12. Flow in each tributary is mainly intermittent at elevations higher than 900 ft above msl. Surface runoff, stormflow discharge, and groundwater baseflow contribute flow to each tributary, which increases with distance downstream and includes substantial contributions from springs. Each tributary conveys surface water south toward Bethel Valley and discharges into Melton Hill Reservoir (Clinch River). This surface water sampling station is located on the main channel of Dunaway Branch, immediately upstream (north) of Bethel Valley Road. This sampling station is hydraulically downgradient (southeast) of Industrial Landfill II and Industrial Landfill VI.

2.0 SAMPLING HISTORY

Eight (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in February 2001 and the most recent sample collected in July 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 94 – 190 mg/L;
- pH of 7.0 – 7.6 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

All of the surface water samples had nitrate concentrations above the applicable analytical reporting limit, with the highest value (0.152 mg/L in February 2003) being an order-of-magnitude below the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

Six surface water samples had (total) uranium concentrations above the applicable analytical reporting limit, with the higher value (0.00161 mg/L in August 2002) being an order-of-magnitude below the drinking water MCL for uranium (0.03 mg/L).

4.3 VOLATILE ORGANIC COMPOUNDS

VOCs were not detected in the any of the surface water samples.

4.4 GROSS ALPHA ACTIVITY

Two surface water samples had gross alpha activity above the applicable MDA and corresponding CE, and both results (3.7 pCi/L in August 2002 and 2 pCi/L in August 2003) are substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

4.5 GROSS BETA ACTIVITY

None of the surface water samples had gross beta activity above the applicable MDA and corresponding CE.

SPRING SCR2.1SP

1.0 LOCATION

There are five primary tributary drainage basins on south Chestnut Ridge (SCR), informally numbered from west to east (SCR1 through SCR5): Dunaway Branch (SCR1) and SCR2 southwest of Y-12, McCoy Branch (SCR3) directly south of Y-12; and SCR4 and SCR5 in southeast of Y-12. Flow in each tributary is mainly intermittent at elevations higher than 900 ft above msl. Surface runoff, stormflow discharge, and groundwater baseflow contribute flow to each tributary, which increases with distance downstream and includes substantial contributions from springs. Each tributary conveys surface water south toward Bethel Valley and discharges into Melton Hill Reservoir (Clinch River). This spring discharges groundwater into the main channel of SCR2 and is hydraulically downgradient (southeast) of Industrial Landfill II, Industrial Landfill IV, and Construction/Demolition Landfill VI.

2.0 SAMPLING HISTORY

Twelve (unfiltered) groundwater samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in January 1998 and the most recent sample collected in July 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the groundwater samples is characterized by:

- TDS of 85 – 221 mg/L;
- pH of 6.9 – 7.8 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

All of the groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the historical maximum value (0.32 mg/L in February 1999) being an order-of-magnitude below the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

All of the groundwater samples had (total) uranium concentrations above the applicable analytical reporting limit, with the historical maximum value (0.0092 mg/L in July 1998) being an order-of-magnitude below the drinking water MCL for uranium (0.03 mg/L).

4.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, low concentrations of VOCs were detected in two groundwater samples: carbon disulfide (2 µg/L) in July 1998 and acetone (10 µg/L) in February 1999. These results may be sampling or analytical artifacts and are considered to be outliers.

4.4 GROSS ALPHA ACTIVITY

Five groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (9.7 pCi/L in July 1998) being less than the drinking water MCL for gross alpha activity (15 pCi/L).

4.5 GROSS BETA ACTIVITY

None of the groundwater samples had gross beta activity above the applicable MDA and corresponding CE.

SPRING SCR2.2SP

1.0 LOCATION

There are five primary tributary drainage basins on south Chestnut Ridge (SCR), informally numbered from west to east (SCR1 through SCR5): Dunaway Branch (SCR1) and SCR2 southwest of Y-12, McCoy Branch (SCR3) directly south of Y-12; and SCR4 and SCR5 in southeast of Y-12. This spring discharges groundwater into the main channel of SCR2. Flow in each tributary is mainly intermittent at elevations higher than 900 ft above msl. Surface runoff, stormflow discharge, and groundwater baseflow contribute flow to each tributary, which increases with distance downstream and includes substantial contributions from springs. Each tributary conveys surface water south toward Bethel Valley and discharges into Melton Hill Reservoir (Clinch River).

2.0 SAMPLING HISTORY

Fifteen (unfiltered) groundwater samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in March 1995 and the most recent sample collected in July 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the groundwater samples is characterized by:

- TDS of 163 – 224 mg/L;
- pH of 6.7 – 7.4 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

All of the groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the historical maximum value (2.67 in February 2001) being substantially below the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

Nine groundwater samples had (total) uranium concentrations above the applicable analytical reporting limit, with the historical maximum value (0.00099 mg/L in July 1997) being several orders-of-magnitude below the drinking water MCL for uranium (0.03 mg/L).

4.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were not detected the groundwater samples.

4.4 GROSS ALPHA ACTIVITY

One groundwater sample had gross alpha activity above the applicable MDA and corresponding CE, and this result (3.7 pCi/L in August 2003) is substantially less than the drinking water MCL for gross alpha activity (15 pCi/L).

4.5 GROSS BETA ACTIVITY

None of the groundwater samples had gross beta activity above the applicable MDA and corresponding CE.

SPRING SCR3.5SP

1.0 LOCATION

There are five primary tributary drainage basins on south Chestnut Ridge (SCR), informally numbered from west to east (SCR1 through SCR5): Dunaway Branch (SCR1) and SCR2 southwest of Y-12, McCoy Branch (SCR3) directly south of Y-12; and SCR4 and SCR5 in southeast of Y-12. Flow in each tributary is mainly intermittent at elevations higher than 900 ft above msl. Surface runoff, stormflow discharge, and groundwater baseflow contribute flow to each tributary, which increases with distance downstream and includes substantial contributions from springs. Each tributary conveys surface water south toward Bethel Valley and discharges into Melton Hill Reservoir (Clinch River).

This spring discharges groundwater into the main channel of McCoy Branch downstream of the Filled Coal Ash Pond (FCAP) and immediately upstream of Rogers Quarry. The FCAP is a former settling basin formed by the construction of an earthen dam across the upper reach of McCoy Branch. Beginning in 1955, the basin received coal ash from the Y-12 Steam Plant that was pumped as slurry over the crest of Chestnut Ridge and gravity-drained into the basin. By 1967, the basin had filled with ash and the slurry was allowed to overtop the dam and flow down McCoy Branch into Rogers Quarry until 1989. Remedial action at the FCAP was completed in April 1997 in accordance with a CERCLA ROD approved in February 1996 (DOE 1996). As described in the remedial action report, CERCLA remedial actions at the FCAP included: (1) raising the crest of the dam, (2) reinforcing the fact of the dam and removing large trees from the face of the dam; (3) installing a subsurface drain; (4) repairing the emergency spillway for the dam; (5) constructing a settling basin and oxygenation weir at the foot of the dam; and (6) replacing a small wetland area in McCoy Branch immediately downstream of the settling basin (DOE 1997). These remedial actions are intended to minimize the migration of contaminants into surface water, minimize direct contact of humans and animals with the ash, reduce the potential for failure of the dam, and preserve the local habitat over the long term (DOE 1996).

2.0 SAMPLING HISTORY

Fourteen (unfiltered) groundwater samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in February 1999 and the most recent sample collected in August 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the groundwater samples is characterized by:

- TDS of 78 – 307 mg/L;
- pH of 5.9 – 8.9 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Six groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest value (0.51 mg/L in January 2003) being an order-of-magnitude below the drinking water MCL for nitrate (10 mg./L).

4.2 URANIUM

One groundwater sample had a (total) uranium concentration above the applicable analytical reporting limit, and this result (0.00523 mg/L in February 2003) is orders-of-magnitude below the drinking water MCL for uranium (0.03 mg/L).

4.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were not detected the groundwater samples.

4.4 GROSS ALPHA ACTIVITY

Seven groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (14.06 pCi/L in January 2003) being slightly below the drinking water MCL for gross alpha activity (15 pCi/L). However, this result is an outlier compared to the other results for gross alpha activity, none of which exceed 3 pCi/L.

4.5 GROSS BETA ACTIVITY

Nine groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (6.75 pCi/L in January 2003) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

SURFACE WATER SAMPLING STATION
SCR3.5SW

1.0 LOCATION

There are five primary tributary drainage basins on south Chestnut Ridge (SCR), informally numbered from west to east (SCR1 through SCR5): Dunaway Branch (SCR1) and SCR2 southwest of Y-12, McCoy Branch (SCR3) directly south of Y-12; and SCR4 and SCR5 in southeast of Y-12. This surface water sampling station is located on the main channel of McCoy Branch. Flow in each tributary is mainly intermittent at elevations higher than 900 ft above msl. Surface runoff, stormflow discharge, and groundwater baseflow contribute flow to each tributary, which increases with distance downstream and includes substantial contributions from springs. Each tributary conveys surface water south toward Bethel Valley and discharges into Melton Hill Reservoir (Clinch River).

This sampling station is in the main channel of McCoy Branch downstream of the Filled Coal Ash Pond (FCAP) and immediately upstream of Rogers Quarry. The FCAP is a former settling basin formed by the construction of an earthen dam across the upper reach of McCoy Branch. Beginning in 1955, the basin received coal ash from the Y-12 Steam Plant that was pumped as slurry over the crest of Chestnut Ridge and gravity-drained into the basin. By 1967, the basin had filled with ash and the slurry was allowed to overtop the dam and flow down McCoy Branch into Rogers Quarry until 1989. Remedial action at the FCAP was completed in April 1997 in accordance with a CERCLA ROD approved in February 1996 (DOE 1996). As described in the remedial action report, CERCLA remedial actions at the FCAP included: (1) raising the crest of the dam, (2) reinforcing the fact of the dam and removing large trees from the face of the dam; (3) installing a subsurface drain; (4) repairing the emergency spillway for the dam; (5) constructing a settling basin and oxygenation weir at the foot of the dam; and (6) replacing a small wetland area in McCoy Branch immediately downstream of the settling basin (DOE 1997). These remedial actions are intended to minimize the migration of contaminants into surface water, minimize direct contact of humans and animals with the ash, reduce the potential for failure of the dam, and preserve the local habitat over the long term (DOE 1996).

2.0 SAMPLING HISTORY

Three (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in August 2003 and the most recent sample collected in July 2004. The grab sampling method was used to collect the sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the surface water sample show:

- TDS of 168 – 221 mg/L;
- pH of 7.1 – 7.5 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

All of the surface water samples had nitrate concentrations above the applicable analytical reporting limit, with the highest result (0.459 mg/L in January 2004) being substantially below the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

All of the surface water samples had (total) uranium concentrations above the applicable analytical reporting limit, with the highest result (0.000601 in January 2004) being substantially below the drinking water MCL for uranium (0.03 mg/L).

4.3 VOLATILE ORGANIC COMPOUNDS

VOCs were not detected in the surface water sample.

4.4 GROSS ALPHA ACTIVITY

One surface water sample had gross alpha activity above the applicable MDA and corresponding CE, and this result (1.8 pCi/L in August 2003) is substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

4.5 GROSS BETA ACTIVITY

None of the surface water samples had gross beta activity above the applicable MDA and corresponding CE.

SPRING SCR4.3SP

1.0 LOCATION

There are five primary tributary drainage basins on south Chestnut Ridge (SCR), informally numbered from west to east (SCR1 through SCR5): Dunaway Branch (SCR1) and SCR2 southwest of Y-12, McCoy Branch (SCR3) directly south of Y-12; and SCR4 and SCR5 in southeast of Y-12. Flow in each tributary is mainly intermittent at elevations higher than 900 ft above msl. Surface runoff, stormflow discharge, and groundwater baseflow contribute flow to each tributary, which increases with distance downstream and includes substantial contributions from springs. Each tributary conveys surface water south toward Bethel Valley and discharges into Melton Hill Reservoir (Clinch River). This spring discharges groundwater into the main channel of SCR4 and is hydraulically downgradient of Industrial Landfill V and Construction/Demolition Landfill VII.

2.0 SAMPLING HISTORY

Twenty-two (unfiltered) groundwater samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in February 1994 and the most recent sample collected in July 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the groundwater samples is characterized by:

- TDS of 118 – 216 mg/L;
- pH of 6.4 – 7.15 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

All of the groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the historical maximum value (2.3 mg/L in January 2001) being less than the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

None of the groundwater samples had (total) uranium concentrations above the applicable analytical reporting limit.

4.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected in the groundwater samples collected in July 1998 (acetone = 12 μg/L), February 2000 (acetone = 8.5 μg/L), July 2000 (methylene chloride = 1.5 μg/L), and January 2002 (carbon disulfide = 0.39 μg/L). These sporadic detections are suspected sampling or analytical artifacts.

4.4 GROSS ALPHA ACTIVITY

Three groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (4.4 pCi/L in July 1999) being substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

4.5 GROSS BETA ACTIVITY

Three groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (3.31 pCi/L in July 2001) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem dose equivalent (the drinking water MCL for gross beta activity).

SPRING SCR7.1SP

1.0 LOCATION

This spring discharges groundwater into the main channel of the western branch of Scarboro Creek in Union Valley east of Y-12, about 2,500 ft east of the boundary of the DOE Oak Ridge Reservation (ORR).

2.0 SAMPLING HISTORY

Eighteen (unfiltered) groundwater samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in March 1996 and the most recent sample collected in July 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the groundwater samples is characterized by:

- TDS of 238 – 340 mg/L;
- pH of 6.6 – 8.9 (field measurements); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Eleven groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the historical maximum value (1.03 mg/L in March 1996) being substantially below the drinking water MCL for nitrate (10 mg/L). Groundwater samples collected after July 2003 were not analyzed for nitrate.

4.2 URANIUM

Only two groundwater samples were analyzed for (total) uranium, and neither sample (collected in March and June 1996) had a concentration above the applicable analytical reporting limit.

4.3 VOLATILE ORGANIC COMPOUNDS

As shown in the following data summary, low concentrations of CTET, chloroethane, PCE, and TCE were detected in eleven groundwater samples, with CTET and TCE detected the most frequently.

Date Sampled	Concentration (µg/L)

These compounds are components of the plume of dissolved VOCs in the Maynardville Limestone that extends from the eastern end of Y-12 into Union Valley east of the ORR boundary.

4.4 GROSS ALPHA ACTIVITY

Five groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (3.68 pCi/L in August 1998) being less than the drinking water MCL for gross alpha activity (15 pCi/L). Groundwater samples collected after July 2003 were not analyzed for gross alpha activity.

4.5 GROSS BETA ACTIVITY

Nine groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (5.68 pCi/L in February 2003) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). Groundwater samples collected after July 2003 were not analyzed for gross beta activity.

SPRING SCR7.8SP

1.0 LOCATION

This spring discharges groundwater into the main channel of the western branch of Scarboro Creek in Union Valley east of Y-12, about 3,000 ft east of the boundary of the DOE Oak Ridge Reservation (ORR).

2.0 SAMPLING HISTORY

Seventeen (unfiltered) groundwater samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in April 1997 and the most recent sample collected in July 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the groundwater samples is characterized by:

- TDS of 170 – 289 mg/L;
- pH of 6.1 – 9.2 (field measurements); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Nine groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the historical maximum value (1.8 mg/L in January 2001) being substantially below the drinking water MCL for nitrate (10 mg/L). Groundwater samples collected after July 2003 were not analyzed for nitrate.

4.2 URANIUM

The groundwater samples were not analyzed for (total) uranium.

4.3 VOLATILE ORGANIC COMPOUNDS

As shown in the following data summary, low concentrations of PCE, toluene, 12DCE, 111TCA, and 11DCA were detected in five groundwater samples collected to date, with PCE and 12DCE detected the most frequently.

Date Sampled	Concentration (µg/L)				
	PCE	12DCE	111TCA	11DCA	Toluene
08/25/97	2 J	1 J	.	.	.
03/03/98	2 J	1 J	.	.	.
08/27/98	2 J	2 J	.	.	.
02/04/99	1 J	1 J	1 J	1 J	.
08/13/01	.	.	.	.	1 J
MCL	**5**	**5**	**5**	**NA**	
Note: "." = Not detected; J = Estimated value; NA = Not applicable					

The source of the VOCs in the groundwater samples from this spring has not been determined. However, each compound except toluene is a confirmed component of the plume of dissolved VOCs in the Maynardville Limestone that extends from the eastern end of Y-12 into Union Valley east of the ORR boundary. Additionally, the spring is located hydraulically downgradient (east) of a former municipal landfill, which also is a likely source of VOCs.

4.4 GROSS ALPHA ACTIVITY

None of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE. Groundwater samples collected after July 2003 were not analyzed for gross alpha activity.

4.5 GROSS BETA ACTIVITY

Seven groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (3.53 pCi/L in July 2002) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem dose equivalent (the drinking water MCL for gross beta activity). Groundwater samples collected after July 2003 were not analyzed for gross beta activity.

SPRING SPR14.0SP

1.0 LOCATION

This spring discharges groundwater from the southern flank of Pine Ridge, about 300 ft north of Bear Creek Road at the western end of the Y-12 Complex. The spring is hydraulically upgradient of all waste-management activities.

2.0 SAMPLING HISTORY

One (unfiltered) groundwater sample has been collected to date to meet the surveillance monitoring objectives of the Y-12 GWPP (February 19, 2004). This sample was collected to evaluate groundwater quality before commencement of the Hollow Fill Construction Project. The grab sampling method was used to collect the sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on available data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the groundwater samples is characterized by:

- TDS of 49 mg/L;
- pH of 6.24 (field measurement); and
- total concentrations of trace metals (except iron) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. The sample was analyzed for all of these constituents and for uranium isotopes (U-234, U-235, U-236, & U-238). None of these contaminants are present at elevated concentrations; only nitrate (0.0316 mg/L) and gross alpha activity (2.6 ± 1.8 pCi/L) were detected in the sample from this spring.

Although not typical groundwater or surface water contaminants in the East Fork Regime, the concentrations of iron (4.14 mg/L) and sulfate (4.87 mg/L) are elevated considering the low level of TDS in the sample (see Section 3.0).

SPRING SS-1

1.0 LOCATION

This spring discharges contaminated groundwater into the main channel of Bear Creek near the confluence of a northern tributary of the creek (NT-1) about 1,800 ft downstream of the headwaters near the west end of Y-12. From its headwaters, Bear Creek flows southwest for approximately 4.5 miles, where it turns northward to flow into East Fork Poplar Creek. In Bear Creek Valley (BCV), the major springs along the south side (SS) of Bear Creek are numbered in ascending order downstream from the headwaters (e.g., SS-1).

Approximately half of the annual precipitation in BCV exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Discharge from springs located along the Maynardville Limestone/Copper Ridge Dolomite boundary on the north slope of Chestnut Ridge dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area., Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Thirty-seven (unfiltered) groundwater samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in August 1990 and the most recent sample collected in July 2004. The grab sampling method was used to collect each sample.

In addition to sampling performed to meet the surveillance monitoring objectives of the Y-12 GWPP, numerous samples have been collected to date for the purposes of other monitoring programs.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the groundwater samples is characterized by:

- TDS of 586 -1,174 mg/L;
- pH of 6.8 – 8.2 (field measurements);
- elevated concentrations of chloride (>100 mg/L), sodium (>30 mg/L), and sulfate (>50 mg/L); and
- total concentrations of trace metals (except uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results obtained since January 1991 that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

All of the groundwater samples had nitrate concentrations above the applicable analytical reporting limit (Table 1), with the historical minimum value (8.22 mg/L in February 1998) being the only result below the drinking water MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds, which are unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988. Located about 1,750 ft east-northeast of spring SS-1, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984. The groundwater contaminant plume originating from the site contains a heterogeneous mixture of inorganic, organic, and radiological contaminants. Nitrate, a principal component of the plume, enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale and recharge of nitrate-contaminated surface water in Bear Creek (DOE 1997). Nitrate is chemically stable and highly mobile in groundwater and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells (and springs), the extent of nitrate contamination in the Maynardville Limestone in BCV west of Y-12, as defined by concentrations above 10 mg/L, is generally characterized by: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for about 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) and is significantly influenced by hydrologic interactions with surface water in Bear Creek. Sampling results for spring SS-1 are representative of nitrate concentrations within the shallow karst network.

Five of the groundwater samples had nitrate concentrations above 50 mg/L (Table 1) and all of these results, including the historical maximum value (142 mg/L in May 1993), were reported for sample collected during the early 1990s. Nitrate concentrations below 25 mg/L were reported for each sample collected since September 1995. This illustrates the decreasing long-term concentration trend indicated by a time-series plot of the nitrate results (Figure 1). The reduced levels of nitrate in the shallow karst network in the Maynardville Limestone, as indicated by the sampling results for spring SS-1, reflect the substantial reduction in the relative flux of nitrate following the closure of the S-3 Ponds in 1984 and the installation of the low permeability cap in 1988 (DOE 1997).

4.2 URANIUM

All of the groundwater samples had (total) uranium concentrations above the applicable analytical reporting limit (Table 1), with 26 of these results exceeding the drinking water MCL for uranium (0.03 mg/L). The contaminant plume emplaced during historical operation of the former S-3 Ponds is the source of the uranium in the groundwater from this spring (DOE 1997).

Considering the slightly acidic to slightly basic pH of the samples from the spring (see Section 3.0), uranium probably occurs in the groundwater as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble complexes with a variety of inorganic anions in the groundwater, such as carbonate (Fetter 1993). A time-series plot of uranium concentrations shows an indeterminate long-term trend, with generally decreasing concentrations since the historical maximum value (0.058 mg/L) in August 1998 (Figure 2).

4.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, at least one of the following VOCs were detected in 16 of the groundwater samples: acetone, chloroform, PCE, TCE, and 12DCE (Table 2). These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. In the Bear Creek watershed west of the flow divide, the VOC plume in the Maynardville Limestone appears to originate near Spoil Area I and to extend several thousand feet westward (parallel with geologic strike) down the axis of BCV, with influx of various VOCs from several different downgradient source areas. The distribution of VOCs within the plume reflects the relative contributions from the source areas and commingling during downgradient transport. Sampling results for spring SS-1 are representative of VOC concentrations in the shallow karst network in the upper (easternmost) part of BCV, where the primary components of the VOC plume are PCE, TCE, and 12DCE (isomers) and the principal source areas include Spoil Area I and the contaminant plume emplaced during historical operation of former S-3 Ponds (DOE 1997).

Based on the detection frequency, the primary VOCs in the groundwater samples are PCE and TCE, with one or both compounds detected in each sample (Table 2). Aside from an anomalous result for acetone (9 µg/L), which is not a primary component of the contaminant plume in the Maynardville Limestone, all of the results for each VOC are estimated values of 3 µg/L or less and are less than the drinking water MCL for each applicable compound (Table 2).

4.4 GROSS ALPHA ACTIVITY

All but one of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE (Table 1), with 23 of these results, including the historical maximum value (29 pCi/L in August 1998 and July 2002) exceed the drinking water MCL for gross alpha activity (15 pCi/L). A time-series plot of the gross alpha activity in samples from this location shows an indeterminate long-term trend (Figure 3).

Available radiological data, summarized below, indicate that uranium isotopes are the likely source of the elevated gross alpha activity in the groundwater from the spring.

Sampling Date	U-234 (pCi/L)	U-238 (pCi/L)
08/20/98	19.32	23.57
01/10/01	13	12
07/12/01	12	11

The contaminant plume emplaced during operation of the former S-3 Ponds is the source of the uranium isotopes (DOE 1997). As with total uranium, the uranium isotopes probably occur in the groundwater as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble complexes with a variety of inorganic anions in the groundwater, such as carbonate (Fetter 1993).

4.5 GROSS BETA ACTIVITY

All of the groundwater samples had gross beta activity above the applicable MDA and corresponding CE (Table 1), with 16 of the results, including the historical maximum value (178 pCi/L in May 1993), exceeding the SDWA screening level (50 pCi/L) equivalent to a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). Although uranium isotopes (and beta particle-emitting daughter products) may contribute to the elevated levels of gross beta activity, the primary source is Tc-99. As shown by the data summarized blow, Tc-99 was detected (i.e., >MDA and CE) in all six samples analyzed for this radionuclide, although the results reflect concentrations that are substantially below the SDWA screening level (3,470 pCi/L) for a 4 mrem/yr dose equivalent from Tc-99.

Sampling Date	Tc-99 (pCi/L)
03/09/95	50.8
09/22/95	95.5
03/18/96	67
08/13/96	48
01/10/01	64
07/12/01	61

This man-made radionuclide is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, which is the only site at Y-12 that received wastes containing Tc-99 (DOE 1997). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells (and springs) in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the transport of Tc-99 in the Maynardville Limestone closely mirrors that of nitrate. A time-series plot of the gross beta activity in samples from this location shows a generally decreasing long-term trend (Figure 4) that is similar to the trend of nitrate concentrations (Figure 1).

SPRING SS-4

1.0 LOCATION

This spring discharges contaminated groundwater into the main channel of Bear Creek downstream of the confluence of a northern tributary of the creek (NT-6) about 8,000 ft downstream of the headwaters near the west end of Y-12. From its headwaters, Bear Creek flows southwest for approximately 4.5 miles, where it turns northward to flow into East Fork Poplar Creek. In Bear Creek Valley (BCV), the major springs along the south side (SS) of Bear Creek are numbered in ascending order downstream from the headwaters (e.g., SS-1).

Approximately half of the annual precipitation in BCV exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Groundwater discharge from springs located along the Maynardville Limestone/Copper Ridge Dolomite boundary on the north slope of Chestnut Ridge dominate the hydrology of the creek. Discharge of (contaminated) groundwater from springs SS-4 and SS-5 sustains flow in the main creek channel during seasonally low flow periods (summer and fall). Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Forty (unfiltered) groundwater samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in August 1990 and the most recent sample collected in July 2004. The grab sampling method was used to collect each sample. Also, samples collected from the spring since January 1996 have been obtained from the mouth of the spring, whereas previous samples were obtained from the point where groundwater from the spring flows into Bear Creek.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the groundwater samples is characterized by:

- TDS of 112 – 788 mg/L;
- pH of 6.5 – 7.8 (field measurements);
- elevated concentrations of chloride (>35 mg/L) and sulfate (>25 mg/L); and
- total concentrations of trace metals (except uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results obtained since January 1991 that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Thirty-four of the groundwater samples had nitrate concentrations above the applicable analytical reporting limit (Table 1), with all but six of the results exceeding the drinking water MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds, which are unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988. Located about 8,000 ft east-northeast of spring SS-4, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984. The groundwater contaminant plume originating from the site contains a heterogeneous mixture of inorganic, organic, and radiological contaminants. Nitrate, a principal component of the plume, enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale and recharge of nitrate-contaminated surface water in Bear Creek (DOE 1997). Nitrate is chemically stable and highly mobile in groundwater and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells (and springs), the extent of nitrate contamination in the Maynardville Limestone in BCV west of Y-12, as defined by concentrations above 10 mg/L, is generally characterized by: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for about 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) and is significantly influenced by hydrologic interactions with surface water in Bear Creek. Sampling results for spring SS-4 are representative of nitrate concentrations within the shallow karst network.

Nitrate concentrations reported for the groundwater samples range between the historical minimum value of 3.12 mg/L in February 1994 and the historical maximum value of 67.6 mg/L in November 1993 (Table 1). A time-series plot of the nitrate concentrations in the samples from this location shows a widely fluctuating, indeterminate long-term trend (Figure 1). Note that these nitrate levels are higher than indicated by sampling results for spring SS-1, which discharges into the main channel of Bear Creek upstream of spring SS-4 and about a mile closer to the former S-3 Ponds. Higher nitrate concentrations in the groundwater discharged from spring SS-4 probably reflects the transfer of contaminants from Bear Creek into the Maynardville Limestone via the losing reach of the creek south of the Oil Landfarm (DOE 1997).

4.2 URANIUM

Thirty-four of the groundwater samples had (total) uranium concentrations above the applicable analytical reporting limit (Table 1), and all of these results exceed the drinking water MCL for uranium (0.03 mg/L). Considering the slightly acidic to slightly basic pH of the samples from the spring (see Section 3.0), uranium probably occurs in the groundwater as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble complexes with a variety of inorganic anions in the groundwater, such as carbonate (Fetter 1993). Located about 4,500 ft upstream of spring SS-4, the Boneyard/Burnyard, where large volumes of uranium-bearing wastes were below the saturated zone, was identified as the principal source of elemental uranium (and alpha radioactivity) in BCV (DOE 1997). In March 2003, a CERCLA remedial action at the site was completed, which involved the construction of an upgradient subsurface drain to hydraulically isolate the buried wastes; the excavation, consolidation, and disposal of about 64,000 yd^3 of wastes that were in contact with groundwater; and the reconstruction of a section of NT-3 that drains the site (BJC 2003).

Uranium concentrations reported for the groundwater samples range between the historical minimum value of 0.031 mg/L in July 1996 and the historical maximum value of 0.332 mg/L in February 2000. A time-series plot of the uranium concentrations in the samples from this location shows a widely fluctuating, indeterminate long-term trend (Figure 2). Note that these uranium levels are substantially higher than indicated by sampling results for spring SS-1, which discharges into Bear Creek upstream of the former Boneyard/Burnyard. Higher uranium concentrations in the groundwater discharged from spring SS-4 is a direct result of the transfer of uranium from Bear Creek into the Maynardville Limestone via the losing reach of the creek downstream of the Boneyard/Burnyard (DOE 1997).

4.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, at least one of the following VOCs were detected in at least one of the groundwater samples: CTET, TCE, 11DCE, and 12DCE (Table 2). These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. In the Bear Creek watershed west of the flow divide, the VOC plume in the Maynardville Limestone appears to originate near Spoil Area I and to extend several thousand feet westward (parallel with geologic strike) down the axis of BCV, with influx of various VOCs from several different downgradient source areas. The distribution of VOCs within the plume reflects the relative contributions from the source areas and commingling during downgradient transport. Sampling results for spring SS-4 are representative of concentrations within the TCE-dominated VOC plume in the shallow karst network downgradient of several known or suspected sources of VOCs, including (listed in sequence from downgradient to upgradient) Sanitary Landfill I, the Hazardous Chemical Disposal Area (located at the former Boneyard/Burnyard, the Rust Spoil Area, the former S-3 Ponds, and Spoil Area I (DOE 1997).

Based on the detection frequency, the primary VOCs in the groundwater samples are TCE and 12DCE (c12DCE), with one or both compounds detected in all but five of the samples (Table 2). The concentrations of both compounds are relatively low, with respective historical maximum values of 20 µg/L and 17 µg/L reported for the sample collected in July 2002. Also, the most recent sampling result (July 2004) shows that TCE concentrations remain slightly above the drinking water MCL for TCE (5 µg/L). In contrast, CTET was detected in only one sample and 11DCE was detected in only two samples. Nevertheless, the summed concentrations of VOCs detected in the samples are typically much higher than summed VOC concentrations in sample from spring SS-1 as a result of the transfer of VOCs from Bear Creek into the Maynardville Limestone via the losing reach of the creek upstream of spring SS-4 (DOE 1997). A time-series plot of the summed concentrations of VOCs in samples from this location show a generally increasing trend (Figure 3) that appears to begin after the location was moved to the spring headwaters in January 1996 (see Section 2.0).

4.4 GROSS ALPHA ACTIVITY

Thirty-four of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, and all of these results exceed the drinking water MCL for gross alpha activity (15 pCi/L). A time-series plot of the gross alpha activity in the samples from this location shows a widely fluctuating, indeterminate long-term trend (Figure 4). Available radiological data, summarized below, indicate that uranium isotopes are the likely source of the elevated gross alpha activity in the groundwater from the spring.

Sampling Date	U-234 (pCi/L)	U-238 (pCi/L)
01/18/91	5.62	9.08
04/10/91	1.74	6.1
07/29/91	14.4	20.9
12/04/91	13.2	10.5
03/10/92	5.19	12.5
06/01/92	15.3	32.3
09/08/92	31.9	27.4
12/16/92	50.2	63.9
02/13/98	19.84	39.75
07/14/98	7.2	14.86
02/02/99	23.39	45.31
08/11/99	19.46	43.31
02/09/00	73.55	137.9
08/03/00	11.52	19.1
01/11/01	28.37	52.1
07/11/01	19.09	39.2
01/08/02	28.11	53.34
07/10/02	18.65	31.07
01/29/03	14.76	22.49
07/28/03	15.3	25.34
01/27/04	7.23	14.43
07/20/04	14.58	28.75

The former Boneyard/Burnyard is the primary source of the uranium isotopes observed in samples from spring SS-4 (DOE 1997). As with total uranium, the uranium isotopes probably occur in the groundwater as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble complexes with a variety of inorganic anions in the groundwater, such as carbonate (Fetter 1993).

4.5 GROSS BETA ACTIVITY

Thirty-four of the groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with 23 of the results exceeding the SDWA screening level (50 pCi/L) equivalent to a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). A time-series plot of the gross beta activity in the samples from this location shows a widely fluctuating, indeterminate long-term trend (Figure 4).

Although uranium isotopes (and beta particle-emitting daughter products) may contribute to the elevated levels of gross beta activity, the primary source is Tc-99. As shown by the following data summary, Tc-99 was detected (i.e., >MDA and CE) in seven of the ten samples analyzed for this radionuclide, and all but one of these results show Tc-99 concentrations that are substantially below the SDWA screening level (3,470 pCi/L) for a 4 mrem/yr dose equivalent from Tc-99.

Sampling Date	Tc-99 (pCi/L)
03/10/92	7.19
06/01/92	<CE
09/08/92	4,550
12/16/92	<CE
02/14/94	137
09/06/94	156
03/09/95	<CE
07/25/95	87.6
03/16/96	52
07/30/96	48

This man-made radionuclide is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, which is the only site at Y-12 that received wastes containing Tc-99 (DOE 1997). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells (and springs) in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the transport of Tc-99 in the Maynardville Limestone closely mirrors that of nitrate.

SPRING SS-5

1.0 LOCATION

This spring discharges contaminated groundwater into the main channel of Bear Creek immediately downstream of the confluence of a northern tributary of the creek (NT-8) that borders the western side of the Bear Creek Burial Grounds waste management area (WMA) about 11,000 ft downstream of the Bear Creek headwaters near the west end of Y-12. From its headwaters, Bear Creek flows southwest for approximately 4.5 miles, where it turns northward to flow into East Fork Poplar Creek. In Bear Creek Valley (BCV), the major springs along the south side (SS) of Bear Creek are numbered in ascending order downstream from the headwaters (e.g., SS-5).

Approximately half of the annual precipitation in BCV exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Groundwater discharge from springs located along the Maynardville Limestone/Copper Ridge Dolomite boundary on the north slope of Chestnut Ridge dominate the hydrology of the creek. Discharge of (contaminated) groundwater from springs SS-4 and SS-5 sustains flow in the main creek channel during seasonally low flow periods (summer and fall). Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Sixty-five (unfiltered) groundwater samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP and the remedial investigation of Bear Creek Valley (DOE 1997), with the first sample collected in August 1990 and the most recent sample collected in July 2004. The 28 samples collected for the remedial investigation (April 1997 – February 1999) were analyzed only for nitrate and/or radioanalytes. The grab sampling method was used to collect each sample.

In addition to sampling performed for the purposes described above, numerous samples have been collected to date for the purposes of other monitoring programs.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the groundwater samples is characterized by:

- TDS of 110 – 494 mg/L;
- pH of 6.5 – 7.9 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals (except uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Forty-nine of the groundwater samples had nitrate concentrations above the applicable analytical reporting limit (Table 1), with results for 20 samples exceeding the drinking water MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds, which are unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988. Located about 8,000 ft east-northeast of spring SS-4, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984. The groundwater contaminant plume originating from the site contains a heterogeneous mixture of inorganic, organic, and radiological contaminants. Nitrate, a principal component of the plume, enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale and recharge of nitrate-contaminated surface water in Bear Creek (DOE 1997). Nitrate is chemically stable and highly mobile in groundwater and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells (and springs), the extent of nitrate contamination in the Maynardville Limestone in BCV west of Y-12, as defined by concentrations above 10 mg/L, is generally characterized by: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for about 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) and is significantly influenced by hydrologic interactions with surface water in Bear Creek. Sampling results for spring SS-5 are representative of nitrate concentrations within the shallow karst network.

Nitrate concentrations reported for the groundwater samples range between the historical minimum value (0.24 mg/L in May 1998) and the historical maximum value (988 mg/L in February 1998). However, the historical maximum value is an outlier compared to the nitrate results reported for the other samples, which are all less than 30 mg/L (Table 1). Excluding this suspected outlier, a time-series plot of the nitrate results shows a generally decreasing long-term concentration trend dominated by wide seasonal concentration fluctuations (Figure 1). Also, the highest concentrations have been reported for samples collected during seasonally low groundwater flow conditions. This suggests that nitrate-contaminated groundwater provides the bulk of the baseflow discharge from the spring, with lower concentrations in samples obtained during seasonally high flow conditions reflecting dilution from uncontaminated (or less contaminated) recharge.

4.2 URANIUM

Thirty-four groundwater samples had (total) uranium concentrations above the applicable analytical reporting limit (Table 1), and 26 of these results exceed the drinking water MCL for uranium (0.03 mg/L). The uranium concentrations range between the historical minimum value of 0.005 mg/L in February 1994 and the historical maximum value of 0.132 mg/L in February 2000. A time-series plot of the uranium concentrations in the samples from this location shows a widely fluctuating, indeterminate long-term trend (Figure 2).

Considering the slightly acidic to slightly basic pH of the samples from the spring (see Section 3.0), uranium probably occurs in the groundwater as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble complexes with a variety of inorganic anions in the groundwater, such as carbonate (Fetter 1993). The sources of uranium in the groundwater discharging from this spring include the Boneyard/Burnyard, which was identified as the principal source of elemental uranium (and alpha radioactivity) in BCV, but also may include uranium transported from sources within the BCBG WMA (DOE 1997) and the S-3 Site.

4.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, at least one of the following VOCs were detected in fifteen of the groundwater samples: acetone, 4-methyl-2-pentanone, TCE, and 12DCE (Table 2). The latter two compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. In the Bear Creek watershed west of the flow divide, the VOC plume in the Maynardville Limestone appears to originate near Spoil Area I and to extend several thousands of feet westward (parallel with geologic strike) down the axis of BCV, with influx of various VOCs from several different downgradient source areas. The distribution of VOCs within the plume reflects the relative contributions from the source areas and commingling during downgradient transport. Sampling results for spring SS-5 are representative of concentrations within the TCE-dominated VOC plume in the shallow karst network downgradient of several sources of VOCs, including the BCBG WMA (DOE 1997).

Based on the detection frequency, the primary VOCs in the groundwater samples are TCE and 12DCE (Table 2). The bulk of the results for each compound are estimated values below 5 μg/L, with the highest concentration (9 μg/L) reported for c12DCE in the sample collected in February 2000. Also, the most recent sampling results show TCE concentrations slightly above the drinking water MCL for TCE (Table 2). In contrast, 4-methyl-2-pentanone was detected in one sample and acetone was detected in only two samples (excluding false positive results).

4.4 GROSS ALPHA ACTIVITY

Forty groundwater samples had gross alpha activity above the applicable MDA and corresponding CE (Table 3), and results for 26 samples exceed the drinking water MCL for gross alpha activity (15 pCi/L). The results for gross alpha activity range between the historical minimum value of 4.45 pCi/L in December 1991 and the historical maximum value of 57 pCi/L in February 2000. A time-series plot of the gross alpha activity in the samples from this location shows a widely fluctuating, indeterminate long-term trend (Figure 3). Uranium isotopes are the source of the elevated gross alpha activity in the groundwater from the spring (Table 3).

As with the elemental uranium in the groundwater from this spring, the former Boneyard/Burnyard and the BCBG WMA are the likely sources of the uranium isotopes (DOE 1997). Similarly, the uranium isotopes probably occur in the groundwater as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble complexes with a variety of inorganic anions in the groundwater, such as carbonate (Fetter 1993).

4.5 GROSS BETA ACTIVITY

Forty groundwater samples had gross beta activity above the applicable MDA and corresponding CE (Table 3), with 13 of the results exceeding the SDWA screening level (50 pCi/L) equivalent for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). A time-series plot of the gross beta activity in the samples from this location shows a widely fluctuating, indeterminate long-term trend (Figure 4).

In addition to uranium isotopes (and beta particle-emitting daughter products), the elevated levels of gross beta activity are attributable to Tc-99. As shown by the following data summary, Tc-99 was detected (i.e., >MDA and CE) in twelve of the 16 samples analyzed for this radionuclide, and all but one of these results show Tc-99 concentrations that are substantially below the SDWA screening level (3,470 pCi/L) for a 4 mrem/yr dose equivalent from Tc-99

Sampling Date	Tc-99 (pCi/L)
03/10/92	7.25
06/01/92	<CE
09/08/92	4,800
12/16/92	<CE
02/02/99	18.42
08/11/99	26.45
02/90/00	55.74
08/03/00	48.25
01/11/01	111.97
07/11/01	119.67
01/08/02	78.57
07/10/02	16.17
01/29/03	35.94
07/28/03	32.18
01/27/04	8.85
07/20/04	36.29

This man-made radionuclide is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, which is the only site at Y-12 that received wastes containing Tc-99 (DOE 1997). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells (and springs) in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the transport of Tc-99 in the Maynardville Limestone closely mirrors that of nitrate.

SPRING SS-6

1.0 LOCATION

This spring discharges groundwater into the main channel of Bear Creek about three miles downstream of the headwaters near the west end of Y-12. From its headwaters, Bear Creek flows southwest for approximately 4.5 miles, where it turns northward to flow into East Fork Poplar Creek. In Bear Creek Valley (BCV), the major springs along the south side (SS) of Bear Creek are numbered in ascending order downstream from the headwaters (e.g., SS-1).

Approximately half of the annual precipitation in Bear Creek Valley (BCV) exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Discharge from springs located along the Maynardville Limestone/Copper Ridge Dolomite boundary on the north slope of Chestnut Ridge dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Thirty-six (unfiltered) groundwater samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in August 1990 and the most recent sample collected in July 2004. The grab sampling method was used to collect each sample. Note that the sample collected on November 1993 may have been inadvertently misidentified as a sample that was collected the same day from surface water sampling station BCK-09.40, and vice versa. Misidentification of these samples in the field is suspected because the analytical results reported for the sample from spring SS-6 are more consistent with the historical data for BCK-09.40 and the analytical results reported for the sample from BCK-09.40 are more consistent with the historical data for spring SS-6. However, there are not any available records that prove the misidentification of these samples; consequently, the analytical results for both samples are considered unusable to meet the surveillance monitoring objectives of the Y-12 GWPP.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the groundwater samples is characterized by:

- TDS of 76 – 272 mg/L, excluding an outlier (580 mg/L) in November 1993 (see Section 2.0);
- pH of 6.5 – 8.6 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and

- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Excluding the groundwater sample collected in November 1993 (see Section 2.0), 14 of the samples had nitrate concentrations above the applicable analytical reporting limit (Table 1), with the historical maximum value (2.33 mg/L in February 2000) being substantially below the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

Excluding the groundwater sample collected in November 1993 (see Section 2.0), seven of the samples had (total) uranium concentrations above the applicable analytical reporting limit (Table 1), with the historical maximum value (0.034 mg/L in February 1998) being the only result above the drinking water MCL.

4.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results and the groundwater sample collected in November 1993 (see Section 2.0), c12DCE was detected in one sample (1 μg/L in February 1998) from this spring.

4.4 GROSS ALPHA ACTIVITY

Excluding the groundwater sample collected in November 1993 (see Section 2.0), nine of the samples had gross alpha activity above the applicable MDA and corresponding CE, with the historical maximum value (10 pCi/L in February 1998) being less than the drinking water MCL for gross alpha activity (15 pCi/L).

4.5 GROSS BETA ACTIVITY

Excluding the groundwater sample collected in November 1993 (see Section 2.0), nine of the samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (47 pCi/L in August 1997) being slightly below the SDWA screening level (50 pCi/L) equivalent to a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). This elevated result is an outlier when compared to the other results, all of which are 12 pCi/L or less.

SPRING SS-6.6

1.0 LOCATION

This spring discharges groundwater into the main channel of Bear Creek about four miles downstream of the headwaters near the west end of Y-12. From its headwaters, Bear Creek flows southwest for approximately 4.5 miles, where it turns northward to flow into East Fork Poplar Creek. In Bear Creek Valley (BCV), the major springs along the south side (SS) of Bear Creek are numbered in ascending order downstream from the headwaters (e.g., SS-6.6).

Approximately half of the annual precipitation in Bear Creek Valley (BCV) exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Discharge from springs located along the Maynardville Limestone/Copper Ridge Dolomite boundary on the north slope of Chestnut Ridge dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Twelve (unfiltered) groundwater samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in April 1997 and the most recent sample collected in March 2004. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the groundwater samples is characterized by:

- TDS of 81 – 240 mg/L;
- pH of 6.3 – 8.0 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in

UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Twelve groundwater samples had nitrate concentrations above the applicable analytical reporting limit (Table 1), with the historical maximum value (0.97 mg/L in January 2000) being substantially below the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

Four groundwater samples had (total) uranium concentrations above the applicable analytical reporting limit (Table 1), with the historical maximum value (0.0155 mg/L in August 1997) less than the drinking water MCL for uranium (0.03 mg/L).

4.3 VOLATILE ORGANIC COMPOUNDS

Traces of benzene (1 μg/L) and toluene (1 μg/L) were detected in the groundwater sample collected in August 1998; both results are probably sampling or analytical artifacts.

4.4 GROSS ALPHA ACTIVITY

Six groundwater samples had gross alpha activity above the applicable MDA and corresponding CE (Table 1), with the historical maximum value (16.32 pCi/L in August 2000) being slightly above the drinking water MCL for gross alpha activity (15 pCi/L). However, the historical maximum value appears to be an outlier when compared to the other results for gross alpha activity, which are all less than 5 pCi/L.

4.5 GROSS BETA ACTIVITY

Ten groundwater samples had gross beta activity above the applicable MDA and corresponding CE (Table 1), with the historical maximum value (48.9 pCi/L in August 2003) being slightly below the SDWA screening level (50 pCi/L) equivalent to a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). However, the historical maximum value appears to be an outlier when compared to the other results for gross beta activity, which are all less than 20 pCi/L.

SPRING SS-7

1.0 LOCATION

This spring discharges groundwater into the main channel of Bear Creek about 4.5 miles downstream of the headwaters near the west end of Y-12. From its headwaters, Bear Creek flows southwest for approximately 4.5 miles, where it turns northward to flow into East Fork Poplar Creek. In Bear Creek Valley (BCV), the major springs along the south side (SS) of Bear Creek are numbered in ascending order downstream from the headwaters (e.g., SS-7).

Approximately half of the annual precipitation in Bear Creek Valley (BCV) exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Discharge from springs located along the Maynardville Limestone/Copper Ridge Dolomite boundary on the north slope of Chestnut Ridge dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Fifteen (unfiltered) groundwater samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in May 1995 and the most recent sample collected in August 2003. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the groundwater samples is characterized by:

- TDS of 119 – 228 mg/L;
- pH of 6.2 – 8.9 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in

UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Fifteen groundwater samples had nitrate concentrations above the applicable analytical reporting limit (Table 1), with the historical maximum value (4.74 mg/L in October 1995) being substantially below the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

Seven groundwater samples had (total) uranium concentrations above the applicable analytical reporting limit (Table 1), including two results (0.036 mg/L in October 1995 and 0.0316 mg/L in September 2001) being slightly above the drinking water MCL for uranium (0.03 mg/L).

4.3 VOLATILE ORGANIC COMPOUNDS

VOCs were not detected in the groundwater samples.

4.4 GROSS ALPHA ACTIVITY

Nine of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE (Table 1), with the historical maximum value (16.4 pCi/L in October 1995) being slightly above the drinking water MCL for gross alpha activity (15 pCi/L).

4.5 GROSS BETA ACTIVITY

Five of the groundwater samples had gross beta activity above the applicable MDA and corresponding CE (Table 1), with the historical maximum value (23.7 pCi/L in October 1995) being substantially below the SDWA screening level for gross beta activity (50 pCi/L) equivalent to a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

SPRING SS-8

1.0 LOCATION

This spring discharges groundwater into the main channel of Bear Creek about 4.5 miles downstream of the headwaters near the west end of Y-12. From its headwaters, Bear Creek flows southwest for approximately 4.5 miles, where it turns northward to flow into East Fork Poplar Creek. In Bear Creek Valley (BCV), the major springs along the south side (SS) of Bear Creek are numbered in ascending order downstream from the headwaters (e.g., SS-8).

Approximately half of the annual precipitation in Bear Creek Valley (BCV) exits via surface water flow in Bear Creek, and possibly higher proportions during winter and early spring, with the remainder of the annual precipitation lost to evapotranspiration and recharge to the groundwater system (DOE 1997). Flow in the creek increases rapidly during rainfall and afterward reflects the relative contributions of overland flow, stormflow, and groundwater discharge. Flow in the main channel and tributaries generally return to pre-precipitation levels within one or two days.

The main channel of Bear Creek functions as a major conduit of the shallow karst network within the Maynardville Limestone, which directly underlies the creek throughout much of BCV (DOE 1997). Discharge from springs located along the Maynardville Limestone/Copper Ridge Dolomite boundary on the north slope of Chestnut Ridge dominate the hydrology of the creek, especially during seasonally dry periods when spring discharge and groundwater baseflow provide most of the flow in the main channel. Additionally, the main channel contains alternating gaining and losing reaches. Each gaining reach generally correlates with a major groundwater discharge area. Losing reaches in upper and middle Bear Creek, play an important role in transferring contaminants from Bear Creek into the Maynardville Limestone.

2.0 SAMPLING HISTORY

Twenty-eight (unfiltered) groundwater samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in August 1990 and the most recent sample collected in August 2003. The grab sampling method was used to collect each sample.

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the groundwater samples is characterized by:

- TDS of 100 – 280 mg/L;
- pH of 6.0 – 8.5 (field measurements);
- calcium-magnesium-bicarbonate dominated major ion chemistry, with low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in

UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Twenty-one groundwater samples had nitrate concentrations above the applicable analytical reporting limit (Table 1), with the historical maximum value (358 mg/L in February 1998) substantially exceeding the drinking water MCL for nitrate (10 mg/L). However, this result is an outlier when compared to the nitrate concentrations reported for the other samples, all of which are less than 1.5 mg/L.

4.2 URANIUM

One groundwater sample had (total) uranium concentrations above the applicable analytical reporting limit (two samples were not analyzed for uranium; Table 1), and this result (0.001 mg/L in November 1993) is substantially below the drinking water MCL for uranium (0.03 mg/L).

4.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, acetone was detected in the groundwater sample collected in June 1992 (7 µg/L).

4.4 GROSS ALPHA ACTIVITY

Four groundwater samples had gross alpha activity above the applicable MDA and corresponding CE (five samples were not analyzed for gross alpha activity; Table 1), with the historical maximum value (6.91 pCi/L in August 1993) being less than the drinking water MCL for gross alpha activity (15 pCi/L).

4.5 GROSS BETA ACTIVITY

Six groundwater samples had gross beta activity above the applicable MDA and corresponding CE (Table 1), with the historical maximum value (4.82 pCi/L in September 2001) being substantially below the SDWA screening level (50 pCi/L) equivalent to a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

SURFACE WATER SAMPLING STATION
Station 8

1.0 LOCATION

This surface water sampling station is located on the exposed section of the main channel of Upper East Fork Poplar Creek (UEFPC) in south-central Y-12, directly southeast of Bldg. 9201-1. Construction of facilities at Y-12 has substantially modified UEFPC, with the headwaters and several thousand feet of the main channel in the upper reach of the creek, including all the northern tributaries of the creek in the western and central sections of Y-12, filled and replaced with an extensive network of underground storm drains. Also, the section of the creek near the eastern end of Y-12 was extensively modified by construction of New Hope Pond (NHP) in 1963 and the closure of NHP in 1988. An unlined surface impoundment, NHP was used to regulate the quantity and quality of surface water exiting Y-12 until it was closed and replace by Lake Reality, a lined surface impoundment built in 1988.

About 80% of dry-weather flow in UEFPC is attributable to once-through non-contact cooling water, condensate, cooling tower blowdown, and potable water treated and discharged from wastewater treatment facilities and the remaining 20% is from groundwater discharge (DOE 1998). In accordance with a flow management program initiated in July 1996, untreated water from the Clinch River intake lines to the DOE water treatment plant that supplies potable water to Y-12 is discharged into the exposed section of the main channel of UEFPC in the south-central section of Y-12 near Bldg. 9201-1. Augmentation of flow in UEFPC is necessary because reduced operations at Y-12 have decreased flow from 10-15 million gallons per day (mgd) to about 2.5 mgd. Flow augmentation also is needed to: (1) achieve the National Pollution Discharge Elimination System (NPDES) minimum daily flow requirement of 7 mgd at Station 17, which is located immediately upstream of where UEFPC exits the DOE Oak Ridge Reservation northeast of Y-12; (2) maintain compliance with NPDES toxicity requirements; and (3) lower the otherwise elevated water temperature in UEFPC.

2.0 SAMPLING HISTORY

Twenty-three (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in February 1999 and the most recent sample collected in July 2004. The grab sampling method was used to collect each sample.

In addition to the sampling performed to meet the surveillance monitoring objectives Y-12 GWPP, surface water samples also have been collected to meet other monitoring requirements, including sampling that the Y-12 Surface Water Program performs as a best management practice and to meet the requirements of DOE Order 450.1. Also, grab sampling and/or flow-proportionate composite sampling is performed to meet the requirements of the Phase I ROD for UEFPC (DOE 1997).

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 150 – 350 mg/L;
- pH of 6.7 – 8.4 (field measurements);
- elevated concentrations of sulfate (>25 mg/L); and

- total concentrations of trace metals (except mercury and uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, the surface-water quality data obtained by the Y-12 GWPP are not flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Nineteen surface water samples had nitrate concentrations above the applicable analytical reporting limit (Table 1), with the historical maximum value (3.9 mg/L in April 1999) being substantially below the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

Fifteen surface water samples had (total) uranium concentrations above the applicable analytical reporting limit (Table 1), including four results that exceed the drinking water MCL for uranium (0.03 mg/L): 0.05 mg/L in March 2000; 0.0558 mg/L and 0.0367 mg/L in February 2001; and 0.04 mg/L in February 2002. Note that all of the elevated uranium results are for samples collected during winter and spring, suggesting higher contaminant flux during seasonally high flow conditions. There are numerous sources of uranium within Y-12 upstream of this sampling station, including inflow of uranium-contaminated groundwater into UEFPC.

4.3 MERCURY

Six surface water samples had (total) mercury concentrations above the applicable analytical reporting limit (Table 1), with the historical maximum value (0.00081 mg/L in July 1999) being substantially below the drinking water MCL for mercury (0.002 mg/L). There are multiple sources of mercury within Y-12 upstream of this sampling station, including inflow of mercury-contaminated groundwater into UEFPC, and the remediation of these sources is the focus of the CERCLA Phase I ROD for mercury source areas in UEFPC (DOE 1997).

4.4 VOLATILE ORGANIC COMPOUNDS

Nineteen surface water samples collected between February 1999 and August 2003 had low concentrations of one or more of the following VOCs (Table 2): bromoform (BFM), bromodichloromethane (BDM), chloroform (CLF), dibromochloromethane (DBM), TCE, and c12DCE. Most of these results are estimated values below 5 μg/L, and none of the concentrations exceed applicable MCLs for drinking water. There are multiple sources of VOCs in Y-12 upstream of this sampling station, including the inflow of VOC-contaminated groundwater into UEFPC. Additionally, trihalomethanes (CLF, BMF, BDM, and DBM) are included in a class of drinking water disinfection byproducts (DBPs) that form through chemical interactions between chlorine and natural organic matter (U.S. Environmental Protection Agency [EPA] 2001). Thus, chlorinated water discharged into UEFPC is a likely source of the DBPs detected in the surface water samples from this sampling station.

4.5 GROSS ALPHA ACTIVITY

Twenty-one surface water samples had gross alpha activity above the applicable MDA and corresponding CE (Table 3), with results reported for five samples, including the historical maximum value (54.97 pCi/L in July 1999), exceeding the drinking water MCL for gross alpha activity (15 pCi/L). Uranium isotopes (U-234 and U-238) are the likely source of the elevated gross alpha activity, with the highest values for each isotope also being reported for the sample collected in July 1999 (Table 3).

4.6 GROSS BETA ACTIVITY

Twenty-two surface water samples had gross beta activity above the applicable MDA and corresponding CE (Table 3), with historical maximum value (36.22 pCi/L in July 1999) being less than the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). As with the gross alpha activity, uranium isotopes are the likely source of the gross beta activity; the highest values for each isotope are reported for the same sample as the historical maximum gross beta result (July 1999).

SURFACE WATER SAMPLING STATION
Station 17

1.0 LOCATION

This surface water sampling station is located on the main channel of Upper East Fork Poplar Creek (UEFPC), just upstream of where UEFPC exits the DOE Oak Ridge Reservation (ORR) northeast of Y-12. Construction of facilities at Y-12 has substantially modified UEFPC, with the headwaters and several thousand feet of the main channel in the upper reach of the creek, including all the northern tributaries of the creek in the western and central sections of Y-12, filled and replaced with an extensive network of underground storm drains. Also, the section of the creek near the eastern end of Y-12 was extensively modified by construction of New Hope Pond (NHP) in 1963 and the closure of NHP in 1988. An unlined surface impoundment, NHP was used to regulate the quantity and quality of surface water exiting Y-12 until it was closed and replace by Lake Reality, a lined surface impoundment built in 1988.

During normal operations, flow in UEFPC is directed through a concrete-lined distribution channel located around the south and east side of Lake Reality. Also, a gravel and perforated pipe underdrain beneath portions of the distribution channel captures shallow groundwater. Until December 1996 when flow was rerouted to bypass Lake Reality, surface flow in the UEFPC distribution channel discharged into Lake Reality (and exited through a weir in the western berm). Beginning in July 1998, flow in the UEFPC distribution channel was diverted through the Lake Reality spillway (LRSPW), which discharges into the mainstream of UEFPC directly north of Lake Reality. Bypassing Lake Reality reduces mercury contributions to dry-weather flow in UEFPC. Station 17 monitors surface water quality in UEFPC approximately 800 ft downstream of LRSPW.

About 80% of dry-weather flow in UEFPC is attributable to once-through non-contact cooling water, condensate, cooling tower blowdown, and potable water treated and discharged from wastewater treatment facilities and the remaining 20% is from groundwater discharge (DOE 1998). In accordance with a flow management program initiated in July 1996, untreated water from the Clinch River intake lines to the DOE water treatment plant that supplies potable water to Y-12 is discharged into the exposed section of the main channel of UEFPC in the south-central section of Y-12 near Bldg. 9201-1. Augmentation of flow in UEFPC is necessary because reduced operations at Y-12 have decreased flow from 10-15 million gallons per day (mgd) to about 2.5 mgd. Flow augmentation also is needed to: (1) achieve the National Pollution Discharge Elimination System (NPDES) minimum daily flow requirement of 7 mgd at Station 17; (2) maintain compliance with NPDES toxicity requirements; and (3) lower the otherwise elevated water temperature in UEFPC.

2.0 SAMPLING HISTORY

Twenty-five (unfiltered) surface water samples collected to date meet the surveillance monitoring objectives of the Y-12 GWPP, with the first sample collected in March 1996 and the most recent sample collected in August 2004. The grab sampling method was used to collect each sample.

In addition to the sampling performed to meet the surveillance monitoring objectives Y-12 GWPP, surface water samples also have been collected to meet other monitoring requirements, including sampling that the Y-12 Surface Water Program performs to comply with the Y-12 NPDES permit, as a best management practice, and to meet the requirements of DOE Order 450.1. Also, grab sampling and/or flow-proportionate composite sampling is performed to meet the requirements of the Phase I ROD for UEFPC (DOE 1997).

3.0 GEOCHEMICAL CHARACTERISTICS

Based on data that meet the surveillance monitoring objectives of the Y-12 GWPP, the geochemistry of the surface water samples is characterized by:

- TDS of 93 – 380 mg/L;
- pH of 6.0 – 8.8 (field measurements);
- elevated concentrations of chloride (>50 mg/L) and sulfate (>25 mg/L); and
- total concentrations of trace metals (except uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater (and surface water) at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

4.0 CONTAMINATION

This section describes analytical results that meet the surveillance monitoring objectives of the Y-12 GWPP for the following surface water contaminants: nitrate, uranium, mercury, VOCs, gross alpha activity, and gross beta activity. One or more of these contaminants may be present in the surface waters as a legacy of historical operations at Y-12, although nitrate is a primary contaminant only in Bear Creek and some of its northern tributaries; mercury is a primary contaminant only in UEFPC; and none of these contaminants are typically present at elevated concentrations in surface waters on Chestnut Ridge south of Y-12. Also, none of the surface-water quality data obtained for any monitoring locations by the Y-12 GWPP are flow-proportionate and, therefore, are not optimal for evaluating contaminant flux (mass transport) at the sampling station.

4.1 NITRATE

Eighteen surface water samples had nitrate concentrations above the applicable analytical reporting limit (Table 1), with the historical maximum value (3 mg/L in April 1999 and March 2000) being substantially below the drinking water MCL for nitrate (10 mg/L).

4.2 URANIUM

Sixteen surface water samples had (total) uranium concentrations above the applicable analytical reporting limit (Table 1), including four results that equal or exceed the drinking water MCL for uranium (0.03 mg/L). There are numerous sources of uranium within Y-12 upstream of this sampling station, including inflow of uranium-contaminated groundwater into UEFPC.

4.3 MERCURY

Six surface water samples had (total) mercury concentrations above the applicable analytical reporting limit (Table 1), with the maximum value (0.001 mg/L in July 1999) being less than the drinking water MCL for mercury (0.002 mg/L). There are multiple sources of mercury within Y-12 upstream of this sampling station, including inflow of mercury-contaminated groundwater into UEFPC, and the remediation of these sources is the focus of the Phase I ROD for UEFPC (DOE 1997).

4.4 VOLATILE ORGANIC COMPOUNDS

Low concentrations of bromodichloromethane (BDM), CTET, chloroform, and PCE were detected in the 18 surface water samples collected from February 1999 to August 2003, with chloroform and PCE detected the most frequently (Table 2). There are multiple sources of VOCs in Y-12 upstream of this sampling station, including the inflow of VOC-contaminated groundwater into UEFPC.

4.5 GROSS ALPHA ACTIVITY

None of the surface water samples were analyzed for gross alpha activity.

4.6 GROSS BETA ACTIVITY

None of the surface water samples were analyzed for gross beta activity.
