TABLES

1.0 INTRODUCTION

This document is a compendium of water quality and hydrologic characterization data obtained through December 2005 from the network of groundwater monitoring wells and surface water sampling stations (including springs and building sumps) at the U.S. Department of Energy (DOE) Y-12 National Security Complex (Y-12) in Oak Ridge, Tennessee that have been sampled since January 2003. The primary objectives of this document, hereafter referenced as the Y-12 Groundwater Protection Program (GWPP) Compendium, are to:

- Serve as a single-source reference for monitoring data that meet the requirements of the Y-12 GWPP, as defined in the Y-12 GWPP Management Plan (BWXT Y-12 L.L.C. [BWXT] 2004);

- Maintain a detailed analysis and evaluation of the monitoring data for each applicable well, spring, and surface water sampling station, with a focus on results for the primary inorganic, organic, and radiological contaminants in groundwater and surface water at Y-12; and

- Ensure retention of "institutional knowledge" obtained over the long-term (>20-year) history of groundwater and surface water monitoring at Y-12 and the related sources of groundwater and surface water contamination.

To achieve these goals, the Y-12 GWPP Compendium brings together salient hydrologic, geologic, geochemical, water-quality, and environmental compliance information that is otherwise disseminated throughout numerous technical documents and reports prepared in support of completed and ongoing environmental contamination assessment, remediation, and monitoring activities performed at Y-12.

The following subsections provide background information regarding the overall scope and format of the Y-12 GWPP Compendium and the planned approach for distribution and revision (i.e., administration) of this "living" document.

1.1 SCOPE

This Y-12 GWPP Compendium includes groundwater monitoring wells granted "active" status in accordance with the Y-12 GWPP Monitoring Optimization Plan (MOP), including wells for which the monitoring status has changed to "inactive" at some time following the sampling events described in this document. The MOP grants active status to any well that meets one or more of the following criteria: (1) the well is designated for monitoring in compliance with applicable state and federal regulations and/or the requirements of DOE Orders; (2) the well is designated for hydrologic monitoring (e.g., water-level elevations); (3) the well is known to yield contaminated groundwater; (4) the well is located hydraulically downgradient of facilities at Y-12, including any known source(s) of groundwater contamination; and (5) the well provides unique hydrologic and/or groundwater quality information (BWXT 2006a). The Y-12 GWPP Compendium provides the following information for wells granted active status under the MOP:

- A summary of pertinent well-construction information (e.g., total depth);

- An overview of the groundwater sampling history for the well and a discussion of distinguishing sampling characteristics (e.g., large water-level fluctuations);

- A discussion of the hydrologic characteristics for the well, based primarily on presampling depth-to-water measurements/groundwater elevations, along with a summary of available results for hydrologic tests (e.g., hydraulic conductivity tests);

- A discussion of the geochemical characteristics of the groundwater in the well based on available analytical results for primary anions and cations, including a discussion of results showing unusually high or low ion concentrations, or other similarly distinctive geochemical characteristics;

- A detailed narrative evaluation of the available analytical results for the well, supported by time-series plots and data summary tables, based on monitoring results that meet the requirements of the Y-12 GWPP for the primary groundwater contaminants at Y-12: nitrate, uranium, volatile organic compounds (VOCs), and radioactivity (gross alpha activity and gross beta activity); and

- A list of plans, documents, and technical reports cited for more detailed information.

The Y-12 GWPP Compendium presents a *Brief* of the above-listed information for each well, which includes a *Summary Cover Sheet* and corresponding *Data Evaluation Narrative*, each of which is divided into the following sections: (1) Installation, Construction, and Location; (2) Sampling History and Characteristics; (3) Hydrologic Characteristics; (4) Geochemical Characteristics; (5) Contamination, with subsections for nitrate, uranium, VOCs, gross alpha activity, gross beta activity, and other contaminants (if any); and (6) References. Section 2 of this introductory report provides a detailed explanation of the data presented in the *Summary Cover Sheet* for each well and Section 3 outlines the types of information provided in the corresponding *Data Evaluation Narrative*.

This Y-12 GWPP Compendium also includes a number of natural springs and surface water sampling locations in the drainage basins associated with Y-12, including sampling locations that are outside the boundary of the DOE Oak Ridge Reservation. The Y-12 GWPP uses these sampling locations for the purposes of Exit Pathway/Perimeter monitoring in accordance with the requirements of DOE Order 450.1. Several of these sampling locations also meet the requirements of other monitoring programs and organizations at Y-12, including National Pollution Discharge Elimination System (NPDES) monitoring performed by the Y-12 Surface Water Program. Based only on selected sampling/analytical results that meet DOE Order monitoring requirements, the Y-12 GWPP Compendium provides the following information for each applicable spring and surface water sampling station:

- The general location of the spring or surface water sampling station, including the Y-12 grid coordinates;

- The purpose for monitoring the spring or surface water sampling station (e.g., DOE Order monitoring) and the sampling history;

- A discussion of the geochemical characteristics of the samples from the spring or surface water stations, based on available analytical results for primary anions and cations;

- A summary of water-quality conditions at each spring or surface water sampling station, based on sampling/analytical results for the following surface water contaminants at Y-12: nitrate, uranium, VOCs, radioactivity (gross alpha activity and gross beta activity), and mercury (selected locations only); and

- A list of plans, documents, and technical reports cited for more detailed information.

As with the wells, the Y-12 GWPP Compendium presents a *Brief* of the above-listed information for each spring and surface water station in a *Summary Cover Sheet* and corresponding *Data Evaluation Narrative*, each formatted with the following sections: (1) Location; (2) Sampling History; (2) Geochemical Characteristics; (4) Principal Contamination, with subsections for nitrate, uranium, VOCs, gross alpha activity, gross beta activity, and other contaminants, such as mercury; and (5) References. Much of the information included in the *Summary Cover Sheet* and *Data Evaluation Narrative* for each spring and surface water sampling station is self-explanatory or is otherwise addressed by the descriptions provided Section 2 and Section 3 of this introductory report.

The Y-12 GWPP Compendium includes only the applicable wells (i.e., those granted "active" status under the MOP) and surface water monitoring stations (including springs) that have been used for groundwater or surface water quality sampling since January 2003. Nevertheless, as described in the following sections, the compendium format accommodates the addition of other sampling locations that may be included in ongoing groundwater and surface water monitoring activities. Additionally, the compendium maintains information regarding wells that were formerly granted active status, but whose monitoring status has changed to inactive (e.g., wells plugged and abandoned to make room for buildings). With this approach, the Y-12 GWPP Compendium eventually may encompass all of the wells at Y-12 that are, or have been, granted "active" status under the MOP.

1.2 FORMAT

To facilitate use as a reference manual, the Y-12 GWPP Compendium is presented in a "handbook" format. This format is intended for wide distribution and consists of a hardcopy of this introductory report along with a compact disk containing four portable document format (PDF) files (Volumes 2, 3, 4, and 5) that have the most up-to-date *Brief* for each applicable well, spring, and surface water sampling station. The PDF files are fully searchable with compatible software (e.g., Adobe Acrobat™). The entire Y-12 GWPP Compendium is divided into five separate volumes in the manner of an encyclopedia, with this introduction being Volume 1 and the *Brief* for each applicable sampling location presented in Volume 2 (Table 1), Volume 3 (Table 2), Volume 4 (Table 3), and Volume 5 (Table 4). The referenced index tables identify the wells (listed in ascending order by well number) included in Volumes 2, 3, and 4 and list the springs and surface water sampling stations included in Volume 5.

1.3 REVISION

The Y-12 GWPP Compendium is a "living" document that will be revised (updated) annually or at an alternative frequency specified by the Y-12 GWPP Manager. The revisions will primarily involve: (1) updating the information presented in this introductory report, particularly the above-referenced index tables and the data-summary tables presented in Section 2; (2) updating the information presented in the *Summary Cover Sheet* and *Data Evaluation Narrative* for each applicable well, spring, or surface water station to incorporate the results of on-going groundwater and surface water quality monitoring activities; and/or (3) adding the *Summary Cover Sheet* and *Data Evaluation Narrative* for applicable wells, springs, or surface water stations not previously included in the Y-12 GWPP Compendium. The current revision of this document includes new *Briefs* for the wells that were sampled during CY 2005, but none of the existing *Briefs* were updated to reflect CY 2005 sampling results. The next annual revision is scheduled to include new *Briefs* and updated *Briefs* for all locations that were sampled at least once during CY 2005 or CY 2006.

The revised version of the “handbook” format will include an updated hardcopy of the introductory report (this document) along with a compact disk that contains a PDF file with the updated *Brief* for each applicable well, spring, and surface water sampling station.

2.0 SUMMARY COVER SHEET

The *Summary Cover Sheet* for each applicable sampling location included in the Y-12 GWPP Compendium serves as a quick reference for general information about the well, spring, or surface water sampling station. This section provides background information regarding the contents of the *Summary Cover Sheet* for each well, which also addresses the contents of the *Summary Cover Shee*t for each spring and surface water station.

The *Summary Cover Sheet* for each applicable monitoring well included in the Y-12 GWPP Compendium, as detailed below, is divided into the following sections: (1) *Location*; (2) *Monitoring Purpose*; (3) *Well Construction*; (4) *Monitored Interval*; (5) *Sampling History*; (6) *Sampling Characteristics*, and (7) *Principal Contaminants*. Information is provided on the *Summary Cover Sheet* unless it is not available (NA) or is not applicable (“.”).

2.1 LOCATION

This section of the *Summary Cover Sheet* provides general location information for the well, including the hydrogeologic regime in which the well is located and the site (Functional Area) with which the well is affiliated. Often, the affiliated site is a source of contamination in the groundwater at the well. The Y-12 GWPP recognizes three broad hydrogeologic regimes at Y-12 (Figure 1): (1) the Bear Creek Hydrogeologic Regime (referenced as the Bear Creek Regime), which encompasses a section of Bear Creek Valley (BCV) west of Y-12; (2) the Upper East Fork Poplar Creek Hydrogeologic Regime (referenced as the East Fork Regime), which encompasses the section of BCV that includes the bulk of the process and support buildings that comprise Y-12; and (3) the Chestnut Ridge Hydrogeologic Regime (referenced as the Chestnut Ridge Regime), which encompasses a section of Chestnut Ridge directly south of Y-12.

2.2 MONITORING PURPOSE

This section of the *Summary Cover Sheet* identifies the applicable groundwater monitoring program under which samples were collected during the most recent year. Although collected for a variety of monitoring purposes, all of the data presented in this document meet U.S. Department of Energy (DOE) Order monitoring requirements. Ongoing groundwater quality monitoring activities in the hydrogeologic regimes at Y-12 are implemented in accordance with the following programs:

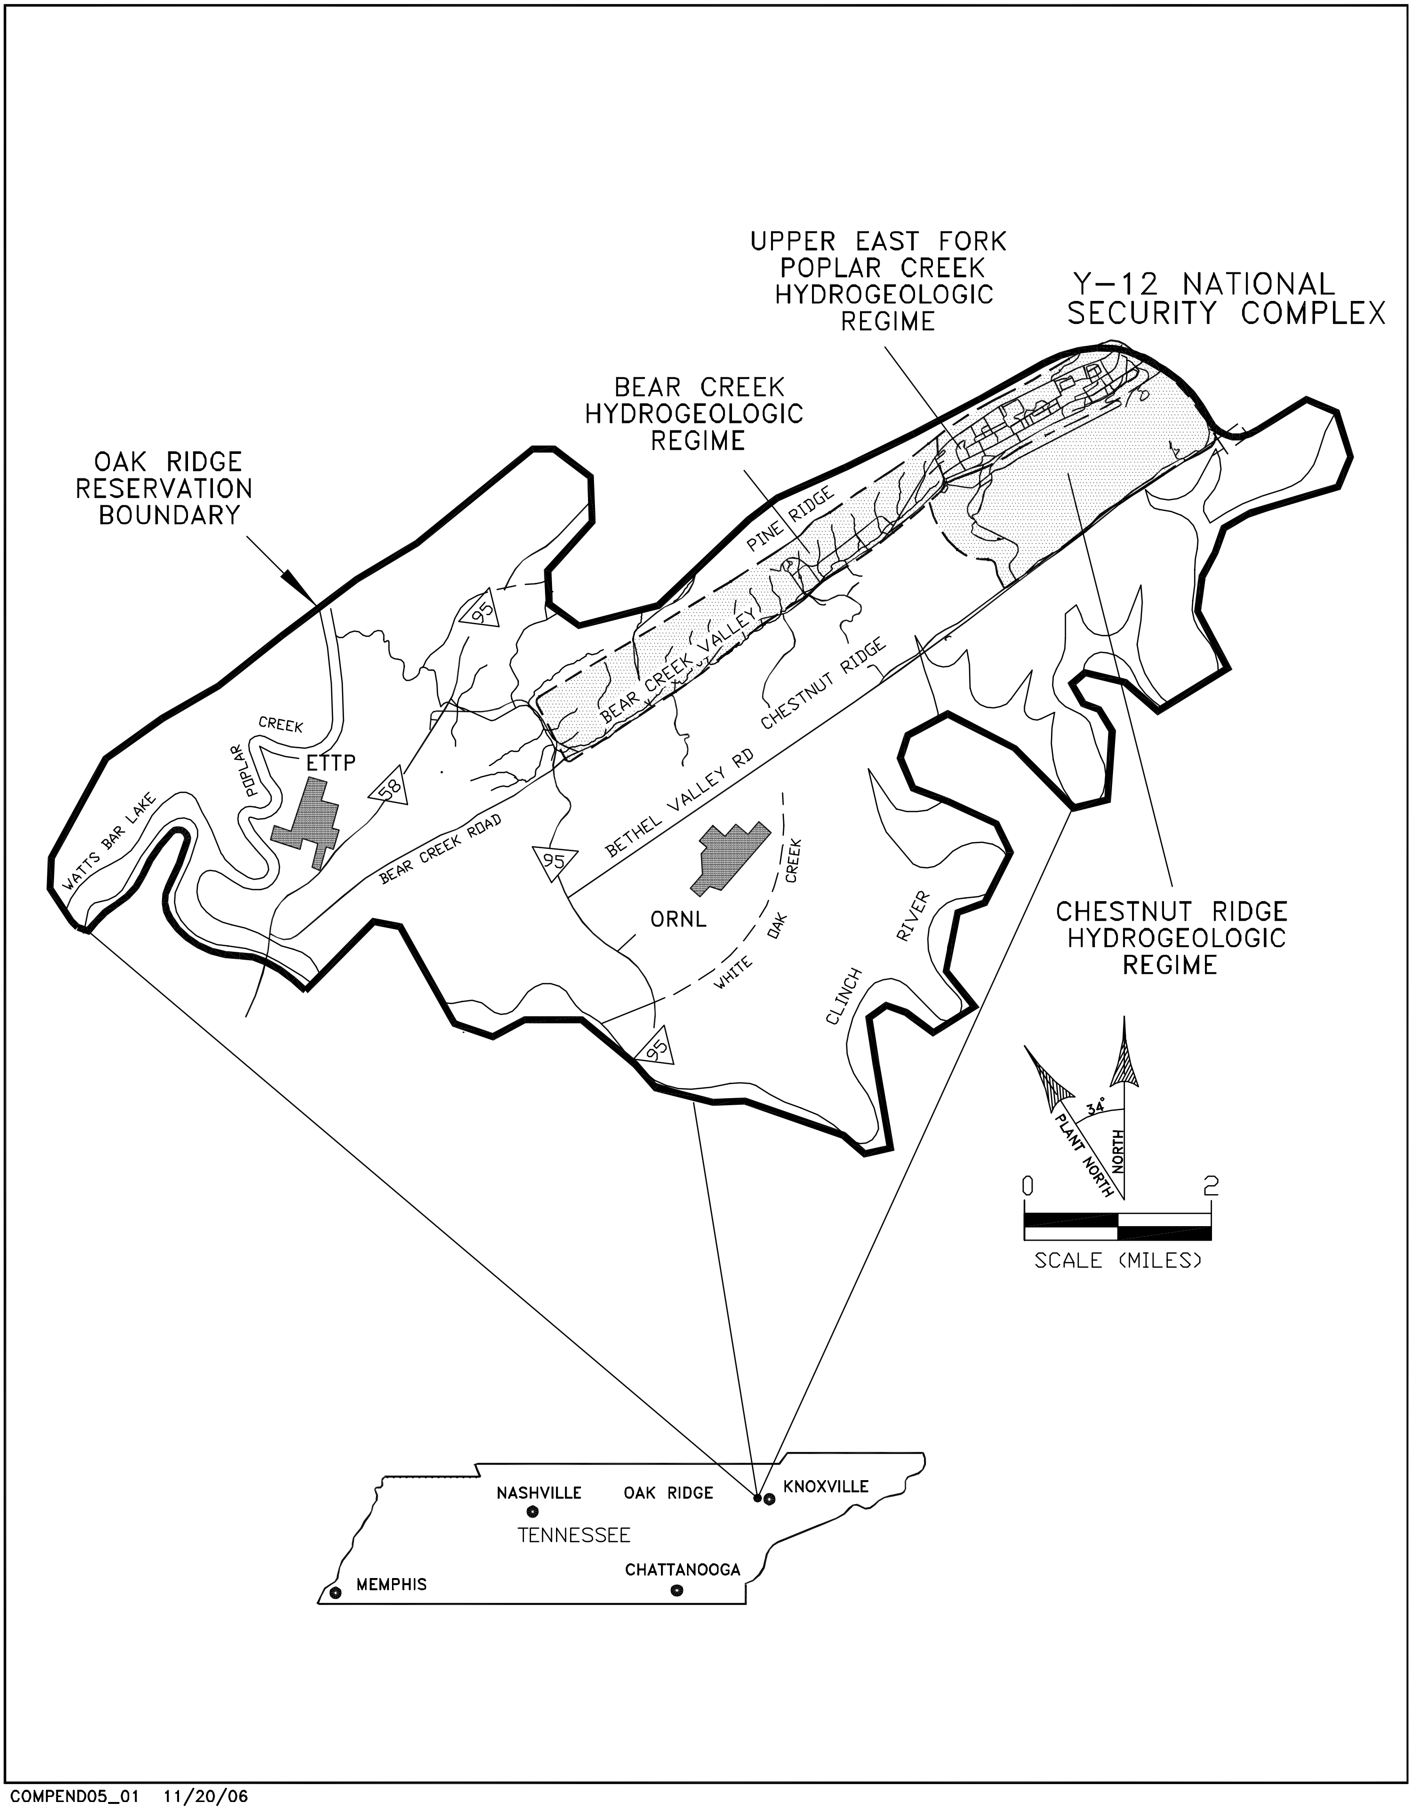

Fig. 1. Hydrogeologic regimes at the Y-12 National Security Complex.

- Resource Conservation and Recovery Act (RCRA) post-closure groundwater quality monitoring, which includes RCRA post-closure detection monitoring and RCRA post-closure corrective action effectiveness monitoring. The former is performed at closed hazardous waste disposal units (HWDUs) that have not released hazardous waste and/or hazardous waste constituents to the groundwater system, and the latter is performed at HWDUs which have released hazardous waste and/or hazardous waste constituents. The requirements for these RCRA monitoring programs are defined in the respective RCRA post-closure permit issued by the Tennessee Department of Environment and Conservation (TDEC) for each hydrogeologic regime and the applicable TDEC regulations governing groundwater monitoring at HWDUs.

- Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) groundwater quality monitoring, which includes: (1) CERCLA baseline monitoring to evaluate pre-remediation groundwater quality; (2) monitoring performed in accordance with the applicable CERCLA record of decision (ROD) and or related decision documents pending final approval of the ROD; and (3) monitoring performed at the Environmental Management Waste Management Facility (EMWMF), which is an active CERCLA-regulated waste disposal site located in the Bear Creek Regime west of Y-12.

- Groundwater quality monitoring performed at several operating and closed non-hazardous waste landfills located south of Y-12 in the Chestnut Ridge Regime. Monitoring at each site is performed in accordance with the operating permit/post-closure plan issued and approved by the TDEC and the TDEC regulations governing groundwater monitoring at non-hazardous solid waste disposal facilities (SWDFs).

- Groundwater quality monitoring performed in each hydrogeologic regime in compliance the requirements of DOE Order 450.1, which mandates monitoring in areas at Y-12 that: (1) are known or suspected sources of groundwater contamination and (2) where contaminants from DOE operations at Y-12 may exit areas under DOE administrative control.

In addition to groundwater quality monitoring, respective networks of groundwater monitoring wells in the Bear Creek Regime, East Fork Regime, and Chestnut Ridge Regime are used for hydrologic monitoring (i.e., are used to determine contemporaneous, regime-wide groundwater surface elevations).

2.3 WELL CONSTRUCTION

This section of the *Summary Cover Sheet* provides selected information regarding the construction of the monitoring well, as reported in: *Updated Subsurface Data Base for Bear Creek Valley, Chestnut Ridge, and Parts of Bethel Valley on the U.S. Department of Energy Oak Ridge Reservation* (BWXT 2003), hereafter referenced as the Y-12 Subsurface Database. Many of the monitoring wells are completed in pairs or clusters, and the *Summary Cover Sheet* notes all paired or clustered wells. For most wells, the total depth of the well (Tag Depth) is in reference to the top of the well casing, whereas other downhole measurements may be in reference to a designated measuring point marked on the top of the Well Wizard™ (TOWW) (a dedicated gas-driven bladder pump) in the well. The type of dedicated sampling equipment (to be used only for the specified well) installed in the well is noted in this section; most monitoring wells have a Well Wizard™ bladder pump. A few wells are equipped with Westbay™ multiport sampling systems that enable collection of representative samples from several discreet depth intervals. Additionally, the following acronyms and abbreviations are used for well casing materials and well screen types (if applicable):

PVC40	-	polyvinyl chloride, schedule 40
PVC/SL	-	PVC/slotted
PVC/SW	-	PVC/spiral wound
PPK	-	pre-packed screen
SF25/SJ55	-	steel; American Petroleum Institute Grade
STL	-	carbon steel
SS	-	stainless steel
SS304	-	stainless steel type 304
SS/SW	-	stainless steel, spiral wound
slot size	-	size of screen openings, in inches (e.g., 0.01)

2.4 MONITORING INTERVAL

This section of the *Summary Cover Sheet* provides selected information regarding the monitored interval for the well, as reported in the Y-12 Subsurface Database. All the monitoring wells at Y-12 that are granted active status under the Y-12 GWPP are completed with manufactured well screens or open-hole monitored intervals, respectively referenced as "Screened" and "Open Hole" on the *Summary Cover Sheet*. Also provided are the depths to the top, bottom, and midpoint of the monitored interval, as measured in ft below ground surface (bgs), and the corresponding elevations in ft above mean sea level (msl).

As noted in the Section 2.3, most of the monitoring wells granted active status under the Y-12 GWPP are equipped with a dedicated sampling pump. Therefore, this section of the *Summary Cover Sheet* for these wells shows the depth to the pump intake, which provides information regarding its relative location within the monitored interval for the well.

This section of the *Summary Cover Sheet* also identifies the geologic formation from which the monitoring well yields groundwater. The primary geologic formations in the vicinity of Y-12 are (listed in order from oldest to youngest): the Rome Formation, which forms Pine Ridge north of Y-12; the Conasauga Group formations (Pumpkin Valley Shale, Rutledge Limestone, Rogersville Shale, Mayville Limestone, Nolichucky Shale, and Maynardville Limestone), which underlie Bear Creek Valley (BCV) and the southern flank of Pine Ridge; and the Knox Group formations (Copper Ridge Dolomite, Chepultepec Dolomite, Longview Dolomite, Kingsport Formation, and Mascot Dolomite), which form Chestnut Ridge south of Y-12 (Figure 2).

The geologic formations in the vicinity of Y-12 comprise two broad hydrogeologic units: the aquifer, consisting of the Maynardville Limestone (upper Conasauga Group) and Knox Group formations; and the aquitard, consisting of the remaining Conasauga Group formations and the Rome Formation. Fractures provide the principal groundwater flowpaths in both units, and dissolution of carbonates in the aquifer has enlarged fractures and produced solution cavities and conduits that greatly enhance its hydraulic conductivity relative to the aquitard. Flow in each unit decreases with depth and flow through the porous rock matrix is minimal in both units. Also, the bulk of the groundwater flow in each unit occurs within a highly permeable hydrogeologic zone, referenced as the "water-table interval" in this section of the *Summary Cover Sheet*, located near the interface between bedrock and weathered bedrock/residuum. In the aquifer, the water-table interval represents an extensively interconnected network of solution conduits and cavities (shallow karst network). Wells completed below the "water-table interval" are noted as monitoring a "bedrock" hydrogeologic zone.

2.5 SAMPLING HISTORY

This section of the *Summary Cover Sheet* presents the groundwater sampling history for the well, including the total number of sampling events with the initial and most recent sampling dates of the current revision (see Section 1.3). The sampling history includes sampling events performed by the Y-12 GWPP (January 1986 – present), samples collected by various programs managed by Bechtel Jacobs Company LLC (October 1996 – present), and selected sampling results obtained for CERCLA remedial investigations in the Bear Creek and East Fork Regimes (1997 – 1998). The sampling history also shows the number of samples that have been obtained with the two groundwater sampling methods that have been employed by the Y-12 GWPP and other organizations: a low-flow minimal drawdown sampling method (hereafter referenced as low-flow sampling) and a "conventional" sampling method. The low-flow sampling method, which is intended to obtain representative groundwater samples that do not include stagnant water in the well casing, involves pumping groundwater from the well at a flow rate that is low enough (<300 milliliters per minute) to minimize drawdown of the water level in the well (<0.1 feet [ft] per quarter-hour) and collecting groundwater samples when regular measurements of pH, conductivity, temperature, oxidation-reduction potential (REDOX), and dissolved oxygen (DO) show minimal variation over four consecutive readings. In contrast, the conventional sampling method involves collecting groundwater samples immediately after purging at least three well volumes of groundwater from the well (if the well does not purge dry) at a much higher pumping rate (1.0 to 1.8 gallons per minute).

2.6 SAMPLING CHARACTERISTICS

Most of the groundwater monitoring wells at Y-12 that are granted active status under the Y-12 GWPP monitor uncontaminated groundwater, exhibit similar hydrologic characteristics (e.g., seasonal water-level fluctuations), and yield groundwater samples with similar geochemical characteristics. As described in the following paragraphs, analytical results some of the wells granted active status are conspicuous with regard to: (1) elevated chromium and/or nickel concentrations believed to be artifacts related to the corrosion of the stainless steel riser casing and/or well screen; (2) unusual geochemical characteristics indicative of residual contamination from the cement grout emplaced during well installation/construction; (3) analytical results that appear to reflect bias from the groundwater sampling method; (4) large temporal fluctuations in groundwater elevations; (5) unusually high or low TDS; (6) acidic (pH < 5.5) groundwater, and (7) some other distinguishing geochemical characteristic.

2.6.1 Well Casing/Screen Corrosion

This characteristic applies to wells that yield groundwater samples containing unusually high concentrations of chromium and/or nickel that are most likely attributable to chemical and/or microbiologically induced corrosion of the stainless steel well casing/screen. Elevated concentrations of these metals reported for samples from the following wells are believed to be artifacts of corrosion of the riser casing/well screen.

GENERALIZED GEOLOGIC CROSS SECTION

COMPEND05_2 11/20/05

Fig. 2. Bedrock geology and topography in the vicinity of the Y-12 National Security Complex.

Table 5. Wells with suspected corrosion of the riser casing/well screen.

BEAR CREEK REGIME	EAST FORK REGIME		CHESTNUT RIDGE REGIME
GW-056	55-2A	GW-380	GW-302
GW-082	59-1A	GW-696	GW-305
GW-715	59-1B	GW-760	GW-339
	GW-190	GW-783	

Redevelopment of these wells prior to sampling is recommended to ensure collection of the most representative groundwater samples

2.6.2 Grout Contamination

This characteristic applies to wells that yield groundwater samples with unusual geochemical characteristics, including strongly basic pH (>9) and elevated concentrations of potassium (>10 mg/L), that are believed to be the result of localized contamination from cement grout circulated into the surrounding bedrock during installation and construction of the well. This grout contamination may occur several years after well installation, especially in karst areas where additional grout (significantly more than the calculated annular space) may have been used to install the well casing. Such geochemical characteristics are indicated by the monitoring results obtained from the wells listed below.

Table 6. Wells that exhibit indicators for grout contamination.

BEAR CREEK REGIME	EAST FORK REGIME	CHESTNUT RIDGE REGIME
None in the Compendium	GW-170	GW-205
	GW-620	GW-679
		GW-757

Redevelopment of these wells prior to sampling is recommended to ensure collection of the most representative (i.e., the least grout-contaminated) groundwater samples.

2.6.3 Water Level Fluctuation

This characteristic applies to wells that have presampling groundwater elevations which exhibit unusually wide temporal (seasonal) fluctuations; the value shown is the difference (in ft) between maximum and minimum depth-to-water measurements recorded during successive quarterly or semiannual groundwater sampling events. Substantial temporal variations in the groundwater elevations may suggest that the monitored interval in the well intercepts highly permeable and well-connected groundwater flowpaths. Typically wells located in the Chestnut Ridge Regime have higher water level fluctuations than wells located in the Bear Creek or East Fork Regimes. The following 20 wells, most of which are located in the Chestnut Ridge Regime, have seasonal water level fluctuations greater than 25 ft.

Table 7. Wells that exhibit wide water-level fluctuations.

BEAR CREEK REGIME	EAST FORK REGIME	CHESTNUT RIDGE REGIME		
GW-123	GW-253	1090	GW-522	GW-742
GW-923	GW-698	GW-173	GW-540	GW-743
	GW-735	GW-322	GW-544	GW-796
		GW-339	GW-560	GW-798
		GW-513	GW-709	GW-801

2.6.4 Total Dissolved Solids (TDS)

This characteristic applies to wells, listed in Table 8, that yield groundwater samples with unusually high (i.e., >850 milligrams per liter [mg/L]) or low TDS (i.e., <150 mg/L), as determined from average values reported for the samples collected since January 1990 (excluding suspected outliers).

Table 8. Wells that yield groundwater with unusually high or unusually low TDS.

WELL LOCATION	WELL DEPTH (ft bgs)	HIGH TDS (Average >850 mg/L)	LOW TDS (Average <150 mg/L)
Bear Creek Regime	<20	GW-100 GW-276 GW-101 GW-537 GW-105	GW-008 GW-237
	20 – 200	GW-085 GW-134-33 GW-246 GW-106 GW-134-35 GW-247 GW-108 GW-134-36 GW-277 GW-109 GW-229 GW-346 GW-122 GW-244 GW-526 GW-245	GW-079 GW-080 GW-287 GW-653
	>200	GW-071 GW-134-18 GW-135-23 GW-123 GW-134-21 GW-135-26 GW-133-01 GW-134-25 GW-615 GW-134-05 GW-135-03 GW-616 GW-134-11 GW-135-06 GW-710 GW-134-15 GW-135-11 GW-711	GW-066 GW-228 GW-312
East Fork Regime	<20	55-1A GW-633 GW-272 GW-691	GW-269 GW-761 GW-273 GW-787
	20 – 200	55-2B GW-274 GW-698 55-2C GW-275 GW-253 GW-690	.
Chestnut Ridge Regime	20 – 200	.	GW-300 GW-796 GW-542 GW-799 GW-564 GW-801

For some wells, the high TDS reflects the degree of groundwater contamination, particularly wells located near the former S-3 Ponds. However, other wells yield uncontaminated groundwater with unusually high TDS, including most of the deepest wells at Y-12 (TDS increases with depth) and shallower wells completed with monitored intervals that do not intercept highly permeable groundwater flowpaths. Similarly, some wells that monitor contaminated and uncontaminated groundwater yield samples with unusually low TDS, which is believed to reflect the relatively short residence time of the groundwater and implies that the wells intercept highly permeable and hydraulically active groundwater flowpaths.

2.6.5 Low pH

This characteristic applies to wells that yield groundwater samples with acidic pH (i.e., below 5.5 standard units). Average pH values determined from data (field measurements) obtained during sampling events performed since January 1990 (excluding suspected outliers) show that, as summarized below in Table 10, fourteen wells yield such acidic groundwater, most of which are located in the Bear Creek Regime.

Table 9. Wells that yield acidic groundwater samples.

BEAR CREEK REGIME		EAST FORK REGIME	CHESTNUT RIDGE REGIME
GW-008	GW-246	GW-108	
GW-046	GW-276	GW-109	.
GW-236	GW-653	GW-273	
GW-243		GW-633	

Most of these wells (GW-108, GW-109, GW-236, GW-243, GW-246, GW-273, GW-276, and GW-633) monitor the highly contaminated, acidic groundwater in the aquitard formations (e.g., Nolichucky Shale) near the west end of Y-12 that is a legacy of the historical operation of the former S-3 Ponds. Other wells that yield groundwater samples with acidic pH (e.g., GW-008, GW-046, and GW-653) monitor groundwater contaminated by chlorinated hydrocarbons, with the low pH being an indicator of ongoing chemical and/or biologically-mediated degradation of the compounds.

2.6.6 Sampling Method Sensitivity

This characteristic applies to wells that yield groundwater samples with substantially different contaminant concentrations depending on the groundwater sampling method. An evaluation of the monitoring data available through August 2000 indicated potential bias related to the groundwater sampling method for 18 monitoring wells (BWXT 2001). Monitoring results obtained since CY 2000 for eight additional wells that had insufficient data for the original study likewise suggested potential sampling method bias. To confirm the apparent bias, the Y-12 GWPP uses a "paired" groundwater sampling approach, whereby the low-flow sampling method is used to collect a sample one day and the conventional sampling method is used to collect a sample the next day. Both samples are then analyzed for the same suite of analytes. As shown on Table 10, paired sampling results have "confirmed" the sampling method bias for 11 wells and "disproved" the sampling bias for seven wells, with "suspected" sampling method bias pending results of paired sampling.

Table 10. Wells evaluated for apparent sampling method bias.

SAMPLING BIAS/WELL NUMBER/WELL LOCATION			PRINCIPAL CONTAMINANTS				
			NITRATE	URANIUM	VOCs	GROSS ALPHA	GROSS BETA

	GW-653	BC	.	.	L	.	.
	GW-782	EF	.	.	X	L	.

Note:

Confirmed = Results of paired sampling confirm the significant difference between concentrations of specified contaminants detected in samples obtained with the conventional sampling and low-flow sampling methods.

Suspected = Historical data show a significant difference between concentrations of specified contaminants detected in samples obtained with the conventional sampling and low-flow sampling methods, but paired sampling results not needed for confirmation. Paired sampling of wells GW-072, GW-624, and GW-626 is scheduled for calendar year (CY) 2005.

Disproved = Results of paired sampling do not support the significant difference in the concentrations of specified contaminants indicated by historical conventional and low-flow sampling results.

BC = Bear Creek Regime

EF = East Fork Regime

CR = Chestnut Ridge Regime

"." = Not a contaminant in the groundwater at the well.

X = A contaminant in the groundwater at the well, but there is no clear significant difference between conventional sampling and low-flow sampling results.

C = Conventional sampling results show significantly higher concentrations of specified contaminant.

L = Low-flow sampling results show significantly higher concentrations of specified contaminant.

2.6.7 Other Characteristics

This characteristic applies to wells that exhibit other distinguishing groundwater sampling characteristics. For example, a well located in the East Fork Regime near the west end of Y-12 (GW-108) yields groundwater samples that effervesce, indicating unusual geochemistry and water quality. Where other distinctive sampling characteristics exist, a detailed discussion of the sampling characteristic(s), including a summary of the applicable geochemical data and/or hydrograph of applicable hydrologic data, is provided in the appropriate section of the data evaluation for the well.

2.7 PRINCIPAL CONTAMINANTS

This section of the *Summary Cover Sheet* provides a summary of the analytical data obtained for the well since January 1991 regarding the concentrations of the principal groundwater contaminants at Y-12: nitrate, uranium, VOCs, gross alpha activity, and gross beta activity. The data summary for each contaminant includes the number of samples (since January 1991) with concentrations that meet the data quality objectives of the Y-12 GWPP and exceed the respective screening levels listed in Table 11; the historical maximum concentration of each contaminant (and associated sampling date); and the long-term contaminant concentration trend (increasing, decreasing, or indeterminate).

Table 11. Principal contaminants and corresponding screening levels.

CONTAMINANT	SCREENING LEVEL
Nitrate (as N)	10 mg/L
Uranium	0.03 mg/L
Summed VOCs	5 micrograms per liter (µg/L)
Gross alpha activity	15 picoCuries per liter (pCi/L)
Gross beta activity	50 pCi/L

Each respective screening level for nitrate, total uranium, and gross alpha activity is the Safe Drinking Water Act (SDWA) maximum contaminant level MCL (MCL) for drinking water. The screening level for summed VOCs is set at a common MCL value. The screening level for gross beta activity is the SDWA screening value for a 4 millirem per year dose equivalent (the MCL for gross beta activity).

The maximum contaminant concentration reported for the location for the most recent revision to the Y-12 GWPP Compendium (see Section 1.3) is shown in a row of boxes located in the upper right corner of each *Summary Cover Sheet*. The contaminant levels that may be presented in the boxes are shown below in Table 12.

Table 12. Explanation for the principal contaminant concentration summary.

CONTAMINANT	NITRATE (mg/L)	URANIUM (mg/L)	SUMMED VOCs (µg/L)	GROSS ALPHA (pCi/L)	GROSS BETA (pCi/L)
Box Options/ Contaminant Concentration Range	. ND <5 5 - 10 10 - 100 100 - 1,000 >1,000	. ND <0.015 0.015 - 0.03 0.03 - 0.3 0.3 - 3.0 >3	. ND <5 5 - 50 50 - 500 500 - 5,000 >5,000	. ND <7.5 7.5 - 15 15 - 150 150 - 1,500 >1,500	. ND <25 25 - 50 50 - 500 500 - 5,000 >5,000
Screening Level	**10**	**0.03**	**5**	**15**	**50**

Note: "." = not analyzed; "ND" = not detected

3.0 DATA EVALUATION NARRATIVE

In conjunction with the *Summary Cover Sheet* for each applicable sampling location (see Section 1.1), each *Brief* in the Y-12 GWPP compendium provides a narrative description and evaluation of the hydrologic and groundwater quality data obtained to date. Each narrative follows a standard format that generally mirrors the corresponding *Summary Cover Sheet*. The following sections provide background information regarding the contents of the *Data Evaluation Narrative* for each monitoring well, which also address corresponding contents of the *Data Evaluation Narrative* for each spring and surface water station.

As detailed below, the *Data Evaluation Narrative* for each monitoring well included in the Y-12 GWPP compendium contains separate subsections regarding: (1) the installation, construction, and location of the well; (2) the sampling history for the well, including detailed descriptions of any distinguishing sampling characteristics; (3) the hydrologic characteristics of the well; (4) the geochemical characteristics of the groundwater samples from the well; (5) the concentrations and characteristics (e.g., temporal concentration fluctuations) of the principal Y-12 groundwater contaminants in the well; and (6) the list of referenced technical reports and documents. Applicable subsections of the *Data Evaluation Narrative* define site-specific and other "special" acronyms and abbreviations, but the following "universal" acronyms and abbreviations are not defined.

bgs	-	below ground surface
CERCLA	-	Comprehensive Environmental Response, Compensation, and Liability Act
DOE	-	U.S. Department of Energy
EPA	-	U.S. Environmental Protection Agency
ft	-	feet
msl	-	mean sea level
mg/L	-	milligrams per liter
ug/L	-	micrograms per liter
PVC	-	polyvinyl chloride
pCi/L	-	picoCuries per liter
RCRA	-	Resource Conservation and Recovery Act
ROD	-	record of decisions
SDWA	-	Safe Drinking Water Act

3.1 INSTALLATION, CONSTRUCTION, AND LOCATION

This subsection of the *Data Evaluation Narrative* for each well provides a description of the location of the well, including a brief description of the applicable functional area (or other nearby topographic/geographic/cultural features), and a short overview of the construction of well. Unless noted otherwise, geographic directions are in reference to the Y-12 Administrative Grid. For wells that monitor contaminated groundwater, this section provides a description of the site that is the known or suspected source of the contamination.

3.2 SAMPLING HISTORY AND CHARACTERISTICS

This subsection of the *Data Evaluation Narrative* for each monitoring well describes the groundwater sampling history for the well, including the initial and most recent sampling dates of the current revision (see Section 1.3) for each applicable groundwater sampling method (conventional sampling and low-flow sampling). Additionally, if the well exhibits any of the sampling characteristics noted on the *Summary Cover Sheet,* as defined in Section 2.6, this subsection presents a detailed description of the sampling characteristic(s), including data summary tables and/or trend charts.

3.3 HYDROLOGIC CHARACTERISTICS

This subsection of the *Data Evaluation Narrative* for each monitoring well describes the hydrologic characteristics of the well, including an overview of local hydrogeology, a summary of available hydraulic data for the well (e.g., hydraulic conductivity test results), the typical depth to the static water level in the well, and the range of water-level fluctuations in the well. Hydrographs of presampling groundwater elevations are provided for wells that exhibit unusually large water-level fluctuations or other distinctive short- or long-term changes in static water levels in the well.

3.4 GEOCHEMICAL CHARACTERISTICS

This subsection of the *Data Evaluation Narrative* for each monitoring well describes the geochemical characteristics of the groundwater samples from the well, including the range of TDS reported for the samples; the range of field pH measurements associated with each sampling event; the major-ion chemistry of the groundwater samples; and the typical concentrations of trace metals detected in the samples. The hydrochemical facies (e.g., calcium-magnesium bicarbonate), as calculated from milliequivalent proportions for a Piper Diagram (Fetter 1994), is provided in this section. Additional information, including applicable data summary tables and/or time-series plots, is provided for wells that yield groundwater samples with: (1) unusually high or unusually low TDS; (2) strongly basic pH and other geochemical indicators of localized grout contamination; or (3) unusually high concentrations of major ions (e.g., chloride).

3.5 CONTAMINATION

This subsection of the *Data Evaluation Narrative* for each monitoring well presents separate descriptions of the analytical data for each of the primary groundwater contaminants at Y-12 (nitrate, uranium, VOCs, gross alpha activity, and gross beta activity) and a detailed evaluation of the results. For some wells, another section is included for other notable contaminants (primarily trace metals) that may be present in the groundwater at the well. The data evaluation includes analytical results that meet data quality objectives, as defined in the Y-12 GWPP Data Management Plan (BWXT 2006b). Where applicable, the data evaluation for each groundwater contaminant includes data summary tables and trend graphs.

The following "universal" acronyms and abbreviations are used without being defined in the applicable subsection of the narrative for monitoring locations.

CTET	-	carbon tetrachloride
DMB	-	dimethylbenzene
ETB	-	ethylbenzene
MC	-	methylene chloride
MDA	-	minimum detectable activity
PCE	-	tetrachloroethene
TCE	-	trichloroethene
TCFM	-	trichlorofluoromethane
VC	-	Vinyl chloride
111TCA	-	1,1,1-trichloroethane
11DCA	-	1,1-dichloroethane
11DCE	-	1,1-dichloroethene
12DCA	-	1,2-dichloroethane
12DCE	-	1,2-dichloroethene
c12DCE	-	cis-1,2-dichloroethene
t12DCE	-	trans-1,2-dichloroethene

WELL 1090

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in 1982, completed with a screened monitored interval from an unknown depth to 96.7 ft bgs, and constructed with 6.5-inch diameter PVC (#40) riser casing and well screen (slot size unknown). The well is located on the crest of Chestnut Ridge south of Y-12, about 300 ft northwest (hydraulically downgradient) of the United Nuclear Corporation Site (UNCS). The UNCS is a closed facility that was used for the disposal of cement-fixed sludge, radiologically-contaminated soils, and demolition debris. A multilayer, low-permeability cap was installed at the site in 1992 in accordance with the CERCLA ROD signed in 1991 (DOE 1991).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fifty-five groundwater samples have been collected from the well to date, with the conventional sampling method used to collect forty-one samples between February 1986 and April 1997 and the low-flow sampling method used to collect fourteen samples between November 1997 and August 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

The well yields groundwater from the Knox Group (Copper Ridge Dolomite). The average static groundwater level in the well is about 49 ft bgs. Presampling depth-to-water measurements for the well indicate unusually wide (>25 ft) fluctuations in seasonal groundwater surface elevations (Figure 1). Similarly wide water-level fluctuations also are evident for other wells located along the crest of Chestnut Ridge, which is both a recharge area and a flow divide, with components of flow to the north down the steep scarp slope of the ridge, parallel to the ridge crest (and geologic strike) to the east, and southward into drainage basins on the broad southern flank of the ridge.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields chloride and sodium-enriched, calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 254 – 342 mg/L;
- pH (field measurements) of 6.4 – 7.6;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of potassium and sulfate (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Groundwater samples from this well typically contain chloride concentrations above 20 mg/L and sodium levels above 10 mg/L, which exceed the respective background levels (UTLs) for groundwater in the Knox Group. Elevated concentrations of these ions may reflect natural levels related to the dissolution of evaporite minerals locally disseminated in the bedrock. Alternatively, elevated chloride and sodium levels in the groundwater at this well may result from the recharge of surface water containing dissolved salt used to de-ice the South Patrol Road and Mt. Vernon Road (the well is located at the intersection of these roads). Similarly elevated levels of chloride and sodium also are evident in other wells at the UNCS (GW-302 and GW-339) that are accessed via these paved roads, whereas much lower chloride and sodium concentrations (less than respective UTLs) are evident in the wells at the site that are accessed via a gravel road (GW-203, GW-205, and GW-221).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion, which is based on the analytical results reported for 36 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Thirty-five of the groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (1.7 mg/L in August 2004) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Five groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.0127 mg/L in July 2002) being below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected at low levels in three groundwater samples (between January 1991 and April 1997). Chloroform was detected in the samples collected in July 1991 (3 μg/L), August 1992 (1 μg/L), and July 1993 (0.9 μg/L). Also, a trace of 12DCE (0.9 μg/L) was detected in a sample collected in July 1991. These results may be sampling or analytical artifacts.

5.4 GROSS ALPHA ACTIVITY

Eleven groundwater samples had gross alpha activity above the applicable MDA and the corresponding CE, with the highest value (4.37 pCi/L in May 1992) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Thirteen groundwater samples had gross beta activity above the applicable MDA and the corresponding CE, with the highest value (12.3 pCi/L in January 2001) being substantially below the SDWA screening level of gross beta activity (50 pCi/L).

WELL 55-1A

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in September 1983, completed with a screened monitored interval from 11 to 19 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and stainless steel (Type 304) well screen (0.01 slot wire-wound). The well forms a cluster with well 55-1B and 55-1C and is located in Bear Creek Valley (BCV), in the western section of Y-12, near the northeast corner of Bldg. 9204-4.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Aside from sampling performed as part of the initial groundwater contamination investigations in BCV during the early 1980s, including an investigation of the source(s) and extent of subsurface mercury contamination within Y-12 (Rothschild et al 1984), a total of three groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain a sample in June 1996 and the low-flow sampling method used to obtain samples in June and November 2004.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in Nolichucky Shale (the Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within this highly permeable zone, which occurs near the transition between unconsolidated material (saprolite and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into the buried northern tributaries of UEFPC and other components of the subsurface drainage system within the highly industrialized areas of Y-12 (DOE 1998). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation at the top of the Conasauga Group that subcrops along the axis of BCV and the original main channel of UEFPC.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 10 ft bgs and exhibits minor (<1 ft) seasonal fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well 55-1A indicate south and southeasterly flow toward UEFPC. However, groundwater flow in the Nolichucky Shale is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Consequently, the direction(s) of groundwater flow in the vicinity of well 55-1A may be primarily eastward (parallel with geologic strike) toward discharge areas in a buried northern tributary of UEFPC.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date show that the well yields mineralized, chloride- and sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 861 – 1000 mg/L;
- pH of 7.45 – 7.5 (field measurements);
- elevated levels of nitrate (>10 mg/L), sodium (>25 mg/L), sulfate (>50 mg/L), and chloride (>100 mg/L); and
- total (unfiltered sample) concentrations of trace metals (except iron and nickel) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that nitrate is the principal contaminant in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected to date had nitrate concentrations above the analytical reporting limit, with two of the results (13.8 mg/L in June 1996 and 12.1 mg/L in June 2004) exceeds the drinking water MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds, which are located near the west end of Y-12 approximately 2,500 ft west of the well. Operation of these former surface impoundments emplaced a heterogeneous mixture of inorganic, organic, and radiological contaminants in the Nolichucky Shale and created a mound in the water table that facilitated contaminant transport/migration east of the hydrologic divide separating the Bear Creek and UEFPC watersheds. Nitrate and other inorganic contaminants within the plume were principal components of the wastes disposed at the site, but some of the inorganic contaminants (e.g., barium) were dissolved from bedrock minerals by the acidic seepage from the ponds.

With concentrations in excess of 10,000 mg/L, nitrate is the primary inorganic contaminant in the S-3 Ponds contaminant plume and, based on the network of existing monitoring wells completed in the Nolichucky Shale east of the site, elevated nitrate concentrations (i.e., >10 mg/L) extend laterally at least 5,000 ft to the east-southeast (parallel with geologic strike) and vertically (parallel with geologic dip) at least 150 ft bgs. Chemically stable and mobile in groundwater, nitrate effectively traces the principal groundwater flow/transport pathways for other similarly mobile contaminants, with the distribution of nitrate in the groundwater suggesting: (1) relatively rapid transport/migration via shallow groundwater flow/transport pathways (<30 ft bgs) which terminate in buried storm drains and utilities, building basement sumps, and the buried northern tributaries and original mainstem of UEFPC within 1,000 ft of the former S-3 Ponds; and (2) substantially slower migration deeper in the bedrock via much longer strike-parallel groundwater flow/transport pathways (e.g., bedding-plane fractures), possibly bound to a relatively narrow band near the middle of the Nolichucky Shale, toward basement sumps in Bldgs. 9204-4, 9201-5, and 9204-2 up to 4,000 ft from the former S-3 Ponds (DOE 1998).

Nitrate results for the groundwater samples collected to date are probably representative of concentrations in the water table interval in the Nolichucky Shale near the northern (upgradient) boundary of the S-3 Ponds contaminant plume, with the center of mass of the plume in the Nolichucky Shale being west-southwest of the well. Also, the similar nitrate concentrations evident in June 1996 (13.8 mg/L) and June 2004 (12.1 mg/L) suggest little if any long-term change in the overall flux of nitrate along the groundwater flow/contaminant transport pathways intercepted by the monitored interval in the well.

5.2 URANIUM

Two of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, but the highest value (0.000986 mg/L in November 2004) is more than an order of magnitude below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were not detected in any of the groundwater samples collected to date.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

One groundwater sample had gross beta activity above the applicable MDA and corresponding CE, and this result (19 pCi/L in June 2004) is substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year does equivalent (the drinking water MCL for gross beta activity). Additionally, the June 1996 sample from well 55-1A was analyzed for Tc-99 and the result was below the MDA. A beta-emitting radionuclide, Tc-99 is a "signature" component of the contaminant plume from the former S-3 Ponds (the only site at Y-12 that received wastes containing Tc-99) that is nearly as mobile as nitrate in the groundwater and shares a similar distribution in the Nolichucky Shale both east and west of the site.

WELL 55-2B

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

The date for installation of this well is not known, but available information show that the well was completed with a screened monitored interval from 20 to 28 ft bgs and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and stainless steel (Type 304) well screen (0.01 slot wire-wound). The well forms a cluster with well 55-2A and 55-2C and is located in Bear Creek Valley (BCV), within the west-central section of Y-12 approximately 400 ft directly east of the Waste Coolant Processing Area (WCPA), which includes the Waste Coolant Storage Tanks and the Waste Coolant Biodegradation Facility, and the Waste Coolant Processing Facility. These facilities were used between 1977 and 1985 to handle and treat large volumes of waste machine coolants that contained very high levels (several thousand parts per million) total organic carbon, chlorinated hydrocarbons, and methyl ethyl ketone (2-butanone) along with metals and depleted uranium (DOE 1998). In August 1988, the WCPA was clean-closed under RCRA, with closure-related wastes sent to the Interim Drum Yard at the west end of Y-12.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Aside from sampling performed as part of the initial groundwater contamination investigations in BCV during the early 1980s, including an investigation of the source(s) and extent of subsurface mercury contamination within Y-12 (Rothschild et al 1984), a total of five groundwater samples have been collected from the well, with the conventional sampling method used to collect one sample in June 1996 and the low-flow sampling method used to collect samples in June 1998, August 1998, June 2004, and November 2004. Note that all of the groundwater sampling dates have occurred during seasonally low groundwater flow conditions (summer and fall). Consequently, the available sampling results may not provide representative data regarding potential seasonal changes in groundwater elevations, geochemical characteristics, and contaminant concentrations (if any).

High TDS is a distinguishing characteristic of the groundwater samples from this well (see Section 4.0).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in Nolichucky Shale (the Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within this highly permeable zone, which occurs near the transition between unconsolidated material (saprolite and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into the buried northern tributaries of UEFPC and other components of the subsurface drainage system within the highly industrialized areas of Y-12 (DOE 1998). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation at the top of the Conasauga Group that subcrops along the axis of BCV and the original main channel of UEFPC.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 6 ft bgs. Also, groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are higher in well 55-2B than in well 55-2C, which is completed at a greater depth (76 ft bgs) in the Nolichucky Shale. Based on the distance between the monitored interval midpoints (elevation) in each well (48.2 ft), the contemporaneous groundwater elevations indicate a downward vertical gradient (0.005) from the water table interval to the shallow bedrock interval.

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well 55-2B indicate south and southeasterly flow toward UEFPC. However, groundwater flow in the Nolichucky Shale is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Consequently, the direction(s) of groundwater flow in the vicinity of well 55-2B may be primarily eastward (parallel with geologic strike) toward discharge areas in a buried northern tributary of UEFPC.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date show that the well yields highly mineralized, nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 1,486 – 1,930 mg/L;
- pH of 6.29 – 6.3 (field measurements);
- very high concentrations of calcium (>300 mg/L) and nitrate (>200 mg/L);
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations);
- elevated total (unfiltered sample) concentrations of strontium (>1 mg/L); and
- total concentrations of other trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that nitrate and VOCs are the principal contaminants in the groundwater at this well.

5.1 NITRATE

As shown in the data summary below, each groundwater sample collected to date had nitrate concentrations above 100 mg/L (more than 10 times the drinking water MCL for nitrate [10 mg/L]), with the most recent sampling results indicating an overall increase in nitrate levels.

Date Sampled	Nitrate as N (mg/L)
06/10/96	117
06/25/98	144
08/03/98	146
06/10/04	222
11/29/04	225

The source of the nitrate in the groundwater at this well is probably the S-3 Ponds, which are former hazardous waste surface impoundments located near the west end of Y-12 approximately 3,000 ft west of the well. Closed in 1988 and covered with a low-permeability cap (and asphalt-paved vehicle parking lot) in 1989, the long-term (34 years) historical operation of the S-3 Ponds emplaced a heterogeneous mixture of inorganic, organic, and radiological contaminants in the Nolichucky Shale and created a mound in the water table that facilitated contaminant transport/migration east of the hydrologic divide separating the Bear Creek and UEFPC watersheds. Nitrate and other inorganic contaminants within the plume were principal components of the wastes disposed at the site, but some of the inorganic contaminants (e.g., strontium) were dissolved from bedrock minerals by the acidic seepage from the ponds. With concentrations in excess of 10,000 mg/L, nitrate is the primary inorganic contaminant in the plume and, based on the network of existing monitoring wells completed in the Nolichucky Shale east of the former S-3 Ponds, elevated nitrate concentrations (i.e., >10 mg/L) extend laterally at least 5,000 ft eastward (parallel with geologic strike) and vertically (parallel with geologic dip) at least 150 ft bgs. Chemically stable and mobile in groundwater, nitrate effectively traces the principal groundwater flow/transport pathways for other similarly mobile contaminants. The distribution of nitrate in the groundwater suggests relatively rapid transport/migration via shallow groundwater flow/transport pathways (<30 ft bgs) which terminate in buried storm drains and utilities, building basement sumps, and the buried northern tributaries and original mainstem of UEFPC within 1,000 ft of the former S-3 Ponds. Substantially slower migration is indicated deeper in the bedrock via much longer strike-parallel groundwater flow/transport pathways (e.g., bedding-plane fractures), possibly bound to a relatively narrow band near the middle of the Nolichucky Shale, toward basement sumps in Bldgs. 9204-4, 9201-5, and 9204-2 up to 4,000 ft from the former S-3 Ponds (DOE 1998).

Nitrate results for the groundwater samples from this well are believed to be representative of concentrations within the shallow flow system (water table interval) in the Nolichucky Shale east of the former S-3 Ponds (DOE 1998). Moreover, the close similarity between these results and contemporaneous nitrate results for samples collected from well 55-2C obtained in June 1996 (118 mg/L), June 1998 (131 mg/L), and August 1998 (135 mg/L) indicate that the nitrate levels in the water table interval are similar to those evident at greater depth (76 ft bgs) in the bedrock. Additionally, as shown by a time-series plot (Figure 1), nitrate concentrations in the shallow groundwater at this well appear to have increased more than 90% through November 2004. Nitrate data for well 55-2C likewise show an increasing concentration trend in the deeper flow system, with an increase of 53% through November 2003 (181 mg/L). Increasing concentrations of nitrate in the groundwater at these wells possibly indicate the continued eastward migration of the center of mass of the S-3 Ponds contaminant plume in the Nolichucky Shale east of the site.

5.2 URANIUM

Two of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, and both results (0.0005 mg/L in June 1996 and 0.015 mg/L in August 1998) are less than the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each of the groundwater sample collected to date (Table 1): dichlorodifluoromethane (DCFM), PCE, TCE, VC, 11DCA, 11DCE, c12DCE, t12DCE, 111TCA, and 1,1,2-trichloro-1,2,2-trichlorofluoroethane, which is also known as freon-113 (F113). These compounds are components of the plume of dissolved VOCs in the groundwater that was emplace during historical operation of the WCPA. Also, soluble compounds leached from contaminated soils in the vadose zone and dissolution of constituents from potential DNAPL below the saturated zone are ongoing secondary sources of VOCs in the groundwater downgradient of this site (DOE 1998). The current network of monitoring wells does not indicate any strongly preferential groundwater flow/transport patterns in the vicinity of the WCPA, with generally eastward (parallel with geologic strike) transport/migration of the mobile components of the VOC plume suggested by the presence of "signature" VOCs in the shallow groundwater at well 55-2B and in discharge from storm drains east of the WCPA and from basement sumps in Bldg. 9204-4 and Bldg. 9201-5 (DOE 1998).

The primary VOCs in the groundwater samples collected to date are PCE, TCE, and 12DCE (c12DCE), which were detected in each sample, with the most recent results (June and November 2004) showing respective concentrations above 600 µg/L, 200 µg/L, and 800 µg/L (Table 1). Note that these concentrations are orders-of-magnitude above the respective MCL for PCE (5 µg/L), TCE (5 µg/L) and c12DCE (70 µg/L). The most recent sampling results show that F113 levels exceed 500 µg/L, but analytical results for this compound were not reported for previous samples. Maximum concentrations of DCFM, t12DCE, and 111TCA are all below 20 µg/L, although historical data are not available for DCFM and t12DCE (results for these compounds were not reported for previous samples).

Several of the VOCs in the groundwater at this well, notably PCE and TCE, are probably primary components of the wastes handled at the WCPA, whereas other compounds in the groundwater, including c12DCE and VC, may be present as a result of natural degradation of related parent compounds. Indeed, the presence of c12DCE in the groundwater is almost certainly attributable to biologically mediated degradation (sequential reductive dechlorination) of PCE. Nevertheless, the data for the geochemical indicator parameters shown in the following summary indicate that the groundwater in this well is not especially conducive to biotic degradation of chlorinated hydrocarbons.

Geochemical Parameter/ Optimum Range (Wilson et al. 1996)	June 2004	November 2004
Nitrate < 1 mg/L	222	225
Iron (II) > 1 mg/L	<0.05*	<0.05*
Sulfate < 20 mg/L	20.8	22.7
Dissolved Oxygen < 0.5 ppm	0.87**	3.69**
REDOX < 50 mV	194**	202**
pH >5 and < 9 st. units	6.29**	6.29**
Note: *Result is for total iron; **Field measurement.		

This suggests that biotic degradation occurs elsewhere (upgradient of the well), with downgradient migration of the parent compounds and degradation products via the groundwater flow/contaminant transport pathways intercepted by the monitored interval in the well.

A time-series plot of the summed VOC concentrations shows a clearly decreasing trend (Figure 2). However, PCE concentrations have increased about 20% from 1998 to 2004 while the concentrations of the other VOCs (with historical results) have decreased (Table 1). These divergent concentration trends possibly indicate continued eastward migration of the parent compound (PCE) from the WCPA and/or reduced biotic degradation upgradient of the well. Additionally, the increasing nitrate concentrations in the groundwater at this well (see Section 5.1) indicate conditions are becoming less conducive to degradation, which may allow PCE concentrations to increase relative to concentrations of degradation products (c12DCE and VC).

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

Three groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (20 pCi/L in November 2004) being below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). Additionally, the June 1996 sample from well 55-2B was analyzed for Tc-99 and the result was below the MDA. A beta-emitting radionuclide, Tc-99 is a "signature" component of the contaminant plume from the former S-3 Ponds that is nearly as mobile as nitrate in the groundwater and shares a similar distribution in the Nolichucky Shale both east and west of the site.

WELL 55-2C

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during August 1983 as part of an investigation to identify the subsurface extent of elemental mercury released during historical operations at Y-12 (Rothschild et. al. 1984). The well was completed with a screened monitored interval from 67.9 to 75.9 ft bgs and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and stainless steel (Type 304) well screen (0.01 slot wire-wound). The well forms a cluster with wells 55-2A and 55-2B and is located in Bear Creek Valley (BCV) at Comprehensive Monitoring Plan Grid B3, which is near the southwest corner of Bldg. 9201-5W in the west-central section of Y-12.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Aside from sampling performed as part of the mercury investigation at Y-12, nine groundwater samples have been collected from the well, with the conventional sampling method used to obtain three samples between June 1996 and March 1997 and the low-flow sampling method used to obtain six samples between June 1998 and November 2003.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the Nolichucky Shale (Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within a highly permeable zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 6.75 ft bgs and exhibits minimal (<1 ft) seasonal fluctuations. Also, the presampling groundwater elevations in this well and the two wells with which it is clustered (55-2A and 55-2B) indicate upward hydraulic gradients from the deeper bedrock (55-2C) to the shallow bedrock interval (55-2B) and downward vertical gradients from the water table interval (55-2A) to the shallow bedrock interval.

Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well 55-2C indicate southeasterly flow toward the Maynardville Limestone and the Upper East Fork Poplar Creek (UEFPC) drainage system. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and original main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred flow in directions that parallel geologic strike (i.e., bedding-plane fractures), which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 1,200 – 1,550;
- pH of 6.8 – 7.1 (field measurements);
- elevated concentrations of inorganic contaminants, notably barium (>1 mg/L), nitrate (>100 mg/L), sodium (>75 mg/L), and strontium (>4 mg/L);
- low molar proportions of chloride, potassium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals (except barium and strontium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that nitrate and VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Eight of the groundwater samples were analyzed for nitrate, with concentrations above 100 mg/L reported for each sample (Table 1), which are an order-of-magnitude higher than the MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds, which emplaced a heterogeneous mixture of inorganic, organic, and radiological contaminants in the Nolichucky Shale and created a mound in the water table that facilitated contaminant transport/migration east of the hydrologic divide separating the Bear Creek and UEFPC watersheds. Nitrate and other inorganic contaminants within the plume were principal components of the wastes disposed at the site, but some of the inorganic contaminants (e.g., barium) were dissolved from bedrock minerals by the acidic seepage from the ponds. With concentrations in excess of 10,000 mg/L, nitrate is the primary inorganic contaminant in the plume and, based on the network of existing monitoring wells completed in the Nolichucky Shale east of the former S-3 Ponds, elevated nitrate concentrations (i.e., >10 mg/L) extend laterally at least 5,000 ft eastward (parallel with geologic strike) and vertically (parallel with geologic dip) at least 150 ft bgs. Chemically stable and mobile in groundwater, nitrate effectively traces the principal groundwater flow/transport pathways for other similarly mobile contaminants, with the distribution of nitrate in the groundwater suggesting: (1) relatively rapid transport/migration via shallow groundwater flow/transport pathways (<30 ft bgs) which terminate in buried storm drains and utilities, building basement sumps, and the buried northern tributaries and original mainstem of UEFPC within 1,000 ft of the former S-3 Ponds; and (2) substantially slower migration deeper in the bedrock via much longer strike-parallel groundwater flow/transport pathways (e.g., bedding-plane fractures), possibly bound to a relatively narrow band near the middle of the Nolichucky Shale, toward basement sumps in Bldgs. 9204-4, 9201-5, and 9204-2 up to 4,000 ft from the former S-3 Ponds (DOE 1998).

Nitrate results for the groundwater samples from this well are believed to be representative of concentrations in the long-term migration/transport pathways at depth in the Nolichucky Shale east of the former S-3 Ponds. Also, increased flux of nitrate along the strike-parallel flow/transport pathways intercepted by the monitored interval in the well is suggested by the overall increase in nitrate concentrations (Figure 1), which increased about 55% between June 1998 (118 mg/L) and March 2003 (182 mg/L). Increasing flux of nitrate potentially indicates the continued eastward (strike-parallel) movement of the center of mass of the contaminant plume in the Nolichucky Shale east of the former S-3 Ponds (DOE 1998).

5.2 URANIUM

Eight of the groundwater samples were analyzed for total uranium, with concentrations at or above the applicable analytical reporting limit detected in the samples collected in August 1998 (0.0127 mg/L) and November 2003 (0.000585 mg/L). Both concentrations are below the MCL for uranium (0.03 mg/L). Uranium is one of the primary components of the contaminant plume emplaced in the Nolichucky Shale during historical operations of the former S-3 Ponds. The low concentrations of uranium in the groundwater samples, in contrast to the very high nitrate levels in the samples, reflects the greater mobility of nitrate in the groundwater relative to that of uranium.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, the following VOCs were detected in the groundwater samples (Table 2): benzene, chloroform, PCE, TCE, toluene, TCFM, VC, 11DCA, 11DCE, 12DCE (c12DCE and t12DCE), and 111TCA. The source of the VOCs, which are not significant components of the contaminant plume originating from the former S-3 Ponds, has not been confirmed, but may be related to historical production and machining operations in Bldgs. 9201-4 and 9201-5 (DOE 1998). Considering the upward vertical hydraulic gradients noted in Section 3, it is possible that DNAPL deeper in the bedrock may be a source of the VOCs in the shallow groundwater at this well.

The principal compounds in the groundwater samples are PCE, TCE, and 12DCE, which were detected in each sample, with maximum concentrations above 500 μg/L, 300 μg/L, and 2,000 μg/L, respectively (Table 2). Secondary compounds are VC, 11DCE, and 111TCA, at least one of which were detected in all but one of the samples, with maximum concentrations slightly above (VC) and below (11DCE and 111TCA) 50 μg/L. Note that the most recent sampling results show that the concentrations of PCE, TCE, c12DCE, 11DCE, and VC remain substantially above respective MCLs (Table 2). In contrast, chloroform, benzene, TCFM, and toluene have been detected infrequently (two samples or less) at much lower concentrations.

Biologically mediated degradation (sequential dechlorination) of PCE and TCE by anaerobic methanotropic organisms in the groundwater may explain the very high levels of 12DCE (c12DCE) and the presence of VC in the groundwater samples from this well. However, as illustrated by the data summarized in Table 3, results for several indicator parameters suggest that the geochemical conditions in the well are not within the optimum range for biotic degradation (dechlorination) of chlorinated hydrocarbons. The REDOX conditions, for instance, do not show the strongly reducing (methanogenic) conditions necessary to transform 12DCE to VC (Chapelle 1996). Considering the upward hydraulic gradient indicated by presampling groundwater elevations (see Section 3.0), perhaps the monitored interval in the well intercepts groundwater flow/transport pathways for dissolved VOCs moving upward from a source (DNAPL) deeper in the bedrock where conditions are better suited for biodegradation.

A time-series plot of summed concentrations of VOCs detected in the groundwater samples (excluding false positive results) shows a clearly decreasing long-term trend (Figure 2). Also, as shown by the data summarized in Table 2, the concentrations of individual VOCs all exhibit decreasing trends. These concurrently decreasing concentration trends suggest a corresponding reduction in the relative flux of dissolved VOCs via the groundwater flow/transport pathways intercepted by the well. Reduced flux of dissolved VOCs also contrasts with the apparently increased flux of nitrate (see Section 5.1). Assuming a heterogeneous mixture of nitrate and

VOCs, the divergent trends potentially reflect groundwater transport from separate respective sources.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

Five of the groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (26.5 pCi/L in June 1998) being less than the SDWA screening level (50 pCi/L) for a 4 millirem dose equivalent (the MCL for gross beta activity).

WELL 55-3A

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

The exact date of installation for this well is unknown, but available information shows that the well was completed in late 1983 with a screened monitored interval from 6.3 to 14.3 ft bgs and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and stainless steel (Type 304) well screen (0.01 slot wire-wound). The well is clustered with deeper wells 55-3B (38 ft bgs) and 55-3C (77 ft bgs) and is located in Bear Creek Valley (BCV) in the west-central section of Y-12, approximately 100 ft south of the central portion of Building 9201-5.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Aside from sampling performed as part of the initial groundwater contamination investigations in BCV during the early 1980s, including an investigation of the source(s) and extent of subsurface mercury contamination within Y-12 (Rothschild et al 1984), only one groundwater sample has been collected from the well to date, with the low-flow sampling method used to obtain the sample in November 2005.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the upper Nolichucky Shale (the Conasauga Group), near the geologic contact with the overlying Maynardville Limestone. The bulk of the groundwater flow in the Nolichucky Shale occurs within this highly permeable zone, which occurs near the transition between unconsolidated material (saprolite and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into the buried northern tributaries of UEFPC and other components of the subsurface drainage system within the highly industrialized areas of Y-12 (DOE 1998). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that subcrops along the axis of BCV and the original main channel of UEFPC.

The static water level in the well occurs at approximately 11 ft bgs. Groundwater elevations recorded during a contemporaneous sampling event (i.e., within 24 hours, November 2005) are higher in well 55-3A than in well 55-3B, which is completed at a greater depth (38 ft bgs) in the Nolichucky Shale. Based on the distance between the monitored interval midpoints in each well (23.8 ft), the contemporaneous groundwater elevations indicate a slightly downward vertical gradient (0.008) within the water table interval from well 55-3A to 55-3B.

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well 55-3A indicate south and southeasterly flow toward the Maynardville Limestone and UEFPC. However, groundwater flow in the Nolichucky Shale is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Additionally, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and original main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, the well is located in the immediate vicinity of a buried former northern tributary of UEFPC that trends along the eastern and southeastern side of Bldg. 9201-5 and may locally influence groundwater flow patterns.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater sample collected in November 2005 suggest that the well yields sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 497 mg/L;
- pH of 7.02 (field measurement);
- very high sulfate (185 mg/L);
- low molar proportions of chloride, nitrate, potassium, and sodium (<10% of total anions/cations);
- slightly elevated nickel concentration (0.0352 mg/L); and
- total (unfiltered sample) concentrations of other trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The elevated sulfate concentration is conspicuous for groundwater from such a shallow depth in the Nolichucky Shale and may be attributable to contamination associated with effluent from one or more sources within Y-12, including numerous potential non-specific sources such as leaking industrial process lines, sanitary sewers, or storm drains.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. Based on the results reported for the groundwater sample collected in November 2005, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

The nitrate concentration reported for the groundwater sample (2.39 mg/L) is less than the drinking MCL for nitrate (10 mg/L), but is substantially above the background level of nitrate (<0.028 mg/L) in uncontaminated groundwater from the Nolichucky Shale in BCV.

5.2 URANIUM

The uranium concentration reported for the groundwater sample (0.000995 mg/L) exceeds the analytical reporting limit but is several orders-of-magnitude below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

As shown in the following data summary, the one groundwater sample collected to date contained extremely high concentrations of PCE, TCE, and c12DCE, with the concentration of each compound being substantially lower than evident in the deeper groundwater from well 55-3B. Note that other VOCs may be present (e.g., <100 µg/L) in the groundwater at either well, but were not "detected" because the groundwater sample from each well was diluted (100X at 55-3A and 1,000X at 55-3B) to obtain an optimum matrix for analysis.

Compound	Concentration (µg/L) in November 2005	
	Well 55-3A (14 ft bgs)	Well 55-3B (38 ft bgs)
PCE	12,000	71,000
TCE	850	5,800
c12DCE	840	1,300

The extremely high concentrations of PCE in the groundwater from wells 55-3A and 55-3B indicate that PCE may be present as a dense nonaqueous phase liquid (DNAPL), with the higher PCE level evident in well 55-3B indicating that the DNAPL may occur at greater depth (i.e., >38 ft bgs) in the bedrock. The source of the PCE is not known, but may be associated with historical operations housed in Bldg. 9201-5, which is approximately 100 ft north (hydraulically upgradient) of the wells. Assuming the presence of DNAPL, a nearby source seems likely considering the nature of DNAPL migration in the subsurface, which would be expected to be density- and/or gravity-driven and to occur independent of the hydraulic gradient. Also, assuming that bedding in the Nolichucky Shale locally dips to the south (grid direction) at an angle of at least 45º, the monitored interval in the well intercepts groundwater flow/transport pathways that subcrop beneath the ground surface within 20 ft of the well. Nevertheless, considering the anisotropy imposed by the dominance of strike-parallel flowpaths (i.e., bedding-plane fractures) in the Nolichucky Shale, the source of the PCE may be located to the west of the wells.

Biologically-mediated degradation of the PCE (dissolved and DNAPL) is almost certainly the source of the TCE and c12DCE in the groundwater from wells 55-3A and 55-3B. However, relative to the PCE levels, the concentrations of TCE and c12DCE are significantly lower (<1% of PCE concentration). These results suggest that, for whatever reason, subsurface geochemical conditions are not optimally conducive to biodegradation. As indicated by the results for selected indicator parameters shown in the following summary, the geochemical conditions in the shallower groundwater from well 55-3A seem less amenable to biodegradation than evident in the deeper groundwater from well 55-3B, where very low dissolved oxygen and moderately negative REDOX suggest conditions better suited to anaerobic biodegradation (dechlorination) of the PCE and other chlorinated hydrocarbons.

Geochemical Parameter/ Optimum Range (Wilson et al. 1996)		November 2005	
		Well 55-3A (14 ft bgs)	Well 55-3B (38 ft bgs)
Nitrate	< 1 mg/L	2.39	<0.28
Iron (II)	> 1 mg/L	0.33*	0.112*
Sulfate	< 20 mg/L	185	30.5
Dissolved Oxygen	< 0.5 ppm	1.1**	0.35**
REDOX	< 50 mV	160**	-66**
pH	>5 and < 9 st. units	7.02**	7.63**
Note: *Result is for total iron; **Field measurement.			

5.4 GROSS ALPHA ACTIVITY

The groundwater sample collected in November 2005 did not have gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

The groundwater sample collected in November 2005 did not have gross beta activity above the applicable MDA and corresponding CE.

WELL 55-3B

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

The exact date of installation for this well is unknown, but available information shows that the well was completed in late 1983 with a screened monitored interval from 30.1 to 38.1 ft bgs and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and stainless steel (Type 304) well screen (0.01 slot wire-wound). The well is clustered with shallower well 55-3A (14 ft bgs) and deeper well 55-3C (77 ft bgs) and is located in Bear Creek Valley (BCV) in the west-central section of Y-12, approximately 100 ft south of the central portion of Building 9201-5.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Aside from sampling performed as part of the initial groundwater contamination investigations in BCV during the early 1980s, including an investigation of the source(s) and extent of subsurface mercury contamination within Y-12 (Rothschild et al 1984), only one groundwater sample has been collected from the well to date, with the low-flow sampling method used to obtain the sample in November 2005.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the upper Nolichucky Shale (the Conasauga Group), near the geologic contact with the overlying Maynardville Limestone. The bulk of the groundwater flow in the Nolichucky Shale occurs within this highly permeable zone, which occurs near the transition between unconsolidated material (saprolite and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into the buried northern tributaries of UEFPC and other components of the subsurface drainage system within the highly industrialized areas of Y-12 (DOE 1998). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that subcrops along the axis of BCV and the original main channel of UEFPC.

The static water level in the well occurs at approximately 11 ft bgs. Groundwater elevations recorded during a contemporaneous sampling event (i.e., within 24 hours, November 2005) are higher in well 55-3A than in well 55-3B, which is completed at a greater depth (38 ft bgs) in the Nolichucky Shale. Based on the distance between the monitored interval midpoints in each well (23.8 ft), the contemporaneous groundwater elevations indicate a slightly downward vertical gradient (0.008) within the water table interval from well 55-3A to 55-3B.

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well 55-3B indicate south and southeasterly flow toward UEFPC. However, groundwater flow in the Nolichucky Shale is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Additionally, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and original main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, the well is located in the immediate vicinity of a buried former northern tributary of UEFPC that trends along the eastern and southeastern side of Bldg. 9201-5 and may locally influence groundwater flow patterns.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater sample collected in November 2005 suggest that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 264 mg/L;
- pH of 7.63 (field measurement);
- elevated chloride (32.7 mg/L);
- low molar proportions of nitrate, potassium, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The elevated chloride concentration is conspicuous for groundwater from such a shallow depth in the Nolichucky Shale and may be attributable to contamination associated with effluent from one or more sources within Y-12, including numerous potential non-specific sources such as leaking industrial process lines, sanitary sewers, or storm drains. It is also possible that the elevated chloride levels are at least partially attributable to the degradation of the chlorinated hydrocarbons in the groundwater (see Sect. 5.3).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. Based on the results reported for the groundwater sample collected in November 2005, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

The concentration of nitrate in the one groundwater sample collected to date did not exceed the analytical reporting limit.

5.2 URANIUM

The concentration of uranium in the one groundwater sample collected to date did not exceed the analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

As shown in the following data summary, the one groundwater sample collected to date contained extremely high concentrations of PCE, TCE, and c12DCE, with the concentration of each compound being substantially higher than evident in the shallower groundwater from well 55-3A. Note that other VOCs may be present (<1,000 μg/L) in the groundwater at either well, but were not "detected" because the groundwater sample from each well was diluted (1,000 X) to obtain an optimum matrix for analysis.

Compound	Concentration (μg/L) in November 2005	
	Well 55-3A (14 ft bgs)	Well 55-3B (38 ft bgs)
PCE	12,000	71,000
TCE	850	5,800
c12DCE	840	1,300

The extremely high concentrations of PCE in the groundwater at wells 55-3A and 55-3B indicate that PCE may be present as a dense nonaqueous phase liquid (DNAPL), with the higher PCE level evident in well 55-3B indicating that the DNAPL may occur at greater depth (i.e., >38 ft bgs) in the bedrock. The source of the PCE is not known, but may be associated with historical operations housed in Bldg. 9201-5, which is approximately 100 ft north (hydraulically upgradient) of the wells. Assuming the presence of DNAPL, a nearby source seems likely considering the nature of DNAPL migration in the subsurface, which would be expected to be density- and/or gravity-driven and to occur independent of the hydraulic gradient. Also, assuming that bedding in the Nolichucky Shale locally dips to the south (grid direction) at an angle of at least 45º, the monitored interval in the well intercepts groundwater flow/transport pathways that subcrop beneath the ground surface within 50 ft of the well. Nevertheless, considering the anisotropy imposed by the dominance of strike-parallel flowpaths (i.e., bedding-plane fractures) in the Nolichucky Shale, the source of the PCE may be located to the west of the wells.

Biologically-mediated degradation of the PCE (dissolved and DNAPL) is almost certainly the source of the TCE and c12DCE in the groundwater from wells 55-3A and 55-3B. However, relative to the PCE levels, the concentrations of TCE and c12DCE are significantly lower (<1% of PCE concentration). These results suggest that, for whatever reason, subsurface geochemical conditions are not optimally conducive to biodegradation. As indicated by the results for selected indicator parameters shown in the following summary, the geochemical conditions in the shallower groundwater from well 55-3A seem less amenable to biodegradation than evident in the deeper groundwater from well 55-3B, where very low dissolved oxygen and moderately negative REDOX suggest conditions better suited to anaerobic biodegradation (dechlorination) of the PCE and other chlorinated hydrocarbons.

Geochemical Parameter/ Optimum Range (Wilson et al. 1996)	**November 2005**	
	Well 55-3A (14 ft bgs)	**Well 55-3B (38 ft bgs)**
Nitrate < 1 mg/L	2.39	<0.28
Iron (II) > 1 mg/L	0.33*	0.112*
Sulfate < 20 mg/L	185	30.5
Dissolved Oxygen < 0.5 ppm	1.1**	0.35**
REDOX < 50 mV	160**	-66**
pH >5 and < 9 st. units	7.02**	7.63**

Note: *Result is for total iron; **Field measurement.

5.4 GROSS ALPHA ACTIVITY

The groundwater sample collected in November 2005 did not have gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

The groundwater sample collected in November 2005 did not have gross beta activity above the applicable MDA and corresponding CE.

WELL 55-6A

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

The date for installation of this well is not known, but available information show that the well was completed in the fall of 1983 or the winter of 1984 with a screened monitored interval from 4.9 to 12.9 ft bgs, and constructed with nominal 4.5-inch PVC (#40) riser casing attached to stainless steel (Type 304) well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley (BCV), within the east-central section of Y-12 just south of the Abandoned Nitric Acid Pipeline (ANAP). Operated between 1951 and 1984, the ANAP transferred nitric-acid wastes generated in processing facilities westward into the former S-3 Ponds, which is a closed hazardous waste disposal site located near the west end of Y-12 approximately 4,000 ft west of well 55-6A.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Aside from sampling performed as part of the initial groundwater contamination investigations in BCV during the early 1980s, groundwater samples were collected from the well in June 1996, June 2004, and November 2004.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in Maryville Limestone (the Conasauga Group). The bulk of the groundwater flow in the Maryville Limestone occurs within this highly permeable zone, which occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into the buried northern tributaries of UEFPC and other components of the subsurface drainage system within the highly industrialized areas of Y-12 (DOE 1998). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that subcrops along the axis of BCV and the original main channel of UEFPC.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 7 ft bgs and exhibits minor (2 ft) seasonal fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well 55-6A indicate south and southeasterly flow toward UEFPC. However, groundwater flow in the Maryville Limestone is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Consequently, the direction(s) of groundwater flow in the vicinity of well 55-6A may be primarily eastward (parallel with geologic strike) toward discharge areas in a buried northern tributary of UEFPC.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 255 – 362 mg/L;
- pH of 6.5 – 6.8 (field measurements);
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and

- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that none of the principal contaminants present at elevated concentrations in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected to date had nitrate concentrations above the analytical reporting limit, and the maximum result (1.88 mg/L in November 2004) is substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

One of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, and this result (0.00737 mg/L in November 2004) is more than an order of magnitude below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were not detected in any of the groundwater samples collected to date.

5.4 GROSS ALPHA ACTIVITY

One of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, and this result (5.5 pCi/L in June 2004) is below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE.

WELL 56-2A

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

The date for installation of this well is not known, but available information show that the well was completed with a screened monitored interval from 7.1 to 15.1 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and stainless steel (Type 304) well screen (0.01 slot wire-wound). The well forms a cluster with well 56-2B and 56-2C and is located in Bear Creek Valley (BCV), within the west-central section of Y-12, about 150 ft south of the southwestern corner of Bldg. 9201-4.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Aside from sampling performed as part of the initial groundwater contamination investigations in BCV during the early 1980s, including an investigation of the source(s) and extent of subsurface mercury contamination within Y-12 (Rothschild et al 1984), a total of three groundwater samples have been collected from the well to date, with the low-flow sampling method used to obtain samples in March 1998, June 2004, and November 2004.

The well does not exhibit distinguishing sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in upper Nolichucky Shale (the Conasauga Group), near the geologic contact with the overlying Maynardville Limestone. The bulk of the groundwater flow in the Nolichucky Shale occurs within this highly permeable zone, which occurs near the transition between unconsolidated material (saprolite and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into the buried northern tributaries of UEFPC and other components of the subsurface drainage system within the highly industrialized areas of Y-12 (DOE 1998). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that subcrops along the axis of BCV and the original main channel of UEFPC.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 8 ft bgs. Additionally, depth-to-water measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show higher groundwater elevations in well 56-2A than in well 56-2B, which is completed at a greater depth in the water table interval in the Nolichucky Shale (39 ft bgs), and are slightly lower than the groundwater elevations in well 56-2C, which is completed much deeper (77 ft bgs) in the Nolichucky Shale (shallow bedrock interval). Based on the distance between the monitored interval midpoints (elevations) in each well, the contemporaneous groundwater elevations indicate a downward vertical gradient (0.015) within the water table interval from well 56-2A to 56-2B, and an upward vertical hydraulic gradient (0.015) from the shallow bedrock (56-2C) to the water table interval (56-2B).

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well 56-2A indicate south and southeasterly flow toward UEFPC. However, groundwater flow in the Nolichucky Shale is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Additionally, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and original main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, the well is located in the immediate vicinity of a buried former northern tributary of UEFPC that trends along the western and southwestern side of Bldg. 9201-4 and may locally influence groundwater flow patterns.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date show that the well yields chloride- and sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 365 – 411 mg/L;
- pH of 7.1 – 7.2 (field measurements);
- elevated concentrations of chloride (>30 mg/L) and sulfate (>50 mg/L);
- low molar proportions of nitrate, potassium, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The elevated sulfate and chloride concentrations in the groundwater samples may reflect local geochemical conditions or contamination from one or more sources within Y-12, including numerous potential non-specific sources such as leaking industrial process lines, sanitary sewers, or storm drains.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected to date had nitrate concentrations above the analytical reporting limit, and the maximum result (0.468 mg/L in November 2004) is substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

One of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, and this result (0.0005 mg/L in March 1998) is more than an order of magnitude below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

As shown in the data summary below, each of the groundwater samples collected to date contained low levels of PCE, TCE, and c12DCE, with the most recent results showing PCE concentrations slightly above and below the drinking water MCL (5 µg/L).

Date Sampled	Concentration (µg/L)		
	PCE	**TCE**	**c12DCE**
03/23/98	48	10	13
06/09/04	7	2 J	3 J
11/18/04	4 J	1 J	3 J
MCL	**5**	**5**	**70**
Note: J = Estimated value			

Historical spills and leaks of chlorinated solvent products and wastes during production and machining operations in Building 9201-5, which is located approximately 500 ft northwest of the well, and/or Building 9201-4 is the suspected source(s) of the dissolved VOCs in the groundwater at this well (DOE 1998). The Waste Coolant Processing area, located about 1,500 ft west (upgradient and along geologic strike) of the well is another potential source of VOCs.

As shown in the preceding data summary, the results indicate that VOC concentrations in the groundwater at the well decreased more than 80% through November 2004. This suggests a long-term decrease in the relative flux of VOCs via the groundwater flow/transport pathways intercepted by the monitored interval in the well, which in turn suggests a corresponding decrease in flux from the applicable source area(s).

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE.

WELL 56-2B

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

The date for installation of this well is not known, but available information show that the well was completed with a screened monitored interval from 30.8 to 38.8 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and stainless steel (Type 304) well screen (0.01 slot wire-wound). The well forms a cluster with well 56-2A and 56-2C and is located in Bear Creek Valley (BCV), within the west-central section of Y-12, about 150 ft south of the southwestern corner of Building. 9201-4.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Aside from sampling performed as part of the initial groundwater contamination investigations in BCV during the early 1980s, including an investigation of the source(s) and extent of subsurface mercury contamination within Y-12 (Rothschild et al 1984), a total of three groundwater samples have been collected from the well to date, with the low-flow sampling method used to obtain samples in March 1998, June 2004, and November 2004.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in upper Nolichucky Shale (the Conasauga Group), near the geologic contact with the overlying Maynardville Limestone. The bulk of the groundwater flow. in the Nolichucky Shale occurs within this highly permeable zone, which occurs near the transition between unconsolidated material (saprolite and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into the buried northern tributaries of UEFPC and other components of the subsurface drainage system within the highly industrialized areas of Y-12 (DOE 1998). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that subcrops along the axis of BCV and the original main channel of UEFPC.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 8 ft bgs. Additionally, depth-to-water measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show lower groundwater elevations in well 56-2B (38.8 ft bgs) than in wells 56-2A and 56-2C, which are completed at shallower (15.1 ft bgs) and deeper (77.3 ft bgs) depths, respectively, in the Nolichucky Shale. Based on the distance between the monitored interval midpoint (elevation) in each well, the contemporaneous groundwater elevations indicate a downward vertical gradient (0.015) within the water table interval from well 56-2A to 56-2B, and an upward vertical hydraulic gradient (0.015) from the shallow bedrock (56-2C) to the water table interval (56-2B).

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well 56-2B indicate south and southeasterly flow toward UEFPC. However, groundwater flow in the Nolichucky Shale is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

Additionally, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and original main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, the well is located in the immediate vicinity of a buried former northern tributary of UEFPC that trends along the western and southwestern side of Bldg. 9201-4 and may locally influence groundwater flow patterns.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date show that the well yields sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 384 – 433 mg/L;
- pH of 7.4 – 7.6 (field measurements);
- sulfate concentrations above 100 mg/L;
- low molar proportions of chloride, nitrate, potassium, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The elevated sulfate concentrations in the groundwater samples may reflect local geochemical conditions or contamination from one or more sources within Y-12, including numerous potential non-specific sources such as leaking industrial process lines, sanitary sewers, or storm drains.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected to date had nitrate concentrations above the analytical reporting limit, and the maximum result (1.29 mg/L in November 2004) is substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

None of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

As shown in the data summary below, each of the groundwater samples collected to date contained PCE, TCE, 12DCE isomers, and 11DCE; the sample collected in June 2004 also contained 1,1,2-trichloro-1,2,2-trifluorethane, which is also known as freon-113 (F113).

Date Sampled	Concentration (µg/L)					
	PCE	TCE	c12DCE	t12DCE	11DCE	F113
03/23/98	870	50	74	1 J	3 J	NR
06/09/04	770	61	98	2 J	2 J	3 J
11/18/04	1,400	85	140	2 J	2 J	.
MCL	**5**	**5**	**70**	**100**	**7**	**NA**
Note: "." = Not detected; NR = Not reported; J = Estimated value						

Historical spills and leaks of chlorinated solvent products and wastes during production and machining operations in Building 9201-5, which is located approximately 500 ft northwest of the well, and/or Building 9201-4 is the suspected source(s) of the dissolved VOCs in the groundwater at this well (DOE 1998). The Waste Coolant Processing area, located about 1,500 ft west (upgradient and along geologic strike) of the well is another potential source of VOCs.

As shown in the preceding data summary, the most recent sampling results show that the concentrations of the PCE, TCE, and c12DCE remain substantially above respective drinking water MCLs. Moreover, the concentrations of PCE, TCE and c12DCE evident in May 2004 are 60-90% higher than corresponding concentrations evident in March 1998. Conversely, the concentrations of t12DCE and 11DCE appear to have remained unchanged over this time. It is not clear from the available data why the concentrations of individual VOCs exhibit such divergent concentration trends, or if the divergent trends are significant with regard to differential migration/transport of VOCs via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

Several of the compounds detected in the groundwater samples, (12DCE and 11DCE), are probably products of the biodegradation of related parent compounds (PCE and TCE) in the groundwater; detection of c12DCE is almost certainly attributable to biologically mediated reductive dechlorination of PCE (Wilson et al. 1996). However, as shown in the following summary, results for selected indicator parameters indicate that the groundwater geochemistry in this well, especially the oxidation-reduction (REDOX) conditions and levels of dissolved oxygen, is not especially conducive to biotic degradation of chlorinated hydrocarbons.

Geochemical Parameter/Optimum Range (Wilson et al. 1996)	June 2004	November 2004
Nitrate < 1 mg/L	1	1
Iron (II) > 1 mg/L	<0.05*	<0.05*
Sulfate < 20 mg/L	102	102
Dissolved Oxygen < 0.5 ppm	1.63**	0.45**
REDOX < 50 mV	152**	158**
pH >5 and < 9 st. units	7.42**	7.35**
Note: *Result is for total iron; **Field measurement.		

This suggests that active biotic degradation of the VOCs occurs elsewhere, probably at greater depth in the bedrock (Nolichucky Shale). This interpretation is supported by the upward vertical hydraulic gradients indicated by presampling groundwater elevations in the well (see Section 3.0), which suggest upward migration of (dissolved) parent compounds and degradation products via the groundwater flow/contaminant transport pathways intercepted by the monitored interval in the well. Well 56-2C, the deepest (about 77 ft bgs) of the three-well cluster (see Section 3.0), has historically higher VOC concentrations than detected in well 55-2B with decreasing concentrations over time.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE.

WELL 56-2C

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during August 1983 as part of an investigation to identify the subsurface extent of elemental mercury released during historical operations at Y-12 (Rothchild et. al. 1984). The well was completed with a screened monitored interval from 69.3 to 77.3 ft bgs and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and stainless steel (Type 304) well screen (0.01 slot wire-wound). The well forms a cluster with wells 56-2A and 56-2B near the southwest corner of Bldg. 9201-4 in the central part of Y-12.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Aside from sampling performed as part of the mercury investigation at Y-12, six groundwater samples have been collected from the well, with the conventional sampling method used in March 1997 and the low-flow sampling method used between March 1998 and November 2003.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the Conasauga Group (Nolichucky Shale). Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 7 ft bgs and exhibits minimal (<1 ft) seasonal fluctuations. Also, the presampling groundwater elevations in this well and the two wells with which it is clustered (56-2A and 56-2B) indicate upward hydraulic gradients from the deeper bedrock (56-2C) to the shallow bedrock interval (55-2B) and downward vertical gradients from the water table interval (55-2A) to the shallow bedrock interval.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields chloride- and sulfate-enriched sodium-bicarbonate groundwater generally characterized by:

- very high TDS (>1,000 mg/L);
- pH of 8.1 – 8.7 (field measurements);
- high levels of chloride (>20 mg/L) and sulfate (>40 mg/L);
- low molar proportions of calcium, magnesium, and potassium (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

These geochemical characteristics reflect the decrease in groundwater flux that occurs with depth in the low-permeability formations of the Conasauga Group (e.g., Nolichucky Shale) in BCV (Solomon et al. 1992). Most of the water table and shallow bedrock wells (i.e., <100 ft bgs) completed in these formations yield calcium-magnesium-bicarbonate groundwater, but a fairly abrupt change to sodium-bicarbonate groundwater occurs at a depth of about 100 ft bgs (in BCV west of Y-12). The sodium-dominated geochemistry of the groundwater is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture and increased fracture spacing (Solomon et al. 1992). Further reduced groundwater flux deeper in the bedrock is indicated by a general increase in TDS and a gradational transition from sodium-bicarbonate groundwater to sodium-chloride groundwater. In areas where the low-permeability formations underlie the industrial sections of Y-12, the geochemical transitions appear to occur at shallower depths, possibly because of long-term pumpage of groundwater from building basement sumps (DOE 1998).

It is not clear if the unusually high chloride and sulfate concentrations typical of the groundwater samples reflect natural geochemical characteristics or if the elevated concentrations are the result of contamination from one or more sources upgradient of the well. Additionally, although the groundwater contains a mixture of dissolved chlorinated hydrocarbons (see Section 5.3) and elevated chloride concentrations in the groundwater samples may be a consequence of the biologically mediated degradation (dechlorination) of these compounds (Hinchee et al. 1995), the most recent monitoring data suggest that the geochemical characteristics of the groundwater, particularly the REDOX conditions, are not especially conducive to biotic degradation of VOCs (Table 1).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Nitrate was detected in four of the groundwater samples, with the highest concentration (1.37 mg/L in May 2003) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

None of the groundwater samples had uranium concentrations at or above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, the following VOCs were detected in each of the groundwater samples (Table 2): PCE, TCE, 12DCE (c12DCE), and VC. The source of the VOCs has not been confirmed, but may be related to historical production and machining operations in Bldgs. 9201-4 and 9201-5 (DOE 1998). Considering the upward vertical hydraulic gradients noted in Section 3, it is possible that DNAPL deeper in the bedrock may be a source of the VOCs.

The principal compounds in the groundwater samples are PCE, TCE, and 12DCE, which were detected in each sample, with maximum historical concentrations above 2,500 μg/L, 1,000 μg/L, and 700 μg/L, respectively (Table 2). Secondary compounds are t12DCE, 11DCE, and VC with maximum historical concentrations below 40 μg/L. Note that the most recent sampling results show that the concentrations of PCE, TCE, c12DCE, and VC remain above respective MCLs (Table 2).

Natural biodegradation of PCE and TCE may explain the presence of c12DCE (biodegradation product) in the groundwater samples from this well, with the VC concentrations suggesting the strongly reducing (methanogenic) conditions necessary to transform 12DCE to VC (Chapelle 1996). However, as noted in Section 4.0, results for several geochemical indicator parameters (e.g., REDOX) are substantially outside the respective optimum range for biotic degradation of chlorinated hydrocarbons. Considering the very high PCE concentrations and the upward hydraulic gradient indicated by presampling groundwater elevations (see Section 3.0), perhaps the monitored interval in the well intercepts groundwater flow/transport pathways for dissolved VOCs moving upward from a source (DNAPL) deeper in the bedrock where conditions are better suited for biodegradation.

Natural biodegradation may explain the generally decreasing VOC concentration trend evident for the well (Figure 1) as well as the unusually high levels of chloride in the well; chloride may accumulate during biologically mediated reductive dechlorination of PCE and related degradation compounds (Hinchee et al. 1995).

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

Only the groundwater sample collected in March 1997 had gross beta activity above the applicable MDA and corresponding CE, and the result (7.8 pCi/L) is significantly below the SDWA screening level for gross beta activity (50 pCi/L).

WELL 59-1A

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during September 1983 as part of an investigation to identify the subsurface extent of elemental mercury released during historical operations at Y-12 (Rothchild et. al. 1984). The well was completed with a screened monitored interval from 5.2 to 13.2 ft bgs and constructed with nominal 4.5-inch diameter PVC riser casing and stainless steel well screen. The well is located in the east-central Y-12 area, on the west side of Bldg. 9202, about half way between First Street to the north and Second Street to the south (unless noted otherwise, all directions are in reference to the Y-12 grid). The well is clustered with wells 59-1B and 59-1C.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Groundwater samples were collected from the well using the low-flow sampling method in March 1998, June 2003, and October 2003.

A conspicuous characteristic of the groundwater samples from this well are elevated concentrations of chromium (maximum = 0.13 mg/L in March 1998) and nickel (maximum = 0.437 mg/L in October 2003) that are most likely attributable to microbiologically-induced corrosion (MIC) of the stainless steel well casing and/or screen. Corrosion of stainless steel may be caused by many different species of bacteria, including iron-related and sulfate-reducing organisms that typically attack the area near welds. Once a colony attaches to the metal it forms a nodule in which to live. The micro-environment within the nodule creates conditions (e.g., acidic pH) that enable the colony to expand and deepen the nodule, which eventually creates a pit or crevice in the metal and facilitates corrosion per the mechanisms described by Driscoll (1986).

The following considerations suggest that elevated concentrations of nickel and chromium in the groundwater samples from this well are most likely attributable to corrosion of the stainless steel (assumed to be Type 304) well screen: (1) there are no known sources of these metals near the well; (2) mobile species of these metals are not typically present in groundwater with the neutral pH evident in the well; (3) Type 304 stainless steel contains 18-20% chromium and 8-12% nickel and is prone to crevice corrosion (Oakley and Korte 1996); and (4) indicator parameters (e.g., dissolved oxygen <1 mg/L and pH between 5.5 and 9) are in the optimum range for MIC by sulfate-reducing bacteria (Sarouhan et al. 1998).

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Nolichucky Shale). The average static groundwater level in the well is 5.3 ft below ground surface. Presampling depth-to-water measurements for the well indicate minimal (<1 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- moderate TDS (>150 mg/L<800 mg/L);
- pH (field measurements) of 6.8 – 7.3;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals, excluding chromium and nickel, that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Each groundwater sample had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.5 mg/L in March 1998) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Each groundwater sample had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.0167 mg/L in March 1998) being less than the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for each groundwater sample show non-detect values or false positive results for all of the VOCs that are confirmed groundwater contaminants in the East Fork Regime.

5.4 GROSS ALPHA ACTIVITY

Each groundwater sample had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (11 pCi/L in June 2003) being less than the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Gross beta activity reported for the groundwater sample collected in June 2003 (10 pCi/L) is the only result to exceed the applicable MDA and corresponding CE, and this result is substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL 59-1B

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during September 1983 as part of an investigation to identify the subsurface extent of elemental mercury released during historical operations at Y-12 (Rothchild et. al. 1984). The well was completed with a screened monitored interval from 28.9 to 36.9 ft bgs and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and stainless steel (Type 304) well screen (0.01 slot wire-wound). The well forms a cluster with wells 59-1A and 59-1C in the east-central Y-12 area, on the west side of Bldg. 9202, about half way between First Street to the north and Second Street to the south.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Four groundwater samples were collected from the well between March 1998 and April 2004. The low-flow sampling method was used to obtain each sample.

A conspicuous characteristic of the groundwater samples from this well are elevated concentrations of chromium (maximum = 0.201 mg/L in June 2003) and nickel (maximum = 0.28 mg/L in March 1998) that are most likely attributable to microbiologically-induced corrosion (MIC) of the stainless steel well casing and/or screen. Corrosion of stainless steel may be caused by many different species of bacteria, including iron-reducing and sulfate-reducing organisms that typically attack the area near welds. Once a colony attaches to the metal it forms a nodule in which to live. The micro-environment within the nodule creates conditions (e.g., acidic pH) that enable the colony to expand and deepen the nodule, which eventually creates a pit or crevice in the metal and facilitates corrosion per the mechanisms described by Driscoll (1986). The following considerations suggest that elevated concentrations of nickel and chromium in the groundwater samples from this well are most likely attributable to corrosion of the stainless steel (Type 304) well screen: (1) there are no known sources of these metals near the well; (2) mobile species of these metals are not typically present in groundwater with the neutral pH evident in the well; (3) Type 304 stainless steel contains 18-20% chromium and 8-12% nickel and is prone to crevice corrosion (Oakley and Korte 1996); and (4) indicator parameters (e.g., dissolved oxygen <1 mg/L and pH between 5.5 and 9) are in the optimum range for MIC by sulfate-reducing bacteria (Sarouhan et al. 1998).

The Y-12 GWPP requested biological testing to assess microbial activity in groundwater at this well in April 2004. The results (shown below) are qualitative bacterial counts of four specific bacteria types that are estimates based on the appearance of the sample after an eight- to ten-day growth period.

Well	Date Sampled	Metals (mg/L)		Bacteria Activity (colony forming units/milliliter)			
		Chromium	Nickel	Heterotrophic Aerobic	Iron-Related	Slime Forming	Sulfate-Reducing
59-1B	04/28/04	0.0335	0.143	100	5,000	>100	1,000

The bacterial counts in this sample confirm that MIC (by iron-related and sulfate-reducing bacteria) is the likely cause of the elevated nickel and chromium concentrations in samples from the well.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Nolichucky Shale). The average static groundwater level is about 4 ft bgs. Presampling depth-to-water measurements for the well indicate minimal (<1 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields chloride-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- moderate TDS (327 mg/L – 397 mg/L);
- pH (field measurements) of 6.9 – 7.1;
- unusually high chloride concentrations (>40 mg/L);
- low molar proportions of potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals, excluding nickel and chromium, that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Three groundwater samples had a nitrate concentration above the applicable analytical reporting limit, with the highest concentration (1.17 mg/L in March 1998) being substantially below the MCL for nitrate (10 mg/L). The sample collected from the well in April 2004 was not analyzed for nitrate.

5.2 URANIUM

Each groundwater sample had a uranium concentration above the applicable analytical reporting limit, with the highest concentration (0.0011 mg/L in June 2003) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Results for the three groundwater samples analyzed for VOCs show non-detect values for all compounds. The sample collected from the well in April 2004 was not analyzed for VOCs.

5.4 GROSS ALPHA ACTIVITY

The gross alpha activity reported for the groundwater sample collected in March 1998 (5.5 pCi/L) is the only result to exceed the applicable MDA and corresponding CE, and this result is substantially below the MCL for gross alpha activity (15 pCi/L). The sample collected from the well in April 2004 was not analyzed for gross alpha activity.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples had gross beta activity above the applicable MDA and corresponding CE. The sample collected from the well in April 2004 was not analyzed for gross beta activity.

WELL 59-1C

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well, an NX core hole that was reamed and completed as a monitoring well, was installed during September 1983 as part of an investigation to identify the subsurface extent of elemental mercury released during historical operations at Y-12 (Rothchild et. al. 1984). The well was completed with a screened monitored interval from 65.9 to 73.9 ft bgs and is constructed with nominal 4.5-inch diameter PVC (#40) riser casing and stainless steel (Type 304) well screen (0.01 slot wire-wound). The well forms a cluster with wells 59-1A and 59-1B in the east-central Y-12 area, on the west side of Bldg. 9202, about half way between First Street to the north and Second Street to the south.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Groundwater samples were collected from the well in March 1997, March 1998, June 2003, and October 2003 using the low-flow sampling method.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the shallow bedrock interval in the Conasauga Group (Nolichucky Shale). The average static groundwater level in the well is 4 ft below ground surface. Presampling depth-to-water measurements for the well indicate minimal (<1 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields chloride-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- moderate TDS (>150 mg/L<800 mg/L);
- pH (field measurements) of 7.6 – 7.7;
- unusually high chloride concentrations (>30 mg/L);
- low molar proportions of potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Three groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.4 mg/L in March 1998) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

None of the groundwater samples had uranium concentrations above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for the groundwater sample collected in October 2003 show non-detect values or false positive results for all of the VOCs that are confirmed groundwater contaminants in the East Fork Regime. However, TCE was detected in the groundwater samples collected in March 1997 (0.9 µg/L), March 1998 (7 µg/L), and June 2003 (6 µg/L), with the latter results being slightly above the MCL for TCE (5 µg/L). TCE has not been detected in any of the groundwater samples collected to date from the shallower wells (59-1A and 59-B) clustered with this well.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples have had gross alpha activity above the applicable MDA and the corresponding CE.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples had gross beta activity above the applicable MDA and corresponding CE.

WELL 60-1B

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in September 1983 as part of an investigation to identify the subsurface extent of elemental mercury released during historical operations at Y-12 (Rothchild et. al. 1984). The well was completed with a screened monitored interval from 21.2 to 29.2 ft bgs and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with wells 60-1A and 60-1C in the southeast-central Y-12 area, on the east side of Bldg. 9201-2, about 200 ft south of Second Street.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Groundwater samples were collected from the well in June and October 2003 using the low-flow sampling method.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Maynardville Limestone). The average static groundwater level in the well is 12 ft below ground surface. Presampling depth-to-water measurements for the well indicate minimal (<1 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- moderate TDS (>150 mg/L<800 mg/L);
- pH (field measurements) of 7.4 and 7.5;
- unusually high concentrations of sulfate (>50 mg/L);
- low molar proportions of chloride, potassium, and sodium (<15% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

None of the groundwater samples had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

None of the groundwater samples had uranium concentrations above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for each groundwater sample show non-detect values or false positive results for all of the VOCs that are confirmed groundwater contaminants in the Bear Creek Regime.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples had gross beta activity above the applicable MDA and corresponding CE.

WELL 60-2A

1.0 *INSTALLATION, CONSTRUCTION, AND LOCATION*

This well was installed in 1983 as part of an investigation to identify the subsurface extent of elemental mercury released during historical operations at Y-12 (Rothchild et. al. 1984). The well was completed with a screened monitored interval from 5.5 to 13.5 ft bgs and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and well screen (0.01 slot wire-wound). The well is located in the southeast-central Y-12 area, near the southeast corner of Bldg. 9201-2, about 200 ft north of Third Street.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Groundwater samples were collected from the well in March 1997, June 2003, and October 2003 using the low-flow sampling method.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Maynardville Limestone). The average static groundwater level in the well is 7.3 ft below ground surface.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- moderate TDS (>150 mg/L<800 mg/L);
- pH (field measurements) of 6.8 – 7;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations);
- unusually high total iron concentrations (>5 mg/L); and
- total (unfiltered sample) concentrations of trace metals (except iron) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

The nitrate concentrations reported for the groundwater samples collected in June and October 2003 were analyzed for nitrate and neither sample had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

The uranium concentration reported for the groundwater sample collected in June 2003 (0.00127 mg/L) exceeds the analytical reporting limit, but is substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Low levels of PCE (0.1 μg/L), TCE (1 μg/L), c12DCE (5 μg/L), 11DCE (0.4 μg/L), and VC (3 μg/L) were detected in the groundwater sample collected in March 2003. Note that the VC concentration exceeds the MCL (2 μg/L). A lower concentration of VC (1 μg/L) was detected in the sample collected in June 2003; VOCs were not detected in the groundwater sample collected in October 2003. These compounds are confirmed components of dissolved VOC plumes in the groundwater hydraulically upgradient to the west and northwest of the well.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples had gross beta activity above the applicable MDA and corresponding CE.

WELL GW-008

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in September 1983, completed with a screened monitored interval from 13 to 25.5 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley (BCV) adjacent to the southwestern disposal plots at the Oil Landfarm. The Oil Landfarm waste disposal plots were used between 1973 and 1982 for biodegradation of about one million gallons of waste oils and machine coolants via landfarming with nutrient-adjusted surface soils during the dry months of each year (April through October). The disposal plots are covered by a low-permeability, mulitlayer cap installed during RCRA closure of the Oil Landfarm in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Aside from sampling performed as part of the initial groundwater contamination investigations in BCV during the early 1980s, a total of 14 groundwater samples have been collected from the well since January 1998, all of which were obtained with the low-flow sampling method.

This well yields groundwater samples with low (<150 mg/L) TDS (see Section 4.0), which suggests short groundwater residence time and indicates that the monitored interval in the well intercepts hydraulically active flowpaths.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in Nolichucky Shale (the Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within this highly permeable zone, which occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek that traverse the Nolichucky Shale and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that stratigraphically overlies the Nolichucky Shale and subcrops along the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 12 ft bgs and exhibits minor (<4 ft) seasonal fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-008 indicate south and southwesterly flow toward the Maynardville Limestone and the main channel of Bear Creek. However, groundwater flow in the Nolichucky Shale is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Consequently, the direction(s) of groundwater flow in the vicinity of well GW-008 may be primarily westward (parallel with geologic strike) toward discharge areas in a northern tributary of Bear Creek (NT-4) that traverses the western boundary of the Oil Landfarm disposal plots approximately 600 ft west of the well.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 57 – 99 mg/L;
- pH of 4.0 – 5.9 (field measurements);
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations);
- unusually high (total) iron (>3 mg/L) and manganese (>2 mg/L) concentrations; and
- total concentrations of trace metals (except iron and magnesium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the contaminants present in the groundwater at this well.

5.1 NITRATE

Eight groundwater samples collected to date had nitrate concentrations above the analytical reporting limit. Except for the nitrate concentration reported for the sample collected in July 2000 (5.7 mg/L), the nitrate levels are all less than 1 mg/L and substantially below the drinking water MCL for nitrate (10 mg/L). The July 2000 result appears to be an outlier and is a likely sampling/analytical artifact.

5.2 URANIUM

None of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected to date (Table 1): benzene, chloroethane, PCE, TCE, toluene, 11DCA, 11DCE, and c12DCE. The Oil Landfarm is the source of these compounds. Landfarming operations at the site emplaced two distinct plumes of dissolved VOCs in the shallow groundwater system, one originating from the northern disposal plots that is dominated by 111TCA, 11DCA, and 11DCE and one originating from the southern disposal plots that is dominated by PCE, TCE, and 12DCE. Maximum concentrations within the plumes do not indicate the presence of DNAPL in the subsurface at the Oil Landfarm (AJA 1997).

The principal VOCs in the groundwater samples are PCE and c12DCE, with historical maximum concentrations of 75 μg/L and 27 μg/L, respectively. Secondary compounds in the samples are TCE, 11DCA, and 11DCE, each with a historical maximum concentration below 20 μg/L, and benzene, which has been detected at very low (estimated) concentrations in all but two of the samples. Summed concentrations of the VOCs detected in each sample collected since January 1998 are all less than 150 μg/L, which is substantially lower than the summed VOC concentrations indicated by historical characterization data (>700 μg/L; Energy Systems 1990). Nevertheless, the most recent monitoring results show that the PCE, TCE, and 11DCE concentrations remain at or above respective MCLs (Table 1).

A time-series plot of the summed concentrations of VOCs detected in each groundwater sample collected since January 1998 shows an increasing long-term trend through July 2002, followed by a generally decreasing trend (Figure 1). Also, some compounds (e.g., PCE) show substantial temporal variations whereas other compounds (e.g., 11DCE) do not. It is not clear from the available data why the concentrations of individual compounds exhibit such divergent temporal variations or if such variations are significant with respect to the overall flux of dissolved VOCs along the shallow groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

Four of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (44.36 pCi/L in January 2003) being substantially above the drinking water MCL for gross alpha activity (15 pCi/L). This result is an outlier compared to the other gross alpha values, which are all less than 5 pCi/L.

5.5 GROSS BETA ACTIVITY

Seven of the groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, with the highest value (43.02 pCi/L in January 2003) being slightly below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). This result is an outlier compared to the other gross beta values, which are all less than 10 pCi/L.

WELL GW-014

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in September 1983, completed with a screened monitored interval from 5.0 to 13.2 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley (BCV) along the eastern border of the Bear Creek Burial Grounds (BCBG) waste management area, approximately 150 ft west of a northern tributary (NT) of Bear Creek (NT-6). The BCBG includes numerous hazardous and nonhazardous waste disposal units that received a mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. Liquid wastes included oils, machine coolants, and borax waste water, all or most of which may have contained varying amounts of radioisotopes (primarily uranium isotopes). In 1989, most of the waste-disposal units in the BCBG waste management area were covered with multi-layer, low-permeability caps installed during RCRA closure of the site.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twelve groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain eight samples between March 1987 and August 1995, and the low-flow sampling method used to obtain four samples between March 2002 and October 2005.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Nolichucky Shale (Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within this highly permeable zone, which occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek that traverse the Nolichucky Shale and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that stratigraphically overlies the Nolichucky Shale and subcrops along the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 5 ft bgs and exhibits seasonal fluctuations of about 3 ft. Upward hydraulic gradients often are evident in the Nolichucky Shale near the northern tributaries of Bear Creek, which are primary discharge areas for the shallow groundwater flow system, one of which is located approximately 150 ft east of the well (NT-6). Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-014 indicate flow to the south and southeast toward the Maynardville Limestone and the main channel of Bear Creek. However, groundwater flow in the Nolichucky Shale is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Consequently, the direction of groundwater flow in the vicinity of well GW-014 may be primarily eastward (parallel with geologic strike) toward discharge areas in NT-6.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 354 – 524 mg/L;
- pH of 6.3 – 7.5 (field measurements);
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- unusually high concentrations of boron (>3 mg/L); and
- total concentrations of trace metals (except boron) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant*, *Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

None of the groundwater samples had nitrate concentrations above the analytical reporting limit.

5.2 URANIUM

All but two of the groundwater samples collected to date have uranium concentrations above the applicable analytical reporting limit, with the highest value (0.008 mg/L in March 1987) being below the drinking water MCL for uranium (0.03 mg/L). The uranium concentrations show a generally decreasing trend, with the most recent results (June and October 2005) being less than 0.002 mg/L.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples (Table 1): PCE, TCE, 12DCE, 11DCE, VC, 111TCA, 12DCA, 11DCA, chloroethane, MC, benzene, toluene, total xylene, acetone, chloroform, 2-hexanone, and ethylbenzene. Waste disposal sites within Burial Ground-A (North and South), which received about two million gallons of waste oils and coolants, are the most likely source of the dissolved VOCs in the shallow groundwater at this well (DOE 1997).

The primary compounds in the groundwater samples are PCE, TCE, 12DCE, VC, and 11DCA, which have respective historical maximum concentrations that exceed 1,000 µg/L (Table 1). Secondary compounds in the samples are 11DCE, 111TCA, chloroethane, and benzene, which have historical maximum concentrations above 100 µg/L. The most recent results (March 2002 to October 2005) show that PCE, TCE, c12DCE, 11DCE, and VC continue to exceed the respective MCLs (Table 1).

The elevated benzene is a distinguishing characteristic of the VOC data for this well. A review of historical data indicates that elevated benzene results have been consistently reported for wells located in areas of Y-12 known to be impacted by historical releases from petroleum fuel underground storage tanks (USTs) and located near the BCBG WMA. Excluding the wells located near USTs, groundwater samples from the following wells at the BCBG WMA had benzene concentrations that exceeded the drinking water MCL (5 µg/L).

Well No.	Depth (ft bgs)	Benzene Concentration (µg/L) / Sampling Date			
		Maximum		Most Recent	
GW-014	13.2	180	11/05/87	4	10/19/05
GW-046	20.3	240	07/09/03	72	07/07/05
GW-068	83.6	51	10/18/05	51	10/18/05
GW-071	219	1,300	06/30/05	1,200	10/20/05
GW-082	34.4	99	08/07/03	ND	10/13/05
GW-117	530	6	11/13/87	ND	09/17/92
GW-118	575	67	11/19/88	1	10/10/93
GW-119	510	20	07/06/88	ND	09/17/92
GW-624	27.2	33	07/15/98	25	10/12/05

Of these, well GW-082 is located on the southwest side of Burial Grounds C-West, and all of the remaining wells are located near Burial Ground A-South: wells GW-014, GW-071, and GW-119 along the eastern boundary; wells GW-117 and GW-118 along the southern boundary; and wells GW-046, GW-068, and GW-624 near the western boundary. Note also the wide range in the total depth of these wells, particularly wells GW-117, GW-118, and GW-119, each of which is artesian. The apparent “clustering” of these wells suggest that benzene is a distinguishing component of the groundwater plume of dissolved VOCs originating from the waste disposal trenches in Burial Ground-A South.

Some of the VOCs in the groundwater samples, particularly c12DCE and VC, are probably present in the groundwater as a consequence of the biotic degradation of PCE and TCE. Also, the dissolved petroleum hydrocarbons (e.g., benzene) in the groundwater may serve as electron donors for biologically mediated dechlorination of PCE and related compounds (Chapelle 1996). However, geochemical characteristics of the groundwater in the well, particularly the REDOX conditions, are not especially conducive to anaerobic biotic degradation (Table 2). Perhaps the monitored interval in the well intercepts groundwater flowpaths that transport dissolved VOCs from source areas where biotic degradation primarily occurs, toward the natural discharge areas for the shallow flow system (i.e., the northern tributaries of Bear Creek that traverse the BCBG WMA).

Summed VOC concentrations show an overall decreasing long-term trend (Figure 1), with similar concentration trends evident for individual compounds (Table 1). Also, the long-term trends for most compounds are dominated by a sharp “spike” in November 1987. The decreasing long-term concentration trends probably reflect reduced flux of VOCs east of the BCBG WMA along the groundwater flowpaths intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

Three of the six groundwater samples collected since March 1990 had gross alpha activity above the applicable MDA and corresponding CE, with the maximum value (5.6 pCi/L in October 2005) being substantially below the drinking water MCL for gross alpha activity (15 pCi/L). Results obtained before January 1990 do not meet applicable data quality objectives because the sample specific MDA and/or CE are not available for these samples.

5.5 GROSS BETA ACTIVITY

One of the six groundwater samples collected since March 1990 had gross beta activity above the applicable MDA and corresponding CE, with that result (9.95 pCi/L in March 1990) being substantially less than the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). Results obtained before January 1990 do not meet applicable data quality objectives because the sample specific MDA and/or CE are not available for these samples.

WELL GW-046

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1983, completed with a screened monitored interval from 5.0 to 20.3 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley (BCV) near the central section of the Bear Creek Burial Grounds (BCBG) waste management area. The BCBG includes numerous hazardous and nonhazardous waste disposal units that received a mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. Liquid wastes included oils, machine coolants, and borax waste water, all or most of which may have contained varying amounts of radioisotopes (primarily uranium isotopes). In 1989, the waste-disposal units in the BCBG waste-management area were covered with multi-layer, low-permeability caps installed during RCRA closure of the site.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-six groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 11 samples between March 1987 and August 1995, and the low-flow sampling method used to obtain 15 samples between January 1998 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

The bulk of the groundwater flow in the Nolichucky Shale occurs within this highly permeable zone, which occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek that traverse the Nolichucky Shale and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that stratigraphically overlies the Nolichucky Shale and subcrops along the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 1 ft bgs and exhibits minor (<5 ft) seasonal fluctuations. Slightly artesian conditions may exist near this well during wetter seasons. Upward hydraulic gradients often are evident in the Nolichucky Shale near the northern tributaries of Bear Creek, which are primary discharge areas for the shallow groundwater flow system, and one of these tributaries (NT-7) traverses the BCBG approximately 150 ft west of the well. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-046 indicate flow to the south and southwest toward the Maynardville Limestone and the main channel of Bear Creek. However, groundwater flow in the Nolichucky Shale is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Consequently, the direction(s) of groundwater flow in the vicinity of well GW-046 may be primarily westward (parallel with geologic strike) toward discharge areas in NT-7.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 90 – 280 mg/L;
- pH of 4.4 – 6.0 (field measurements);
- unusually low concentrations of calcium (<20 mg/L) and magnesium (<5 mg/L) along with unusually high concentrations of chloride (>20 mg/L);
- low molar proportions of potassium, sulfate, and sodium (<10% of total anions/cations);
- unusually high concentrations of iron (>3 mg/L) and manganese (>1 mg/L); and
- total concentrations of trace metals (except iron and manganese) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

It is not clear if the unusually high chloride concentrations typical of the groundwater samples reflect localized geochemical conditions or contamination from inorganic wastes disposed in the BCBG. Additionally, although the groundwater contains a mixture of dissolved chlorinated hydrocarbons (see Section 5.3) and elevated chloride concentrations in the groundwater samples may be a consequence of the biologically mediated degradation (dechlorination) of these compounds (Hinchee et al. 1995). The most recent monitoring data suggest that the geochemical characteristics of the groundwater (particularly the REDOX conditions) are not especially conducive to biotic degradation of VOCs (Table 1).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the respective monitoring data reported for the groundwater samples collected since August 1995, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Thirteen groundwater samples had nitrate concentrations above the analytical reporting limit, with the highest concentration (2.7 mg/L in July 2000) being substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

None of the groundwater samples had uranium concentrations above the analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples (Table 2): benzene, chloroethane, chloroform, total xylene, MC, PCE, TCE, toluene, TCFM, VC, 11DCA, 12DCA, 11DCE, 12DCE isomers, 111TCA, and 1,1,2-trichloro-1,2,2-trifluoroethane (freon-113). Waste disposal sites within Burial Ground-A (North and South), which received about two million gallons of waste oils and coolants, are the most likely source of the dissolved VOCs in the shallow groundwater at this well and the DNAPL encountered more than 300 ft bgs in wells located south (down-dip) of BG-A South (DOE 1997).

The primary compounds in the groundwater samples are PCE, TCE, c12DCE, and VC, which were detected in all but one of the samples and have respective historical maximum concentrations that exceed 1,000 μg/L (Table 2). Secondary compounds in the samples are

11DCE, 111TCA, and 11DCA, which also were detected in all but one of the samples and have historical maximum concentrations above 100 µg/L. Benzene, t12DCE, chloroform, chloromethane, and total xylene also have been detected in most of the samples and, excluding suspected outlier results in July 2003 for benzene (240 µg/L) and t12DCE (100 µg/L), the historical maximum concentrations of these compounds are all less than 50 µg/L. Freon-113 and TCFM (freon-11) have been detected in each sample analyzed for these compounds (Table 2), with higher concentrations (>50 µg/L) reported for Freon-113. Methylene chloride and toluene were only detected in a few samples and these results are probably analytical artifacts.

Some of the VOCs in the groundwater samples, particularly c12DCE and VC, are probably present in the groundwater as a consequence of the biotic degradation of related parent compounds (PCE and TCE). Also, the dissolved petroleum hydrocarbons in the groundwater may serve as electron donors for biologically mediated dechlorination of PCE and related compounds (Chapelle 1996). Additionally, the acidic pH of the groundwater samples may be at least partially attributable to abiotic degradation of 111TCA, which chemically degrades to acetic acid (McCarty 1996). However, as noted in Section 4.0, several geochemical characteristics of the groundwater in the well, particularly the REDOX conditions, are not especially conducive to anaerobic biotic degradation. Perhaps the monitored interval in the well intercepts groundwater flowpaths that transport dissolved VOCs from source areas where biotic degradation primarily occurs, toward the natural discharge areas for the shallow flow system (i.e., the northern tributaries of Bear Creek that traverse the BCBG WMA).

Summed VOC concentrations show an indeterminate long-term trend (Figure 1), with diverse concentration trends evident for individual compounds (Table 2). For instance, the benzene concentration trend is clearly skewed by the suspected outlier result obtained in July 2003 (230 µg/L). Also, the long-term concentration trends for several compounds, notably PCE, are dominated by sharp temporal fluctuations; why some compounds exhibit such wide temporal concentrations and others do not is not clear from the available data. Indeterminate long-term trends are evident for other compounds, as illustrated by the concentrations of 12DCA in July 1998 (7 µg/L), July 2000 (2 µg/L), and July 2003 (13 µg/L). It is not clear from the available data if the divergent long-term concentration trends are indicative of corresponding changes in the relative flux of VOCs along the groundwater flowpaths intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

Ten of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the historical maximum value (10.26 pCi/L in January 1995) being slightly below the drinking water MCL for gross alpha activity (15 pCi/L). However, the historical maximum value is an outlier compared to the other results for gross alpha activity, none of which exceed 3 pCi/L.

5.5 GROSS BETA ACTIVITY

Ten of the groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the historical maximum value (10.78 pCi/L in January 1995) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). Nevertheless, the historical maximum value appears to be an outlier compared to the other results for gross beta activity, none of which exceed 6 pCi/L.

WELL GW-052

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in November 1983, completed with a screened monitored interval from 4 to 20 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley (BCV) west of Y-12, approximately 200 ft north of the main channel of Bear Creek and between northern tributaries (NT) of the creek (NT-6 and NT-7) that drain sections of the Bear Creek Burial Grounds (BCBG) waste management area (WMA). The BCBG includes numerous hazardous and nonhazardous waste disposal units that received a mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. Liquid wastes included oils, machine coolants, and borax waste water, all or most of which may have contained varying amounts of radioisotopes (primarily uranium isotopes). In 1989, most of the waste-disposal units in the BCBG waste-management area were covered with multi-layer, low-permeability caps installed during RCRA closure of the site.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Seven groundwater samples have been collected to date, with the conventional sampling method used to collect five samples between June 1990 and April 1993 and the low-flow sampling method used to obtain samples in March and August 2004. The sampling history includes annual and semiannual sampling frequencies and, as indicated by the preceding sampling dates, an extended period (April 1993 – March 2004) when no groundwater samples were collected from the well.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Maynardville Limestone (Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths and groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995). The depth of the well and its location relative to the geologic contact between the Maynardville Limestone and the underlying Nolichucky Shale suggest that the monitored interval is completed near the middle of the Maynardville Limestone.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 8 ft bgs and exhibits unusually large (approximately 14 ft) temporal (seasonal) fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-052 indicate a westerly flow direction, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone and the main channel of Bear Creek south of the well.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the unfiltered groundwater samples collected to date indicate that the well yields sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 184 – 434 mg/L;
- pH (field measurements) of 6.4 – 7.4;
- elevated sulfate concentrations (>20 mg/L) relative to other wells completed at similarly shallow depths in the Maynardville Limestone;
- low molar proportions of chloride, potassium, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals (except uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that each of the principal contaminants except VOCs are present at elevated concentrations in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit (Table 1), including four samples with concentrations that exceed the MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds, which are unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988. These former surface impoundments, which are underlain by the Nolichucky Shale approximately 9,500 ft east-northeast of well GW-052, were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984. Infiltration from the ponds emplaced a heterogeneous mixture of inorganic, organic, and radiological contaminants in the groundwater, some of which were dissolved from bedrock minerals by the acidic seepage from the ponds. Nitrate is one of the principal inorganic contaminants, is chemically stable and highly mobile in groundwater, and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells in BCV, the extent of nitrate contamination in the Maynardville Limestone west of the former S-3 Ponds, as defined by concentrations above 10 mg/L, is generally characterized by: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for about 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) and is significantly influenced by hydrologic interactions with surface water in Bear Creek.

As shown by the data summarized in Table 1, nitrate concentrations reported for the groundwater samples collected to date show a clearly decreasing trend following the historical maximum concentration in June 1990 (28 mg/L). Also, the historical nitrate results, which were reported for samples obtained with the conventional sampling method, indicate wide temporal fluctuations in nitrate concentrations, although there are insufficient data to evaluate any corresponding relationship with groundwater flow conditions. Conversely, the much lower nitrate concentrations reported for the samples collected in March (2.94 mg/L) and August 2004 (2.9 mg/L), which were obtained with the low-flow sampling method, show much lower levels and suggest minimal temporal variation. The long-term decrease in nitrate concentrations in the shallow groundwater at this well is attributable to the reduced flux of nitrate following closure of the former S-3 Ponds in 1984 and installation of the low-permeability cap in 1989 (DOE 1997).

It is possible that the lower and less variable nitrate concentrations indicated by the most recent groundwater sampling results may be at least partially attributable to the change from the conventional sampling method to the low-flow sampling method. The latter method involves purging the well at a flow rate that this low enough to (<300 milliliters per minute) to minimize drawdown of the water level in the well (<0.1 ft per quarter hour). At five minute intervals after the water-level drawdown has stabilized, field personnel record measurements of selected indicator parameters (e.g., pH) and collect (unfiltered) groundwater samples once the field measurements for each parameter show minimal variation over four consecutive readings. In contrast, under the conventional sampling method, field personnel collect groundwater samples immediately after purging at least three well volumes of groundwater at a pumping rate which may substantially lower the water level in the well (or purge the well dry). Conventional sampling would be expected to induce groundwater inflow from the flowpaths that may not be near the well, whereas low-flow sampling may induce inflow primarily from the groundwater flowpaths located nearest to the well. Assuming advective transport of nitrate via multiple groundwater flowpaths in the water table interval, purging the well in accordance with the conventional sampling method may result in the collection of groundwater samples with higher concentrations of nitrate (and other contaminants) relative to samples obtained with the low-flow sampling method.

5.2 URANIUM

All of the groundwater samples collected to date had uranium concentrations above the applicable analytical reporting limit (Table 1), and results for all but one of the samples exceed the drinking water MCL for uranium (0.03 mg/L). There are several sources of uranium in BCV hydraulically upgradient of well GW-052, including the contaminant plume originating from the former S-3 Ponds and inflow of uranium-contaminated surface water in Bear Creek. The CERCLA remedial investigation for BCV identified the former Boneyard/Burnyard (BYBY) as the primary source of uranium in groundwater from the Maynardville Limestone hydraulically downgradient (west) of the site (DOE 1997), which is about 4,500 ft east of well GW-052. Uranium-bearing wastes disposed at the BYBY were below the seasonally high water table and the limestone bedrock provided a ready source of dissolved carbonate, which combined with uranyl cations leached from the wastes and greatly increased what would otherwise be relatively limited uranium mobility in the neutral pH groundwater in the Maynardville Limestone (DOE 1997). As a major source area, the BYBY was prioritized for CERCLA remedial action, which was completed in May 2003 and involved: (1) the excavation and on-site consolidation/off-site disposal of about 81,000 yd^3 of waste materials; (2) construction of a multi-layer low-permeability cap over waste materials consolidated on site; and

(3) reconstruction of a northern tributary of Bear Creek (NT-3) that drains the site (BJC 2004).

Total uranium concentrations reported for the groundwater samples range between the historical maximum value of 0.089 mg/L in December 1992 and the historical minimum value of 0.0262 mg/L in March 2004 (the only result that is less than the MCL). These results reflect a temporally variable but generally decreasing long-term concentration trend. It is unclear from the available data if the temporal fluctuations in uranium levels reflect corresponding short-term variations in groundwater flow conditions and, assuming advective transport in the groundwater, corresponding changes in the relative flux of uranium along the groundwater flowpaths intercepted by the monitored interval in the well. Also, because of the long gap in the sampling history for the well (see Section 2.0), it is not clear if the decreased concentrations of uranium in the shallow groundwater at this well may be directly attributable to the CERCLA remedial action at the BYBY.

Unlike the nitrate results described in Section 5.1, the historical conventional sampling results for total uranium are less clearly distinguished from the recent low-flow sampling results, as illustrated by the similar uranium concentrations detected in the samples collected with the respective method in March 1992 (0.042 mg/L) and August 2004 (0.0467 mg/L). Thus, it is not clear from the available data if the apparent reduction in the concentrations of uranium in the groundwater at this well is an artifact of the change in the groundwater sampling method.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were not detected in any of the groundwater samples collected to date.

5.4 GROSS ALPHA ACTIVITY

All of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE (Table 2), and all of these results exceed the drinking water MCL for gross alpha activity (15 pCi/L). Uranium isotopes (and alpha-emitting daughters) are the source of elevated gross alpha activity in the groundwater at this well, with the most recent (March and August 2004) sampling results confirming the continued presence of U-234 and U-238 in the well (Table 2). The contaminant plumes originating from the former S-3 Ponds and the BYBY are primary sources of uranium isotopes in groundwater and surface water in BCV west of Y-12, with the latter site being the closest and most likely source of the uranium isotopes in the shallow groundwater at well GW-052 (DOE 1997). As with total uranium (see Section 5.2), uranium isotopes leached from wastes disposed at the BYBY probably combined with carbonate dissolved from the (limestone) bedrock, which greatly increased their relatively limited mobility in the neutral pH groundwater in the Maynardville Limestone (DOE 1997).

Gross alpha activity values reported for the groundwater samples range between the historical maximum value of 49 pCi/L in December 1992 and the historical minimum value of 16 pCi/L in August 2004. These results reflect a temporally variable but generally decreasing long-term trend for gross alpha activity in the shallow groundwater at this well. This long-term trend generally mirrors the similar trend defined by the sampling results for total uranium and likewise may be attributed to reduced flux of uranium isotopes in response to the CERCLA remedial action at the BYBY during the spring and summer of 2003.

5.5 GROSS BETA ACTIVITY

All of the groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE (Table 2), including results for four samples that exceed the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). The gross beta activity reported for the sample collected in June 1990 (120 pCi/L) is the historical maximum value for the well. Although uranium isotopes and related daughter products contribute to the gross beta activity in the groundwater at this well, the most recent sampling results (March and August 2004) indicate that Tc-99 also is a source of the beta activity (Table 2). *Technetium-99 is a "signature" component of the contaminant plume* emplaced during historical operation of the former S-3 Ponds because it is the only site at Y-12 which received wastes that contained Tc-99 (DOE 1998). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the groundwater transport of Tc-99 in the Maynardville Limestone closely mirrors that of nitrate.

The gross beta activity values reported for the groundwater samples have decreased from above 50 pCi/L in the early 1990s to below 20 pCi/L in March and August 2004 (Table 2). This decreasing long-term trend generally mirrors the similar trend defined by the sampling results for gross alpha activity (and total uranium) and likewise may be attributed to reduced flux of uranium isotopes in the Maynardville Limestone (and Bear Creek) as a result of the CERCLA remedial action at the BYBY, along with continued long-term decrease in the relative flux of Tc-99 (and nitrate) evident following closure/capping of the former S-3 Ponds.

WELL GW-053

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in November 1983, completed with a screened monitored interval from 11.4 to 32.8 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley (BCV) west of Y-12, approximately 500 ft south of the western portion of the Bear Creek Burial Grounds (BCBG) waste management area (WMA). Additionally, the well is located approximately 100 ft north of the main channel of Bear Creek, about 150 ft east of a northern tributaries (NT) of the creek (NT-7) that drains the central section of the BCBG WMA. The BCBG includes numerous hazardous and nonhazardous waste disposal units that received a mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. Liquid wastes included oils, machine coolants, and borax waste water, all or most of which may have contained varying amounts of radioisotopes (primarily uranium isotopes). In 1989, most of the waste-disposal units in the BCBG waste-management area were covered with multi-layer, low-permeability caps installed during RCRA closure of the site.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-two groundwater samples have been collected to date, with the conventional sampling method used to collect 22 samples between June 1990 and September 1997 and the low-flow sampling method used to obtain ten samples between March 1998 and October 2005.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Maynardville Limestone (Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths and groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 6 ft bgs and exhibits seasonal fluctuations of about 8 ft. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-053 indicate a westerly flow direction, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone and the main channel of Bear Creek south of the well.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the unfiltered groundwater samples collected to date indicate that the well yields sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 377 – 528 mg/L;
- pH (field measurements) of 6.0 – 7.7;
- low molar proportions of chloride, potassium, sodium, and sulfate (<5% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the respective monitoring data reported for the 29 groundwater samples collected since March 1991, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Five groundwater samples had nitrate concentrations at or above the applicable analytical reporting limit, with the maximum value (0.9 mg/L in December 1991) being substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Twenty-six groundwater samples had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.008 mg/L in September 1991) being below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples (Table 1): PCE, TCE, 12DCE, 11DCE, VC, 111TCA, 12DCA, 11DCA, chloroethane, benzene, acetone, and 2-butanone. Waste disposal sites within Burial Ground-A (North and South), which received about two million gallons of waste oils and coolants, are the most likely source of the dissolved VOCs in the shallow groundwater at this well (DOE 1997).

The primary compounds in the groundwater samples are TCE, 12DCE, VC, and 11DCA which were detected in nearly every sample (Table 1). Historical results show that 12DCE, VC, and 11DCA have the highest maximum values (> 20 µg/L) and that VC concentrations have exceeded the MCL (2 µg/L). However, the most recent results (June and October 2005) show that VC is no longer detected and c12DCE concentrations still have the highest values (> 10 µg/L). The secondary compounds (PCE, 11DCE, 111TCA, and 12DCA) have been detected at very low (estimated) levels in less than half of the groundwater samples collected from the well, and PCE is the only secondary VOC that has been detected in the samples collected since September 1992 (Table 1).

Some of the VOCs in the groundwater samples, particularly c12DCE and VC, are probably present in the groundwater as a consequence of the biotic degradation of related parent compounds (PCE and TCE). Although sporadically detected at very low levels, the dissolved benzene in the groundwater may serve as an electron donor for biologically mediated dechlorination of PCE and related compounds (Chapelle 1996). Also, the geochemical characteristics of the groundwater in the well, except for iron concentrations, are conducive to anaerobic biotic degradation (Table 2).

A time-series plot of the summed VOC concentrations shows an overall decreasing long-term trend (Figure 1), which is similar to the long-term trend for all primary VOCs except for TCE (Table 1). The TCE trend shows an indeterminate trend, the significance of this trend is questionable because all of the TCE results are estimated values below the reporting limit. The decreasing long-term concentration trends probably reflect reduced flux of VOCs south of the BCBG WMA along the shallow groundwater flowpaths intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

Nine groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the maximum value (11 pCi/L in June 2005) being below the drinking water MCL for gross alpha activity (15 pCi/L). However, this result is a suspected outlier because the eight other detected results are less than 5 pCi/L, and the most recent sample (October 2005) was below the MDA.

5.5 GROSS BETA ACTIVITY

Eleven groundwater samples had gross beta activity above the applicable MDA and corresponding CE limits, with the maximum value (9.6 pCi/L in September 1991) being substantially less than the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). All of the gross beta results for the 13 groundwater samples collected since March 1996 have been below the MDA.

WELL GW-056

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in November 1985, completed with a screened monitored interval from approximately 50 to 55 ft bgs, and constructed with nominal 2.5-inch stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley (BCV) about two miles west of Y-12, near the confluence of the main channel of Bear Creek and a northern tributary (NT) of the creek (NT-8) that drains the western sections of the Bear Creek Burial Grounds (BCBG) waste management area (WMA). This well is a component of Exit Pathway Picket A, which consists of a series of wells (GW-056, GW-057, GW-683, GW-684, and GW-685) completed at different depths (and hydrostratigraphic zones) along a strike-normal transect across the Maynardville Limestone (Figure 1). The Maynardville Limestone underlies Bear Creek throughout BCV and the hydrologic interaction between the creek and the shallow karst network in the Maynardville Limestone provide the primary exit-pathways for groundwater and surface water contaminants.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-one groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 23 samples between June 1990 and August 1997, and the low-flow sampling method used to obtain 8 samples between February 1998 and April 2004.

Groundwater samples from this well are distinguished by elevated total (unfiltered sample) concentrations of chromium and nickel that are probably attributable to chemical and/or microbiologically-induced corrosion of the stainless steel riser casing and/or well screen (see Section 5.6).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the Maynardville Limestone (Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths and groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 3 ft bgs and exhibits moderate (5 ft) seasonal fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-056 indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date indicate that the well yields somewhat mineralized, calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 364 – 746 mg/L;
- pH (field measurements) of 6.3 – 7.7;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and

- total concentrations of trace metals (except chromium and nickel) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on data reported for samples collected since February 1991, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Nineteen of the groundwater samples had nitrate concentrations above the analytical reporting limit, with all of the results being less than 1 mg/L and substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

All but one of the groundwater samples had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.0081 mg/L in February 1997) being substantially below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in six groundwater samples collected to date: acetone, chloroform, PCE, TCE, 12DCE (isomers), and 111TCA. These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. In the Bear Creek watershed west of the flow divide, which occurs near the west end of Y-12, the VOC plume in the Maynardville Limestone appears to originate near Spoil Area I and extends several thousand feet westward (parallel with geologic strike) down the axis of BCV, with influx of various VOCs from several different downgradient source areas, including the BCBG. The distribution of VOCs within the plume reflects the relative contributions from the source areas and commingling during downgradient transport. Plume constituents in the upper part of BCV are TCE, c12DCE, and PCE; source areas include Spoil Area I and the former S-3 Ponds. Farther downgradient (west), major inputs of VOCs occur from the Rust Spoil Area or a nearby source in the Bear Creek floodplain; the Oil Landfarm WMA, including the former Hazardous Chemical Disposal Area (HCDA) and Sanitary Landfill I; and inflow of VOC-contaminated groundwater and surface water that discharges from a northern tributary of Bear Creek (NT-7) that traverses the BCBG. The highest VOC concentrations within the plume exceed 300 µg/L and occur in the deeper groundwater south (down dip) of the HCDA. These high concentrations coincide with downward vertical hydraulic gradients in the Maynardville Limestone in this area and a major losing reach of the main channel of Bear Creek south-southwest of Sanitary Landfill I (DOE 1997).

The concentrations of VOCs detected in the groundwater samples from this well are 5 µg/L or less, with TCE and 12DCE being the only compounds detected in more than one of the samples. The highest concentrations were reported for acetone and PCE, with the latter result being equal to the drinking water MCL (5 µg/L). Results for all other compounds are 2 µg/L or less. Also, none of the samples collected since July 1999 contained VOCs.

5.4 GROSS ALPHA ACTIVITY

Seventeen groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (18 pCi/L in January 2000) being slightly above the drinking water MCL for gross alpha activity (15 pCi/L). However, this value appears to be an outlier in comparison with the other results for gross alpha activity, all of which are less than 10 pCi/L, most being less than 5 pCi/L.

5.5 GROSS BETA ACTIVITY

Eighteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (20 pCi/L in January 2000) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

5.6 OTHER

As noted in Section 2.0, the groundwater samples from this well typically contain elevated nickel concentrations; 16 of the samples had chromium and/or nickel concentrations above respective UTLs (Table 1), including seven samples with chromium above the federal drinking water MCL (0.1 mg/L) and ten samples with nickel above the state drinking water MCL (0.1 mg/L). Corrosion of the stainless steel well casing and screen in the well is the suspected source of the nickel (and chromium) in the samples because: (1) mobile species of nickel are not typically present in groundwater with the neutral pH evident in the well; (2) Type 304 stainless steel contains 18-20% chromium and 8-12% nickel and is prone to crevice corrosion (Oakley and Korte 1996); and (3) microbiological sampling results, summarized below, support the possibility of microbiologically induced corrosion (MIC).

Date Sampled	Bacteria Activity (colony forming units/milliliter)			
	Heterotrophic Aerobic	Iron-Related	Slime Forming	Sulfate-Reducing
04/27/04	500,000	<100	50,000	<1,000

These results, which are based on qualitative bacterial counts estimated from the appearance of the groundwater sample after an eight- to nine-day growth period, confirm substantial microbial activity in the groundwater at this well, including the presence of bacteria (e.g., slime-forming bacteria) that have been documented to cause MIC of stainless steel (Sarouhan et. al. 1998).

WELL GW-061

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in March 1984, completed with a screened monitored interval from 17.5 to 24.6 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley (BCV) west of Y-12, about 650 ft south of the Bear Creek Burial Grounds (BCBG) waste management area (WMA) and about 25 ft south of the main channel of Bear Creek. The BCBG includes numerous hazardous and nonhazardous waste disposal units that received a mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. Liquid wastes included oils, machine coolants, and borax waste water, all or most of which may have contained varying amounts of radioisotopes (primarily uranium isotopes). In 1989, most of the waste-disposal units in the BCBG waste-management area were covered with multi-layer, low-permeability caps installed during RCRA closure of the site.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-five groundwater samples have been collected to date, with the conventional sampling method used to collect 21 samples between August 1989 and September 1995 and the low-flow sampling method used to obtain four samples between March 2002 and October 2005.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maynardville Limestone (Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths and groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995). The depth of the well (about 25 ft bgs) and its location relative to Bear Creek (about 25 ft south) and the Maynardville Limestone/Nolichucky Shale geologic contact suggest that the monitored interval is completed directly downdip of Bear Creek near the middle portion of the Maynardville Limestone.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 12 ft bgs, with seasonal fluctuations of about 7 ft excluding one measurement (24.3 ft bgs in September 1992) that is a suspected outlier. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-061 indicate a westerly flow direction, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone and the main channel of Bear Creek.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the unfiltered groundwater samples collected to date indicate that the well yields sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 206 – 476 mg/L;
- pH (field measurements) of 6.7 – 7.5;
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations);
- elevated concentrations (maximum > 20 mg/L) of aluminum and iron, related to elevated total suspended solid (>200 mg/L) concentrations in some samples; and
- total (unfiltered sample) concentrations of trace metals (except aluminum, iron, and uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that each of the principal contaminants except VOCs are present at elevated concentrations in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit (Table 1), including 13 samples with concentrations that exceed the MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds, which are unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988. These former surface impoundments, which are underlain by the Nolichucky Shale approximately 9,000 ft east of well GW-061, were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984. Infiltration from the ponds emplaced a heterogeneous mixture of inorganic, organic, and radiological contaminants in the groundwater, some of which were dissolved from bedrock minerals by the acidic seepage from the ponds. Nitrate is one of the principal inorganic contaminants, is chemically stable and highly mobile in groundwater, and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells in BCV, the extent of nitrate contamination in the Maynardville Limestone west of the former S-3 Ponds, as defined by concentrations above 10 mg/L, is generally characterized by: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for about 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) and is significantly influenced by hydrologic interactions with surface water in Bear Creek. Because well GW-061 is shallow and located about 25 ft south of the main channel of Bear Creek, the elevated nitrate concentrations in the groundwater samples from the well probably reflect localized inflow of nitrate-contaminated surface water from the creek.

Nitrate concentrations reported for the groundwater samples collected to date range from about 6 mg/L to 27 mg/L (Table 1), with the highest concentrations (> 20 mg/L) reported for samples collected between September 1991 and September 1994. Also, the nitrate concentrations clearly exhibit significant temporal (seasonal) fluctuations, with the lowest levels typically reported for samples collected during seasonally high groundwater flow (winter and spring), and the highest concentrations (including the historical maximum in June 1992) typically reported for samples collected during seasonally low flow conditions (summer and fall). This relationship suggests seasonal (or episodic) "dilution" from recharge of uncontaminated (or less nitrate-contaminated) groundwater via the flow/transport pathways intercepted by the monitored interval in the well.

A time-series plot of nitrate concentrations in the groundwater samples shows an indeterminate long-term trend dominated by wide temporal (seasonal) fluctuations (Figure 1). The nitrate results obtained with the low-flow sampling method seemingly exhibit less temporal variability than the conventional sampling results. This may be related to inherent differences in the manner in which each sampling method induces inflow of groundwater into the well. Conventional sampling involves aggressively purging the well (1-2 gallons per minute), which may induce inflow from water-producing features (and inflow of surface water from Bear Creek) that may not be proximal to the monitored interval. In contrast, low-flow sampling involves purging the well at a flow rate low enough (<300 milliliters per minute) to ensure minimal water-level drawdown in the well (<1 ft per quarter hour), which induces groundwater flow from the water-producing features near the well.

5.2 URANIUM

All of the groundwater samples collected to date had uranium concentrations above the applicable analytical reporting limit (Table 1), including 17 samples that exceed the drinking water MCL for uranium (0.03 mg/L). There are several sources of uranium in BCV hydraulically upgradient of well GW-061, including the contaminant plume originating from the former S-3 Ponds and inflow of uranium-contaminated surface water in Bear Creek. The CERCLA remedial investigation for BCV identified the former Boneyard/Burnyard (BYBY) as the primary source of uranium in groundwater in the Maynardville Limestone hydraulically downgradient (west) of the site (DOE 1997), which is about 5,000 ft east of well GW-061. Uranium-bearing wastes disposed at the BYBY were below the seasonally high water table and the limestone bedrock provided a ready source of dissolved carbonate, which combined with uranyl cations leached from the wastes and greatly increased what would otherwise be relatively limited uranium mobility in the neutral pH groundwater in the Maynardville Limestone (DOE 1997). As a major source area, the BYBY was prioritized for CERCLA remedial action, which was completed in May 2003 and involved: (1) the excavation and on-site consolidation/off-site disposal of about 81,000 yd^3 of waste materials; (2) construction of a multi-layer low-permeability cap over waste materials consolidated on site; and (3) reconstruction of a northern tributary of Bear Creek (NT-3) that drains the site (BJC 2004).

Total uranium concentrations reported for the groundwater samples collected to date range from 0.017 mg/L to 0.088 mg/L (Table 1), with the highest concentrations (> 0.07 mg/L) reported for samples collected between September 1991 and September 1994. The uranium concentrations clearly exhibit significant temporal (seasonal) fluctuations, with the lowest levels typically reported for samples collected during seasonally high groundwater flow (winter and spring), and the highest concentrations (including the historical maximum in September 1994) typically reported for samples collected during seasonally low flow conditions (summer and fall). This relationship suggests seasonal (or episodic) "dilution" from recharge of uncontaminated (or less uranium-contaminated) groundwater during the winter and spring via the flow/transport pathways intercepted by the monitored interval in the well. As with nitrate, the elevated uranium concentrations in the groundwater samples from the well may reflect localized inflow of contaminated surface water from Bear Creek.

A time-series plot of uranium concentrations in the groundwater samples shows an indeterminate long-term trend dominated by wide temporal (seasonal) fluctuations (Figure 2). As with nitrate concentrations (see Section 5.1), the uranium results obtained with the low-flow sampling method seemingly exhibit less temporal variability than the conventional sampling results. This may be related to inherent differences in the manner in which each sampling method induces inflow of groundwater into the well. Conventional sampling involves aggressively purging the well (1-2 gallons per minute), which may induce inflow from water-producing features (and inflow of surface water from Bear Creek) that may not be proximal to the monitored interval. In contrast, low-flow sampling involves purging the well at a flow rate low enough (<300 milliliters per minute) to ensure minimal water-level drawdown in the well (<1 ft per quarter hour), which induces groundwater flow from the water-producing features near the well. Note that the uranium concentrations are lower in CY 2005 than in CY 2002 (Figure 2), which may reflect the CERCLA remedial actions completed in May 2003 at the BYBY (described above).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected at low levels in four groundwater samples: a trace (<1µg/L) of TCE was detected in two samples (September 1991 and June 1994); 12DCE (total) was detected (2 µg/L) in one sample (September 1992); and acetone (6 µg/L) and 2-butanone (8 µg/L) were detected in one sample (September 1994). Acetone and 2-butanone are common laboratory reagents (possible artifacts) and these results are considered to be outliers.

5.4 GROSS ALPHA ACTIVITY

All of the groundwater samples collected since March 1990 had gross alpha activity above the applicable MDA and corresponding CE (Table 1), and twelve of these results exceed the drinking water MCL for gross alpha activity (15 pCi/L). Uranium isotopes (and alpha-emitting daughters) are the source of elevated gross alpha activity in the groundwater at this well, with the most recent (June and October 2005) sampling results confirming the continued presence of U-234 (6.5-6.8 pCi/L) and U-238 (12 pCi/L) in the well. The contaminant plumes originating from the former S-3 Ponds and the BYBY are primary sources of uranium isotopes in groundwater and surface water in BCV west of Y-12, with the latter site being the closest and most likely source of the uranium isotopes in the shallow groundwater at well GW-061 (DOE 1997). As with total uranium (see Section 5.2), uranium isotopes leached from wastes disposed at the BYBY probably combined with carbonate dissolved from the (limestone) bedrock, which greatly increased their relatively limited mobility in the neutral pH groundwater in the Maynardville Limestone and the surface water in Bear Creek (DOE 1997). Also, because the monitored interval of well GW-061 is located about 25 ft directly downdip of Bear Creek (see Section 3.0), the elevated gross alpha activity in the groundwater at the well probably reflects localized inflow of contaminated surface water from the creek.

A time-series plot of the gross alpha activity in the groundwater samples collected since March 1990, which is similar to the trend for uranium concentrations (see Section 5.3), shows an indeterminate long-term trend dominated by wide temporal (seasonal) fluctuations (Figure 3). The alpha activities reported for samples collected in the early to mid-1990s exhibit significant temporal (seasonal) fluctuations, with the lowest levels typically reported for samples collected during seasonally high groundwater flow (winter and spring), and the highest concentrations (including the historical maximum in September 1994) typically reported for samples collected during seasonally low flow conditions (summer and fall). This relationship suggests seasonal (or episodic) "dilution" from recharge of less contaminated groundwater (or surface water from Bear Creek) via the flow/transport pathways intercepted by the monitored interval in the well. Note that the alpha activity reported for samples collected in CY 2005 are significantly lower than reported in CY 2002 (Figure 3), which may reflect the CERCLA remedial actions completed in May 2003 at the BYBY (see Section 5.3).

5.5 GROSS BETA ACTIVITY

All of the groundwater samples collected since March 1990 had gross beta activity above the applicable MDA and corresponding CE (Table 1), including results for eight samples that exceed the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). Although uranium isotopes (see Section 5.4) and related daughter products contribute to the gross beta activity in the groundwater at this well, the most recent sampling results (June and October 2005) indicate that Tc-99 (39-40 pCi/L) also is a source of beta activity. Technetium-99 is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds because it is the only site at Y-12 which received wastes that contained Tc-99 (DOE 1998). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Also, because the monitored interval of well GW-061 is located about 25 ft directly downdip of Bear Creek (see Section 3.0), the elevated gross beta activity in the groundwater at the well probably reflects localized inflow of nitrate-contaminated surface water from the creek.

A time-series plot of the gross beta activity in the groundwater samples collected since March 1990 shows an indeterminate long-term trend dominated by wide temporal (seasonal) fluctuations (Figure 3), which is similar to the concentration trends for nitrate, uranium, and gross alpha. As with gross alpha activity, the beta activities reported for samples collected in the early to mid-1990s exhibit significant temporal (seasonal) fluctuations, with the lowest levels typically reported for samples collected during seasonally high groundwater flow (winter and spring), and the highest levels (including the historical maximum in September 1991) typically reported for samples collected during seasonally low flow conditions (summer and fall). This relationship suggests seasonal (or episodic) "dilution" from recharge of less contaminated groundwater (or surface water from Bear Creek) via the flow/transport pathways intercepted by the monitored interval in the well. Note that the beta activity reported for samples collected in CY 2005 are sharply lower than reported in CY 2002 (Figure 3), which may reflect the CERCLA remedial actions completed in May 2003 at the BYBY (see Section 5.3).

WELL GW-064

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in March 1984, completed with a screened monitored interval from 46.8 to 52.7 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is paired with well GW-065 and is located in Bear Creek Valley (BCV) west of Y-12, directly south of the main channel of Bear Creek and approximately 450 ft west (downgradient) of the Rust Spoil Area, which was used from 1975 to 1983 for disposal of construction debris generated at Y-12.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-six groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 32 samples between November 1987 and August 1995, and the low-flow sampling method used to obtain four samples between March 1998 and July 2005. Samples were collected on a quarterly frequency between November 1987 and August 1996, with semiannual sampling in 1998 and 2005.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the shallow bedrock interval in the Maynardville Limestone (Conasauga Group), which trends northeast-southwest along the axis of BCV, dips southeast at an angle of 45º - 55º, and underlies the main channel of Bear Creek. The Maynardville Limestone exhibits the hydrologic characteristics typical of karst aquifers, with most of the groundwater flow occurring at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (shallow karst network). Hydrologic interaction between Bear Creek and the shallow karst network provides the principal exit-pathway for contaminants released from source areas within the Bear Creek watershed west of Y-12. Deeper in the subsurface, below the shallow karst network, fractures provide the primary groundwater flowpaths, and the bulk permeability generally decreases with depth because of decreased fracture aperture and increased fracture spacing (Solomon et. al. 1992). Also, distinct lithologic and hydrologic characteristics differentiate seven hydrostratigraphic zones (numbered from bottom to top) in the Maynardville Limestone (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

The static water level in the well occurs at an average depth of about 23 ft bgs and exhibits maximum seasonal water-level fluctuations up to approximately 15 ft. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-064 indicate westerly local flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the unfiltered groundwater samples collected to date show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 176 – 777 mg/L;
- pH of 6.9 – 7.6 (field measurements);
- low molar proportions of chloride, sulfate, potassium, and sodium (<10% of total anions/cations); and

- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that nitrate and VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

All groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit (Table 1), including 11 samples with concentrations that exceed drinking water MCL for nitrate (10 mg/L). Elevated nitrate concentrations in the samples indicate that the monitored interval for the well in the well intercepts water-producing features that are hydraulically connected with the heterogeneous plume of inorganic, organic, and radiological contaminants originating from the former S-3 Ponds. Located hydraulically upgradient approximately 3,000 ft east-northeast of the well, these unlined surface impoundments received several million gallons of nitric-acid wastes generated at Y-12 between 1951 and 1984, and were filled and covered with a low-permeability cap during RCRA closure of the site in 1989. Nitrate is a principal component of the contaminant plume, is chemically stable and highly mobile in groundwater, and is believed to effectively delineate the primary groundwater flow/contaminant transport pathways in the Maynardville Limestone (DOE 1997).

As shown by the groundwater sampling results summarized in Table 1, nitrate concentrations above the drinking water MCL (10 mg/L) were reported for each sample collected between November 1987 (25 mg/L, the historical maximum value) and January 1990 (11 mg/L). However, all of the samples collected since November 1990 had nitrate concentrations below the MCL (Table 1). Additionally, unlike the nitrate concentrations evident in the groundwater at other wells completed at shallow depths in the Maynardville Limestone wells west of Y-12, the nitrate results for this well do not indicate wide temporal (seasonal) concentration fluctuations, as illustrated by the concentrations evident in March (1.88 mg/L) and August 2005 (2.55 mg/L). This suggests that the monitored interval in the well may not intercept the most permeable flowpaths at shallow depths in the Maynardville Limestone, where nitrate concentrations typically exhibit pronounced temporal fluctuations in response to seasonal (and episodic) recharge/discharge cycles.

A time-series plot of nitrate concentrations detected in the groundwater samples collected to date spans three-year (August 1995 – March 1998) and seven-year (July 1998 – March 2005) periods when no samples were collected from the well, but shows a clearly decreasing long-term concentration trend (Figure 1). The overall decrease from the nitrate concentrations mirrors with the substantially reduced flux of nitrate in the Maynardville Limestone following the closure/capping of the former S-3 Ponds. Also, as indicated by selected data included in the following summary, the increasing time for nitrate levels to decrease by at least 50% indicates that the rate of concentration decrease has slowed considerably and may have reached asymptotic levels in the groundwater at this well.

Sampling Date	Elapsed Time (Days)	Nitrate (mg/L)	Relative % Decrease
07/19/88	.	25	.
11/02/90	837	12	52%
06/23/94	1,379	5.5	54%
07/26/05	4,051	2.55	54%

5.2 URANIUM

Twenty-one groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.0098 mg/L in July 1998) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected to date (Table 2): acetone, CTET, chloroform, MC, PCE, TCE, vinyl acetate, 2-hexanone, 12DCE, 11DCA, and 111TCA. The presence of VOCs in the samples indicates that the monitored interval in the well intercepts groundwater flow/transport pathways for VOCs released from one or more upgradient sources that contribute to an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. Available data for the network of wells completed in the Maynardville Limestone west of the flow divide indicate that VOC-contaminated groundwater, as defined by individual or summed VOC concentrations above 5 µg/L, appears to originate near Spoil Area I and to extend hydraulically downgradient for several thousand feet westward (parallel with geologic strike) down the axis of BCV. The apparent distribution of VOCs within the plume reflects the relative influx from multiple source areas, commingling during downgradient groundwater transport, and hydraulic communication with Bear Creek (DOE 1997). In the upper part of BCV, hydraulically upgradient of well GW-064, the primary VOCs are TCE, c12DCE, and PCE and the confirmed or suspected source areas include Spoil Area I, the contaminant plume emplaced during historical operation of the former S-3 Ponds, and the Rust Spoil Area (or nearby source within the Bear Creek floodplain), the latter site considered a primary source of TCE.

Based on frequency of detection and concentration magnitude, the primary VOCs in the groundwater samples collected from well GW-064 to date are TCE and 12DCE (Table 2). The dominant compound is TCE, which was detected in every sample collected to date, with a historical maximum concentration of 210 µg/L in November 1987 and concentrations above 100 µg/L reported for more than half of the samples. Additionally, the most recent sampling results (March and August 2005) indicate that the TCE concentrations remain substantially above the drinking water MCL (5 µg/L). The only other VOC that was detected n each sample is 12DCE, although the historical maximum concentration (98 µg/L) is a suspected outlier because all the other results are below 20 µg/L, and the most recent sampling results show estimated concentrations below 5 µg/L (Table 2). Secondary compounds detected in the samples are CTET, chloroform, PCE, and 111TCA, each of which has been detected in more than half of the samples collected to date, although only chloroform and PCE were detected in the samples collected since August 1995, and only PCE was detected in samples collected since July 1998. Aside from a suspected outlier result for PCE (53 µg/L in November 1987), all of the results for these secondary VOCs are less than 10 µg/L and the bulk of the results are estimated concentrations below 5 µg/L (Table 2). The remaining compounds were detected in only a few samples and are probably analytical artifacts.

Review of the VOC data summarized in Table 2 indicates that the concentrations of TCE in the groundwater at this well exhibits significant short-term temporal variability, but the other compounds do not. This is illustrated by the respective TCE and PCE concentrations detected in the groundwater samples collected in August 1992 (100 µg/L and 1 µg/L), October 1992 (130 µg/L and 1 µg/L), and February 1993 (100 µg/L and 1 µg/L). Assuming a heterogeneous mixture of dissolved VOCs in the karst network at shallow depths in the Maynardville Limestone, it is unclear why the concentrations of TCE and PCE do not exhibit concurrent temporal fluctuations. Perhaps the TCE and PCE (and other VOCs) are not well mixed in the groundwater system, but instead occur within separate, discreet transport pathways that are intercepted by the monitored interval in the well. The divergent concentration trends also may reflect differential transport from separate source areas, with decreased flux from the source of TCE (Rust Spoil Area) and comparably more consistent flux of PCE from another upgradient source (e.g., Spoil Area I). Also, the TCE concentrations show a fairly consistent relationship with seasonal groundwater flow conditions, with "peak" concentrations typically evident during seasonally low-flow conditions (summer and fall) and low concentrations evident during seasonally high flow conditions. This relationship suggests that the concentrations of TCE in the groundwater flow/transport pathways intercepted by the monitored interval in this well are influenced by the inflow of uncontaminated (or less TCE-contaminated) recharge during seasonally (and episodically) high flow conditions. Conversely, the concentrations of other VOCs (PCE) do not show any similar apparent correlation with seasonal flow conditions, which again suggests separate sources of the VOCs detected in the groundwater samples from this well.

A time-series plot of TCE concentrations detected in the groundwater samples collected to date incorporates the previously noted gaps in the sampling history for the well and shows a clearly decreasing long-term concentration trend (Figure 2). The overall decrease in TCE levels probably reflects the reduced flux of VOCs in the Maynardville Limestone following the closure/capping of the former S-3 Ponds and long-term natural attenuation of the VOC sources at Spoil Area I and the Rust Spoil Area, both of which were closed without further remedial action (e.g., waste removal or installation of low-permeability cap). Indeed, reduced flux of TCE (and other VOCs) in response to the closure capping of the former S-3 Ponds may account for the approximately 50% concentration decrease evident during the late 1980s and early 1990s. Since then, the rate of concentration decrease appears to have slowed and to be largely controlled by the relative rate of various natural attenuation processes, including the apparent cyclic inflow of uncontaminated (or less-contaminated) recharge.

5.4 GROSS ALPHA ACTIVITY

Six groundwater samples collected since February 1991 had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (5.66 pCi/L in August 1992) being below the MCL for gross alpha activity (15 pCi/L). None of the samples collected since August 1995 had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

Twenty groundwater samples collected since February 1991 had gross beta activity above the applicable MDA and corresponding CE, with the highest value (43.7 pCi/L in March 1995) being below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). None of the samples collected since July 1998 had gross beta activity above the applicable MDA and corresponding CE.

WELL GW-066

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in March 1984, completed with a screened monitored interval from 50 to 54.9 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is paired with a shallower well (GW-067) and is located in Bear Creek Valley (BCV) next to the main channel of Bear Creek immediately south of the Oil Landfarm waste management area (WMA), approximately one mile west of Y-12. This WMA encompasses the Oil Landfarm (the only RCRA-regulated site in the WMA), the former Boneyard/Burnyard (BYBY) and Hazardous Chemical Disposal Area (HCDA), and Sanitary Landfill I. All of these facilities are closed, with the Oil Landfarm covered by a low-permeability cap installed during RCRA closure of the site in 1989, and subsurface wastes removed from the BYBY and HCDA during CERCLA remedial actions completed in 2003.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Five groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain one sample in September 1995, and the low-flow sampling method used to obtain four samples between March 2002 and September 2005.

Unusually low levels of TDS (<150 mg/L) are a distinguishing characteristic of the groundwater samples from this well (see Section 4.0). Low TDS levels suggest relatively low residence time for the groundwater, which indicates that the monitored interval for the well intercepts highly permeable groundwater flowpaths. However, TDS concentrations were significantly higher (>500 mg/L) in the groundwater samples collected from the well before August 2002. The low TDS levels in the samples collected in March and September 2005 may reflect CERCLA remedial actions at the BYBY, completed in May 2003.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maynardville Limestone (Conasauga Group), which trends northeast-southwest along the axis of BCV, dips southeast at an angle of 45º - 55º, and underlies the main channel of Bear Creek. The Maynardville Limestone exhibits the hydrologic characteristics typical of karst aquifers, with most of the groundwater flow occurring at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (shallow karst network). Hydrologic interaction between Bear Creek and the shallow karst network provides the principal exit-pathway for contaminants released from source areas within the Bear Creek watershed west of Y-12. Deeper in the subsurface, below the shallow karst network, fractures provide the primary groundwater flowpaths, and the bulk permeability generally decreases with depth because of decreased fracture aperture and increased fracture spacing (Solomon et. al. 1992). Also, distinct lithologic and hydrologic characteristics differentiate seven hydrostratigraphic zones (numbered from bottom to top) in the Maynardville Limestone (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

The static water level in the well occurs at an average depth of about 9 ft bgs and exhibits maximum seasonal fluctuations of approximately 4 ft. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-066 indicate westerly local flow directions, parallel with the direction of geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the unfiltered groundwater samples collected to date show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 107 – 582 mg/L (107 and 142 mg/L in March and September 2005);
- pH of 6.72 – 7.38 (field measurements);
- low molar proportions of chloride, sulfate, potassium, and sodium (<10% of total anions/cations);
- elevated concentrations (> 2 mg/L) of aluminum and iron, most likely reflecting the elevated suspended solid concentration (e.g., 82 mg/L in March 2005); and
- total concentrations of other trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Three groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (7.4 mg/L in September 1995) being below the drinking water MCL for nitrate (10 mg/L). Although below the MCL, these nitrate concentrations substantially exceed background levels (<0.028 mg/L) in uncontaminated groundwater in BCV, and indicate that the monitored interval in the well intercepts water-producing features that are hydraulically connected with the heterogeneous plume of inorganic, organic, and radiological contaminants originating from the former S-3 Ponds. Located hydraulically upgradient approximately 3,400 ft east-northeast of the well, these unlined surface impoundments received several million gallons of nitric-acid wastes generated at Y-12 between 1951 and 1984, and were filled and covered with a low-permeability cap during RCRA closure of the site in 1989. Nitrate is a principal component of the contaminant plume, is chemically stable and highly mobile in groundwater, and is believed to effectively delineate the primary groundwater flow/contaminant transport pathways in the Maynardville Limestone (DOE 1997).

5.2 URANIUM

Four groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.0097 mg/L in September 1995) being below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected to date (Table 2): PCE, TCE, 12DCE (c12DCE), 11DCE, and 11DCA. The presence of VOCs in the samples indicates that the monitored interval in the well intercepts groundwater flow/transport pathways for VOCs released from one or more upgradient sources that contribute to an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. Available data for the network of wells completed in the Maynardville Limestone west of the flow divide indicate that VOC-contaminated groundwater, as defined by individual or summed VOC concentrations above 5 µg/L, appears to originate near Spoil Area I and to extend hydraulically downgradient for several thousand feet westward (parallel with geologic strike) down the axis of BCV. The apparent distribution of VOCs within the plume reflects the relative influx from multiple source areas, commingling during downgradient groundwater transport, and hydraulic communication with Bear Creek (DOE 1997). In the upper part of BCV, hydraulically upgradient (east-northeast) of the well, the primary VOCs are TCE, c12DCE, and PCE and the confirmed or suspected source areas include Spoil Area I, the contaminant plume emplaced during historical operation of the former S-3 Ponds, and the Rust Spoil Area (or nearby source within the Bear Creek floodplain), the latter site considered a primary source of TCE.

As shown in the following data summary, only fairly low concentrations of VOCs have been detected in the groundwater samples collected to date, and no VOCs were detected in the samples collected most recently (March and September 2005).

Sampling Date	**VOC (µg/L)**					
	PCE	**TCE**	**12DCE**	**c12DCE**	**11DCE**	**11DCA**
09/27/95	21	12	3 J	NR	2 J	1 J
03/25/02	8	5 J	2 J	2 J	.	.
08/13/02	6	4 J	.	.	.	.
03/14/05	.	.	.	.	.	.
09/06/05	.	.	.	.	.	.
MCL	**5**	**5**	**NA**	**70**	**7**	**NA**
Note: "." = Not detected; J = Estimated value; NA = Not applicable; NR = Not reported						

These results suggest that VOCs have been flushed from the groundwater flow/transport pathways intercepted by the monitored interval in the well. This may be a direct consequence of the CERCLA remedial actions ant the BYBY and HCDA, which involved construction of an upgradient subsurface drain to hydraulically isolate the buried wastes; excavation, disposal, and consolidation of wastes above and below the saturated zone; and the reconstruction of a northern tributary of Bear Creek (NT-3) that drains the site.

5.4 GROSS ALPHA ACTIVITY

Four groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (7.4 pCi/L in March 2002) being below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Two groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, with the highest value (13.6 pCi/L in September 1995) being below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-068

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in March 1984, completed with a screened monitored interval from 70 to 83.6 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley (BCV) immediately south of the central part of the Bear Creek Burial Grounds (BCBG) waste management area (WMA). The BCBG includes numerous hazardous and nonhazardous waste disposal units that received a mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. Liquid wastes included oils, machine coolants, and borax waste water, all or most of which may have contained varying amounts of radioisotopes (primarily uranium isotopes). In 1989, most of the waste-disposal units in the BCBG waste-management area were covered with multi-layer, low-permeability caps installed during RCRA closure of the site.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Ten groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain eight samples between March 1987 and March 1990, and the low-flow sampling method used to obtain samples in June 2005 and October 2005. This sampling history includes an extended period (15 years) when no groundwater samples were collected from the well.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Nolichucky Shale (Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within this highly permeable zone, which occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek that traverse the Nolichucky Shale and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that stratigraphically overlies the Nolichucky Shale and subcrops along the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 6 ft bgs and exhibits seasonal fluctuations of about 2 ft. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-068 indicate flow to the south and southwest toward the Maynardville Limestone and the main channel of Bear Creek. However, groundwater flow in the Nolichucky Shale is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Consequently, the direction(s) of groundwater flow in the vicinity of well GW-068 may be primarily westward (parallel with geologic strike) toward discharge areas in NT-7 (located about 275 ft west of the well).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 322 – 350 mg/L;
- pH of 7.5 – 8 (field measurements);
- low molar proportions of sodium, potassium, chloride and sulfate (<10% of total anions/cations);
- slightly elevated (>0.015 mg/L) lead concentrations; and
- total concentrations of other trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Four of the groundwater samples collected to date had nitrate concentrations above the analytical reporting, with the highest value (1.22 mg/L) being substantially below the MCL (10 mg/L). Notably, nitrate concentrations have remained below reporting limits in all of the groundwater samples collected from the well since August 1989.

5.2 URANIUM

Four of the groundwater samples collected to date had uranium concentrations above the analytical reporting, with the highest value (0.003 mg/L) being an order of magnitude below the MCL for uranium (0.03 mg/L). As with nitrate, the uranium concentrations have remained below reporting limits in all of the groundwater samples collected from the well since August 1989.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples (Table 2): PCE, TCE, 12DCE, 11DCE, VC, 111TCA, 12DCA, 11DCA, chloroethane, chloroform, MC, acetone, benzene, toluene, total xylene, 2-hexanone, 4-methyl-2-pentanone (4M2P), and CTET. Waste disposal sites within Burial Ground-A (North and South), which received about two million gallons of waste oils and coolants, are the most likely source of the dissolved VOCs in the shallow groundwater at this well and the DNAPL encountered more than 300 ft bgs in wells located south (down-dip) of BG-A South (DOE 1997).

The primary compounds in the groundwater samples are PCE, TCE, 12DCE, 11DCE, VC, and 11DCA, which have been detected in every sample and have respective historical maximum concentrations that exceed 100 µg/L (Table 1). Secondary compounds in the samples are 111TCA, chloroform, and benzene, which have historical maximum concentrations above 30 µg/L. The most recent results (June and October 2005) show that TCE, c12DCE, 11DCE, VC, and benzene concentrations continue to exceed the respective MCLs (Table 1).

The presence of benzene is a distinguishing characteristic of the VOC data for this well. A review of historical data indicates that elevated benzene results have been consistently reported for wells located in areas of Y-12 known to be impacted by historical releases from petroleum fuel underground storage tanks (USTs) and located near the BCBG WMA. Excluding the wells located near USTs, groundwater samples from the following wells at the BCBG WMA had benzene concentrations that exceeded the drinking water MCL (5 µg/L).

Well No.	Depth (ft bgs)	Benzene Concentration (µg/L) / Sampling Date			
		Maximum		Most Recent	
GW-014	13.2	180	11/05/87	4	10/19/05
GW-046	20.3	240	07/09/03	72	07/07/05
GW-068	83.6	51	10/18/05	51	10/18/05
GW-071	219	1,300	06/30/05	1,200	10/20/05
GW-082	34.4	99	08/07/03	ND	10/13/05
GW-117	530	6	11/13/87	ND	09/17/92
GW-118	575	67	11/19/88	1	10/10/93
GW-119	510	20	07/06/88	ND	09/17/92
GW-624	27.2	33	07/15/98	25	10/12/05

Of these, well GW-082 is located on the southwest side of Burial Grounds C-West, and all of the remaining wells are located near Burial Ground A-South: wells GW-014, GW-071, and GW-119 along the eastern boundary; wells GW-117 and GW-118 along the southern boundary; and wells GW-046, GW-068, and GW-624 near the western boundary. Note also the wide range in the total depth of these wells, particularly wells GW-117, GW-118, and GW-119, each of which is artesian. The apparent “clustering” of these wells suggest that benzene is a distinguishing component of the groundwater plume of dissolved VOCs originating from the waste disposal trenches in Burial Ground-A South.

Some of the VOCs in the groundwater samples, particularly c12DCE and VC, are probably present in the groundwater as a consequence of the biotic degradation of PCE and TCE. Also, the dissolved petroleum hydrocarbons (e.g., benzene) in the groundwater may serve as electron donors for biologically mediated dechlorination of PCE and related compounds (Chapelle 1996). However, some of the geochemical characteristics of the groundwater in the well (e.g., iron and dissolved oxygen levels) are not especially conducive to anaerobic biotic degradation (Table 2). Perhaps the monitored interval in the well intercepts groundwater flowpaths that transport dissolved VOCs from source areas where biotic degradation primarily occurs, toward the natural discharge areas for the shallow flow system (i.e., NT-7 that traverses the BCBG WMA).

A time-series plot of the summed VOC concentrations shows a variable and overall indeterminate long-term trend that encompasses the 15-year (March 1990 – June 2005) gap in the sampling history for the well (Figure 1). Notably, concentrations of PCE and TCE have decreased significantly since March 1990, while concentrations of their degradation products (12DCE and VC) show a significant increase (Table 1). These divergent trends provide additional evidence that biotic degradation of PCE and TCE is ongoing, possibly at areas located upgradient of the well.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected since March 1990 had gross alpha activity above the applicable MDA and corresponding CE. Results obtained before January 1990 do not meet applicable data quality objectives because the sample specific MDA and/or CE are not available for these samples.

5.5 GROSS BETA ACTIVITY

Two of the groundwater samples collected since March 1990 had gross beta activity above the applicable MDA and corresponding CE, with the maximum value (11 pCi/L in October 2005) being substantially less than the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). Results obtained before January 1990 do not meet applicable data quality objectives because the sample specific MDA and/or CE are not available for these samples.

WELL GW-071

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in March 1984, completed with a screened monitored interval from 195 to 219 ft bgs, and constructed with nominal 2.5-inch stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-072 and is located immediately south of the eastern part of the Bear Creek Burial Grounds (BCBG) waste management area. The BCBG includes numerous hazardous and nonhazardous waste disposal units that received a mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. Liquid wastes included oils, machine coolants, and borax waste water, all or most of which may have contained varying amounts of radioisotopes (primarily uranium isotopes). In 1989, most of the waste-disposal units in the BCBG waste management area were covered with multi-layer, low-permeability caps installed during RCRA closure of the site.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Nineteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 13 samples between March 1987 and June 1991, and the low-flow sampling method used to obtain six samples between March 2002 and October 2005. The sampling history includes both quarterly and semiannual sampling frequencies and encompasses an extended period (June 1991 – March 2002) when samples were not collected from the well.

In June 2005, it was determined that the intake for the dedicated sampling pump (Well Wizard™) in the well was at a depth of 133 ft bgs, which is approximately 60 ft above the top of the monitored interval in the well (195 ft bgs). New tubing was used to extend the pump intake to a depth nearer the midpoint of the monitored interval (207 ft bgs), with the samples collected in June and October 2005 being the first obtained with the intake at the new location. Previous groundwater samples collected when the pump intake was so far from the water-producing features intercepted by the monitored interval seem likely to have included "stagnant" water from inside the well casing, particularly the samples collected with the low-flow sampling method. This sampling method involves purging the well at a flow rate that this low enough to (<300 milliliters per minute) to minimize drawdown of the water level in the well (<0.1 ft per quarter hour). At five minute intervals after the water-level drawdown has stabilized, field personnel record measurements of selected indicator parameters (e.g., pH). Groundwater samples are collected once the field measurements for each parameter show minimal variation over four consecutive readings. In contrast, under the conventional sampling method, groundwater samples are collected after at least three well volumes of groundwater have been purged from the well at a pumping rate which may substantially lower the water level in the well. Although the conventional sampling method is more likely than the low-flow method to have induced inflow of groundwater from the water producing feature(s) intercepted by the monitored interval, the samples obtained with this method when the pump intake was 60 ft above the monitored interval also probably included the water from inside the well casing.

Historical data obtained before June 2005 (i.e., when the sampling pump intake was not within the monitored interval) show that the groundwater in the well contains a diverse mixture of chlorinated hydrocarbons and petroleum hydrocarbons. However, as illustrated by the respective maximum concentrations of VOCs detected in samples collected in March/August 2004 and in June/October 2005, summarized below, substantially higher concentrations of most VOCs were detected in the samples obtained after the sampling pump intake was extended to the monitored interval. These findings suggest that all the VOC results obtained may not be representative of the actual concentrations in the groundwater outside the well casing.

COMPOUND	VOC CONCENTRATION (µg/L)		% DIFFERENCE
	2004 Maximum	2005 Maximum	
PCE	540	950	43%
TCE	74	120	38%

Freon-113	190	390	51%

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the Nolichucky Shale (the Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within the water table interval, which is a highly permeable zone that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek that traverse the Nolichucky Shale and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that statigraphically overlies the Nolichucky Shale and subcrops along the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 5 ft bgs and exhibits minor seasonal fluctuations (<4 ft). The shallow depth of the static water level in this well suggests nearly artesian flow conditions, which are evident in other wells that intercept the semi-confined groundwater flow/transport pathways at depth in the low-permeability shale formations of the Conasauga Group in BCV. Moreover, measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in well GW-071 are typically higher than evident in well GW-072, which is completed at a shallower depth (101 ft bgs) in the Nolichucky Shale. Based on the distance between the monitored interval midpoint (elevation) in each well (116.6 ft), the contemporaneous groundwater elevations indicate upward vertical hydraulic gradients (0.012 – 0.016) from the deeper bedrock interval (GW-071) to the shallow bedrock interval (GW-072).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for groundwater samples collected in June and October 2005 show that the well yields sodium-bicarbonate groundwater generally characterized by:

- TDS of 842 – 970 mg/L;
- pH of 10.1 – 11.5 (field measurements);
- elevated concentrations of chloride (>35 mg/L) compared to other wells completed at similar depths in the Nolichucky Shale;
- low molar proportions of calcium, magnesium, potassium and sulfate (<5% of total anions/cations); and
- total concentrations of other trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

These geochemical characteristics reflect the decrease in groundwater flux that occurs with depth in the low-permeability Conasauga Group formations (e.g., Nolichucky Shale) in BCV (Solomon et al. 1992). Most of the water table and shallow (i.e., <100 ft bgs) bedrock wells in these formations yield calcium-magnesium-bicarbonate groundwater. A fairly abrupt change to sodium-bicarbonate groundwater occurs at a depth of about 100 ft bgs and is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture or increased fracture spacing (Solomon et al. 1992). Further reduced groundwater flux deeper in the bedrock is indicated by a general increase in TDS and a gradational transition from sodium-bicarbonate groundwater to sodium-chloride groundwater.

Considering the upward hydraulic gradients noted in Section 3.0, the elevated levels of chloride in the groundwater at this well potentially reflects upward movement of chloride from the more chloride-enriched groundwater deeper in the bedrock. Also, the elevated chloride levels may be at least partially attributable to the biologically-mediated degradation of chlorinated hydrocarbons in the groundwater (see Section 5.3), which often results in the accumulation of inorganic chloride (Hinchee et al. 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As noted in Section 2.0, the sampling results obtained since June 2005 are considered to be most representative of the groundwater in the well. Accordingly, the following sections are based on these results, which show that VOCs are the principal contaminants present in the groundwater.

5.1 NITRATE

Nitrate was not detected in the groundwater samples collected in June and October 2005.

5.2 URANIUM

The uranium concentration reported for the groundwater sample collected in October 2005 (0.00054 mg/L) slightly exceeds the analytical reporting limit but is several orders of magnitude below the drinking water MCL (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Because the intake of the pump was located above the monitored interval of the well until June 2005, historical VOC data (1987 – 2004) is considered qualitative. These results are presented in

Table 1 for comparison purposes; however the following discussion is based on the most recent and most representative data available.

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected in June and October 2005 (Table 2): acetone, benzene, chloroethane, CTET, ethylbenzene, PCE, TCE, toluene, VC, total xylene, 11DCA, 11DCE, c12DCE, t12DCE, 111TCA, dichlorofluoromethane (DCFM), and 1,1,2-trichloro-1,2,2-trifluoroethane, which is also known as Freon-113 (F113). Waste disposal areas within Burial Ground A (North and South), which received about two million gallons of waste oils and coolants, are the most likely source of the plume of dissolved VOCs in the shallow groundwater at this well (DOE 1997). Waste disposal trenches in Burial Ground A-South also are the suspected source of DNAPL (primarily PCE and TCE) that was encountered at more than 300 ft bgs in a well installed directly south (down-dip) the area (Haase and King 1990). Thus, with DNAPL documented to be present at depth in the bedrock and, as noted in Section 4.0, the upward hydraulic gradients, it is possible that the presence of VOCs in the groundwater at this well reflects the upward migration of the parent compounds (and related degradation products) from DNAPL deeper in the bedrock.

Based on concentration magnitude, the primary VOCs detected in the groundwater samples are benzene, PCE, 11DCA, and 111TCA, each of which has a maximum concentration above 500 µg/L, with the most recent sampling results showing benzene and 11DCA concentrations remain above 1,000 µg/L (Table 2). The results also show that PCE, 111TCA, and benzene concentrations are above applicable drinking water MCLs (11DCA does not have an MCL). Secondary compounds detected n the samples are TCE, 11DCE, and F113, which have maximum concentrations 100 µg/L, and the sampling results show that TCE and 11DCE levels are several orders of magnitude above the drinking water MCLs (5 µg/L and 7 µg/L, respectively). Although the remaining compounds have been detected less frequently and/or at substantially lower levels, with maximum concentrations below 50 µg/L evident for all compounds except DCFM (58 µg/L), the most recent sampling results show that concentrations of CTET and VC exceed respective MCLs (5 µg/L and 2 µg/L).

Many of the VOCs detected in the groundwater samples are probably present in the groundwater as a consequence of biotic degradation (sequential dechlorination) of related parent compounds. Results for pertinent indicator parameters, especially the strongly negative REDOX, suggest that the geochemical conditions in the groundwater at this well are conducive to biotic degradation of chlorinated hydrocarbons (Table 3). Also, the dissolved petroleum hydrocarbons in the groundwater may serve as electron donors for biotic dechlorination (Chapelle 1996). Considering the upward vertical gradients noted in Section 4.0, the high levels of some degradation products, notably 11DCA, may indicate upward migration from the source(s) of related parent compounds deeper in the subsurface.

The groundwater samples from this well, including samples collected before the sampling pump intake was moved into the monitored interval for the well, are distinguished by the very high benzene concentrations. Indeed, groundwater samples with similar levels of benzene (i.e., >1,000 µg/L) were collected only from wells located in areas of Y-12 known to be impacted by historical releases from petroleum fuel underground storage tanks (USTs). Moreover, a review of the historical data indicate that, excluding benzene results for wells located at UST sites and results for other wells (and springs) that are obvious outliers compared to available data for the sampling location, benzene concentrations above the drinking water MCL (5 µg/L) have been reported only for groundwater samples from the following wells, which are all located near the BCBG WMA.

Well No.	Depth (ft bgs)	Benzene Concentration (µg/L) / Sampling Date			
		Maximum		Most Recent	
GW-014	13.2	180	11/05/87	4	10/19/05
GW-046	20.3	240	07/09/03	72	07/07/05
GW-068	83.6	51	10/18/05	51	10/18/05
GW-071	219	1,300	06/30/05	1,200	10/20/05
GW-082	34.4	99	08/07/03	ND	10/13/05
GW-117	530	6	11/13/87	ND	09/17/92
GW-118	575	67	11/19/88	1	10/10/93
GW-119	510	20	07/06/88	ND	09/17/92
GW-624	27.2	33	07/15/98	25	10/12/05

Of these, well GW-082 is located on the southwest side of Burial Ground C-West, and all of the remaining wells are located near Burial Ground A-South: wells GW-014, GW-071, and GW-119 along the eastern boundary; wells GW-117 and GW-118 on the southern boundary; and wells GW-046, GW-068, and GW-624 near the western boundary. Note the wide range in the total depth of these wells, particularly wells GW-117, GW-118, and GW-119, each of which is artesian. The apparent "clustering" of these wells suggest that benzene is a distinguishing component of the groundwater plume of dissolved VOCs originating from the waste disposal trenches in Burial Ground-A South.

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity above the MDA was reported for the groundwater sample collected in October 2005 and this result (10 pCi/L in June 1991) is below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

None of the groundwater samples (June or October 2005) had gross beta activity above the applicable MDA and corresponding CE.

WELL GW-072

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in March 1984, completed with a screened monitored interval from 84.5 to 98.4 ft bgs, and constructed with nominal 2.5-inch stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-071, which is completed at a greater depth (219 ft bgs), and is located immediately south of the eastern part of the Bear Creek Burial Grounds (BCBG) waste management area. The BCBG includes numerous hazardous and nonhazardous waste disposal units that received a mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. Liquid wastes included oils, machine coolants, and borax waste water, all or most of which may have contained varying amounts of radioisotopes (primarily uranium isotopes). In 1989, most of the waste-disposal units in the BCBG waste management area were covered with multi-layer, low-permeability caps installed during RCRA closure of the site.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Nineteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 15 samples between March 1987 and October 2005, and the low-flow sampling method used to obtain four samples between March 2002 and October 2005. The sampling history includes both quarterly and semiannual sampling frequencies and encompasses an extended period (June 1991 – March 2002) when samples were not collected from the well.

An evaluation of the monitoring data available through December 2004 indicated potential bias related to the groundwater sampling method. However, it was not clear if the change in sampling method explained the apparent increase in VOC concentrations or if the higher concentrations are the result of a corresponding increase in the relative flux of VOCs along the flowpaths intercepted by the monitored interval in the well. Results of "paired" sampling performed during June and October 2005, when groundwater samples were collected with the low-flow sampling method one day and the conventional sampling method the next day, apparently confirm the sampling-method bias. As shown by the data summarized in Table 1, there is no distinct difference between the low-flow sampling and conventional sampling results for various geochemical parameters (e.g., pH) or inorganic analytes (e.g., chloride), but the samples obtained with the conventional sampling method had substantially higher summed VOC concentrations than the samples obtained with the low-flow method.

Inherent differences in the manner in which each sampling method induces inflow of groundwater into the well may explain the disparity between the conventional and low-flow sampling results for VOCs. Conventional sampling involves purging up to three well volumes of groundwater from the well at about 1-2 gallons per minute, which may substantially lower the water level in the well and induce inflow from water-producing features (i.e., fractures, cavities, conduits) that may not contribute to well recharge under normal conditions. In contrast, low-flow sampling involves purging the well at flow rate low enough (<300 milliliters per minute) to ensure minimal water-level drawdown in the well (<1 ft per quarter hour), which induces groundwater inflow only from the water-producing feature(s) proximal to the monitored interval. Thus, the conventional sampling method may induce greater inflow of VOC-contaminated groundwater than does the low-flow sampling method.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow (<100 ft bgs) bedrock interval in the Nolichucky Shale (the Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within the water table interval, which is a highly permeable zone that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek that traverse the Nolichucky Shale and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that statigraphically overlies the Nolichucky Shale and subcrops along the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 8 ft bgs and exhibits minor seasonal fluctuations (<4 ft). Depth-to-water measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in well GW-072 are typically lower than evident in well GW-071, which is completed at a greater depth (219 ft bgs) in the Nolichucky Shale. Based on the distance between the monitored interval midpoint (elevation) in each well (116.6 ft), the contemporaneous groundwater elevations indicate upward vertical hydraulic gradients (0.012 – 0.016) from the deeper bedrock interval (GW-071) to the shallow bedrock interval (GW-072).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples collected to date show that the well yields chloride-enriched, sodium-bicarbonate groundwater generally characterized by:

- TDS of 238 – 309 mg/L;
- pH (field measurements) of 9.47 – 10.9;
- elevated concentrations of chloride (>30 mg/L) compared to other wells completed at similar depths in the Nolichucky Shale;
- very low molar proportions of calcium, magnesium, potassium and sulfate (<5% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

These geochemical characteristics reflect the decrease in groundwater flux that occurs with depth in the low-permeability Conasauga Group formations (e.g., Nolichucky Shale) in BCV (Solomon et al. 1992). Most of the water table and shallow (i.e., <100 ft bgs) bedrock wells in these formations yield calcium-magnesium-bicarbonate groundwater. A fairly abrupt change to sodium-bicarbonate groundwater occurs at a depth of about 100 ft bgs and is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture or increased fracture spacing (Solomon et al. 1992). Further reduced groundwater flux deeper in the bedrock is indicated by a general increase in TDS and a gradational transition from sodium-bicarbonate groundwater to sodium-chloride groundwater.

Considering the upward vertical gradients noted in Section 4.0, upwelling of chloride-enriched groundwater from deeper in the flow system possibly explains the elevated chloride levels in the shallower groundwater at this well. Also, the elevated chloride levels may be at least partially attributable to the biologically-mediated degradation of chlorinated hydrocarbons in the groundwater (see Section 5.3), which often results in the accumulation of inorganic chloride (Hinchee et al. 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Two of the groundwater samples collected to date had a nitrate concentration above the applicable analytical reporting limit, and the highest result (0.17 mg/L in June 1987) is substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Two of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, and these results (0.001 mg/L in November 1987 and June 1988) are substantially below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected to date (Table 2): acetone, benzene, chloroethane, chloroform, MC, PCE, toluene, VC, xylenes, 111TCA, 11DCA, 11DCE, and c12DCE. Waste disposal areas within Burial Ground A (North and South), which received about two million gallons of waste oils and coolants, are the most likely source of the plume of dissolved VOCs in the shallow groundwater at this well (DOE 1997). Waste disposal trenches in Burial Ground A-South also are the suspected source of DNAPL (primarily PCE and TCE) that was encountered more than 300 ft bgs in a well installed directly south (down-dip) the area (Haase and King 1990).

The primary VOC in the groundwater samples is 11DCA, which has been detected in all but three of the samples collected to date, and has substantially higher concentrations than all other VOCs detected in the samples (Table 2). The next most frequently detected compounds are MC (detected in 11 samples with a maximum concentration of 6 µg/L in November 1987), 11DCE and 12DCE (both detected in six samples, including each of the samples obtained since March 2002). The most recent sampling results show that the concentrations of 11DCE and VC, which was detected only in samples obtained since June 2005, exceed drinking water MCLs (7 µg/L and 2 µg/L, respectively).

As noted in Section 2.0, preliminary indications that VOC concentrations potentially may be biased by the groundwater sampling method are confirmed by the results of “paired” sampling performed in June and October 2005. This is illustrated by the VOC results summarized below, which show substantially higher 11DCA and 11DCE concentrations in samples obtained with the conventional sampling method, but similar concentrations for other compounds detected in samples obtained with either method. As noted in Section 2.0 the conventional sampling method may induce greater inflow of groundwater containing 11DCA than does the low-flow sampling method. However, it is not clear from the available data why the sampling method would significantly influence the concentrations of one compound and not another. Perhaps the VOCs do not extensively intermix in the groundwater, but are separated in discrete flowpaths and become mixed in the well, with the higher concentrations of 11DCA indicating greater inflow from more permeable and/or numerous flowpaths relative to inflow from the flowpaths that contain other VOCs. Also, there may be multiple subsurface sources of the VOCs in the groundwater at this well, and the conventional sampling method may induce greater proportional inflow from the water-producing feature(s) connected to a VOC source dominated by 11DCA.

VOC	Concentration (µg/L)			
	Low-Flow Sampling June 20, 2005	**Conventional Sampling June 21, 2005**	**Low-Flow Sampling October 18, 2005**	**Conventional Sampling October 19, 2005**
PCE	2 J	.	.	.
c12DCE	2 J	5	4 J	10
11DCE	4 J	13	14	23
VC	.	2	2	3
11DCA	75	180	160	350
Chloroethane	1 J	4 J	4 J	6
MC	.	2 J	.	3 J
Benzene	.	1 J	.	2 J

Note: "." = Not detected; J = Estimated value below laboratory reporting limit

Most of the VOCs detected in the groundwater samples are probably present in the groundwater as a consequence of biotic degradation (sequential dechlorination) of related parent compounds. Results for pertinent indicator parameters, especially the strongly negative REDOX, suggest that the geochemical conditions in the groundwater at this well are conducive to biotic degradation of chlorinated hydrocarbons (Table 3), which may explain the relative lack of PCE and 111TCA in the samples relative to their respective degradation products (e.g., 11DCE and 11DCA). Also, the dissolved petroleum hydrocarbons (benzene) in the groundwater may serve as electron donors for biotic dechlorination (Chapelle 1996). Considering the upward vertical gradients noted in Section 4.0, the predominance of degradation products in the shallower groundwater at this well may indicate upward migration from the source(s) of related parent compounds deeper in the subsurface.

As indicated by the preceding discussion, 11DCA dominates the suite of VOCs detected in the groundwater samples, and a time-series plot of the 11DCA results shows a clearly increasing long-term trend (Figure 1), as illustrated by the initial concentration of 6 µg/L in November 1991 and the most recent (conventional sampling) concentration of 350 µg/L in October 2005. Increasing concentration trends are not evident for the other VOCs detected in the groundwater samples, as illustrated by the time-series plot of MC concentrations (Figure 1). All other factors being equal, such divergent trends for individual compounds again suggests that there may be multiple sources of the VOCs in the groundwater flow/transport pathways intercepted by the monitored interval in the well. It also appears that there has been little if any long-term change in the relative flux from the source(s) of some VOCs concurrent, but a substantial increase in the relative flux from the source(s) of 11DCA.

5.4 GROSS ALPHA ACTIVITY

Four of the groundwater samples collected since January 1990 had gross alpha activity above the applicable MDA and corresponding CE, and the highest result (3.66 pCi/L in September 1990) is substantially below the drinking water MCL for gross alpha activity (15 pCi/L). Results obtained before January 1990 do not meet applicable data quality objectives because the sample specific MDA and/or CE are not available for these samples.

5.5 GROSS BETA ACTIVITY

Four of the groundwater samples collected since January 1990 had gross beta activity above the applicable MDA and corresponding CE, with the maximum value (5.7 pCi/L in February 1990) being substantially less than the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). Results obtained before January 1990 do not meet applicable data quality objectives because the sample specific MDA and/or CE are not available for these samples.

WELL GW-077

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in March 1984, completed with a screened monitored interval from 87.4 to 100.3 ft bgs, and constructed with nominal 2.37-inch outside diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-078 and is located on the southern flank of Pine Ridge west of Y-12, about 1,700 ft west of the Bear Creek Burial Grounds (BCBG) waste management area. The BCBG encompass several closed former hazardous waste disposal units, including numerous waste disposal trenches that received a diverse mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. The various components of the BCBG are covered by low-permeability, multilayer caps installed during RCRA closure of the site in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain six samples between June 1990 and April 1997, and the low-flow sampling method used to obtain fourteen samples between February 1998 and August 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the shallow bedrock interval (<100 ft bgs) in the Conasauga Group (Nolichucky Shale). Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 3 ft bgs and exhibits moderate fluctuations (<10 ft).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 168 – 257 mg/L;
- pH (field measurements) of 6.8 – 8.9;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for 17 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Eight groundwater samples had nitrate concentrations above the analytical reporting limit, with the highest concentration (3.3 mg/L in August 2000) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Only one uranium result reported for the sample collected in July 1998 (0.0097 mg/L) has exceeded the analytical reporting limits, and this result is substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected in three groundwater samples. Relatively low levels of 111TCA were detected in the samples collected in April 1997 (16 µg/L), February 1998 (9 µg/L), and July 1998 (4 µg/L); PCE also was detected in February 1998 (1 µg/L). Neither VOC was detected in subsequent samples.

5.4 GROSS ALPHA ACTIVITY

Gross alpha results reported for the samples collected in February 1998 (1.39 pCi/L) and August 2001 (2.02 pCi/L) exceed the applicable MDA and corresponding CE and are substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Seven groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (35.75 pCi/L in February 1998) being less than the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-078

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in March 1984, completed with a screened monitored interval from 11.7 to 21.1 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-077 and is located on the southern flank of Pine Ridge west of Y-12, about 1,700 ft west of the Bear Creek Burial Grounds (BCBG) waste management area. The BCBG encompass several closed former hazardous waste disposal units, including numerous waste disposal trenches that received a diverse mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. The various components of the BCBG are covered by low-permeability, multilayer caps installed during RCRA closure of the site in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain six samples between June 1990 and April 1997, and the low-flow sampling method used to obtain 14 samples between February 1998 and August 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the shallow bedrock interval (<100 ft bgs) in the Conasauga Group (Nolichucky Shale). Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 3 ft bgs and exhibits moderate seasonal fluctuations (<10 ft).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 144 – 249 mg/L;
- pH (field measurements) of 6.8 – 8.1;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for 17 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Five groundwater samples had nitrate concentrations above the analytical reporting limit, with the highest concentration (2.2 mg/L in August 2000) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Only the uranium concentration reported for the groundwater sample collected in July 1998 (0.0115 mg/L) exceeds the analytical reporting limit, and this result is below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected in only one groundwater sample: acetone was detected in the sample collected in July 1998 (5 µg/L). This result is probably a sampling or analytical artifact and is an outlier.

5.4 GROSS ALPHA ACTIVITY

Six groundwater samples had gross alpha activity above the MDA and corresponding CE, with the highest value (2.51 pCi/L in February 1991) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Six groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (13.13 pCi/L in February 1998) being less than the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-079

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in March 1984, completed with a screened monitored interval from 49.9 to 64.9 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-080 and is located on the southern flank of Pine Ridge west of Y-12, about 1,500 ft west of the northernmost section of the Bear Creek Burial Grounds (BCBG) waste management area. The BCBG encompass several closed former hazardous waste disposal units, including numerous waste disposal trenches that received a diverse mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. The various components of the BCBG are covered by low-permeability, multilayer caps installed during RCRA closure of the site in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-four groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 19 samples between May 1990 and September 1997, and the low-flow sampling method used to obtain 15 samples between February 1998 and August 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the shallow bedrock interval (<100 ft bgs) in the Conasauga Group (Rogersville Shale). Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 17 ft bgs and exhibits moderate seasonal fluctuations (<10 ft).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 100 – 202 mg/L;
- pH (field measurements) of 6.9 – 8.4;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for 30 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Six groundwater samples had nitrate concentrations above the analytical reporting limit, with the highest concentration (1.8 mg/L in August 2000) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Only the uranium concentration reported for the groundwater sample collected in August 2003 (0.00571 mg/L) exceeds the analytical reporting limit, and this result is substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for each groundwater sample show non-detect values or false positive results for all of the VOCs analyzed.

5.4 GROSS ALPHA ACTIVITY

Six groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (6.79 pCi/L in July 1996) being below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Ten groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (6.95 pCi/L in January 2001) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-080

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in March 1984, completed with a screened monitored interval from 20.8 to 29.7 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-079 on the southern flank of Pine Ridge west of Y-12, about 1,500 ft west of the northernmost section of the Bear Creek Burial Grounds (BCBG) waste management area. The BCBG encompass several closed former hazardous waste disposal units, including numerous waste disposal trenches, which are covered by low-permeability, mulitlayer caps installed during RCRA closure of the site in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-nine groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 24 samples between May 1990 and September 1997, and the low-flow sampling method used to obtain 15 samples between February 1998 and August 2004.

The well yields groundwater samples with low TDS (see Section 4.0), which suggests short groundwater residence time and indicates that the monitored interval in the well intercepts hydraulically active flowpaths.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the shallow bedrock interval in the Conasauga Group (Rogersville Shale). The average static groundwater level in the well is 19 ft bgs. Presampling depth-to-water measurements for the well indicate moderate fluctuations (<10 ft) in seasonal groundwater surface elevations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 68 – 182 mg/L;
- pH (field measurements) of 5.4 – 8.4;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations);
- unusually high total iron concentrations (>8 mg/L); and
- total (unfiltered sample) concentrations of trace metals (except iron) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion

5.1 NITRATE

Eight samples had nitrate concentrations above the analytical reporting limit. Aside from the nitrate concentration reported for the sample collected in February 1999 (431 mg/L), which is most likely a sampling or analytical artifact, the highest value (3 mg/L in August 2000) is substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Only the uranium concentration reported for the sample collected in June 1994 (0.001 mg/L) exceeds the analytical reporting limit, and this result is substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected in six of the 35 groundwater samples collected from the well since January 1991. A trace of 4-methyl-2-pentanone (1 μg/L) was detected in the groundwater sample collected in September 1991. Four consecutive groundwater samples had 111TCA: September 1997 (630 μg/L), February 1998 (30 μg/L), July 1998 (10 μg/L), and February 1999 (2 μg/L). The sample collected in September 1997 also contained a trace of PCE (0.9 μg/L). Aside from a trace of chloromethane (3 μg/L) detected in the sample collected in August 2000, VOCs have not been detected in the groundwater samples collected from the well since February 1999.

5.4 GROSS ALPHA ACTIVITY

Thirteen of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (4.64 pCi/L in March 1995) being below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Seventeen of the groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (40.33 pCi/L in July 1998) being slightly below the SDWA screening level for gross beta activity (50 pCi/L). However, this result is probably an outlier because the other gross beta results are much lower (11.9 pCi/L in July 1996 is the next highest).

WELL GW-082

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in March 1984, completed with a screened monitored interval from 24.1 to 34.4 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley (BCV) about halfway between the fork in a northern tributary of Bear Creek (NT-8) that drains the western and northwestern sections of Bear Creek Burial Grounds (BCBG) waste management area. The BCBG includes numerous former hazardous and nonhazardous waste disposal areas that received a diverse mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. Liquid wastes included oils, machine coolants, and borax waste water, all or most of which may have contained varying amounts of radioisotopes (primarily uranium isotopes). In 1989, most of the waste-disposal units in the BCBG waste-management area were covered with multi-layer, low-permeability caps installed during RCRA closure of the site.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-three groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 32 samples between March 1987 and August 2003, and the low-flow sampling method used to obtain 11 samples between June 1998 and August 2004.

An evaluation of the monitoring data available through August 2000 indicated potential bias related to the groundwater sampling method: (unfiltered) samples obtained with the conventional sampling method had substantially lower contaminant (VOC) concentrations than samples obtained with the low-flow sampling method (AJA 2001). Results of "paired sampling" performed during February and August 2003, when groundwater samples were collected with the low-flow sampling method one day and the conventional sampling method the next day, confirm a sampling-method bias. However, as shown by the data summarized in Table 1, the samples obtained with the conventional method have substantially higher VOC concentrations instead of substantially lower concentrations, as indicated by the study. The significant difference between the two sampling method results noted in the study probably reflects an increase in contaminant flux during the time period spanning the change in methods. Note that the groundwater samples obtained with each sampling method have similar geochemical characteristics (Table 1).

Inherent differences in the manner in which each sampling method induces inflow of groundwater into the well may explain the disparity between the conventional and low-flow sampling results for VOCs. Conventional sampling involves purging up to three well volumes of groundwater from the well at about 1-2 gallons per minute, which may substantially lower the water level in the well and induce inflow from water-producing features (i.e., fractures, cavities, conduits) that may not contribute to well recharge under normal conditions. In contrast, low-flow sampling involves purging the well at flow rate low enough (<300 milliliters per minute) to ensure minimal water-level drawdown in the well (<1 ft per quarter hour), which induces groundwater inflow only from the water-producing feature(s) proximal to the monitored interval. Thus, the conventional sampling method has much greater local hydrologic influence (particularly in directions parallel with geologic strike) and substantially increases the relative inflow of VOC-contaminated groundwater into the well.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maryville Limestone (Conasauga Group). The bulk of the groundwater flow in the Maryville Limestone occurs within a highly permeable zone (the water table interval) that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek that traverse the Maryville Limestone and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that stratigraphically overlies the Maryville Limestone and subcrops along the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 17 ft bgs and exhibits relatively minor (<2 ft) seasonal fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-082 indicate south and southwesterly flow down the southern flank of Pine Ridge. However, groundwater flow in the Nolichucky Shale is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Consequently, the direction(s) of groundwater flow in the vicinity of well GW-082 may be primarily westward (parallel with geologic strike) toward discharge areas in the upper reaches of a northern tributary of Bear Creek (NT-8) on the northwest boundary of the BCBG waste management area approximately 300 ft west of the well.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 178 – 822 mg/L, excluding suspected outliers in September 1990 (44 mg/L) and August 2003 (955 mg/L);
- pH of 5.0 – 7.9 (field measurements);
- chloride concentrations above 100 mg/L;
- low molar proportions of potassium, sulfate, and sodium (<10% of total anions/cations);
- unusually high concentrations of boron (>20 mg/L), barium (>1 mg/L), and manganese (>1 mg/L); and
- total concentrations of trace metals (except barium, boron, and manganese) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The unusually high chloride concentrations in the groundwater samples may reflect local geochemical conditions or contamination from inorganic wastes disposed in the BCBG. Additionally, the elevated chloride levels may be a consequence of the biologically mediated degradation (dechlorination) of the chlorinated hydrocarbons in the groundwater (Hinchee et al. 1995). As illustrated by the most recent sampling results summarized in Table 2, the geochemical characteristics of the groundwater (particularly the REDOX conditions) appear to be conducive to biotic degradation of VOCs (see Section 5.3).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the respective monitoring data reported for the groundwater samples collected from the well since January 1991, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Nitrate concentrations at or above the applicable reporting limit were detected in the groundwater samples collected in February 2001 (0.0726 mg/L) and December 2002 (0.0802 mg/L) and both of these results are substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Uranium concentrations at or above the applicable reporting limit were detected in the groundwater samples collected in June 1991 (0.001 mg/L), July 1998 (0.0109 mg/L), and February 2001 (0.00646 mg/L); these results reflect background levels that are substantially below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the each groundwater sample (Table 3): benzene, chloroethane, total xylene, PCE, TCE, VC, 11DCA, 11DCE, 12DCE (c12DCE), and 111TCA. These compounds are all components of a plume of dissolved VOCs in the shallow groundwater downgradient of the waste disposal sites within Burial Ground-C West, with mobile components of the plume being transported toward natural groundwater discharge areas in the northern tributaries of Bear Creek west of the BCBG (DOE 1997). Many of the compounds, particularly c12DCE and VC may be present as a direct consequence of the natural biotic degradation of related parent compounds (e.g., PCE and TCE) disposed in BG-C West. The geochemical characteristics of the groundwater appear to be conducive to biodegradation of chlorinated hydrocarbons (see Section 4.0), with the strongly negative REDOX conditions and low levels of dissolved oxygen (Table 2) suggesting the strongly reducing (methanogenic) conditions necessary to transform 12DCE isomers to VC (Chapelle 1996).

The primary compounds in the groundwater samples are 12DCE (c12DCE), 11DCA, and VC, with historical maximum concentrations exceeding 1,000 μg/L for 12DCE and 11DCA, and exceeding 100 μg/L for VC (Table 2). The initial detection of VC (December 1991) and 11DCA (April 1997) and subsequent increasing concentration of both VOCs suggests a staggered "breakthrough" of components of the dissolved VOC plume. Also, the most recent (low-flow sampling) results show that the concentrations of c12DCE and VC remain at least an order-of-magnitude above respective drinking water MCLs (Table 2). Secondary compounds in the groundwater samples are benzene, chloroethane, 11DCE, and 111TCA. Historical maximum concentrations for these VOCs are all less than 100 μg/L, with the most recent sampling results showing concentrations of none of these compounds are above applicable MCLs. In contrast to the primary and secondary VOCs in the samples, PCE, TCE, and total xylene have only been detected in one sample each and all these results are estimated values below 5 μg/L.

As noted in Section 2.0, results of "paired" sampling in CY 2003 show that the conventional sampling method obtains groundwater samples with substantially higher VOC concentrations than groundwater samples obtained with the low-flow sampling method. Conventional sampling may yield samples with higher VOC concentrations because the more aggressive purging (see Section 2.0) may induce greater flow of contaminated groundwater into the well from primary contaminant flowpaths that are further from the well. However, there are substantial differences between the conventional and low-flow sampling results for individual VOCs, with the largest concentration differences evident for 11DCA and the smallest differences evident for chloroethane (Table 4).

Respective time-series plots of summed VOC concentrations reported for samples obtained with the conventional sampling method and low-flow sampling method (Figure 1) suggest increasing long-term concentration trends. The conventional sampling results show summed VOC concentrations steadily increased from 71 μg/L in March 1991 to 263 μg/L in April 1997 and dropped to 163 μg/L in August 1997, with an order-of-magnitude concentration increase indicated by conventional sampling VOC results obtained in February 2003 (4,325 μg/L) and August 2003 (4,786 μg/L). The low-flow sampling data likewise indicate an order-of-magnitude increase in summed VOC concentrations between July 1998 (185 μg/L) and February 2002 (3,104 μg/L), followed by a generally decreasing trend through August 2004 (745 μg/L). Increases in the summed VOC concentrations indicated by both conventional and low-flow sampling data are primarily attributable to substantially higher concentrations of 12DCE and 11DCA (Table 3). These trends probably reflect an overall increase in the relative flux of these compounds in the groundwater flow/transport pathways intercepted by the monitored interval in the well. However, the recent decreasing trend suggests that a "pulse" of dissolved VOCs may have been intercepted by the monitored interval of the well.

5.4 GROSS ALPHA ACTIVITY

Two of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (4.75 pCi/L in December 1995) being substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Seven of the groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (7.9 pCi/L in August 2004) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-085

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during March 1984, completed with a screened monitored interval from 48.4 to 58.8 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-086 and is located in Bear Creek Valley (BCV) west of Y-12, on the east side of the Oil Landfarm waste management area (WMA), about 500 ft west of a northern tributary (NT) of Bear Creek (NT-2), several of which trend northeast-southwest across the southern flank of Pine Ridge west of Y-12 and are numbered in ascending order downstream from the headwaters of Bear Creek.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-eight groundwater samples have been collected from the well, with the conventional sampling method used to obtain 34 samples between November 1987 and September 1997 and the low-flow sampling method used to obtain 14 samples between March 1998 and August 2004.

Unusually high levels of TDS are a distinguishing characteristic of the groundwater samples from this well and are a direct consequence of contamination from the former S-3 Ponds (see Section 5.0.).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Nolichucky Shale (Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within a highly permeable zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek that traverse the Nolichucky Shale and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that stratigraphically overlies the Nolichucky Shale and subcrops along the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 10 ft bgs and exhibits seasonal fluctuations up to 5 ft. Also, measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in well GW-085 are typically higher than evident in well GW-086, which is completed at shallower depths (30 ft bgs) in the Nolichucky Shale. Based on the distance between the monitored interval midpoint (elevation) in each well (28 ft), the contemporaneous groundwater elevations indicate upward vertical hydraulic gradients (0.01 – 0.04) from the shallow bedrock interval (GW-085) to the water table interval (GW-086).

Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-085 indicate southwesterly flow toward the Maynardville Limestone and the main channel of Bear Creek. However, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred strike-parallel flow directions which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 390 – 2,020;
- pH of 6.4 – 7.5 (field measurements);
- elevated concentrations of inorganic contaminants, particularly barium (>1 mg/L) and nitrate (>100 mg/L), the latter of which dominates the ion chemistry of the samples and are the likely source of the unacceptably high relative percent difference (RPD) between respective summed millequivalent concentrations of anions and cations (i.e., the ion-charge balance error exceeds 20%) determined for samples collected in February 1993 (RPD = -77.8%), February 1994 (RPD = -32.1%), and June 1995 (RPD = 51.7%);
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals (except barium and strontium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the monitoring data reported for the groundwater samples collected since February 1990, nitrate and gross beta activity are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Nitrate concentrations above the analytical reporting limit were reported for each groundwater sample, with all but four samples having concentrations above 100 mg/L, including 15 samples with concentrations above 300 mg/L (Table 1). The source of the nitrate is the former S-3 Ponds, which are located about 3,000 ft directly east of the well near the headwaters of Bear Creek at the west end of Y-12, and are four unlined surface impoundments that were filled and covered with a multilayer low-permeability cap (and an asphalt-paved parking lot) during RCRA closure of the site in 1988. The ponds were used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12, which emplaced an extensive plume of groundwater contamination containing a heterogeneous mixture of inorganic, organic, and radiological contaminants. Some of the inorganic contaminants (e.g., nitrate and uranium) were entrained in the nitric acidic wastes and others (e.g., barium and strontium) were dissolved from bedrock minerals. Nitrate is the primary inorganic contaminant in the plume and, based on the existing network of monitoring wells in the Nolichucky Shale west of the former S-3 Ponds, the extent of elevated nitrate concentrations (i.e., >10 mg/L) in the groundwater suggest: (1) relatively rapid, westward transport/migration via shallow (<30 ft bgs) strike-parallel flowpaths (i.e., bedding-plane fractures) that terminate in the northern tributaries of Bear Creek located about 1,500 ft (NT-1) and 2,500 ft (NT-2) west of the former S-3 Ponds; and (2) substantially slower migration deeper in the bedrock via much longer strike-parallel flowpaths, with upward hydraulic gradients promoting upwelling of nitrate-contaminated groundwater into the shallow flow system near NT-1 and NT-2 (DOE 1997).

As noted previously, nitrate concentrations reported for most of the groundwater samples exceed 100 mg/L (Table 1), with 17 results exceeding 200 mg/L (Table 1). Note that the historical maximum nitrate concentration (2,139 mg/L in February 1993) and historical minimum nitrate concentration (17 mg/L in June 1995) are considered qualitative because of the ion charge-balance errors for these samples (see Section 4.0); both results also appear to be outliers compared to the nitrate concentrations reported for the other groundwater samples. Additionally, the nitrate concentrations exhibit a wide range of temporal fluctuations, but do not show a consistent relationship with groundwater flow conditions, as illustrated by temporal "peak" concentrations reported for samples obtained during both seasonally high and low flow conditions (Figure 1). These results are representative of concentrations in the shallow groundwater flow system in the Nolichucky Shale west of NT-2, which, as noted previously, is a discharge area for nitrate-contaminated groundwater from the shallow flow system. Elevated nitrate concentrations in groundwater at this well also show that the leading western edge of the nitrate plume in the Nolichucky Shale west of the former S-3 Ponds occurs somewhere west of the well toward NT-3 (DOE 1997).

A time-series plot of the nitrate concentrations detected in the groundwater samples (excluding the results considered qualitative because of ion charge-balance errors) shows a generally indeterminate trend dominated by what appear to be long-term concentration cycles (Figure 1). Nitrate concentrations generally increased between May 1990 (115 mg/L) and October 1993 (312.6 mg/L), subsequently decrease through March 1998 (43 mg/L), increased again through February 2002 (244 mg/L), and again decreased through August 2004 (70.7 mg/L), which is the lowest concentration reported since August 1998 (58 mg/L). This nitrate concentration trend potentially reflects a sequence of cyclic "pulses" in the relative flux of nitrate via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.2 URANIUM

Eleven groundwater samples had total uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.00201 mg/L in February 2001) being and order-of-magnitude below the MCL for uranium (0.03 mg/L). Uranium is one of the primary components of the contaminant plume emplaced in the Nolichucky Shale during historical operations of the former S-3 Ponds. The low concentrations of uranium in the groundwater at this well, in contrast to the very high nitrate levels, illustrate the significantly greater attenuation of uranium relative to nitrate.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected only in five of the groundwater samples, with chloroform detected in three samples, bromodichloromethane detected in two samples, and acetone detected in one sample.

5.4 GROSS ALPHA ACTIVITY

Eleven groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with results for samples collected February 1992 (32.4 pCi/L), August 1992 (44.1 pCi/L), October 1992 (15.9 pCi/L), and February 1993 (17.3 pCi/L) exceeding the MCL for gross alpha activity (15 pCi/L). These results may be sampling or analytical artifacts, possibly related to analytical interference from the high TDS of the (unfiltered) groundwater samples. Also, seven samples collected between June 1994 and October 1995 were analyzed for U-234 and U-238, which are alpha-emitting radionuclides most likely to be present in the groundwater. Aside from a suspected outlier reported for the sample collected in June 1995 (U-234 of 219 pCi/L), only two results exceed the MDA and corresponding CE, and both of these are less than 1 pCi/L.

5.5 GROSS BETA ACTIVITY

Each groundwater sample had gross beta activity above the applicable MDA and corresponding CE, with results for more than 80% (33) of the samples exceeding the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the MCL for gross beta activity). The source of the gross beta activity in the groundwater at this well is Tc-99, which is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds (the only site at Y-12 to receive wastes containing Tc-99). As shown in Table 1, Tc-99 was detected (i.e., >MDA and CE) in the twelve samples analyzed for this beta-emitting radionuclide, with the highest values reported for the samples collected in October 1993 (331 pCi/L) and August 2001 (370 pCi/L). Note that all the Tc-99 results are substantially below the SDWA screening level (3,790 pCi/L) for a 4 mrem/yr dose equivalent. Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in Nolichucky Shale west of the former S-3 Ponds, the extent of elevated (>50 pCi/L) gross beta activity in the groundwater suggests that the distribution of Tc-99 closely mirrors that of nitrate, with primarily westward strike-parallel transport in the water table and bedrock intervals toward discharge areas in NT-1 and NT-2 (DOE 1997).

Results for gross beta activity reported for the groundwater samples show a fairly wide range between the historical minimum value (24.6 pCi/L in October 1991) and historical maximum value (320 pCi/L in February 2003), which may be at least partially attributable to analytical interferences related to the high TDS of the samples. As with nitrate concentrations in the samples, gross beta activity also does not exhibit a consistent relationship with groundwater flow conditions, with temporal "peak" concentrations reported for samples obtained during both seasonally high and low flow conditions. In any case, elevated gross beta activity in the groundwater at this well reflects the transport of Tc-99 in the shallow flow system in the Nolichucky Shale west of NT-2 (DOE 1997).

A time-series plot of the gross beta activity reported for the groundwater samples shows a generally increasing long term trend through February 2003 (320 pCi/L), the historical maximum value for the well, followed by a decreasing trend through August 2004 (80 pCi/L), which is the lowest value reported since March 1999 (48 pCi/L) (Figure 2). Also, although the gross beta results show substantially wider temporal variability, the results suggest long-term concentration cycles corresponding with those indicated by the nitrate data. Like the nitrate concentrations, the gross beta activity potentially reflects a series of cyclic "pulses" in the relative flux of Tc-99 via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

WELL GW-097

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in September 1984, completed with a screened monitored interval from 9.3 to 19.2 ft bgs, and constructed with nominal 2.5-inch stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with wells GW-098 and GW-120, and is located in Bear Creek Valley (BCV) adjacent to the southwestern disposal plots at the Oil Landfarm, approximately 350 ft north of the main channel of Bear Creek and 150 ft east of a northern tributary of the creek (NT-4) that drains the western portion of the Oil Landfarm waste management area (WMA). The Oil Landfarm consisted of waste disposal plots that were used between 1973 and 1982 for biodegradation of about one million gallons of waste oils and machine coolants via landfarming with nutrient-adjusted surface soils during the dry months of each year (April through October). The disposal plots are covered by a low-permeability, multilayer cap installed during RCRA closure of the Oil Landfarm in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Seventeen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 13 samples between March 1987 and January 1990, and the low-flow sampling method used to obtain four samples between June 1998 and August 2005. The sampling history includes both quarterly and semiannual sampling frequencies and encompasses extended periods (January 1990 – June 1998 and July 1998 – March 2005) when no samples were collected from the well.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in Nolichucky Shale (the Conasauga Group), which trends northeast-southwest through BCV, dips to the southeast at 45º - 55º, and directly underlies many of the primary sources of groundwater contamination west of Y-12. The bulk of the groundwater flow in the Nolichucky Shale occurs within the water table interval, a highly permeable zone that typically occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek. These tributaries traverse from northeast to southwest across the Nolichucky Shale and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that statigraphically overlies the Nolichucky Shale and subcrops along the axis of BCV and the main channel of Bear Creek.

The static water level in the well occurs at an average depth of about 8 ft bgs and exhibits maximum seasonal fluctuations of approximately 2 ft. Moreover, depth-to-water measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in well GW-097 are typically higher than evident in well GW-098, which is completed at a greater depth (104 ft bgs) in the Nolichucky Shale. Based on the distance between the monitored interval midpoint (elevation) in each well (76 ft), the contemporaneous groundwater elevations indicate downward vertical hydraulic gradients (0.017 –0.061) from the water table interval (GW-097) to the shallow bedrock interval (GW-098).

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-097 indicate south and southwesterly flow toward the Maynardville Limestone and the main channel of Bear Creek. However, groundwater flow in the Nolichucky Shale is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Consequently, the direction(s) of groundwater flow in the vicinity of well GW-097 may be primarily westward (parallel with geologic strike) toward discharge areas in NT-4, which traverses the western boundary of the Oil Landfarm WMA approximately 150 ft west of the well.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples collected to date show that the well yields calcium-bicarbonate groundwater generally characterized by:

- TDS of 608 – 655 mg/L;
- pH of 6.43 – 6.9 (field measurements);
- low concentrations of magnesium (<10 mg/L) and elevated levels of chloride (>25 mg/L) and sulfate (>25 mg/L) compared to other wells completed at similar depth in the Nolichucky Shale;
- low molar proportions of potassium and sodium (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

It is not clear from the available data why the magnesium concentrations are so low. Additionally, the elevated sulfate and chloride concentrations may reflect natural geochemical characteristics in the Nolichucky Shale, or may be the result of contamination from one or more sources hydraulically upgradient of the well. Also, considering that the groundwater contains a mixture of chlorinated hydrocarbons (see Section 5.3), elevated chloride concentrations in the groundwater samples may be a consequence of the biologically mediated degradation (dechlorination) of these compounds (Hinchee et al. 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Only one of the groundwater samples collected to date had a nitrate concentration above the applicable analytical reporting limit, and this result (0.0791 mg/L in March 2005) is substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Nine groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest value (0.0228 mg/L in July 1998) being below the MCL for uranium (0.03 mg/L). However, this result is a suspected outlier because the other uranium results are at or below 0.005 mg/L.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected to date (Table 1): acetone, benzene, chloroethane, chloroform, ethylbenzene (ETB), methylene chloride, PCE, TCE, toluene, xylene, 11DCA, 12DCE (c12DCE), 111TCA, and 4-methyl-2-pentanone (4M2P). Note, however, that no VOCs were detected in the sample collected most recently (August 2005). Nevertheless, the detection of VOCs in the previous samples indicates that the monitored interval for the well intercepts groundwater flow/transport pathways followed by mobile components of the subsurface contaminant plume emplaced during historical operation of the former Oil Landfarm. Waste disposal operations at the site emplaced two distinct plumes of dissolved VOCs in the shallow groundwater, one originating from the northern disposal plots that is dominated by 111TCA, 11DCA, and 11DCE and one originating from the southern disposal plots that is dominated by PCE, TCE, and 12DCE. Maximum concentrations within the plumes do not indicate the presence of DNAPL in the subsurface at the Oil Landfarm (DOE 1997). Considering the location of the well relative to the Oil Landfarm disposal plots and the preferred strike-parallel direction of groundwater flow in the Nolichucky Shale, the (former) presence of dissolved VOCs in the well indicates primarily westward groundwater transport toward discharge areas in NT-4.

Based on frequency of detection and concentration magnitude, principal VOCs detected in the groundwater samples collected to date are 12DCE (c12DCE) and 11DCA (Table 1). At least one of these VOCs was detected in all but one of the samples, with historical maximum concentrations of 27 µg/L for 12DCE and 13 µg/L for 11DCA. Secondary compounds in the samples are chloroethane and methylene chloride, one or both of which was detected in each sample collected between March 1987 and September 1989, but not in any of the samples collected since then, and most of these results are less than 10 µg/L. Each of the remaining compounds was detected in no more than three of the samples collected to date and the bulk of these results are estimated values below 5 µg/L (Table 1). Moreover, no VOCs were detected in the sample collected most recently (August 2005).

The apparent dominance of 12DCE and 11DCA in the groundwater samples potentially reflects the biologically mediated degradation (sequential dechlorination) of respective parent compounds (PCE and 111TCA) in the groundwater. Additionally, dissolved hydrocarbons (e.g., benzene) in the groundwater may serve as electron donors necessary for co-metabolic transformation of the chlorinated hydrocarbons (McCarty 1996). However, as illustrated by the data summarized in Table 2, results for several indicator parameters suggest that selected geochemical characteristics of the groundwater at this well generally are not within the optimum range for biotic degradation of chlorinated hydrocarbons. The REDOX conditions, for instance, do not suggest the strongly reducing (methanogenic) conditions necessary to transform 12DCE to VC (Chapelle 1996). Perhaps the monitored interval for the well intercepts groundwater flow/transport pathways for degradation products migrating hydraulically downgradient of the source area(s) where geochemical conditions promote more effective biotic dechlorination. This too may explain the infrequent detection of parent compounds (PCE and 111TCA) as well as 12DCE and 11DCA degradation products (VC and chloroethane) in the groundwater samples from this well.

A time-series plot of the summed concentrations of VOCs detected in each groundwater sample collected to date shows an overall decreasing trend dominated by a "peak" concentration in November 1987 (80 µg/L) and the gaps in the sampling history for the well (Figure 1). Also, as illustrated by the selected sampling results included in the following summary, summed VOC concentrations initially decreased fairly rapidly, but subsequently the rate of decease slowed considerably.

Sampling Date	**Elapsed Time (Days)**	**Summed VOCs (mg/L)**	**Relative % Decrease**
03/17/87	.	53	.
04/25/88	548	23	52%
03/08/05	3,590	11	54%

The initial, more rapid decrease probably mirrors the substantially reduced flux of VOCs in the Nolichucky Shale following installation of the low-permeability cap over the Oil Landfarm. The much slower, subsequent decrease in VOC concentrations suggest long-term natural attenuation in the shallow flow system, including flushing of residual contamination by seasonal (and episodic) recharge/discharge cycles. In any case, the decrease in the concentrations of VOCs in the well suggests a corresponding decrease in the discharge of VOC-contaminated groundwater into NT-4.

5.4 GROSS ALPHA ACTIVITY

One groundwater sample collected since January 1990 (the sample-specific MDA and/or CE are not available for previous samples) had gross alpha activity above the applicable MDA and corresponding CE. This result (1.42 pCi/L in January 1990) is well below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Three groundwater samples collected since January 1990 (the sample-specific MDA and/or CE are not available for previous samples) had gross beta activity above the applicable MDA and corresponding CE, with the highest value (9.22 pCi/L in June 1998) being below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-098

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in September 1984, completed with a screened monitored interval from 77 to 104 ft bgs, and constructed with nominal 4.5-inch stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with wells GW-097 and GW-120 and is located in Bear Creek Valley (BCV) adjacent to the southwestern disposal plots at the Oil Landfarm, about 350 ft north of the main channel of Bear Creek and 150 ft east of a northern tributary (NT) of the creek (NT-4) that drains the western portion of the Oil Landfarm waste management area (WMA). The Oil Landfarm waste disposal plots were used between 1973 and 1982 for biodegradation of about one million gallons of waste oils and machine coolants via landfarming with nutrient-adjusted surface soils during the dry months of each year (April through October). The disposal plots are covered by a low-permeability, multilayer cap installed during RCRA closure of the Oil Landfarm in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Aside from sampling performed as part of the initial groundwater contamination investigations in BCV during the early 1980s, a total of 17 groundwater samples have been collected from the well since January 1998. The conventional sampling method was used to obtain 13 samples between March 1987 and January 1990, and the low-flow sampling method used to obtain four samples between March 2001 and August 2004. The sampling history includes both quarterly and semiannual sampling frequencies and encompasses an extended period (January 1990 – March 2001) when samples were not collected from the well.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in Nolichucky Shale (the Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within a highly permeable zone (the water table interval) that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek that traverse the Nolichucky Shale and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that statigraphically overlies the Nolichucky Shale and subcrops along the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 9 ft bgs and exhibits minor (<5 ft) seasonal fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-098 indicate south and southwesterly flow toward the Maynardville Limestone and the main channel of Bear Creek. However, groundwater flow in the Nolichucky Shale is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Consequently, the direction(s) of groundwater flow in the vicinity of well GW-098 may be primarily westward (parallel with geologic strike) toward discharge areas in NT-4, which traverses the western boundary of the Oil Landfarm WMA approximately 150 ft west of the well.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples collected to date show that the well yields moderately mineralized, chloride-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 582 – 922 mg/L;
- pH of 6.44 – 6.9 (field measurements);
- chloride concentrations above 100 mg/L;
- low molar proportions of potassium, sulfate, and sodium (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the contaminants present in the groundwater at this well.

5.1 NITRATE

Only one of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit, and that result (0.1 mg/L in March 1989) is substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Total uranium concentrations at or above the applicable analytical reporting limit were reported for ten of the groundwater samples collected to date, with the highest value (0.00213 mg/L in March 2001) being below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected to date (Table 1): acetone, benzene, chloroethane, chloroform (CLF), ethylbenzene (ETB), methylene chloride (MC), PCE, TCE, toluene (TOL), xylene, 11DCA, 11DCE, 12DCE (c12DCE), 111TCA, and 4-methyl-2-pentanone (4M2P). The Oil Landfarm is the source of these compounds. Landfarming operations at the site emplaced two distinct plumes of dissolved VOCs in the shallow groundwater, one originating from the northern disposal plots that is dominated by 111TCA, 11DCA, and 11DCE and one originating from the southern disposal plots that is dominated by PCE, TCE, and 12DCE. Maximum concentrations within the plumes do not indicate the presence of DNAPL in the subsurface at the Oil Landfarm (AJA 1997).

Based on frequency of detection and concentration magnitude, principal VOCs in the groundwater samples are 12DCE (c12DCE) and TCE, one or both of which were detected in each sample collected to date, with historical maximum concentrations of 30 μg/L and 13 μg/L, respectively (Table 1). Secondary compounds in the samples are 11DCA, 11DCE, and 111TCA, at least one of which was detected in each sample, with historical maximum concentrations of 6 μg/L, 6 μg/L, and 2 μg/L, respectively. All of the other VOCs, including PCE and several petroleum hydrocarbons, were detected infrequently in samples collected during the late 1980s, with the highest concentrations reported for acetone (8 μg/L). Also, the most recent sampling results (February and August 2004) show that TCE concentrations remain at or above the drinking water MCL (Table 1).

A time-series plot of the summed concentrations of VOCs detected in each groundwater sample collected to date shows an overall decreasing trend (Figure 1). The summed VOC concentrations show an increasing trend between March 1987 (33 μg/L) and January 1990 (62 μg/L) dominated by wide temporal fluctuations and much lower concentrations evident after the 11-year gap in the sampling history for the well (Figure 1). Long- and short-term changes in summed VOC concentrations are primarily attributable to corresponding changes in the levels of 12DCE; whereas results for other compounds show minimal long- or short-term variation, as illustrated by the 11DCA concentrations detected in the samples collected in March 1987 (3 μg/L), April 1988 (3 μg/L), March 2001 (2 μg/L), and February 2004 (2 μg/L). The increasing summed VOC concentrations (before 1990) generally precede installation of the low-permeability cap at the site, with the decreasing summed concentrations evident thereafter reflecting an overall reduction in the flux of dissolved VOCs along the groundwater flow/transport pathways intercepted by the monitored interval in the well. The divergent concentration trends for individual compounds may be a function of the differences in the relative mobility of each compound in the groundwater.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected since January 1990 had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected since January 1990 had gross beta activity above the applicable MDA and corresponding CE.

WELL GW-100

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in September 1984, completed with a screened monitored interval from 4 to 21 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley (BCV) west of Y-12, on the north side of Bear Creek approximately 1,100 ft west-southwest of the former S-3 Ponds. This site consists of four unlined surface impoundments that were filled and covered with a multilayer low-permeability cap (and an asphalt-paved parking lot) during RCRA closure of the site in 1988. The surface impoundments were used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12, which emplace a large heterogeneous mixture of inorganic, organic, and radiological contaminants in the subsurface that remains one of the primary sources of groundwater and surface water contamination in BCV.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Sixteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 14 samples between January 1986 and September 1995, and the low-flow sampling method used to obtain samples in March and August 2004. The sampling history includes both quarterly and semiannual sampling frequencies and encompasses two large gaps when samples were not collected from the well: January 1990 – September 1995 and October 1995 –March 2004.

High total dissolved solids (TDS) is a distinguishing characteristic of the groundwater samples from this well (see Section 4.0) and a direct consequence of contamination associated with historical operation of the former S-3 Ponds (see Section 5.0).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Maynardville Limestone (Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995). Based on the depth of the well and its location relative to the (projected) geologic contact between the Maynardville Limestone and the underlying Nolichucky Shale, the monitored interval in the well potentially intercepts groundwater flow/transport pathways within the highly permeable zone near the bottom of the formation.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 3 ft bgs and exhibits minor seasonal fluctuations (<2 ft). Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV and on Chestnut Ridge, groundwater elevation isopleths in the vicinity of the well indicate flow to the west, parallel with geologic strike of the Maynardville Limestone and the main channel of Bear Creek.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date indicate that the well yields slightly acidic, chloride- and nitrate-enriched (contaminated) calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 1,160 – 2,508 mg/L;
- pH (field measurements) of 6.63 – 6.9;
- elevated concentrations of chloride and nitrate (e.g., 314 mg/L and 51.3 mg/L, respectively, in August 2004);
- low molar proportions of potassium, sodium, and sulfate (<10% of total anions/cations);
- elevated concentrations of several trace metals, notably chromium and nickel; and
- total concentrations of trace metals (except chromium and nickel) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, only nitrate is a contaminant in the groundwater at this well.

5.1 NITRATE

Nitrate concentrations reported for all of the groundwater samples collected to date exceed the drinking water MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds. Nitrate is a principal component of the contaminant plume that originates from the site, and it enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale and recharge of nitrate-contaminated surface water in Bear Creek (DOE 1997). Nitrate is chemically stable and highly mobile in groundwater and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells in the Maynardville Limestone in BCV west of Y-12, the extent of elevated nitrate concentrations (i.e., >10 mg/L) in the groundwater indicate: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for about 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) than the deeper bedrock and is significantly influenced by hydrologic interactions with surface water in Bear Creek.

Nitrate concentrations reported for the groundwater samples collected to date range from about 50 mg/L to over 450 mg/L (Table 1), with the highest concentrations reported for samples collected before January 1990. The most recent sampling results (March and August 2004) are similar to the historical minimum value (52 mg/L in January 1986), although this historic result appears to be an outlier compared to the other results obtained before January 1990 (Table 1). Unlike other wells that yield nitrate-contaminated groundwater from the Maynardville Limestone, the nitrate results for this well do not appear to exhibit strong seasonal fluctuations or display any consistent relationship with groundwater flow conditions, as illustrated by the temporal peak concentrations reported for samples collected during seasonally high flow (e.g., 438 mg/L in February 1989) and seasonally low flow (e.g., 457 mg/L in September 1988). A time-series plot of the nitrate data for the well reflects the varying sampling frequency and the substantial gaps in the sampling history for the well (see Section 2.0), but shows a clearly decreasing long-term trend (Figure 1). The decreasing trend coincides with installation of the low-permeability cap at the former S-3 Ponds during RCRA closure of the site in 1988, and reflects the substantial reduction in the relative flux of nitrate along the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.2 URANIUM

Thirteen of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit (Table 1), including results for three samples that exceed the drinking water MCL for uranium (0.03 mg/L): 0.23 mg/L in January1986, 0.053 mg/L in May 1986, and 0.074 mg/L in November 1987. Although below the MCL, many of the uranium results exceed the applicable UTL (0.004 mg/L). Elevated levels of uranium in the groundwater samples from this well result from downgradient migration/transport of uranium from the contaminant plume emplaced during historical operation of the former S-3 Ponds. Uranium was entrained in the nitric acid wastes disposed at the site and is a primary component of the S-3 Ponds contaminant plume. The extent of uranium migration/transport from the plume is largely controlled by the pH of the groundwater. Within the acidic groundwater near the former surface impoundments, uranium is probably present as uranyl cations that tend to form complexes with a wide variety of inorganic anions (Fetter 1993). Under the more neutral pH typical of groundwater in the Maynardville Limestone, uranyl cations may complex with carbonate dissolved from the bedrock, which greatly increases the mobility of uranium.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results for common laboratory reagents (e.g., methylene chloride), none of the groundwater samples collected since January 1990 contained VOCs.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected since January 1990 had gross alpha activity above the applicable MDA and corresponding CE. Gross alpha activity results reported for previous samples are qualitative (the sample-specific MDA and CE are not available).

5.5 GROSS BETA ACTIVITY

One of the groundwater samples collected since January 1990 had gross beta activity above the applicable MDA and corresponding CE (4.88 pCi/L in September 1995). Gross beta activity results reported for previous samples are qualitative (the sample-specific MDA and CE are not available). The lack of elevated gross beta activity in the groundwater at this well is somewhat surprising because Tc-99, a primary component of the S-3 Ponds contaminant plume, is a beta-emitting radionuclide that is highly mobile in groundwater and is present in the wells that are hydraulically upgradient (east-northeast) and downgradient (west-southwest) of the well. Moreover, the samples collected most recently (March and August 2004) were analyzed for Tc-99 and both results are below the respective MDA for each sample. These results are consistent with the low levels of gross beta activity and shows that, for reasons not readily apparent from the available data, Tc-99 is not transported via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

WELL GW-101

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during September 1984, completed with a screened monitored interval from about 10 to about 18 ft bgs, and constructed with nominal 2.5-inch diameter PVC riser casing and well screen (0.01 slot spiral-wound). The well is located in Bear Creek Valley (BCV) west of Y-12, approximately 150 ft directly west of the former S-3 Ponds and 350 ft southeast of a northern tributary (NT) of Bear Creek (NT-1). The S-3 Ponds were four unlined surface impoundments that were filled and covered with a multilayer low-permeability cap (and an asphalt-paved parking lot) during RCRA closure of the site in 1988. The surface impoundments were used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12, which emplaced a large heterogeneous mixture of inorganic, organic, and radiological contaminants in the subsurface that remains one of the primary sources of groundwater and surface water contamination in BCV.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Nine groundwater samples have been collected from the well, with the conventional sampling method used to obtain seven samples between January 1986 and April 1991 and the low-flow sampling method used to obtain samples in March and August 2004. The sampling history includes a generally semiannual sampling frequency and, as indicated by the preceding sampling dates, an extended period (April 1991 – March 2004) when no groundwater samples were collected from the well.

High total dissolved solids (TDS) is a distinguishing characteristic of the groundwater samples from this well (see Section 4.0) and a direct consequence of contamination associated with historical operation of the former S-3 Ponds (see Section 5.0).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the upper part of the Nolichucky Shale (Conasauga Group). The water table interval is a highly permeable zone that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock and transmits the bulk of the groundwater in the Nolichucky Shale. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek, which traverse the Nolichucky Shale from northeast to southwest throughout BCV west of Y-12 and are numbered in ascending order downstream from the headwaters of the creek. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that stratigraphically overlies the Nolichucky Shale and subcrops beneath the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 6 ft bgs and exhibits minor (<2 ft) seasonal fluctuations. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-101 indicate flow to the west-southwest toward the Maynardville Limestone and the main channel of Bear Creek. However, as noted previously, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred strike-parallel flow directions that may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Consequently, groundwater near well GW-101 probably flows primarily to the west toward discharge areas in NT-1.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the unfiltered groundwater samples collected to date show that the well yields calcium-magnesium-bicarbonate groundwater that has been substantially impacted by inorganic contaminants (e.g., nitrate) emplaced in the subsurface upgradient of the well during historical operation of the former S-3 Ponds. However, the geochemical characteristics indicated by the analytical results reported for samples collected between January 1986 and April 1991 differ substantially from the geochemical characteristics indicated by the analytical results reported for the samples collected most recently (March and August 2004). The first group of samples, which were obtained with the conventional sampling method, are characterized by extremely high TDS (>10,000 mg/L) attributable to the very high levels of nitrate (>5,000 mg/L) and other ions (e.g., calcium >3,000 mg/L), along with very high total concentrations of several trace metals, including aluminum (>25 mg/L), barium (>10 mg/L), iron (>30 mg/L), manganese (>5 mg/L), and strontium (>20 mg/L). In contrast, the samples collected most recently, which were obtained using the low-flow sampling method, had substantially lower TDS (919 mg/L in March 2004 and 1,000 mg/L in August 2004) corresponding with the much lower concentrations of nitrate (e.g., 61.2 mg/L in March 2004 and 84.2 mg/L in August 2004) and other ions. Concentrations of trace metals in the samples collected most recently also are substantially lower than historical levels (e.g., barium = 0.707 mg/L in August 2004), but remain above background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, nitrate is the primary contaminant present at elevated levels in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit (Table 1), with concentrations above 1,000 mg/L reported for each of the samples collected between January 1986 (3,613 mg/L) and April 1991 (1,423 mg/L). Note that the latter result is qualitative because of an unacceptably high charge balance error (-50.1%), as determined by the percent difference between the summed millequivalent concentrations of the primary anions and cations. The source of the nitrate is the contaminant plume emplaced during historical operations of the former S-3 Ponds. Nitrate is chemically stable and highly mobile in groundwater and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from this site. Based on the existing network of monitoring wells in the Nolichucky Shale in BCV west of Y-12, the extent of elevated nitrate concentrations (i.e., >10 mg/L) in the groundwater suggest: (1) transport/migration in the unconsolidated zone (water table interval) directly south toward the headwaters of Bear Creek; (2) westward transport/migration via shallow (<30 ft bgs) strike-parallel flowpaths (i.e., bedding-plane fractures) that terminate in the northern tributaries of Bear Creek located about 1,500 ft (NT-1) and 2,500 ft (NT-2) west of the former S-3 Ponds; (3) vertically migration parallel with geologic dip, driven by the greater density of the highly mineralized and acidic wastewater, and (4) substantially slower migration deeper in the bedrock via much longer strike-parallel flowpaths, with upward hydraulic gradients promoting upwelling of nitrate-contaminated groundwater into the shallow flow system near NT-1 and NT-2 (DOE 1997).

A time-series plot of the nitrate concentrations shows a clearly decreasing trend (Figure 1). As noted previously and illustrated by the data in Table 1, the nitrate concentrations detected in the groundwater samples collected in March and August 2004 are substantially lower than historical levels, although both results show that the nitrate levels in the shallow groundwater at this well remain substantially above the drinking water MCL for nitrate (10 mg/L). For instance, the nitrate concentration reported for the groundwater sample collected in March 2004 (61.2 mg/L) reflects a 97% decrease from the nitrate level evident in January 1991 (2,510 mg/L). Other wells completed at shallow depths in the Nolichucky Shale downgradient of the former S-3 Ponds likewise show lower nitrate concentrations than indicated by historical data for the wells. The reduced levels of nitrate in groundwater at these wells are primarily attributable to the substantially reduced flux of nitrate (and other contaminants) in the shallow groundwater flow system that occurred in response to the closure of the S-3 Ponds in 1984 and the installation of the low-permeability cap in 1988 (DOE 1997).

5.2 URANIUM

All of the groundwater samples collected to date had uranium concentrations above the applicable analytical reporting limit (Table 1), with concentrations that exceed the drinking water MCL for uranium (0.03 mg/L) reported for all but the most recently collected samples, which are almost an order-of-magnitude below the MCL. As noted previously, historical data show that the groundwater in this well and elsewhere immediately downgradient of the former S-3 Ponds contains elevated concentrations of several trace metals, some of which were entrained in the wastes disposed at the site (e.g., uranium) and others were dissolved from minerals in the residuum and bedrock (Nolichucky Shale) underlying the site (e.g., barium). The uranium in the groundwater probably occurs as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble complexes with a variety of inorganic anions (Fetter 1993). Thus, the distribution of elevated uranium concentrations in the Nolichucky Shale near the former S-3 Ponds is largely confined to the low-pH groundwater within about 500 ft of the site (DOE 1997).

A time-series plot of the uranium concentrations in each sample from the well shows a clearly decreasing concentration trend (Figure 2). As illustrated by the data summarized in Table 1, total uranium concentrations reported to date show a reduction of about 53% between January 1986 (0.096 mg/L) and April 1991 (0.045 mg/L) and a further reduction of more than 90% through March (0.0032 mg/L) and August 2004 (0.00367 mg/L). The substantial concentration decrease indicated by the most recent sampling results, as with the nitrate concentrations reported for these samples, is primarily attributable to the substantially reduced flux of contaminants in the shallow groundwater flow system in response to the closure of the S-3 Ponds.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, none of the groundwater samples collected to date contained VOCs.

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity above the applicable MDA and corresponding CE was reported for four of the groundwater samples collected since May 1990 (Table 1), and each of these results exceed the drinking water MCL for gross alpha activity (15 pCi/L). However, none of the gross alpha activity results obtained since January 1991 exceed the applicable MDA and/or the associated CE. Additionally, the gross alpha activity reported for the groundwater samples collected before May 1990 do not meet data quality objectives (DQOs) because the sample-specific MDA and corresponding CE are not available for these samples. Historical results for gross alpha activity probably inaccurate because of analytical interferences associated with the very high TDS in these (unfiltered) samples. Also, low levels of gross alpha activity in the groundwater at this well are supported by the radiological analyses of the samples collected in March and August 2004, which show very low levels (<4 pCi/L) of U-234 and U-238, which are alpha-particle emitting radionuclides and confirmed components of the groundwater contaminant plume originating from the former S-3 Ponds.

5.5 GROSS BETA ACTIVITY

Gross beta activity above the applicable MDA and corresponding CE was reported for three of the groundwater samples collected since May 1990 (Table 1). Each of these results is below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). As with gross alpha activity, the results for gross beta activity reported for groundwater samples collected before May 1990 do not meet applicable DQOs, and the historical results probably incorporate analytical interferences associated with the high TDS in the samples. Relatively low levels of gross beta activity in the groundwater at this well are supported by the results of radiological analyses of the samples collected in March and August 2004, which show values below the respective MDA for Tc-99, a beta-particle emitting radionuclide and a "signature" component of the groundwater contaminant plume originating from the former S-3 Ponds. Based on the existing network of monitoring wells in Nolichucky Shale west of the former S-3 Ponds, the extent of elevated (>50 pCi/L) gross beta activity in the groundwater suggests that the distribution of Tc-99 closely mirrors that of nitrate, with transport in the water table interval south toward Bear Creek and more westward (strike-parallel) transport in the bedrock intervals toward discharge areas in NT-1 and NT-2 (DOE 1997). Considering that the most recent sampling results show that nitrate concentrations in the groundwater at this well remain above 50 mg/L, the lack of Tc-99 in the groundwater is somewhat surprising. Thus, it is possible that the Tc-99 results are inaccurate because of analytical interferences associated with the very high TDS in these samples.

WELL GW-105

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during September 1984, completed with a screened monitored interval from 9.5 to 17 ft bgs, and constructed with nominal 2.5-inch diameter PVC (#40) riser casing and well screen (0.01 slot). The well forms a cluster with well GW-106 and is located in Bear Creek Valley (BCV) near the west end of Y-12, at the Rust Garage (RG) about 250 ft east-southeast of the former S-3 Ponds. The RG once housed several petroleum fuel underground storage tanks (USTs) and associated service lines and dispenser, a fuel unloading station, and drum storage area for used oil (DOE 1998). Located directly west of the RG, the former S-3 Ponds were four unlined surface impoundments that were used from 1951 to 1984 primarily for the percolation/evaporation of nitric acid effluent (with depleted uranium in solution) piped from process buildings in the central section of Y-12. Each pond contains several feet of sludge produced during the neutralization of the liquid wastes prior to RCRA closure of the site in 1988, when the ponds were filled with aggregate and covered with a multilayer low-permeability cap (including an asphalt-paved parking lot).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Seventeen groundwater samples have been collected from the well, with the conventional sampling method used to obtain 15 samples between January 1986 and January 1990, and the low-flow sampling method used to obtain samples in June and October 2003.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the Nolichucky Shale (Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within a highly permeable zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 5 ft bgs and exhibits minimal (<2 ft) seasonal fluctuations. Also, presampling groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are lower in well GW-105 than well GW-106, which is completed at a greater depth (75 ft bgs) in the Nolichucky Shale. Based on the distance (51 ft) between the monitored interval midpoint (elevation) in each well, the contemporaneous groundwater elevations indicate upward vertical hydraulic gradients (0.005 - 0.01) during seasonally high and low flow conditions.

Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-105 indicate southeasterly flow toward the Maynardville Limestone and the Upper East Fork Poplar Creek (UEFPC) drainage system. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and original main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred flow in directions that parallel geologic strike (i.e., bedding-plane fractures), which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 2,690 – 6,070 mg/L;
- pH of 6.5 – 7.1 (field measurements);
- high concentrations of nitrate (>500 mg/L);
- low molar proportions of chloride, potassium, and sulfate (<10% of total anions/cations); and
- elevated total concentrations of several trace metals, particularly barium (>2 mg/L) and strontium (>1 mg/L), that substantially exceed the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that nitrate is the principal contaminant present in the groundwater at this well.

5.1 NITRATE

Each groundwater sample contained nitrate concentrations of at least 350 mg/L, with concentrations above 1,000 mg/L reported for all but five of the samples, including the samples collected most recently (Table 1). The source of the nitrate is the former S-3 Ponds, which emplaced a heterogeneous mixture of inorganic, organic, and radiological contaminants in the Nolichucky Shale and created a mound in the water table that facilitated contaminant transport/migration east of the hydrologic divide separating the Bear Creek and UEFPC watersheds. Nitrate and other inorganic contaminants within the plume were principal components of the wastes disposed at the site, but some of the inorganic contaminants (e.g., barium) were dissolved from bedrock minerals by the acidic seepage from the ponds. With concentrations in excess of 10,000 mg/L, nitrate is the primary inorganic contaminant in the plume and, based on the network of existing monitoring wells completed in the Nolichucky Shale east of the former S-3 Ponds, elevated nitrate concentrations (i.e., >10 mg/L) extend laterally at least 5,000 ft eastward (parallel with geologic strike) and vertically (parallel with geologic dip) at least 150 ft bgs. Chemically stable and mobile in groundwater, nitrate effectively traces the principal groundwater flow/transport pathways for other similarly mobile contaminants, with the distribution of nitrate in the groundwater suggesting: (1) relatively rapid transport/migration via shallow groundwater flow/transport pathways (<30 ft bgs) which terminate in buried storm drains and utilities, building basement sumps, and the buried northern tributaries and original mainstem of UEFPC within 1,000 ft of the former S-3 Ponds; and (2) substantially slower migration deeper in the bedrock via much longer strike-parallel groundwater flow/transport pathways (e.g., bedding-plane fractures), possibly bound to a relatively narrow band near the middle of the Nolichucky Shale, toward basement sumps in Bldgs. 9204-4, 9201-5, 9201-4, and 9204-2 up to 4,000 ft from the former S-3 Ponds (DOE 1998).

The highest nitrate concentrations, including the historical maximum concentration (2,619 mg/L in January 1986), were reported for groundwater samples collected before installation of the low-permeability cap at the former S-3 Ponds. Nevertheless, comparably high nitrate concentrations (>1,000 mg/L) also were reported for samples obtained after installation of the cap (e.g., 1,840 mg/L in September 1989). These results are believed to be representative of nitrate concentrations in the short-term migration/transport pathways at shallow depths in the Nolichucky Shale east of the former S-3 Ponds (DOE 1998). Also, considering the upward vertical hydraulic gradients indicated by presampling groundwater elevations (see Section 3.0), the concentrations of nitrate (and other contaminants) in the shallow groundwater at this well may at least partially reflect influx from deeper in the bedrock.

A time-series plot of the nitrate concentrations in the groundwater samples spans the 13-year gap in the sampling history for the well, but the data suggests a possible decreasing long-term trend (Figure 1), with the nitrate concentration evident in March 2003 (350 mg/L) being the lowest reported for the well. Moreover, as illustrated by the barium and strontium data summarized in Table 1, concentration decreases also are evident for other inorganic contaminants in the groundwater samples. Concurrently decreasing concentrations of nitrate and other inorganic compounds suggest a corresponding reduction in the relative flux of contaminants. Reduced flux of contaminants via the shallow groundwater flow/transport pathways intercepted by the monitored interval in the well suggest that the center of mass of the contaminant plume in the Nolichucky Shale east of the former S-3 Ponds lies to the east (parallel with geologic strike) of this well and is continuing to slowly move eastward (DOE 1998).

5.2 URANIUM

Total uranium concentrations at or above the applicable analytical reporting limit were detected in fourteen of the groundwater samples, with the highest concentration (0.014 mg/L in March 1987) being less than the MCL (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

No VOCs were detected in the groundwater samples collected from well GW-105 during CY 2003.

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity reported for the groundwater samples obtained before January 1991, which includes all but two of the samples from this well, are considered qualitative because the applicable MDA and corresponding CE are not available for these samples. Also, the most recent (May and October 2003) sampling results for gross alpha activity are below the applicable MDA, although each of these samples has an unusually high MDA (23 pCi/L and 200 pCi/L, respectively). The MDAs may be an artifact of the high TDS in the samples, which may cause significant analytical interferences for gross alpha activity. Consequently, filtered groundwater samples from this well may be best suited for radiological analyses.

5.5 GROSS BETA ACTIVITY

Gross beta activity reported for the groundwater samples obtained before January 1991, which includes all but two of the samples from this well, are considered qualitative because the applicable MDA and corresponding CE are not available for these samples. Also, the most recent (May and October 2003) sampling results for gross beta activity are below the applicable MDA, although each of these samples has an unusually high MDA (97 pCi/L and 810 pCi/L, respectively). The MDAs may be an artifact of the high TDS in the samples, which may cause analytical interferences for gross beta activity. Consequently, filtered groundwater samples from this well may be best suited for radiological analyses.

WELL GW-106

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during September 1984, completed with a screened monitored interval from 53 to 75 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and well screen (0.01 slot). The well forms a cluster with well GW-105 and is located in Bear Creek Valley (BCV) near the west end of Y-12, at the Rust Garage (RG) about 250 ft east-southeast of the former S-3 Ponds. The RG once housed several petroleum fuel underground storage tanks (USTs) and associated service lines and dispenser, a fuel unloading station, and drum storage area for used oil (DOE 1998). Located directly west of the RG, the former S-3 Ponds were four unlined surface impoundments that were used from 1951 to 1984 primarily for the percolation/evaporation of nitric acid effluent (with depleted uranium in solution) piped from process buildings in the central section of Y-12. Each pond contains several feet of sludge produced during the neutralization of the liquid wastes prior to RCRA closure of the site in 1988, when the ponds were filled with aggregate and covered with a multilayer low-permeability cap (including an asphalt-paved parking lot).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Seventeen groundwater samples have been collected from the well, with the conventional sampling method used to obtain 15 samples between January 1986 and January 1990, and the low-flow sampling method used to obtain samples in June and October 2003.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the Nolichucky Shale (Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within a highly permeable zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 1.5 ft bgs and exhibits minimal (<1 ft) seasonal fluctuations. Also, presampling groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are higher in well GW-106 than well GW-105, which is completed at a shallower depth (17 ft bgs) in the Nolichucky Shale. Based on the distance (51 ft) between the monitored interval midpoint (elevation) in each well, the contemporaneous groundwater elevations indicate upward vertical hydraulic gradients (0.005 - 0.01) during seasonally high and low flow conditions.

Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-106 indicate southeasterly flow toward the Maynardville Limestone and the Upper East Fork Poplar Creek (UEFPC) drainage system. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred flow in directions that parallel geologic strike (i.e., bedding-plane fractures), which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 2,425 - 4,850 mg/L;
- pH of 6.9 – 7.1 (field measurements);
- high concentrations of nitrate (>500 mg/L);
- low molar proportions of chloride, potassium, and sulfate (<10% of total anions/cations); and
- elevated total concentrations of several trace metals, particularly barium (>4 mg/L) and strontium (>20 mg/L), that substantially exceed the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that nitrate and VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Each groundwater sample contained nitrate concentrations of at least 400 mg/L, with concentrations above 1,000 mg/L reported for six of the samples (Table 1). The source of the nitrate is the former S-3 Ponds, which emplaced a heterogeneous mixture of inorganic, organic, and radiological contaminants in the Nolichucky Shale and created a mound in the water table that facilitated contaminant transport/migration east of the hydrologic divide separating the Bear Creek and UEFPC watersheds. Nitrate and other inorganic contaminants within the plume were principal components of the wastes disposed at the site, but some of the inorganic contaminants (e.g., barium) were dissolved from bedrock minerals by the acidic seepage from the ponds. With concentrations in excess of 10,000 mg/L, nitrate is the primary inorganic contaminant in the plume and, based on the network of existing monitoring wells completed in the Nolichucky Shale east of the former S-3 Ponds, elevated nitrate concentrations (i.e., >10 mg/L) extend laterally at least 5,000 ft eastward (parallel with geologic strike) and vertically (parallel with geologic dip) at least 150 ft bgs. Chemically stable and mobile in groundwater, nitrate effectively traces the principal groundwater flow/transport pathways for other similarly mobile contaminants, with the distribution of nitrate in the groundwater suggesting: (1) relatively rapid transport/migration via shallow groundwater flow/transport pathways (<30 ft bgs) which terminate in buried storm drains and utilities, building basement sumps, and the buried northern tributaries and original mainstem of UEFPC within 1,000 ft of the former S-3 Ponds; and (2) substantially slower migration deeper in the bedrock via much longer strike-parallel groundwater flow/transport pathways (e.g., bedding-plane fractures), possibly bound to a relatively narrow band near the middle of the Nolichucky Shale, toward basement sumps in Bldgs. 9204-4, 9201-5, 9201-4, and 9204-2 up to 4,000 ft from the former S-3 Ponds (DOE 1998).

The highest nitrate concentrations, including the historical maximum concentration (3,190 mg/L in September 1988), were reported for groundwater samples collected before installation of the low-permeability cap over the former S-3 Ponds. Also, the most recent sampling results show nitrate concentrations (e.g., 740 mg/L in May 2003) that are about 30% lower than the nitrate levels evident shortly before installation of the cap (e.g., 1,172 mg/L in September 1987), but are about 50 to 80% higher than nitrate concentrations evident shortly after installation of the cap (e.g., 400 mg/L in December 1989). Additionally, the nitrate result reported for the sample collected in January 1990 (706 mg/L) is considered qualitative because of the ion charge balance error for the sample (i.e., relative percent difference between respective summed millequivalent concentrations of the major cations and anions exceeds 20%). The nitrate results for this well are believed to be representative of concentrations in the long-term, strike-parallel groundwater flow/transport pathways at depth in the Nolichucky Shale east of the former S-3 Ponds (DOE 1998).

A time-series plot of nitrate concentrations in the groundwater samples (excluding the qualitative result noted above) spans the 13-year gap in the sampling history for the well and shows a fairly indeterminate long term concentration trend (Figure 1). The trend suggests sharply lower flux of nitrate following installation of the low-permeability cap at the former S-3 Ponds, but minimal changes in the relative flux of nitrate since then. Similarly indeterminate concentration trends also are evident for other inorganic contaminants in the groundwater samples, as illustrated by the barium results summarized in Table 1, and likewise suggest minimal changes in the relative flux of inorganic contaminants via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.2 URANIUM

Total uranium concentrations at or above the applicable analytical reporting limit were detected in thirteen of the groundwater samples, with the highest concentration (0.013 mg/L in March 1988) being less than the MCL (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Aside from sporadic (false positive) results for common laboratory reagents (e.g., acetone), none of the VOCs that are confirmed groundwater contaminants at Y-12 were detected in the groundwater samples.

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity reported for the groundwater samples obtained before January 1991, which includes all but two of the samples from this well, are considered qualitative because the applicable MDA and corresponding CE are not available for these samples. Also, the most recent (May and October 2003) sampling results for gross alpha activity are below the applicable MDA, although each of these samples has an unusually high MDA (68 pCi/L and 230 pCi/L, respectively). The MDAs may be an artifact of the high TDS in the samples, which may cause significant analytical interferences for gross alpha activity. Consequently, filtered groundwater samples from this well may be best suited for radiological analyses.

5.5 GROSS BETA ACTIVITY

Gross beta activity reported for the groundwater samples obtained before January 1991, which includes all but two of the samples from this well, are considered qualitative because the applicable MDA and corresponding CE are not available for these samples. Also, the most recent (May and October 2003) sampling results for gross alpha activity are below the applicable MDA, although each of these samples has an unusually high MDA (210 pCi/L and 610 pCi/L, respectively). The MDAs may be an artifact of the high TDS in the samples, which may cause analytical interferences for gross beta activity. Consequently, filtered groundwater samples from this well may be best suited for radiological analyses.

WELL GW-108

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during September 1984, completed with a screened monitored interval from 41 to 58.6 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and well screen (0.01 slot). The well forms a cluster with wells GW-107 and GW-109 and is located in Bear Creek Valley (BCV) near the west end of Y-12, about 800 ft southeast of the former S-3 Ponds. The former S-3 Ponds were four unlined surface impoundments that were used from 1951 to 1984 primarily for the percolation/evaporation of nitric acid effluent (with depleted uranium in solution) piped from process buildings in the central section of Y-12. Each pond contains several feet of sludge produced during the neutralization of the liquid wastes prior to RCRA closure of the site in 1988, when the ponds were filled with aggregate and covered with a multilayer low-permeability cap (including an asphalt-paved parking lot).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-four groundwater samples have been collected from the well, with the conventional sampling method used to obtain 20 samples between January 1986 and August 1997, and the low-flow sampling method used to obtain 14 samples between March 1998 and July 2004.

Extremely high levels of TDS and fairly low pH are distinguishing characteristics of the groundwater samples from this well and are a direct consequence of contamination from the former S-3 Ponds (see Section 5.0).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the Nolichucky Shale (Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within a highly permeable zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 5 ft bgs and exhibits minimal (<2 ft) seasonal fluctuations. Also, groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are lower in well GW-108 than in wells GW-107 and GW-109, which are completed at shallower (14 ft bgs) and deeper (128 ft bgs) depths, respectively, in the Nolichucky Shale. Based on the distance between the monitored interval midpoints (elevation) in each well, the contemporaneous groundwater elevations indicate an upward vertical hydraulic gradient (0.046) from the deeper bedrock (GW-109) to the shallow bedrock interval (GW-108) and a downward vertical gradient (0.002) from the water table interval (GW-107) to the shallow bedrock interval.

Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-108 indicate southeasterly flow toward the Maynardville Limestone and the Upper East Fork Poplar Creek (UEFPC) drainage system. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and original main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred flow in

directions that parallel geologic strike (i.e., bedding-plane fractures), which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 29,000 – 86,400 mg/L;
- pH of 5.01 – 6.03 (field measurements);
- very high concentrations (>10,000 mg/L) of calcium and nitrate, the latter of which is the likely source of the unacceptably high relative percent difference (RPD) between respective summed millequivalent concentrations of anions and cations (i.e., the ion-charge balance error exceeds 20%) determined for the sample collected in August 1997 (RPD = -34.1%);
- low molar proportions of chloride, potassium, and sulfate (<10% of total anions/cations); and
- elevated total concentrations of several trace metals, particularly barium (>80 mg/L) and strontium (>30 mg/L), that substantially exceed the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on respective monitoring data reported for the groundwater samples collected from the well since June 1995, the principal contaminants present in the groundwater at this well are nitrate, VOCs, and gross beta activity.

5.1 NITRATE

Each groundwater sample contained nitrate concentrations of at least 8,500 mg/L, with concentrations above 10,000 mg/L reported for most of the samples (Table 1). The source of the nitrate is the former S-3 Ponds, which emplaced a heterogeneous mixture of inorganic, organic, and radiological contaminants in the Nolichucky Shale and created a mound in the water table that facilitated contaminant transport/migration east of the hydrologic divide separating the Bear Creek and UEFPC watersheds. Nitrate and other inorganic contaminants within the plume were principal components of the wastes disposed at the site, but some of the inorganic contaminants (e.g., barium) were dissolved from bedrock minerals by the acidic seepage from the ponds. With concentrations in excess of 10,000 mg/L, nitrate is the primary inorganic contaminant in the plume and, based on the network of existing monitoring wells completed in the Nolichucky Shale east of the former S-3 Ponds, elevated nitrate concentrations (i.e., >10 mg/L) extend laterally at least 5,000 ft eastward (parallel with geologic strike) and vertically (parallel with geologic dip) at least 150 ft bgs. Chemically stable and mobile in groundwater, nitrate effectively traces the principal groundwater flow/transport pathways for other similarly mobile contaminants, with the distribution of nitrate in the groundwater suggesting: (1) relatively rapid transport/migration via shallow groundwater flow/transport pathways (<30 ft bgs) which terminate in buried storm drains and utilities, building basement sumps, and the buried northern tributaries and original mainstem of UEFPC within 1,000 ft of the former S-3 Ponds; and (2) substantially slower migration deeper in the bedrock via much longer strike-parallel groundwater flow/transport pathways (e.g., bedding-plane fractures), possibly bound to a relatively narrow band near the middle of the Nolichucky Shale, toward basement sumps in Bldgs. 9204-4, 9201-5, and 9204-2 up to 4,000 ft from the former S-3 Ponds (DOE 1998).

Very high nitrate concentrations (and TDS) are characteristic of the groundwater samples from this well, most of which had concentrations above 10,000 mg/L. The historical maximum nitrate value (19,700 mg/L in August 1997) is qualitative because the ion-charge balance error (see Section 4.0), and the next highest result was 13,300 mg/L (July 2000). These results are believed to be representative of nitrate concentrations in the short-term migration/transport pathways at shallow depths in the Nolichucky Shale east of the former S-3 Ponds (DOE 1998). Also, considering the upward vertical hydraulic gradients indicated by presampling groundwater elevations (see Section 3.0), the concentrations of nitrate (and other contaminants) in the shallow groundwater at this well may at least partially reflect influx from deeper in the bedrock.

A time-series plot of the nitrate concentrations in the groundwater samples, excluding the qualitative result (August 1997), shows a generally decreasing long-term trend (Figure 1), with a series of cyclical "peak" nitrate levels evident in February 1999 (11,800 mg/L), July 2000 (13,300 mg/L), January 2003 (10,400 mg/L). The deceasing long-term trend suggests an overall decrease in the relative flux of nitrate via the groundwater flowpaths intercepted by the monitoring interval in the well, which may indicate a corresponding reduction in the flux of nitrate from the deeper bedrock intervals. The cyclical peak concentrations potentially reflect temporal variations in the relative efficiency of natural attenuation processes that influence nitrate levels in the groundwater.

5.2 URANIUM

Total uranium concentrations at or above the applicable analytical reporting limit were detected in 13 of the groundwater samples (Table 1), with the highest concentration (0.0205 mg/L in January 2001) being less than the MCL (0.03 mg/L). The contaminant plume emplaced in the Nolichucky Shale during historical operation of the former S-3 Ponds is the most likely source of the uranium. Considering the acidic pH of the samples from the well (see Section 4.0), uranium probably occurs in the groundwater as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble complexes with a variety of inorganic anions (Fetter 1993). The concentrations of uranium in the groundwater at this well, in contrast to the very high nitrate levels, illustrate the significantly greater attenuation of uranium relative to nitrate.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample collected from the well (Table 2): acetone, benzene, bromoform, bromomethane, chloroform, chloromethane, methylene chloride (MC), PCE, TCE, and 11DCE. These compounds are components of the contaminant plume originating from the former S 3-Ponds. Compared to other components of the Eastern S-3 Ponds Plume (e.g., nitrate), the relatively low concentrations of VOCs in the shallow groundwater at well GW-108 primarily reflects the substantially smaller volume of organic wastes disposed at the site (DOE 1998).

The primary VOCs in the groundwater samples are MC, chloroform, chloromethane, and bromomethane, which have the maximum concentrations of 69 μg/L, 38 μg/L, 79 μg/L, and 170 μg/L, respectively (Table 2). However, the maximum chloromethane and bromomethane concentrations are potential outliers that were reported for the sample collected in July 2000; excluding these results, the concentrations of these VOCs are less than 30 μg/L. Most recent samples show that MC concentrations remains substantially above the MCL (5 μg/L). Secondary VOCs in the groundwater samples are acetone, with concentrations above 10 μg/L reported for the most recent samples (e.g., 18 μg/L in July 2004), along with low concentrations (estimated values below 5 μg/L) of PCE, TCE, bromoform, and benzene.

A time-series plot of the summed concentration of VOCs detected in each groundwater sample (excluding the outliers mentioned above) shows an indeterminate trend (Figure 2). The significance of this trend is questionable because sampling results obtained between June 1995 and March 1998 contain several false positive results for chloroform and acetone (Table 2), which lowered the summed VOC concentration value for these samples and skews the long-term concentration trend.

5.4 GROSS ALPHA ACTIVITY

Eight of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE (Table 1), all of which exceed the MCL (15 pCi/L). However, one of these results (1,335 pCi/L in January 2003) is a suspected outlier because the other results are significantly lower (146 pCi/L to 700 pCi/L). Analytical results for samples obtained in CY 1996 (November), CY 2000 (January), and CY 2002 (January and July) show that uranium isotopes (U-234 and U-238) are a source of gross alpha activity in the groundwater. All of the results for U-234 (ranging from 13.1-18.47 pCi/L) and U-238 (ranging from 5.19 – 6.22 pCi/L) were above the applicable MDA and CE; however, the consistently low results for these isotopes do not support the high gross alpha activity reported for samples from the well. The inconsistent detection and widely variable results for gross alpha activity may be related to analytical interference associated with the very high TDS of the (unfiltered) groundwater samples (see Section 4.0).

5.5 GROSS BETA ACTIVITY

Each groundwater sample from the well had gross beta activity of at least 7,500 pCi/L, which is significantly above the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the MCL for gross beta activity). The source of the gross beta activity in the groundwater at this well is Tc-99, which is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds (the only site at Y-12 to receive wastes containing Tc-99). As shown in Table 1, Tc-99 was detected (i.e., >MDA and CE) in all of the samples analyzed for this beta-emitting radionuclide, with the highest value (30,625 pCi/L) reported for the most recent sample (July 2003).

A time-series plot of the gross beta activity in each sample shows a generally increasing long-term trend (Figure 3), although the most recent data suggest a modest decrease in gross beta activity between January 2003 (14,510 pCi/L) and August 2004 (12,100 pCi/L). The generally increasing long-term trend potentially reflects a corresponding increase in the overall flux of Tc-99 within the strike-parallel groundwater flowpaths in the Nolichucky Shale east of the S-3 Ponds. However, the increasing trend for Tc-99 contrasts with the decreasing trend for nitrate, which seems unusual considering that both contaminants are stable and highly mobile in the groundwater system. Such divergent concentration trends probably reflect the complex hydrochemical dynamics within the contaminant plume originating from the S-3 Ponds. For example, nitrate concentrations within the plume may be reduced by natural attenuation processes which do not affect Tc-99. The divergent concentration trends also may correspond with differences in the history of nitrate and Tc-99 waste disposal at the former S-3 Ponds. The site regularly received nitrate wastes (via pipeline from process buildings in Y-12), but got only periodic shipments of wastes containing Tc-99. This may have emplaced a series of Tc-99 "slugs" within the more continuous stream of nitric-acid wastes. Thus, the increasing Tc-99 activity evident in well GW-108 may reflect a temporal flux increase corresponding to one or more "slugs" of Tc-99 wastes migrating eastward along strike-parallel groundwater flowpaths in the Nolichucky Shale.

WELL GW-109

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during September 1984, completed with a screened monitored interval from 96.6 to 128.5 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and well screen (0.01 slot). The well forms a cluster with wells GW-107 and GW-108 and is located in Bear Creek Valley (BCV) near the west end of Y-12, about 800 ft southeast of the former S-3 Ponds. The former S-3 Ponds were four unlined surface impoundments that were used from 1951 to 1984 primarily for the percolation/evaporation of nitric acid effluent (with depleted uranium in solution) piped from process buildings in the central section of Y-12. Each pond contains several feet of sludge produced during the neutralization of the liquid wastes prior to RCRA closure of the site in 1988, when the ponds were filled with aggregate and covered with a multilayer low-permeability cap (including an asphalt-paved parking lot).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-two groundwater samples have been collected from the well, with the conventional sampling method used to obtain 16 samples between January 1986 and June 1995, and the low-flow sampling method used to obtain six samples between September 1999 and October 2003.

Extremely high levels of TDS and slightly low pH are distinguishing characteristics of the groundwater samples from this well and are a direct consequence of contamination from the former S-3 Ponds (see Section 5.0).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the Nolichucky Shale (Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within a highly permeable zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 2 ft bgs and exhibits minimal (<2 ft) seasonal fluctuations. Also, groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are higher in well GW-109 than in wells GW-107 and GW-108, which are completed at shallower depths (14 ft bgs and 58 ft bgs, respectively) in the Nolichucky Shale. Based on the distance between the monitored interval midpoints (elevation) in each well, the contemporaneous groundwater elevations indicate an upward vertical hydraulic gradient (0.046) from the deeper bedrock (GW-109) to the shallow bedrock interval (GW-108) and a downward vertical gradient (0.002) from the water table interval (GW-107) to the shallow bedrock interval.

Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-109 indicate southeasterly flow toward the Maynardville Limestone and the Upper East Fork Poplar Creek (UEFPC) drainage system. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and original main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred flow in

directions that parallel geologic strike (i.e., bedding-plane fractures), which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 49,800 – 57,598 mg/L;
- pH of 5.39 – 5.84 (field measurements);
- very high concentrations (>10,000 mg/L) of nitrate and calcium;
- low molar proportions of chloride, potassium, and sulfate (<10% of total anions/cations); and
- elevated total concentrations of several trace metals, particularly barium (>80 mg/L) and strontium (>60 mg/L), that substantially exceed the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995). Furthermore, concentrations of cadmium (> 1 mg/L) and mercury (> 0.01 mg/L) significantly exceed applicable MCLs (0.005 mg/L and 0.002 mg/L, respectively).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on respective monitoring data reported for the six groundwater samples collected from the well since June 1995, the principal contaminants present in the groundwater at this well are nitrate, VOCs, and gross beta activity.

5.1 NITRATE

Each groundwater sample contained nitrate concentrations of at least 8,000 mg/L, with a concentration above 10,000 mg/L reported for the most recent sample (Table 1). The source of the nitrate is the former S-3 Ponds, which emplaced a heterogeneous mixture of inorganic, organic, and radiological contaminants in the Nolichucky Shale and created a mound in the water table that facilitated contaminant transport/migration east of the hydrologic divide separating the Bear Creek and UEFPC watersheds. Nitrate and other inorganic contaminants (e.g., cadmium) within the plume were principal components of the wastes disposed at the site, but some of the inorganic contaminants (e.g., barium) were dissolved from bedrock minerals by the acidic seepage from the ponds. With concentrations in excess of 10,000 mg/L, nitrate is a primary inorganic contaminant in the plume and, based on the network of existing monitoring wells completed in the Nolichucky Shale east of the former S-3 Ponds, elevated nitrate concentrations (i.e., >10 mg/L) extend laterally at least 5,000 ft eastward (parallel with geologic strike) and vertically (parallel with geologic dip) at least 150 ft bgs. Chemically stable and mobile in groundwater, nitrate effectively traces the principal groundwater flow/transport pathways for other similarly mobile contaminants, with the distribution of nitrate in the groundwater suggesting: (1) relatively rapid transport/migration via shallow groundwater flow/transport pathways (<30 ft bgs) which terminate in buried storm drains and utilities, building basement sumps, and the buried northern tributaries and original mainstem of UEFPC within 1,000 ft of the former S-3 Ponds; and (2) substantially slower migration deeper in the bedrock via much longer strike-parallel groundwater flow/transport pathways (e.g., bedding-plane fractures), possibly bound to a relatively narrow band near the middle of the Nolichucky Shale, toward basement sumps in Bldgs. 9204-4, 9201-5, and 9204-2 up to 4,000 ft from the former S-3 Ponds (DOE 1998).

Very high nitrate concentrations (and TDS) are characteristic of the groundwater samples from this well, all of which had concentrations above 8,000 mg/L. These results are believed to be representative of nitrate concentrations in the migration/transport pathways at intermediate depths in the Nolichucky Shale east of the former S-3 Ponds (DOE 1998). The concentration levels of most inorganic contaminants (nitrate, barium, strontium, uranium) are fairly similar in contemporaneous samples from wells GW-109 and GW-108; however, cadmium and mercury concentrations are significantly above respective MCLs in samples from well GW-109 (see Section 3.0) and are not detected in samples from well GW-108. The elevated concentrations of these heavy metals in samples from well GW-109 may reflect density driven migration to greater depths beneath the former S-3 Ponds.

A time-series plot of the nitrate concentrations in the groundwater samples shows a fluctuating and generally indeterminate long-term trend (Figure 1), with higher concentrations evident during seasonally low flow conditions (October). The significance of this trend is questionable because the minimum (8,700 mg/L) and maximum (10,800 mg/L) concentrations were both reported for samples collected during CY 2003, which are within the range of nitrate concentrations reported for the eight samples collected from the well during CY 1986 and CY 1987 (8,620 – 11,199 mg/L). The fairly stable nitrate concentrations probably reflect lower groundwater flux at greater depths in the Nolichucky Shale (see Section 3.0)

5.2 URANIUM

Total uranium concentrations above the applicable analytical reporting limit were detected in all of the groundwater samples (Table 1), with the highest concentration (0.032 mg/L in June 1995) slightly above the MCL for uranium (0.03 mg/L). The contaminant plume emplaced in the Nolichucky Shale during historical operation of the former S-3 Ponds is the most likely source of the uranium. Considering the acidic pH of the samples from the well (see Section 4.0), uranium probably occurs in the groundwater as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble complexes with a variety of inorganic anions (Fetter 1993). The concentrations of uranium in the groundwater at this well, in contrast to the very high nitrate levels, illustrate the significantly greater attenuation of uranium relative to nitrate.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample collected from the well (Table 2): acetone, bromoform, chloroform, methylene chloride (MC), toluene, PCE, TCE, 12DCE, and 11DCE. These compounds are components of the contaminant plume originating from the former S-3 Ponds. Compared to other components of the Eastern S-3 Ponds Plume (e.g., nitrate), the relatively low concentrations of VOCs in the shallow groundwater at well GW-109 primarily reflects the substantially smaller volume of organic wastes disposed at the site (DOE 1998).

The primary VOCs in the groundwater samples are PCE, MC, chloroform, and acetone, which have the maximum concentrations of 180 μg/L, 35 μg/L, 19 μg/L, and 24 μg/L, respectively (Table 2). Most recent samples show that PCE and MC concentrations remain substantially above the applicable MCL (5 μg/L for both). Note that PCE concentrations are significantly higher in samples from GW-109 than in shallower well GW-108 (similar to cadmium and mercury concentrations, see Section 5.1), which may reflect density driven migration to greater depths beneath the S-3 Site because PCE is dense and not very soluble in water. Secondary VOCs in the groundwater samples are 12DCE, 11DCE, bromoform, and toluene. None of these compounds were detected in samples collected from the well during CY 2000, and the CY 2003 results for these compounds are either estimated values below 5 μg/L (11DCE, bromoform, and toluene) or not detected (12DCE).

A time-series plot of the summed concentration of VOCs detected in each groundwater sample shows a clearly decreasing trend (Figure 2), which may be skewed by the high acetone result (240 µg/L) reported for the initial sample (June 1995). The concentrations of all compounds have decreased between June 1995 and May 2003 (Table 2), more significantly for acetone (94%) than for PCE (11%). Acetone is significantly less dense and more soluble in groundwater than PCE (Fetter 1994), and the upward vertical hydraulic gradient (see Section 3.0) may at least partially explain the rapid concentration decrease for acetone.

5.4 GROSS ALPHA ACTIVITY

Only one of the groundwater samples from well GW-109 had gross alpha activity above the applicable MDA and corresponding CE (Table 1), which also exceeds the MCL (15 pCi/L). The inconsistent detection of gross alpha activity may be related to analytical interference associated with the very high TDS of the (unfiltered) groundwater samples (see Section 4.0), and the elevated result (122 pCi/L) reported for the June 1995 sample is a suspected outlier.

5.5 GROSS BETA ACTIVITY

Each groundwater sample from the well had gross beta activity exceeding 7,500 pCi/L, which is significantly above the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the MCL for gross beta activity). The source of the gross beta activity in the groundwater at this well is Tc-99, which is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds (the only site at Y-12 to receive wastes containing Tc-99). As shown in Table 1, Tc-99 was detected at very high levels (~20,000 pCi/L) in both of the samples (May and October 2000) analyzed for this beta-emitting radionuclide.

A time-series plot of the gross beta activity in each sample shows a generally increasing trend (Figure 3). This potentially reflects a corresponding increase in the overall flux of Tc-99 within the strike-parallel groundwater flowpaths in the Nolichucky Shale east of the S-3 Ponds. The increasing trend for Tc-99 contrasts with the indeterminate trend for nitrate, which seems unusual considering that both contaminants are stable and highly mobile in the groundwater system. The difference between the concentration trends probably reflect the complex hydrochemical dynamics within the contaminant plume originating from the S-3 Ponds. For example, nitrate concentrations within the plume may be reduced by attenuation processes that do not affect Tc-99. The differing concentration trends also may correspond with differences in the history of nitrate and Tc-99 waste disposal at the former S-3 Ponds. The site regularly received nitrate wastes (via pipeline from process buildings in Y-12), but got only periodic shipments of wastes containing Tc-99. This may have emplaced a series of Tc-99 "slugs" within the more continuous stream of nitric-acid wastes. Thus, the increasing beta activity evident in well GW-109 may reflect a temporal flux increase corresponding to one or more "slugs" of Tc-99 wastes migrating eastward along strike-parallel groundwater flowpaths in the Nolichucky Shale.

WELL GW-115

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in November 1984, completed with a screened monitored interval from 37.6 to 53.0 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley north of Bear Creek Valley Road near the west end of Y-12 and is hydraulically upgradient of all known sources of groundwater contamination at Y-12.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fifty-two groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 38 samples between March 1987 and August 1997, and the low-flow sampling method used to obtain 14 samples between January 1998 and January 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Maryville Limestone). Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 7 ft bgs and exhibits moderate seasonal fluctuations (<10 ft).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 222 – 391 mg/L;
- pH (field measurements) of 6.2 – 7.9;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for 34 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Thirteen groundwater samples had nitrate concentrations above the analytical reporting limit, with the highest concentration (1.6 mg/L in July 2000) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Two groundwater samples had uranium concentrations above the analytical reporting limit, and both results (0.001 mg/L in September 1993 and August 1994) are substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected at low levels in four groundwater samples: acetone (25 μg/L) in July 1991, MC (2 μg/L) in September 1993, acetone (140 μg/L) and benzene (8 μg/L) in July 2000, and chloromethane (1 μg/L) in July 2001. These results are probably analytical artifacts because the well is located upgradient of all potential sources of VOCS.

5.4 GROSS ALPHA ACTIVITY

Nine groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (8.59 pCi/L in July 2003) being below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Sixteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (13.3 pCi/L in October 1991) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-122

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in July 1985, completed with an open-hole monitored interval from 92 to 142 ft bgs, and constructed with nominal 4.5-inch diameter steel (SF25) riser casing. The well is paired with deeper well GW-123 (572 ft bgs), and is located in Bear Creek Valley (BCV) approximately 400 ft southwest of the former S-3 Ponds. Located near the western end of Y-12 and north of the headwaters of Bear Creek, the S-3 Ponds consist of four contiguous, unlined surface impoundments that were used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12, and were closed in accordance with applicable RCRA regulations in 1988. Closure included removal of liquid wastes and stabilization of sludge remaining in each pond, which were then filled and covered with a multilayer low-permeability cap and completed with an asphalt-paved parking lot in 1989. Historical operation of the S-3 Ponds created a large mound in the water table that dissipated after the site was closed and capped, and emplaced a heterogeneous mixture of inorganic, organic, and radiological contaminants in the subsurface that remains a primary source of groundwater and surface water contamination in BCV.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-one groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 19 samples between December 1986 and April 1991, and the low-flow sampling method used to obtain samples in March and August 2005. The sampling history includes a quarterly sampling frequency followed by a 14-year period (April 1991 – March 2005) when no samples were collected from the well.

Unusually high levels of TDS are a distinguishing characteristic of the groundwater samples from this well (see Section 4.0) and are a direct consequence of contamination associated with historical operation of the former S-3 Ponds (see Section 5.0).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the intermediate depth (100-300 ft bgs) bedrock interval in the Nolichucky Shale (Conasauga Group), which trends northeast-southwest along the northern slope of BCV, dips to the southeast at an angle of 45º - 55º, and is bordered on the southeast by the overlying Maynardville Limestone, a highly permeable karst aquifer that provides the principal pathway for subsurface contaminant migration in BCV. (Note that the well is located within the outcrop area of the Maynardville Limestone). The bulk of the groundwater flow in the Nolichucky Shale occurs in a highly permeable zone (the water table interval) that occurs near the transition between unconsolidated material (residuum and weathered bedrock). Also, the highly acidic wastes from the S-3 Site dissolved carbonate strata interbedded within the Nolichucky Shale and greatly enhanced the relative permeability of these strata-bound flowpaths within several hundred feet of the site.

Groundwater flow in the water table interval in the Nolichucky Shale is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek, which traverse the formation from northeast to southwest throughout BCV west of Y-12 and are numbered in ascending order downstream from the headwaters of the creek. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone.

The static water level in the well occurs at an average depth of approximately 12 ft bgs and exhibits maximum seasonal fluctuations less than 10 ft. The direction of groundwater flow near the well, as indicated by groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for nearby monitoring wells, is primarily westward, parallel with geologic strike (i.e., bedding-plane fractures) in the Nolichucky Shale.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date indicate that the well yields highly mineralized, nitrate-contaminated, sodium- and chloride-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 1,990 – 4,836 mg/L;
- pH (field measurements) of 6.42 – 6.8;
- high concentrations of nitrate (>200 mg/L), sodium (>95 mg/L), and chloride (>85 mg/L);
- low molar proportions of potassium and sulfate (<5% of total anions/cations);
- elevated concentrations of barium (>2 mg/L), boron (>0.4 mg/L), and strontium (>10 mg/L); and
- total concentrations of other trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Dissolution of the carbonate bedrock underlying the former S-3 Ponds by the many years of acidic seepage from the site, in addition to inorganic constituents entrained in the wastes disposed at the site, accounts for the TDS and extremely high concentrations of some trace metals, particularly barium and strontium, in the groundwater at this well.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. Based on the results reported for the groundwater samples collected to date, nitrate is the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Eighteen of the groundwater samples collected to date were analyzed for nitrate (Table 1) and all of these results exceed the drinking water MCL for nitrate (10 mg/L). The elevated nitrate concentrations indicate that the monitored interval in the well intercepts water-producing features that are hydraulically connected with the heterogeneous plume of inorganic, organic, and radiological contaminants originating from the former S-3 Ponds. Nitrate is a primary component of the contaminant plume, is chemically stable and highly mobile in groundwater, and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Additionally, the greater density of the highly mineralized acidic wastewater disposed at the site promoted density-driven vertical migration via strike- and dip-parallel flowpaths in the Nolichucky Shale.

As noted previously, all of the groundwater samples had nitrate concentrations above the MCL, with the historical maximum concentration (1,400 mg/L) reported for the sample collected in November 1988 (Table 1). However, this result is considered qualitative because the ion charge-balance error calculated for the sample (-25.2%), which expresses the percent difference between the summed millequivalent concentrations of primary anions and cations in the groundwater, exceeds the DQO (+/-20%). Similarly, the historical minimum nitrate concentration (210 mg/L in April 1991) also is qualitative because of the charge balance error (38.7%). Charge balance errors for both samples are probably related to the nitrate concentrations.

Nitrate results reported for the groundwater samples collected before April 1991 range from 600 to 1,000 mg/L, but the most recent results are significantly lower (Table 1). A time-series plot of the nitrate results (excluding the qualitative results described above) shows a clearly decreasing long-term concentration trend dominated by wide short-term fluctuations (Figure 1). The overall decrease from the nitrate concentrations evident in groundwater samples collected from the well during the late-1980s reflects the substantially reduced flux of nitrate in the Nolichucky Shale in response to the closure of the former S-3 Ponds in 1988 and installation of the low-permeability cap at the site in 1989.

5.2 URANIUM

Thirteen groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit (Table 1), with the highest value (0.012 mg/L in November 1988) being below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results (available since January 1991) and low levels (<10 µg/L) of several common laboratory reagents (e.g., chloroform, MC, toluene, xylene, and acetone) that were detected in samples collected before December 1989, a trace of PCE was detected in one sample from the well (1 µg/L in January 1991). However, no VOCs were detected in the samples collected in March and August 2005.

5.4 GROSS ALPHA ACTIVITY

Two of the eight groundwater samples collected since January 1990 (the sample-specific MDA and/or CE are not available for previous samples) had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (12.18 pCi/L in July 1990) being below the MCL for gross alpha activity (15 pCi/L). None of the samples collected since July 1990 had gross alpha activity above the applicable MDA and/or CE.

5.5 GROSS BETA ACTIVITY

Four of the eight groundwater samples collected since January 1990 (the sample-specific MDA and/or CE are not available for previous samples) had gross beta activity above the applicable MDA and corresponding CE, including one value (53.65 pCi/L in January 1990) exceeding the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). The most recent results show that gross beta levels are substantially below the screening level (16 pCi/L in March 2005 and <MDA in August 2005).

WELL GW-123

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in July 1985, completed with an open-hole monitored interval from 522 to 572 ft bgs, and constructed with 4.5-inch diameter steel riser casing. The well forms a cluster with well GW-122 and is located in Bear Creek Valley west of Y-12, about 500 ft southwest (hydraulically downgradient) of the former S-3 Ponds, which are a major source of groundwater contamination in Bear Creek Valley. Located at the headwaters of Bear Creek, the S-3 Ponds consisted of four unlined surface impoundments, each with a 2.5 million gallon capacity, that were used between 1951 and 1984 for the disposal of acidic, radioactive liquid wastes generated primarily at Y-12. The S-3 Ponds were covered with a multi-layer, low permeability cap (including asphalt paving) during RCRA closure of the site in 1988.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-five groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 23 samples between December 1986 and September 1992, and the low-flow sampling method used to obtain samples in February and August 2003.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the deep bedrock interval (>400 ft bgs) in the Conasauga Group (Nolichucky Shale). Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 18 ft bgs and exhibits unusually wide (>50 ft) fluctuations. Excluding the very low groundwater elevations evident in May 1991 (949.45 ft above msl) and May 1992 (950.45 ft above msl), however, groundwater elevations in the well have fluctuated less than 15 ft (Figure 1).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields sodium-chloride-bicarbonate groundwater generally characterized by:

- high TDS (>800 mg/L);
- pH (field measurements) of 6.2 – 10.8;
- low molar proportions of calcium, magnesium, potassium, and sulfate (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for nine groundwater samples collected from the well since January 1991.

5.1 NITRATE

None of the groundwater samples had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

None of the groundwater samples had uranium concentrations above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for seven groundwater samples show non-detect values or false positive results for all of the VOCs that are confirmed groundwater contaminants in the Bear Creek Regime. A trace concentration (0.5 μg/L) of benzene was detected in the samples collected in July 1991 and October 1991, with a similar concentration of toluene (0.9 μg/L) also reported for the sample collected in July 1991. Toluene also was detected in October 1991 but this result is a false positive.

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity above the applicable MDA and corresponding CE was reported for the groundwater samples collected in March 1992 (21.5 pCi/L) and October 2001 (1.41 pCi/L). Accurate measurement of gross alpha activity may be limited by the high level of TDS in the groundwater samples from this well.

5.5 GROSS BETA ACTIVITY

Six of the groundwater samples had gross beta activity above the applicable MDA and corresponding CE. These results show gross beta activity near 10 pCi/L through each quarter of 1991, followed by a sharp spike in March 1992 (36.1 pCi/L) and subsequent a decrease below the MDA in February and August 2003. Accurate measurement of gross beta activity may be limited by the high level of TDS in the groundwater samples from this well.

WELL GW-124

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in July 1985 and was completed with an open-hole monitored interval from 100 to 150 ft bgs and nominal 4.5-inch diameter steel (SF25) riser casing. The well is paired with deep well GW-125 (552 ft bgs), and is located in Bear Creek Valley (BCV) west of Y-12, approximately 400 ft south of the former S-3 Ponds. Located near the western end of Y-12 and north of the headwaters of Bear Creek, the S-3 Ponds consist of four contiguous, unlined surface impoundments that were used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12, and were closed in accordance with applicable RCRA regulations in 1988. Closure included removal of liquid wastes and stabilization of sludge remaining in each pond, which were then filled and covered with a multilayer low-permeability cap and completed with an asphalt-paved parking lot in 1989. Historical operation of the S-3 Ponds created a large mound in the water table that dissipated after the site was closed and capped, and emplaced a heterogeneous mixture of inorganic, organic, and radiological contaminants in the subsurface that remains a primary source of groundwater and surface water contamination in BCV.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Nineteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 15 samples between December 1986 and September 1995, and the low-flow sampling method used to obtain four samples between March 2001 and August 2005. The sampling history includes a quarterly sampling frequency followed by 6-year (September 1995 – March 2001) and 4-year (August 2001 – March 2005) periods when no samples were collected from the well.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the intermediate depth (100-300 ft bgs) bedrock interval in the Maynardville Limestone (Conasauga Group), which trends northeast-southwest along the axis of BCV, dips southeast at an angle of 45º - 55º, and underlies the main channel of Bear Creek. The Maynardville Limestone exhibits the hydrologic characteristics typical of karst aquifers, with most of the groundwater flow occurring at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (shallow karst network). Hydrologic interaction between Bear Creek and the shallow karst network provides the principal exit-pathway for contaminants released from source areas within the Bear Creek watershed west of Y-12. Deeper in the subsurface, below the shallow karst network, fractures provide the primary groundwater flowpaths, and the bulk permeability generally decreases with depth because of decreased fracture aperture and increased fracture spacing (Solomon et al. 1992). Also, distinct lithologic and hydrologic characteristics differentiate seven hydrostratigraphic zones (numbered from bottom to top) in the Maynardville Limestone (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

The static water level in the well occurs at an average depth of approximately 15.5 ft bgs and exhibits seasonal fluctuations up to 8 ft. Directions of groundwater flow near the well, as indicated by groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for nearby monitoring wells, are primarily westward, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date indicate that the well yields sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 530 – 1,786 mg/L;
- pH (field measurements) of 6.4 – 6.97;
- elevated concentrations of sulfate (>60 mg/L), chloride (>30 mg/L), and nitrate (>10 mg/L) relative to other wells of similar depth in the Maynardville Limestone;
- low molar proportions of sodium & potassium (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Dissolution of the carbonate bedrock underlying the former S-3 Ponds by the many years of acidic seepage from the site, in addition to inorganic constituents entrained in the wastes disposed at the site, accounts for the TDS and elevated concentrations of inorganic compounds (e.g., nitrate) in the groundwater at this well.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. Based on the results reported for the groundwater samples collected to date, nitrate and gross beta activity are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Sixteen of the groundwater samples collected to date were analyzed for nitrate (Table 1), and all of these results show nitrate concentrations above the drinking water MCL (10 mg/L). The elevated nitrate concentrations indicate that the monitored interval in the well intercepts water-producing features that are hydraulically connected with the heterogeneous plume of inorganic, organic, and radiological contaminants emplaced during historical operation of the former S-3 Ponds. Nitrate is a primary component of the contaminant plume, is chemically stable and highly mobile in groundwater, and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Nitrate probably enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale and recharge of nitrate-contaminated surface water in Bear Creek (DOE 1997).

As noted previously, all of the groundwater samples had nitrate concentrations above the MCL, with the highest concentration (1,510 mg/L) reported for the sample collected in June 1988 (Table 1). However, this result is considered qualitative because the ion charge-balance error calculated for the sample (-62.6%), as expressed by the percent difference between the summed millequivalent concentrations of primary anions and cations in the groundwater, exceeds the DQO (+/-20%) for the Y-12 GWPP. Similarly, two unusually low nitrate concentrations (26 mg/L in November 1988 and 17 mg/L in March 1989) also are qualitative because of the ion charge balance errors (54.1% and 37.4%, respectively).

A time-series plot of the nitrate concentrations (excluding the qualitative results described above) shows a generally decreasing long-term concentration trend which began abruptly after the sample collected in August 1988 (Figure 1). The overall decrease from the nitrate concentrations evident in the late-1980s undoubtedly reflects the substantially reduced flux of nitrate in the

Maynardville Limestone in response to the closure of the former S-3 Ponds in 1988 and installation of the low-permeability cap at the site in 1989.

5.2 URANIUM

Eighteen groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit (Table 1), with the highest value (0.008 mg/L in December 1986) being below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive VOC results and low levels (<10 µg/L) of several common laboratory reagents (e.g., chloroform, MC, toluene, xylene, and acetone) detected in a few groundwater samples collected before March 1989, one or more of the following VOCs were detected in all but three of the samples collected to date: PCE, TCE, 12DCE, and/or chloroform (Table 2). These VOCs are confirmed components of the contaminant plume emplaced during historical operation of the former S-3 Ponds, but are typically present in the groundwater at substantially lower concentrations compared to other components of the plume (e.g., nitrate). This is because wastewaters that contained chlorinated solvents and other organic chemicals were not extensively disposed at the site (DOE 1997).

Based on concentration levels, the primary compounds in groundwater at this well are PCE and TCE (Table 2). The historical maximum value for PCE (21 µg/L in June 1987) and TCE (12 µg/L in October and November 1987) exceed the respective drinking water MCL (5 µg/L for both). Only PCE has been detected at a very low level (2 µg/L) since September 1995, and no VOCs were detected in the samples collected most recently (March and August 2005). The present lack of VOCs in the groundwater at this well generally mirrors the sharply reduced levels of nitrate in the well and likewise reflect the substantially reduced flux of VOCs (and other similarly mobile contaminants) via the groundwater flow/transport pathways intercepted by the monitored interval in the well as a direct consequence of closure of the former S-3 Ponds in 1988 and installation of the low-permeability cap at the site in 1989.

5.4 GROSS ALPHA ACTIVITY

Three of the six groundwater samples collected since January 1990 (the sample-specific MDA and/or CE are not available for previous samples) had gross alpha activity above the applicable MDA and corresponding CE (Table 1), with the highest value (8.17 pCi/L in January 1990) being below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

All of the groundwater samples collected since January 1990 (the sample-specific MDA and/or CE are not available for previous samples) had gross beta activity above the applicable MDA and corresponding CE (Table 1). Additionally, all but one result exceeds the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). The source of the gross beta activity in the groundwater at this well is most likely Tc-99, which was detected in the groundwater samples collected in March 2005 (61 pCi/L) and August 2005 (82 pCi/L). Note that Tc-99 is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, which is the only site at Y-12 that received wastes containing this radionuclide (DOE 1997). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the transport of Tc-99 in the Maynardville Limestone closely mirrors that of nitrate, which reflects their common source and their similar transport characteristics in the groundwater.

A time-series plot of the results for gross beta activity obtained since January 1990 shows a decreasing long-term trend (Figure 2). As with nitrate and VOC concentrations, this decreasing beta activity trend probably reflects the substantially reduced flux of Tc-99 in the Maynardville Limestone in response to the closure of the former S-3 Ponds in 1988 and installation of the low-permeability cap at the site in 1989.

WELL GW-127

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

The date for installation of this well is not known, but available information show that the well was completed with a screened monitored interval from 14 to 24 ft bgs, and constructed with nominal 2-inch diameter PVC (#40) riser casing and well screen (0.01 slot). The well is located in Bear Creek Valley (BCV) west of Y-12, approximately 300 ft west-southwest of the former S-3 Ponds and 100 ft north of the main channel of Bear Creek. Located near the western end of Y-12 and north of the headwaters of Bear Creek, the S-3 Ponds consist of four contiguous, unlined surface impoundments that were used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12, and were closed in accordance with applicable RCRA regulations in 1988. Closure included removal of liquid wastes and stabilization of sludge remaining in each pond, which were then filled and covered with a multilayer low-permeability cap and completed with an asphalt-paved parking lot in 1989. Historical operation of the S-3 Ponds created a large mound in the water table that dissipated after the site was closed and capped, and emplaced a heterogeneous mixture of inorganic, organic, and radiological contaminants in the subsurface that remains a primary source of groundwater and surface water contamination in BCV.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twelve groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 10 samples between December 1986 and January 1990, and the low-flow sampling method used to obtain two samples between June and October 2005. The sampling history includes a quarterly sampling frequency followed by a 15-year period (January 1990 – June 2005); when no groundwater samples were collected from the well.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Nolichucky Shale (Conasauga Group), which trends northeast-southwest along the northern slope of BCV, dips to the southeast at an angle of 45º-55º, and is bordered on the southeast by the overlying Maynardville Limestone, a highly permeable karst aquifer that provides the principal pathway for contaminant migration in BCV. The water table interval is a highly permeable zone that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock and transmits the bulk of the groundwater in the Nolichucky Shale. Moreover, the highly acidic wastes from the former S-3 Ponds dissolved carbonate strata interbedded within the Nolichucky Shale and greatly enhanced the relative permeability of these strata-bound flowpaths within several hundred feet of the site. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek, which traverse the Nolichucky Shale from northeast to southwest throughout BCV west of Y-12 and are numbered in ascending order downstream from the headwaters of the creek. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone.

The static water level in the well occurs at an average depth of approximately 13 ft bgs and exhibits minor (<3 ft) seasonal fluctuations. Directions of groundwater flow near the well, as indicated by groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for nearby monitoring wells, indicate components of flow to the west, parallel with the trend (strike) of bedding in Nolichucky Shale, and to the south-south west, across geologic-strike toward the Maynardville Limestone and the main channel of Bear Creek. However, as noted previously, the Nolichucky Shale exhibits strongly anisotropic flow via strike-parallel flowpaths (i.e., bedding-plane fractures) oriented in directions that may or may not coincide with the flow directions inferred from groundwater elevation isopleths, and dissolution of carbonate strata by the acidic seepage locally enhanced strata-bound groundwater flow/contaminant transport in directions parallel with geologic strike and dip.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples collected to date show that the well yields calcium-magnesium-bicarbonate groundwater that is generally characterized by:

- TDS of 521 –932 mg/L;
- pH (field measurements) of 6.58 – 7.1;
- high concentrations of sodium (>40 mg/L), chloride (>30 mg/L), and sulfate (>50 mg/L);
- low concentrations of potassium (below detection limits); and
- total concentrations of trace metals (except uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, all of these principal contaminants have been present in the groundwater at this well, but none have been detected at levels that exceed drinking water MCLs in samples collected since January 1990.

5.1 NITRATE

Eleven groundwater samples collected to date had nitrate concentrations at or above the applicable reporting limit (Table 1), including three samples with concentrations that exceed the drinking water MCL for nitrate (10 mg/L). The historical maximum nitrate concentration (63.4 mg/L) was reported for the sample collected in December 1986, with lower levels (<15 mg/L) reported for all subsequent samples. Moreover, nitrate concentrations have been below the MCL in the all of the samples collected since August 1988, and the nitrate was not detected (i.e., <0.028 mg/L reporting limit) in the sample collected most recently (October 2005). Considering that the well is only 300 ft from the former S-3 Ponds, where nitrate concentrations in the shallow groundwater exceed 1,000 mg/L, the relatively low nitrate concentrations in the well suggest that the monitored interval does not intercept groundwater flow/transport pathways that are extensively connected with the contaminant plume emplaced during historical operation of the site. Nitrate is a principal component of the plume, is stable and highly mobile in groundwater, and is believed to effectively trace the primary flowpaths for other similarly mobile components from the former S-3 Ponds. Thus, the present lack of nitrate in the groundwater from this well mirrors the substantially reduced flux of nitrate (and other similarly mobile contaminants) that occurred in the shallow groundwater flow system after the site was closed and capped in the late 1980s.

5.2 URANIUM

All groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit (Table 1), including 10 concentrations that exceeded the MCL for uranium (0.03 mg/L). The historical maximum uranium concentration (0.885 mg/L) was reported for the sample collected in December 1986. Uranium concentrations decreased by about 50% from December 1986 through January 1990 (0.434 mg/L), and are below the MCL in June and October 2005 (Table 1). As with the nitrate concentrations in the groundwater from the well, the elevated uranium levels indicated by the historical sampling results suggest that the monitored interval for the well intercepts the groundwater flow/transport pathways that are hydraulically connected with the contaminant plume emplace during historical operation of the former S-3 Ponds. Uranium was entrained in the nitric-acid wastes disposed at the site and is a primary component of the plume. In the acidic groundwater nearest the site, uranium is probably present as uranyl cations, which are prone to pH sensitive sorption reactions (Fetter 1993). Considering that the infiltration of acidic wastes was discontinued in 1984 and the site has been covered by a low-permeability cap since 1989, subsequent recharge/discharge cycles have substantially buffered the acidic pH of the groundwater such that the more neutral pH now evident in the well promotes attenuation (sorption) of the uranyl cations. Additionally, as with nitrate, the closure and capping of the former S-3 Ponds substantially reduced the relative flux of uranium in the shallow groundwater flow system downgradient of the site.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results (screened in samples collected since January 1991) and very low levels (<5 µg/L) of several common laboratory reagents (e.g., acetone) detected in samples collected before May 1989, two VOCs (PCE and chloroform) have been detected in at least three samples collected from the well to date (Table 2). Both of these VOCs are minor components of the contaminant plume originating from the former S-3 Ponds. Compared to the inorganic components of the plume, particularly nitrate, VOCs are present at substantially lower concentrations, primarily because the related wastes (e.g., chlorinated solvents) were not extensively disposed at the former S-3 Ponds (DOE 1997).

The historical maximum value for PCE (42 µg/L in August 1988) exceeds the drinking water MCL (5 µg/L), but only trace levels (3 µg/L or less) were detected in subsequent samples (March, May, and December 1999, and January 1990). Moreover, no VOCs were detected in the samples collected in June and October 2005. The lack of VOCs in the groundwater from the well again reflects the substantially reduced flux of contaminants in the shallow groundwater flow system that occurred after the former S-3 Ponds were closed and capped.

5.4 GROSS ALPHA ACTIVITY

All three of the groundwater samples collected since January 1990 (the sample-specific MDA and/or CE are not available for previous samples) had gross alpha activity above the applicable MDA and corresponding CE (Table 1), including one concentration (267 pCi/L in January 1990) that exceeded the MCL for gross alpha activity (15 pCi/L). No gross alpha activity has been detected at concentrations that exceeded the MCL since January 1990, which is supported by the isotopic uranium results reported for the samples collected in June and October 2005, which show low levels (<10 pCi/L) of U-234 and U-238 (Table 1).

5.5 GROSS BETA ACTIVITY

Two of the three groundwater samples collected since January 1990 (the sample-specific MDA and/or CE are not available for previous samples) had gross beta activity above the applicable MDA and corresponding CE (Table 1), including one value (308 pCi/L in January 1990) exceeding the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). The groundwater samples collected in June and October 2005 had gross beta activity below the SDWA screening level. Also, radiological analyses of the samples collected in June and October 2005 suggests that the source of the gross beta activity may be Tc-99 (Table 1), a beta-particle emitting radionuclide that is a principal component of the contaminant plume from the former S-3 Ponds.

WELL GW-133
Sampling Port 01

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located in Bear Creek Valley (BCV) near the west end of Y-12, approximately 200 ft northeast of the former S-3 Ponds. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 55 to 599 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from eight sampling ports, with port 01 being 552 ft bgs (Figure 1). Only two samples have been collected from this port, one in August 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 01 yields groundwater from the deep bedrock (Rogersville Shale) interval in the Conasauga Group formations that subcrop along the southern flank of Pine Ridge. The bulk of the groundwater flow in the low-permeability formations (e.g., Rogersville Shale) occurs within a highly conductive zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into the northern tributaries of Bear Creek, which trend southwest across the southern flank of Pine Ridge and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a more permeable (karst) formation that subcrops along the axis of BCV and the main channel of Bear Creek.

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 01 yields highly mineralized sodium-bicarbonate groundwater generally characterized by:

- TDS of 1,120 – 1,190 mg/L;
- pH (field measurements) of 7.67 – 8.09;
- fluoride concentrations near 5 mg/L (e.g., 4.91 mg/L in August 2004);

- low molar proportions of calcium, chloride, magnesium, potassium, and sulfate (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

These geochemical characteristics reflect the decrease in groundwater flux that occurs with depth in the low-permeability Conasauga Group formations (e.g., Rogersville Shale) in BCV (Solomon et al. 1992). Most of the water table and shallow (i.e., <100 ft bgs) bedrock wells in these formations yield calcium-magnesium-bicarbonate groundwater. A fairly abrupt change to sodium-bicarbonate groundwater occurs at a depth of about 100 ft bgs and is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture or increased fracture spacing (Solomon et al. 1992). Further reduced groundwater flux deeper in the bedrock (>300 ft bgs) is indicated by a general increase in TDS and a gradational transition from sodium-bicarbonate groundwater to sodium-chloride groundwater.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

None of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

None of the groundwater samples collected to date had total uranium concentrations above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

None of the groundwater samples collected to date contained VOCs.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE. Additionally, the sample collected in August 2004 was analyzed for Tc-99; the analytical result is below the MDA.

WELL GW-133
Sampling Port 05

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located in Bear Creek Valley (BCV) near the west end of Y-12, approximately 200 ft northeast of the former S-3 Ponds. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 55 to 599 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from eight sampling ports, with port 05 being 487 ft bgs (Figure 1). Only two samples have been collected from this port, one in August 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 05 yields groundwater from the deep bedrock (Rogersville Shale) interval in the Conasauga Group formations that subcrop along the southern flank of Pine Ridge. The bulk of the groundwater flow in the low-permeability formations (e.g., Rogersville Shale) occurs within a highly conductive zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into the northern tributaries of Bear Creek, which trend southwest across the southern flank of Pine Ridge and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a more permeable (karst) formation that subcrops along the axis of BCV and the main channel of Bear Creek.

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 05 yields mineralized sodium-bicarbonate groundwater generally characterized by:

- TDS of 657 – 664 mg/L;
- pH (field measurements) of 8.47 – 8.69;
- fluoride concentrations above 2 mg/L (e.g., 2.16 mg/L in August 2004);
- low molar proportions of calcium, chloride, magnesium, potassium, and sulfate (<10% of total anions/cations); and

- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

These geochemical characteristics reflect the decrease in groundwater flux that occurs with depth in the low-permeability Conasauga Group formations (e.g., Rogersville Shale) in BCV (Solomon et al. 1992). Most of the water table and shallow (i.e., <100 ft bgs) bedrock wells in these formations yield calcium-magnesium-bicarbonate groundwater. A fairly abrupt change to sodium-bicarbonate groundwater occurs at a depth of about 100 ft bgs and is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture or increased fracture spacing (Solomon et al. 1992). Further reduced groundwater flux deeper in the bedrock (>300 ft bgs) is indicated by a general increase in TDS and a gradational transition from sodium-bicarbonate groundwater to sodium-chloride groundwater.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

None of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

None of the groundwater samples collected to date had a uranium concentration above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

None of the groundwater samples collected to date contained VOCs.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE. Additionally, the sample collected in August 2004 was analyzed for Tc-99; the analytical result is below the MDA.

WELL GW-133
Sampling Port 08

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located in Bear Creek Valley (BCV) near the west end of Y-12, approximately 200 ft northeast of the former S-3 Ponds. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 55 to 599 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from eight sampling ports, with port 08 being 427 ft bgs (Figure 1). Only two samples have been collected from this port, one in August 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 08 yields groundwater from the deep bedrock (Rogersville Shale) interval in the Conasauga Group formations that subcrop along the southern flank of Pine Ridge. The bulk of the groundwater flow in the low-permeability formations (e.g., Rogersville Shale) occurs within a highly conductive zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek, which trend southwest across the southern flank of Pine Ridge and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a more permeable (karst) formation that subcrops along the axis of BCV and the main channel of Bear Creek.

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 08 yields mineralized sodium-bicarbonate groundwater generally characterized by:

- TDS of 551 – 555 mg/L;
- pH (field measurements) of 8.11 – 8.51;
- low molar proportions of calcium, chloride, fluoride, magnesium, potassium, and sulfate (<10% of total anions/cations); and

- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

These geochemical characteristics reflect the decrease in groundwater flux that occurs with depth in the low-permeability Conasauga Group formations (e.g., Rogersville Shale) in BCV (Solomon et al. 1992). Most of the water table and shallow (i.e., <100 ft bgs) bedrock wells in these formations yield calcium-magnesium-bicarbonate groundwater. A fairly abrupt change to sodium-bicarbonate groundwater occurs at a depth of about 100 ft bgs and is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture or increased fracture spacing (Solomon et al. 1992). Further reduced groundwater flux deeper in the bedrock (>300 ft bgs) is indicated by a general increase in TDS and a gradational transition from sodium-bicarbonate groundwater to sodium-chloride groundwater.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

None of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

None of the groundwater samples collected to date had a total uranium concentration above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Low concentrations of the following petroleum hydrocarbons were detected in the groundwater sample collected in August 1999: ethylbenzene (8 μg/L), toluene (2 μg/L), and styrene (3 μg/L). The well is hydraulically upgradient of all known sources of groundwater contamination located near the west end of Y-12, including contamination attributed to historical leaks of petroleum fuel from underground storage tanks formerly located at the Rust Garage Area southeast of the well. It is possible that the presence of these VOCs in the groundwater sample reflects the localized, residual contamination associated in some way with the drilling of the original core hole in which the well was constructed. These compounds were not detected in the August 2004 sample from the port.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE. Additionally, the sample collected in August 2004 was analyzed for Tc-99; the analytical result is below the MDA.

WELL GW-133
Sampling Port 10

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located in Bear Creek Valley (BCV) near the west end of Y-12, approximately 200 ft northeast of the former S-3 Ponds. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 55 to 599 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from eight sampling ports, with port 10 being 405 ft bgs (Figure 1). Only two samples have been collected from this port, one in August 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 10 yields groundwater from the deep bedrock (Rogersville Shale) interval in the Conasauga Group formations that subcrop along the southern flank of Pine Ridge. The bulk of the groundwater flow in the low-permeability formations (e.g., Rogersville Shale) occurs within a highly conductive zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into the northern tributaries of Bear Creek, which trend southwest across the southern flank of Pine Ridge and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a more permeable (karst) formation that subcrops along the axis of BCV and the main channel of Bear Creek.

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 10 yields mineralized sodium-bicarbonate groundwater generally characterized by:

- TDS of 658 – 717 mg/L;
- pH (field measurements) of 8.18 – 8.44;
- fluoride concentrations above 2 mg/L (e.g., 2.78 mg/L in August 2004);
- low molar proportions of calcium, chloride, magnesium, potassium, and sulfate (<10% of total anions/cations); and

- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

These geochemical characteristics reflect the decrease in groundwater flux that occurs with depth in the low-permeability Conasauga Group formations (e.g., Maryville Limestone) in BCV (Solomon et al. 1992). Most of the water table and shallow (i.e., <100 ft bgs) bedrock wells in these formations yield calcium-magnesium-bicarbonate groundwater. A fairly abrupt change to sodium-bicarbonate groundwater occurs at a depth of about 100 ft bgs and is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture or increased fracture spacing (Solomon et al. 1992). Further reduced groundwater flux deeper in the bedrock (>300 ft bgs) is indicated by a general increase in TDS and a gradational transition from sodium-bicarbonate groundwater to sodium-chloride groundwater.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

None of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

None of the groundwater samples collected to date had a total uranium concentration above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

None of the groundwater samples collected to date contained VOCs.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE. Additionally, the sample collected in August 2004 was analyzed for Tc-99; the analytical result is below the MDA, which is consistent with the gross beta result for this sample.

WELL GW-133
Sampling Port 14

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located in Bear Creek Valley (BCV) near the west end of Y-12, approximately 200 ft northeast of the former S-3 Ponds. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 55 to 599 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from eight sampling ports, with port 14 being 313 ft bgs (Figure 1). Only two samples have been collected from this port, one in August 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 14 yields groundwater from the intermediate depth bedrock (Maryville Limestone) interval in the Conasauga Group formations that subcrop along the southern flank of Pine Ridge. The bulk of the groundwater flow in the low-permeability formations (e.g., Maryville Limestone) occurs within a highly conductive zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek, which trend southwest across the southern flank of Pine Ridge and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a more permeable (karst) formation that subcrops along the axis of BCV and the main channel of Bear Creek.

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 14 yields moderately mineralized sodium-bicarbonate groundwater generally characterized by:

- TDS of 718 – 746 mg/L;
- pH (field measurements) of 8.4 – 8.51;
- fluoride concentrations above 2 mg/L (e.g., 3.12 mg/L in August 2004);

- low molar proportions of calcium, chloride, fluoride, magnesium, potassium, and sulfate (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

These geochemical characteristics reflect the decrease in groundwater flux that occurs with depth in the low-permeability Conasauga Group formations (e.g., Maryville Limestone) in BCV (Solomon et al. 1992). Most of the water table and shallow (i.e., <100 ft bgs) bedrock wells in these formations yield calcium-magnesium-bicarbonate groundwater. A fairly abrupt change to sodium-bicarbonate groundwater occurs at a depth of about 100 ft bgs and is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture or increased fracture spacing (Solomon et al. 1992). Further reduced groundwater flux deeper in the bedrock (>300 ft bgs) is indicated by a general increase in TDS and a gradational transition from sodium-bicarbonate groundwater to sodium-chloride groundwater.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

None of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

One of the groundwater samples collected to date had a total uranium concentration above the applicable analytical reporting limit, and this result (0.00137 mg/L in August 1999) is substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Low (estimated) concentrations of the following petroleum hydrocarbons were detected in the groundwater samples: benzene (3 μg/L in August 1999 and 4 μg/L in August 2004), ethylbenzene (1 μg/L in August 1999 and 2 μg/L in August 2004), and styrene (1 μg/L in August 1999 and August 2004). The well is hydraulically upgradient of all known sources of groundwater contamination located near the west end of Y-12, including contamination attributed to historical leaks of petroleum fuel from underground storage tanks formerly located at the Rust Garage Area southeast of the well.

There are several potential sources of the petroleum hydrocarbons in the groundwater samples from this sampling port: (1) residual contamination from installation of the well; (2) contamination from components of the Westbay sampling equipment that are made of or contain petroleum-based materials; (3) contamination of the samples during sampling or handling; and (4) traces of natural hydrocarbons in the low-permeability bedrock.

Residual contamination from installation/construction of the well seems an unlikely source of the hydrocarbons in light of the age of the well (>8 years). Moreover, well installation and construction was closely supervised and controlled to exclude usage of petroleum-based drilling equipment lubricants. Additionally, well installation/construction records do not note any accidental spills/leaks of petroleum-based fluids from the drilling rig or support equipment during installation of the well.

Contamination from components of the Westbay sampling equipment in the well is possible, as several components of the sampling apparatus contain petroleum hydrocarbons. However, it is not known if the hydrocarbons are leachable from these components and repeated sampling since installation of the equipment would be expected to "flush" any leached constituents from the sampling port. Also, such systemic contamination from components of the Westbay sampling equipment would be expected to result in consistent contamination of samples from multiple, if not all, sampling ports. However, only some of the other ports repeatedly yield samples that contain petroleum hydrocarbons. Indeed, these compounds have not been detected consistently in any of the samples collected to date from eight of the sampling ports in the well. In addition, these hydrocarbons have been observed in groundwater samples from some deeper wells that are not instrumented with Westbay sampling equipment.

Contamination of the samples during collection or handling also may be possible, but is not indicated by results for associated quality assurance samples (i.e., petroleum hydrocarbons are not detected in the field or trip blanks). Similarly, data for laboratory blank samples do not support contamination during storage and/or analysis in the laboratory. Also, contamination of the samples during collection at the well head seems very unlikely again because such systemic contamination would result in the detection of petroleum hydrocarbons in the samples collected from other ports in the well.

Traces of petroleum hydrocarbons naturally present at depth in the low-permeability bedrock may explain the detection of these compounds in the groundwater samples from this port. These hydrocarbons have been observed in groundwater samples from some deeper wells that are not instrumented with Westbay sampling equipment.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE. However, the sample collected in August 2004 was analyzed for Tc-99 (a beta-particle emitter) and the reported Tc-99 concentration (40 pCi/L) exceeds both the applicable MDA (13 pCi/L) and the corresponding CE (8.6 pCi/L). Note that Tc-99 is at least partially volatilized during sample preparation for analysis of gross beta activity, so the level of Tc-99 is typically higher (if present in the sample) than the gross beta activity.

WELL GW-133
Sampling Port 17

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located in Bear Creek Valley (BCV) near the west end of Y-12, approximately 200 ft northeast of the former S-3 Ponds. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 55 to 599 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from eight sampling ports, with port 17 being 253 ft bgs (Figure 1). Only two samples have been collected from this port, one in August 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 17 yields groundwater from the bedrock (Maryville Limestone) interval in the Conasauga Group formations that subcrop along the southern flank of Pine Ridge. The bulk of the groundwater flow in the low-permeability formations (e.g., Maryville Limestone) occurs within a highly conductive zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek, which trend southwest across the southern flank of Pine Ridge are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a more permeable (karst) formation that subcrops along the axis of BCV and the main channel of Bear Creek.

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 17 yields mineralized sodium-bicarbonate groundwater generally characterized by:

- TDS of 620 – 672 mg/L;
- pH (field measurements) of 8.49 – 8.7;
- fluoride concentrations above 2 mg/L (e.g., 2.98 mg/L in August 2004);
- low molar proportions of calcium, chloride, magnesium, potassium, and sulfate (<10% of total anions/cations); and

- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

These geochemical characteristics reflect the decrease in groundwater flux that occurs with depth in the low-permeability Conasauga Group formations (e.g., Maryville Limestone) in BCV (Solomon et al. 1992). Most of the water table and shallow (i.e., <100 ft bgs) bedrock wells in these formations yield calcium-magnesium-bicarbonate groundwater. A fairly abrupt change to sodium-bicarbonate groundwater occurs at a depth of about 100 ft bgs and is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture or increased fracture spacing (Solomon et al. 1992). Further reduced groundwater flux deeper in the bedrock (>300 ft bgs) is indicated by a general increase in TDS and a gradational transition from sodium-bicarbonate groundwater to sodium-chloride groundwater.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

None of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

None of the groundwater samples collected to date had a total uranium concentration above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

A low (estimated) concentration of benzene (1 μg/L) was detected in the groundwater sample collected in August 1999. The well is hydraulically upgradient of all known sources of groundwater contamination located near the west end of Y-12, including contamination attributed to historical leaks of petroleum fuel from underground storage tanks formerly located at the Rust Garage Area southeast of the well. It is possible that the presence of benzene in the groundwater sample reflects the localized, residual contamination associated in some way with the drilling of the original core hole in which the well was constructed.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE. Additionally, the sample collected in August 2004 was analyzed for Tc-99; the analytical result is below the MDA.

WELL GW-133
Sampling Port 21

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located in Bear Creek Valley (BCV) near the west end of Y-12, approximately 200 ft northeast of the former S-3 Ponds. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 55 to 599 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from eight sampling ports, with port 21 being 158 ft bgs (Figure 1). Only three samples have been collected from this port, one in August 1999 and two (duplicate) in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 21 yields groundwater from the intermediate depth bedrock (Maryville Limestone) interval in the Conasauga Group formations that subcrop along the southern flank of Pine Ridge. The bulk of the groundwater flow in the low-permeability formations (e.g., Maryville Limestone) occurs within a highly conductive zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek, which trend southwest across the southern flank of Pine Ridge and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a more permeable (karst) formation that subcrops along the axis of BCV and the main channel of Bear Creek.

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 21 yields sodium-enriched, calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 295 – 355 mg/L;
- pH (field measurements) of 7.84 – 7.87;
- sodium concentrations above 50 mg/L (e.g., 66.4 mg/L in August 2004);

- low molar proportions of chloride, fluoride, potassium, and sulfate (<10% of total anions/cations);
- total strontium concentrations that typically exceed 1 mg/L (e.g., 1.66 mg/L in August 2004); and
- total (unfiltered sample) concentrations of trace metals (except strontium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

These geochemical characteristics reflect the decrease in groundwater flux that occurs with depth in the low-permeability Conasauga Group formations (e.g., Maryville Limestone) in BCV (Solomon et al. 1992). Most of the water table and shallow (i.e., <100 ft bgs) bedrock wells in these formations yield calcium-magnesium-bicarbonate groundwater. A fairly abrupt change to sodium-bicarbonate groundwater occurs at a depth of about 100 ft bgs and is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture or increased fracture spacing (Solomon et al. 1992). Further reduced groundwater flux deeper in the bedrock (>300 ft bgs) is indicated by a general increase in TDS and a gradational transition from sodium-bicarbonate groundwater to sodium-chloride groundwater.

A combination of several natural geochemical processes probably account for the high strontium concentrations in the groundwater samples from this port, including: mixing of sulfate-enriched groundwater with brines at depth, which may cause the precipitation of barite and celestite ($SrSO_4$); upward diffusion of solutes from brines in the deeper bedrock; and matrix diffusion from the bedrock (Saunders and Toran 1992).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

None of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

None of the groundwater samples collected to date had a total uranium concentration above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

A low (estimated) concentration of 111TCA (1 μg/L) was detected in the groundwater sample collected in August 1999. The well is hydraulically upgradient of all known sources of groundwater contamination located near the west end of Y-12, where there are several contaminant plumes that contain a variety of dissolved VOCs, including 111TCA.

5.4 GROSS ALPHA ACTIVITY

None of groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE. Additionally, the sample collected in August 2004 was analyzed for Tc-99; the analytical result is below the MDA.

WELL GW-133
Sampling Port 24

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located in Bear Creek Valley (BCV) near the west end of Y-12, approximately 200 ft northeast of the former S-3 Ponds. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 55 to 599 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from eight sampling ports, with port 24 being 93 ft bgs (Figure 1). Only two samples have been collected from this port, one in August 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 24 yields groundwater from the shallow bedrock (Maryville Limestone) interval in the Conasauga Group formations that subcrop along the southern flank of Pine Ridge. The bulk of the groundwater flow in the low-permeability formations (e.g., Maryville Limestone) occurs within a highly conductive zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek, which trend southwest across the southern flank of Pine Ridge and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a more permeable (karst) formation that subcrops along the axis of BCV and the main channel of Bear Creek.

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 24 yields sodium-enriched, calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 291 – 299 mg/L;
- pH (field measurements) of 7.29 – 7.55;
- sodium concentrations above 40 mg/L (e.g., 44.9 mg/L in August 2004);

- low molar proportions of chloride, fluoride, potassium, and sulfate (<10% of total anions/cations);
- total strontium concentrations that typically exceed 1 mg/L (e.g., 1.66 mg/L in August 2004); and
- total (unfiltered sample) concentrations of trace metals (except strontium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

These geochemical characteristics reflect the decrease in groundwater flux that occurs with depth in the low-permeability Conasauga Group formations (e.g., Maryville Limestone) in BCV (Solomon et al. 1992). Most of the water table and shallow (i.e., <100 ft bgs) bedrock wells in these formations yield calcium-magnesium-bicarbonate groundwater. A fairly abrupt change to sodium-bicarbonate groundwater occurs at a depth of about 100 ft bgs and is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture or increased fracture spacing (Solomon et al. 1992). Further reduced groundwater flux deeper in the bedrock (>300 ft bgs) is indicated by a general increase in TDS and a gradational transition from sodium-bicarbonate groundwater to sodium-chloride groundwater.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

None of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

None of the groundwater samples collected to date had a total uranium concentration above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Low (estimated) concentrations of carbon tetrachloride (2 μg/L), styrene (2 μg/L), and 111TCA (1 μg/L) were detected in the groundwater sample collected in August 1999 and the sample collected in August 2004 had a trace (1 μg/L) of styrene. The well is hydraulically upgradient of all known sources of groundwater contamination located near the west end of Y-12, where there are several contaminant plumes that contain a variety of dissolved VOCs, including carbon tetrachloride, 111TCA, and petroleum hydrocarbons (e.g., styrene).

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity reported for the groundwater sample collected in August 1999 (270 pCi/L) exceeds the applicable MDA and corresponding CE and is more than 10 times the drinking water MCL for gross alpha activity (15 pCi/L). In contrast, the gross alpha activity reported for the sample collected in August 2004 does not exceed the MDA.

5.5 GROSS BETA ACTIVITY

Gross beta activity reported for the groundwater sample collected in August 1999 (56 pCi/L) exceeds the applicable MDA and corresponding CE and is slightly above the Safe Drinking Water Act screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). In contrast, the gross beta activity reported for the sample collected in August 2004 does not exceed the MDA. Moreover, the sample collected in August 2004 was analyzed for Tc-99; which is a beta-emitting radionuclide and a principal component of the groundwater contaminant plume that originates from former S-3 Ponds, and the analytical result for Tc-99 does not exceed the MDA.

WELL GW-134
Sampling Port 05

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located in Bear Creek Valley (BCV) near the west end of Y-12, approximately 450 ft southeast of the former S-3 Ponds. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 35 to 842 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 05 being 740 ft bgs (Figure 1). Only two samples have been collected from this port, one in August 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 05 yields groundwater from the deep bedrock (Maryville Limestone) interval in the Conasauga Group formations that subcrop along the southern flank of Pine Ridge and dip to the southeast below the Knox Group formations that form Chestnut Ridge. The bulk of the groundwater flow in the low-permeability formations (e.g., Maryville Limestone) occurs within a highly conductive zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of decreased fracture frequency, reduced fracture aperture, and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs via flowpaths oriented parallel with geologic strike (e.g., bedding plane fractures).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 05 yields highly mineralized sodium-chloride-bicarbonate groundwater generally characterized by:

- TDS of 8,510 – 9,200 mg/L;
- pH (field measurements) of 7.2 – 7.22;
- high concentrations of nitrate (e.g., 860 mg/L in August 2004);
- low molar proportions of calcium, fluoride, magnesium, potassium, and sulfate (<10% of total anions/cations);
- elevated levels of barium (>2 mg/L), lithium (>1 mg/L), and strontium (>8 mg/L); and
- total (unfiltered sample) concentrations of trace metals (except barium, lithium, and strontium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance

limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

These geochemical characteristics reflect the decrease in groundwater flux that occurs with depth in the low-permeability Conasauga Group formations (e.g., Maryville Limestone) in BCV (Solomon et al. 1992). Most of the water table and shallow (i.e., <100 ft bgs) bedrock wells in these formations yield calcium-magnesium-bicarbonate groundwater. A fairly abrupt change to sodium-bicarbonate groundwater occurs at a depth of about 100 ft bgs and is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture or increased fracture spacing (Solomon et al. 1992). Further reduced groundwater flux deeper in the bedrock (>300 ft bgs) is indicated by a general increase in TDS and a gradational transition from sodium-bicarbonate groundwater to sodium-chloride groundwater.

Elevated trace metal concentrations are attributable to natural geochemical processes at depth, including: mixing of sulfate-enriched groundwater with brines at depth, which may cause the precipitation of barite ($BaSO_4$) and celestite ($SrSO_4$); upward diffusion of solutes from brines in the deeper bedrock; and matrix diffusion from disseminated minerals in the bedrock (Toran and Saunders 1992).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

The groundwater samples collected in August 1999 and August 2004 had nitrate concentrations of 1,173 mg/L and 860 mg/L, respectively. These nitrate results potentially reflect a generally decreasing long-term concentration trend.

The source of the nitrate is the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds, which were four contiguous, unlined surface impoundments used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric-acid wastes generated at Y-12. The ponds also received periodic shipments of Tc-99 wastes generated at the DOE Savannah River Plant. During RCRA closure of the site in 1988, the ponds were backfilled and covered with a multilayer low-permeability cap (and an asphalt-paved parking lot). Operation of the ponds emplaced a contaminant plume containing a heterogeneous mix of inorganic, organic, and radiological contaminants. With concentrations in excess of 10,000 mg/L, nitrate is the primary inorganic component of the plume and, based on available data from the network of existing monitoring wells, elevated concentrations (>10 mg/L) of nitrate extend at least 5,000 ft east-southeast and west-southwest (parallel with geologic strike) of the former S-3 Ponds, and approximately 1,000 ft south-southwest (across geologic strike) toward the main channel of Bear Creek (DOE 1997). The elongated geometry of the plume reflects the preferred strike-parallel direction of groundwater flow/contaminant transport in BCV.

The gradational decrease in bulk permeability and groundwater flux that occurs with depth (see Section 3.0) has generally limited the vertical (down-dip) extent of the S-3 Ponds contaminant plume, with the very high nitrate concentrations (>1,000 mg/L) evident for the groundwater samples from sampling port 05 showing that the plume extends at least 750 ft bgs. Moreover, the nitrate concentrations reported for all sampling ports more than 300 ft bgs are substantially higher than evident for sampling ports at shallower depths (Figure 1) because seasonal recharge/discharge cycles more effectively flush nitrate (and other contaminants) from the shallow groundwater flow system (DOE 1997). The elevated nitrate concentrations at depth reflect downward vertical migration driven by the greater density of the highly mineralized and acidic wastewater (Toran and Saunders 1992) and the hydraulic head created by site operations.

5.2 URANIUM

Total uranium concentrations above the applicable analytical reporting limit were reported for the groundwater samples collected in August 1999 (0.00154 mg/L) and August 2004 (0.00274 mg/L). Both of these results are substantially less than the drinking water MCL for uranium (0.03 mg/L). Along with nitrate, uranium is a principal component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. Thus, the low (background) levels of uranium in the groundwater from sampling port 05 reflect the substantially lower mobility and greater attenuation of uranium relative to that of nitrate.

5.3 VOLATILE ORGANIC COMPOUNDS

A low (estimated) concentration of benzene (1 μg/L) was detected in the groundwater sample collected in August 1999 and was not detected in the sample collected in August 2004. Benzene is not a major component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds.

5.4 GROSS ALPHA ACTIVITY

The gross alpha activity result reported for each groundwater sample collected to date does not exceed the applicable MDA.

5.5 GROSS BETA ACTIVITY

The gross beta activity result reported for each groundwater sample collected to date does not exceed the applicable MDA. Additionally, the sample collected in August 2004 was analyzed for Tc-99, a beta-emitting radionuclide that is a primary component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. The analytical result for Tc-99 is below the MDA, which is surprising because the distribution of Tc-99 typically mirrors that of nitrate (see Section 5.1). For reasons not readily apparent from the available data, Tc-99 is not transported via the groundwater flow/transport pathways intercepted by the interval monitored by this port.

WELL GW-134
Sampling Port 11

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located in Bear Creek Valley (BCV) near the west end of Y-12, approximately 450 ft southeast of the former S-3 Ponds. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 35 to 842 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 11 being 578 ft bgs (Figure 1). Three samples have been collected from this port, two in August 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 11 yields groundwater from the deep bedrock (Nolichucky Shale) interval in the Conasauga Group formations that subcrop along the southern flank of Pine Ridge and dip to the southeast below the Knox Group formations that form Chestnut Ridge. The bulk of the groundwater flow in the low-permeability formations (e.g., Nolichucky Shale) occurs within a highly conductive zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of decreased fracture frequency, reduced fracture aperture, and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs via flowpaths oriented parallel with geologic strike (e.g., bedding plane fractures).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 11 yields highly mineralized sodium-chloride-bicarbonate groundwater generally characterized by:

- TDS of 2,640 – 6,330 mg/L;
- pH (field measurements) of 7.6 – 7.77;
- extremely high concentrations nitrate (e.g., 877 mg/L in August 2004);
- low molar proportions of calcium, fluoride, magnesium, potassium, and sulfate (<10% of total anions/cations);
- elevated levels of strontium (>3 mg/L); and

- total (unfiltered sample) concentrations of trace metals (except strontium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

These geochemical characteristics reflect the decrease in groundwater flux that occurs with depth in the low-permeability Conasauga Group formations (e.g., Maryville Limestone) in BCV (Solomon et al. 1992). Most of the water table and shallow (i.e., <100 ft bgs) bedrock wells in these formations yield calcium-magnesium-bicarbonate groundwater. A fairly abrupt change to sodium-bicarbonate groundwater occurs at a depth of about 100 ft bgs and is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture or increased fracture spacing (Solomon et al. 1992). Further reduced groundwater flux deeper in the bedrock (>300 ft bgs) is indicated by a general increase in TDS and a gradational transition from sodium-bicarbonate groundwater to sodium-chloride groundwater. Elevated strontium concentrations are attributable to natural geochemical processes at depth, including: mixing of sulfate-enriched groundwater with brines at depth, which may cause the precipitation of celestite ($SrSO_4$); upward diffusion of solutes from brines in the deeper bedrock; and matrix diffusion from disseminated minerals in the bedrock (Toran and Saunders 1992).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Nitrate concentrations of 237 mg/L and 877 mg/L were reported for the groundwater samples collected in August 1999 and August 2004, respectively. These nitrate results potentially reflect a generally increasing long-term concentration trend.

The source of the nitrate is the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds, which were four contiguous, unlined surface impoundments used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric-acid wastes generated at Y-12. The ponds also received periodic shipments of Tc-99 wastes generated at the DOE Savannah River Plant. During RCRA closure of the site in 1988, the ponds were backfilled and covered with a multilayer low-permeability cap (and an asphalt-paved parking lot). Operation of the ponds emplaced a contaminant plume containing a heterogeneous mix of inorganic, organic, and radiological contaminants. With concentrations in excess of 10,000 mg/L, nitrate is the primary inorganic component of the plume and, based on available data from the network of existing monitoring wells, elevated concentrations (>10 mg/L) of nitrate extend at least 5,000 ft east-southeast and west-southwest (parallel with geologic strike) of the former S-3 Ponds, and approximately 1,000 ft south-southwest (across geologic strike) toward the main channel of Bear Creek (DOE 1997). The elongated geometry of the plume reflects the preferred strike-parallel direction of groundwater flow/contaminant transport in BCV.

The gradational decrease in bulk permeability and groundwater flux that occurs with depth (see Section 3.0) has generally limited the vertical (down-dip) extent of the S-3 Ponds contaminant plume, with the very high nitrate concentrations (>1,000 mg/L) evident for the groundwater samples from the deepest sampling port in well GW-134 (sampling port 5) showing that the plume extends at least 750 ft bgs. Moreover, the nitrate concentrations reported for all sampling ports more than 300 ft bgs are substantially higher than evident for sampling ports at shallower depths (Figure 1) because seasonal recharge/discharge cycles more effectively flush nitrate (and other contaminants) from the shallow groundwater flow system (DOE 1997). The elevated nitrate concentrations at depth reflect downward vertical migration driven by the greater density of the highly mineralized and acidic wastewater (Toran and Saunders 1992) and the hydraulic head created by site operations.

5.2 URANIUM

Total uranium concentrations above the applicable analytical reporting limit were reported for the groundwater samples collected in August 1999 (0.00157 mg/L) and August 2004 (0.00248 mg/L). Both of these results are substantially less than the drinking water MCL for uranium (0.03 mg/L). Along with nitrate, uranium is a principal component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. Thus, the low (background) levels of uranium in the groundwater from sampling port 11 reflect the substantially lower mobility and greater attenuation of uranium relative to that of nitrate.

5.3 VOLATILE ORGANIC COMPOUNDS

A low (estimated) concentration of carbon disulfide (2 μg/L) was detected in one of the groundwater samples collected in August 1999. This compound is not a major component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds.

5.4 GROSS ALPHA ACTIVITY

The gross alpha activity result reported for each groundwater sample collected to date does not exceed the applicable MDA.

5.5 GROSS BETA ACTIVITY

The gross beta activity result reported for each groundwater sample collected to date does not exceed the applicable MDA. Additionally, the sample collected in August 2004 was analyzed for Tc-99, a beta-emitting radionuclide that is a primary component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. The analytical result for Tc-99 is below the MDA, which is surprising because the distribution of Tc-99 typically mirrors that of nitrate (see Section 5.1). For reasons not readily apparent from the available data, Tc-99 is not transported via the groundwater flow/transport pathways intercepted by the interval monitored by this port.

WELL GW-134
Sampling Port 15

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located in Bear Creek Valley (BCV) near the west end of Y-12, approximately 450 ft southeast of the former S-3 Ponds. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 35 to 842 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 15 being 486 ft bgs (Figure 1). Four samples have been collected from this port, one in March 1996, two in August 1999, and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 15 yields groundwater from the deep bedrock (Nolichucky Shale) interval in the Conasauga Group formations that subcrop along the southern flank of Pine Ridge and dip to the southeast below the Knox Group formations that form Chestnut Ridge. The bulk of the groundwater flow in the low-permeability formations (e.g., Nolichucky Shale) occurs within a highly conductive zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of decreased fracture frequency, reduced fracture aperture, and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs via flowpaths oriented parallel with geologic strike (e.g., bedding plane fractures).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 15 yields highly mineralized sodium-chloride-bicarbonate groundwater generally characterized by:

- TDS of 6,460 – 16,500 mg/L;
- pH (field measurements) of 6.83 – 7.22;
- extremely high concentrations nitrate (e.g., 887 mg/L in August 2004);
- low molar proportions of calcium, fluoride, magnesium, potassium, and sulfate (<10% of total anions/cations);
- elevated levels of strontium (>3 mg/L); and

- total (unfiltered sample) concentrations of trace metals (except strontium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

These geochemical characteristics reflect the decrease in groundwater flux that occurs with depth in the low-permeability Conasauga Group formations (e.g., Nolichucky Shale) in BCV (Solomon et al. 1992). Most of the water table and shallow (i.e., <100 ft bgs) bedrock wells in these formations yield calcium-magnesium-bicarbonate groundwater. A fairly abrupt change to sodium-bicarbonate groundwater occurs at a depth of about 100 ft bgs and is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture or increased fracture spacing (Solomon et al. 1992). Further reduced groundwater flux deeper in the bedrock (>300 ft bgs) is indicated by a general increase in TDS and a gradational transition from sodium-bicarbonate groundwater to sodium-chloride groundwater. Elevated strontium concentrations are attributable to natural geochemical processes at depth, including: mixing of sulfate-enriched groundwater with brines at depth, which may cause the precipitation of celestite ($SrSO_4$); upward diffusion of solutes from brines in the deeper bedrock; and matrix diffusion from disseminated minerals in the bedrock (Toran and Saunders 1992).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Nitrate concentrations of 3,987 mg/L and 887 mg/L were reported for the groundwater samples collected in August 1999 and August 2004, respectively. These nitrate results potentially reflect a decreasing long-term concentration trend.

The source of the nitrate is the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds, which were four contiguous, unlined surface impoundments used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric-acid wastes generated at Y-12. The ponds also received periodic shipments of Tc-99 wastes generated at the DOE Savannah River Plant. During RCRA closure of the site in 1988, the ponds were backfilled and covered with a multilayer low-permeability cap (and an asphalt-paved parking lot). Operation of the ponds emplaced a contaminant plume containing a heterogeneous mix of inorganic, organic, and radiological contaminants. With concentrations in excess of 10,000 mg/L, nitrate is the primary inorganic component of the plume and, based on available data from the network of existing monitoring wells, elevated concentrations (>10 mg/L) of nitrate extend at least 5,000 ft east-southeast and west-southwest (parallel with geologic strike) of the former S-3 Ponds, and approximately 1,000 ft south-southwest (across geologic strike) toward the main channel of Bear Creek (DOE 1997). The elongated geometry of the plume reflects the preferred strike-parallel direction of groundwater flow/contaminant transport in BCV.

The gradational decrease in bulk permeability and groundwater flux that occurs with depth (see Section 3.0) has generally limited the vertical (down-dip) extent of the S-3 Ponds contaminant plume, with the very high nitrate concentrations (>1,000 mg/L) evident for the groundwater samples from the deepest sampling port in well GW-134 (sampling port 5) showing that the plume extends at least 750 ft bgs. Moreover, the nitrate concentrations reported for all sampling ports more than 300 ft bgs are substantially higher than evident for sampling ports at shallower depths (Figure 1) because seasonal recharge/discharge cycles more effectively flush nitrate (and other contaminants) from the shallow groundwater flow system (DOE 1997). The elevated nitrate concentrations at depth reflect downward vertical migration driven by the greater density of the highly mineralized and acidic wastewater (Toran and Saunders 1992) and the hydraulic head created by site operations.

5.2 URANIUM

Total uranium concentrations above the applicable analytical reporting limit were reported for the groundwater samples collected in August 1999 (0.0018 mg/L) and August 2004 (0.00277 mg/L). Both of these results are substantially less than the drinking water MCL for uranium (0.03 mg/L). Along with nitrate, uranium is a principal component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. Thus, the low (background) levels of uranium in the groundwater from sampling port 15 reflect the substantially lower mobility and greater attenuation of uranium relative to that of nitrate.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were not detected in the groundwater samples collected to date.

5.4 GROSS ALPHA ACTIVITY

The gross alpha activity result reported for each groundwater sample collected to date does not exceed the applicable MDA.

5.5 GROSS BETA ACTIVITY

The gross beta activity result reported for each groundwater sample collected to date does not exceed the applicable MDA. Additionally, the sample collected in August 2004 was analyzed for Tc-99, a beta-emitting radionuclide that is a primary component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. The analytical result for Tc-99 is below the MDA, which is surprising because the distribution of Tc-99 typically mirrors that of nitrate (see Section 5.1). For reasons not readily apparent from the available data, Tc-99 is not transported via the groundwater flow/transport pathways intercepted by the interval monitored by this port.

WELL GW-134
Sampling Port 18

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located in Bear Creek Valley (BCV) near the west end of Y-12, approximately 450 ft southeast of the former S-3 Ponds. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 35 to 842 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 18 being 426 ft bgs (Figure 1). Three samples have been collected from this port, two in August 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 18 yields groundwater from the deep bedrock (Nolichucky Shale) interval in the Conasauga Group formations that subcrop along the southern flank of Pine Ridge and dip to the southeast below the Knox Group formations that form Chestnut Ridge. The bulk of the groundwater flow in the low-permeability formations (e.g., Nolichucky Shale) occurs within a highly conductive zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of decreased fracture frequency, reduced fracture aperture, and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs via flowpaths oriented parallel with geologic strike (e.g., bedding plane fractures).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 18 yields highly mineralized sodium-chloride-bicarbonate groundwater generally characterized by:

- TDS of 4,880 – 12,700 mg/L;
- pH (field measurements) of 7.14 – 7.37;
- extremely high concentrations nitrate (e.g., 1,340 mg/L in August 2004);
- low molar proportions of calcium, fluoride, magnesium, potassium, and sulfate (<10% of total anions/cations);
- elevated levels of barium (>2 mg/L), lithium (>1 mg/L), and strontium (>4 mg/L); and

- total (unfiltered sample) concentrations of trace metals (except barium, lithium, and strontium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

These geochemical characteristics reflect the decrease in groundwater flux that occurs with depth in the low-permeability Conasauga Group formations (e.g., Nolichucky Shale) in BCV (Solomon et al. 1992). Most of the water table and shallow (i.e., <100 ft bgs) bedrock wells in these formations yield calcium-magnesium-bicarbonate groundwater. A fairly abrupt change to sodium-bicarbonate groundwater occurs at a depth of about 100 ft bgs and is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture or increased fracture spacing (Solomon et al. 1992). Further reduced groundwater flux deeper in the bedrock (>300 ft bgs) is indicated by a general increase in TDS and a gradational transition from sodium-bicarbonate groundwater to sodium-chloride groundwater.

Elevated trace metal concentrations are attributable to natural geochemical processes at depth, including: mixing of sulfate-enriched groundwater with brines at depth, which may cause the precipitation of barite ($BaSO_4$) and celestite ($SrSO_4$); upward diffusion of solutes from brines in the deeper bedrock; and matrix diffusion from disseminated minerals in the bedrock (Toran and Saunders 1992).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Nitrate concentrations of 2,333 mg/L and 1,340 mg/L were reported for the groundwater samples collected in August 1999 and August 2004, respectively. These nitrate results potentially reflect a decreasing long-term concentration trend.

The source of the nitrate is the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds, which were four contiguous, unlined surface impoundments used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric-acid wastes generated at Y-12. The ponds also received periodic shipments of Tc-99 wastes generated at the DOE Savannah River Plant. During RCRA closure of the site in 1988, the ponds were backfilled and covered with a multilayer low-permeability cap (and an asphalt-paved parking lot). Operation of the ponds emplaced a contaminant plume containing a heterogeneous mix of inorganic, organic, and radiological contaminants. With concentrations in excess of 10,000 mg/L, nitrate is the primary inorganic component of the plume and, based on available data from the network of existing monitoring wells, elevated concentrations (>10 mg/L) of nitrate extend at least 5,000 ft east-southeast and west-southwest (parallel with geologic strike) of the former S-3 Ponds, and approximately 1,000 ft south-southwest (across geologic strike) toward the main channel of Bear Creek (DOE 1997). The elongated geometry of the plume reflects the preferred strike-parallel direction of groundwater flow/contaminant transport in BCV.

The gradational decrease in bulk permeability and groundwater flux that occurs with depth (see Section 3.0) has generally limited the vertical (down-dip) extent of the S-3 Ponds contaminant plume, with the very high nitrate concentrations (>1,000 mg/L) evident for the groundwater samples from the deepest sampling port in well GW-134 (sampling port 5) showing that the plume extends at least 750 ft bgs. Moreover, the nitrate concentrations reported for all sampling ports more than 300 ft bgs are substantially higher than evident for sampling ports at shallower depths (Figure 1) because seasonal recharge/discharge cycles more effectively flush nitrate (and other contaminants) from the shallow groundwater flow system (DOE 1997). The elevated nitrate concentrations at depth reflect downward vertical migration driven by the greater density of the highly mineralized and acidic wastewater (Toran and Saunders 1992) and the hydraulic head created by site operations.

5.2 URANIUM

Total uranium concentrations above the applicable analytical reporting limit were reported for the groundwater samples collected in August 1999 (0.00284 mg/L) and August 2004 (0.00224 mg/L). Both of these results are substantially less than the drinking water MCL for uranium (0.03 mg/L). Along with nitrate, uranium is a principal component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. Thus, the low (background) levels of uranium in the groundwater from sampling port 18 reflect the substantially lower mobility and greater attenuation of uranium relative to that of nitrate.

5.3 VOLATILE ORGANIC COMPOUNDS

A low (estimated) concentration of styrene (3 μg/L) was detected in the groundwater sample collected in August 1999. Styrene is not a major component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA. Additionally, the sample collected in August 2004 was analyzed for Tc-99, a beta-emitting radionuclide that is a primary component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. The analytical result for Tc-99 is below the MDA, which is surprising because the distribution of Tc-99 typically mirrors that of nitrate (see Section 5.1). For reasons not readily apparent from the available data, Tc-99 is not transported via the groundwater flow/transport pathways intercepted by the interval monitored by this port.

WELL GW-134
Sampling Port 21

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located in Bear Creek Valley (BCV) near the west end of Y-12, approximately 450 ft southeast of the former S-3 Ponds. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (Haase and King 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 35 to 842 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 21 being 371 ft bgs (Figure 1). Three samples have been collected from this port to date, two in August 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 21 yields groundwater from the deep bedrock (Nolichucky Shale) interval in the Conasauga Group formations that subcrop along the southern flank of Pine Ridge and dip to the southeast below the Knox Group formations that form Chestnut Ridge. The bulk of the groundwater flow in the low-permeability formations (e.g., Nolichucky Shale) occurs within a highly conductive zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of decreased fracture frequency, reduced fracture aperture, and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs via flowpaths oriented parallel with geologic strike (e.g., bedding plane fractures).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 21 yields highly mineralized sodium-chloride-bicarbonate groundwater generally characterized by:

- TDS of 5,620 – 6,370 mg/L;
- pH (field measurements) of 7.7 – 7.8;
- high concentrations of nitrate (e.g., 733 mg/L in August 2004);
- low molar proportions of calcium, fluoride, magnesium, potassium, and sulfate (<10% of total anions/cations);
- elevated levels of strontium (>2 mg/L); and

- total (unfiltered sample) concentrations of trace metals (except strontium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

These geochemical characteristics reflect the decrease in groundwater flux that occurs with depth in the low-permeability Conasauga Group formations (e.g., Nolichucky Shale) in BCV (Solomon et al. 1992). Most of the water table and shallow (i.e., <100 ft bgs) bedrock wells in these formations yield calcium-magnesium-bicarbonate groundwater. A fairly abrupt change to sodium-bicarbonate groundwater occurs at a depth of about 100 ft bgs and is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture or increased fracture spacing (Solomon et al. 1992). Further reduced groundwater flux deeper in the bedrock (>300 ft bgs) is indicated by a general increase in TDS and a gradational transition from sodium-bicarbonate groundwater to sodium-chloride groundwater. Elevated strontium concentrations are attributable to natural geochemical processes at depth, including: mixing of sulfate-enriched groundwater with brines at depth, which may cause the precipitation of celestite ($SrSO_4$); upward diffusion of solutes from brines in the deeper bedrock; and matrix diffusion from disseminated minerals in the bedrock (Toran and Saunders 1992).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

The groundwater samples collected in August 1999 and August 2004 had nitrate concentrations of 818 mg/L and 733 mg/L, respectively. The source of the nitrate is the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds, which were four contiguous, unlined surface impoundments used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric-acid wastes generated at Y-12. The ponds also received periodic shipments of Tc-99 wastes generated at the DOE Savannah River Plant. During RCRA closure of the site in 1988, the ponds were backfilled and covered with a multilayer low-permeability cap (and an asphalt-paved parking lot). Operation of the ponds emplaced a contaminant plume containing a heterogeneous mix of inorganic, organic, and radiological contaminants. With concentrations in excess of 10,000 mg/L, nitrate is the primary inorganic component of the plume and, based on available data from the network of existing monitoring wells, elevated concentrations (>10 mg/L) of nitrate extend at least 5,000 ft east-southeast and west-southwest (parallel with geologic strike) of the former S-3 Ponds, and approximately 1,000 ft south-southwest (across geologic strike) toward the main channel of Bear Creek (DOE 1997). The elongated geometry of the plume reflects the preferred strike-parallel direction of groundwater flow/contaminant transport in BCV.

The gradational decrease in bulk permeability and groundwater flux that occurs with depth (see Section 3.0) has generally limited the vertical (down-dip) extent of the S-3 Ponds contaminant plume, with the very high nitrate concentrations (>1,000 mg/L) evident for the groundwater samples from the deepest sampling port in well GW-134 (sampling port 5) showing that the plume extends at least 750 ft bgs. Moreover, the nitrate concentrations reported for all sampling ports more than 300 ft bgs (e.g., port 21) are substantially higher than evident for sampling ports at shallower depths (Figure 1) because seasonal recharge/discharge cycles more effectively flush nitrate (and other contaminants) from the shallow groundwater flow system (DOE 1997). The elevated nitrate concentrations at depth reflect downward vertical migration driven by the greater density of the highly mineralized and acidic wastewater (Toran and Saunders 1992) and the hydraulic head created by site operations.

5.2 URANIUM

Total uranium concentrations above the applicable analytical reporting limit were reported for the groundwater samples collected in August 1999 (0.00235 mg/L) and August 2004 (0.0023 mg/L). Both of these results are substantially less than the drinking water MCL for uranium (0.03 mg/L). Along with nitrate, uranium is a principal component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. Thus, the low (background) levels of uranium in the groundwater from sampling port 21 reflect the substantially lower mobility and greater attenuation of uranium relative to that of nitrate.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were not detected in the groundwater samples collected to date.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA. Additionally, the sample collected in August 2004 was analyzed for Tc-99, a beta-emitting radionuclide that is a primary component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. The analytical result for Tc-99 is below the MDA, which is surprising because the distribution of Tc-99 typically mirrors that of nitrate (see Section 5.1). For reasons not readily apparent from the available data, Tc-99 is not transported via the groundwater flow/transport pathways intercepted by the interval monitored by this port.

WELL GW-134
Sampling Port 25

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located in Bear Creek Valley (BCV) near the west end of Y-12, approximately 450 ft southeast of the former S-3 Ponds. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 35 to 842 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 25 being 286 ft bgs (Figure 1). Only two samples have been collected from this port, one in August 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 25 yields groundwater from the intermediate depth bedrock (Nolichucky Shale) interval in the Conasauga Group formations that subcrop along the southern flank of Pine Ridge and dip to the southeast below the Knox Group formations that form Chestnut Ridge. The bulk of the groundwater flow in the low-permeability formations (e.g., Nolichucky Shale) occurs within a highly conductive zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of decreased fracture frequency, reduced fracture aperture, and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs via flowpaths oriented parallel with geologic strike (e.g., bedding plane fractures).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 25 yields sodium-bicarbonate groundwater generally characterized by:

- TDS of 918 and 929 mg/L;
- pH (field measurements) of 8.9;
- unusually high carbonate alkalinity (e.g., 59.8 mg/L in August 2004);
- low molar proportions of calcium, chloride, fluoride, magnesium, potassium, and sulfate (<10% of total anions/cations);
- elevated levels of boron (>1 mg/L); and

- total (unfiltered sample) concentrations of trace metals (except boron) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

These geochemical characteristics reflect the decrease in groundwater flux that occurs with depth in the low-permeability Conasauga Group formations (e.g., Nolichucky Shale) in BCV (Solomon et al. 1992). Most of the water table and shallow (i.e., <100 ft bgs) bedrock wells in these formations yield calcium-magnesium-bicarbonate groundwater. A fairly abrupt change to sodium-bicarbonate groundwater occurs at a depth of about 100 ft bgs and is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture or increased fracture spacing (Solomon et al. 1992). Further reduced groundwater flux deeper in the bedrock (>300 ft bgs) is indicated by a general increase in TDS and a gradational transition from sodium-bicarbonate groundwater to sodium-chloride groundwater.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

The groundwater sample collected in August 1999 had a nitrate concentration of 0.05331 mg/L, and nitrate was not detected in August 2004. The low level of nitrate is particularly surprising in light of the proximity of well GW-134 to the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds, which were four contiguous, unlined surface impoundments used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric-acid wastes generated at Y-12. The ponds also received periodic shipments of Tc-99 wastes generated at the DOE Savannah River Plant. During RCRA closure of the site in 1988, the ponds were backfilled and covered with a multilayer low-permeability cap (and an asphalt-paved parking lot). Operation of the ponds emplaced a contaminant plume containing a heterogeneous mix of inorganic, organic, and radiological contaminants. With concentrations in excess of 10,000 mg/L, nitrate is the primary inorganic component of the plume and, based on available data from the network of existing monitoring wells, elevated concentrations (>10 mg/L) of nitrate extend at least 5,000 ft east-southeast and west-southwest (parallel with geologic strike) of the former S-3 Ponds, and approximately 1,000 ft south-southwest (across geologic strike) toward the main channel of Bear Creek (DOE 1997). The elongated geometry of the plume reflects the preferred strike-parallel direction of groundwater flow/contaminant transport in BCV.

Compared to the substantially higher nitrate concentrations reported for sampling ports that are shallower (e.g., port 33) and deeper (e.g., port 21) in the well (Figure 1), the background levels of nitrate evident in the groundwater samples from port 25 potentially indicate significant lithologic and/or stratigraphic control on down-dip migration/transport of the mobile components of the S-3 Ponds contaminant plume. Sampling port 25 also may yield groundwater from a low-yield (matrix) interval in the bedrock that is not well connected to the fractures which transmit the nitrate-contaminated groundwater.

5.2 URANIUM

Total uranium concentrations above the applicable analytical reporting limit were reported for the groundwater samples collected in August 1999 (0.00235 mg/L) and August 2004 (0.0023 mg/L). Both of these results are substantially less than the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

A low (estimated) concentration of styrene (1 µg/L) was detected in the groundwater sample collected in August 1999. Styrene is not a major component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds.

5.4 GROSS ALPHA ACTIVITY

The gross alpha activity result reported for each groundwater sample collected to date does not exceed the applicable MDA.

5.5 GROSS BETA ACTIVITY

The gross beta activity result reported for each groundwater sample collected to date does not exceed the applicable MDA. Additionally, the sample collected in August 2004 was analyzed for Tc-99, a beta-emitting radionuclide that is a primary component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. The analytical result for Tc-99 is below the MDA, which is consistent with the results for gross beta activity.

WELL GW-134
Sampling Port 29

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located in Bear Creek Valley (BCV) near the west end of Y-12, approximately 450 ft southeast of the former S-3 Ponds. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (Haase and King 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 35 to 842 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 29 being 171 ft bgs (Figure 1). Only two samples have been collected from this port, one in August 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 29 yields groundwater from the intermediate depth bedrock (Nolichucky Shale) interval in the Conasauga Group formations that subcrop along the southern flank of Pine Ridge and dip to the southeast below the Knox Group formations that form Chestnut Ridge. The bulk of the groundwater flow in the low-permeability formations (e.g., Nolichucky Shale) occurs within a highly conductive zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of decreased fracture frequency, reduced fracture aperture, and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs via flowpaths oriented parallel with geologic strike (e.g., bedding plane fractures).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 29 yields sodium-bicarbonate groundwater generally characterized by:

- TDS of 410 and 478 mg/L;
- pH (field measurements) of 8.7 and 9.05;
- low molar proportions of calcium, chloride, fluoride, magnesium, potassium, and sulfate (<10% of total anions/cations);
- elevated levels of boron (>1 mg/L); and
- total (unfiltered sample) concentrations of trace metals (except boron) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

These geochemical characteristics reflect the decrease in groundwater flux that occurs with depth in the low-permeability Conasauga Group formations (e.g., Nolichucky Shale) in BCV (Solomon et al. 1992). Most of the water table and shallow (i.e., <100 ft bgs) bedrock wells in these formations yield calcium-magnesium-bicarbonate groundwater. A fairly abrupt change to sodium-bicarbonate groundwater occurs at a depth of about 100 ft bgs and is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture or increased fracture spacing (Solomon et al. 1992). Further reduced groundwater flux deeper in the bedrock (>300 ft bgs) is indicated by a general increase in TDS and a gradational transition from sodium-bicarbonate groundwater to sodium-chloride groundwater.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

The groundwater sample collected in August 1999 had a nitrate concentration of 0.05376 mg/L, and nitrate was not detected in August 2004. The low level of nitrate is particularly surprising in light of the proximity of well GW-134 to the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds, which were four contiguous, unlined surface impoundments used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric-acid wastes generated at Y-12. The ponds also received periodic shipments of Tc-99 wastes generated at the DOE Savannah River Plant. During RCRA closure of the site in 1988, the ponds were backfilled and covered with a multilayer low-permeability cap (and an asphalt-paved parking lot). Operation of the ponds emplaced a contaminant plume containing a heterogeneous mix of inorganic, organic, and radiological contaminants. With concentrations in excess of 10,000 mg/L, nitrate is the primary inorganic component of the plume and, based on available data from the network of existing monitoring wells, elevated concentrations (>10 mg/L) of nitrate extend at least 5,000 ft east-southeast and west-southwest (parallel with geologic strike) of the former S-3 Ponds, and approximately 1,000 ft south-southwest (across geologic strike) toward the main channel of Bear Creek (DOE 1997). The elongated geometry of the plume reflects the preferred strike-parallel direction of groundwater flow/contaminant transport in BCV.

Compared to the substantially higher nitrate concentrations reported for sampling ports that are shallower (e.g., port 33) and deeper (e.g., port 21) in the well (Figure 1), the background levels of nitrate evident in the groundwater samples from port 29 potentially indicate significant lithologic and/or stratigraphic control on down-dip migration/transport of the mobile components of the S-3 Ponds contaminant plume. Sampling port 29 also may yield groundwater from a low-yield (matrix) interval in the bedrock that is not well connected to the fractures which transmit the nitrate-contaminated groundwater.

5.2 URANIUM

A total uranium concentration above the applicable analytical reporting limit was reported for the groundwater sample collected in August 1999 (0.000721 mg/L) and this result is substantially less than the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

A low (estimated) concentration of styrene (1 µg/L) was detected in the groundwater sample collected in August 2004. Styrene is not a major component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA. Additionally, the sample collected in August 2004 was analyzed for Tc-99, a beta-emitting radionuclide that is a primary component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. The analytical result for Tc-99 is below the MDA, which is consistent with the results for gross beta activity.

WELL GW-134
Sampling Port 33

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located in Bear Creek Valley (BCV) near the west end of Y-12, approximately 450 ft southeast of the former S-3 Ponds. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 35 to 842 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 33 being 106 ft bgs (Figure 1). Only two samples have been collected from this port, one in August 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 33 yields groundwater from the shallow bedrock interval in the uppermost formation of the Conasauga Group (Maynardville Limestone). The Maynardville Limestone subcrops along the axis of BCV, underlies the main channel of Bear Creek, and dips to the southeast below the Knox Group carbonates that form Chestnut Ridge. The bulk of the groundwater flow in the Maynardville Limestone occurs at shallow depths (<150 ft bgs) in an extensively interconnected network of solution conduits and cavities (shallow karst network). Below the shallow karst network, orthogonal sets of permeable, planar fractures (e.g., bedding plane fractures) form water-producing zones within an essentially impermeable matrix, with preferred flow in directions that parallel geologic strike. Because the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity decreases with depth (Solomon et. al. 1992). Additionally, there are seven stratigraphic zones (number from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et. al. 1995). The more permeable zones are at the bottom (Zone 2) and top (zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater flow in this formation (Goldstrand 1995).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 33 yields nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 929 and 1,560 mg/L;
- pH (field measurements) of 7.2 and 7.45;
- nitrate concentrations above 50 mg/L;
- low molar proportions of chloride, fluoride, potassium, sodium, and sulfate (<10% of total anions/cations); and

- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

The groundwater samples collected in August 1999 and August 2004 had nitrate concentrations of 214.5 mg/L and 91.4 mg/L, respectively. These nitrate results, which substantially exceed the drinking water MCL for nitrate (10 mg/L), suggest a decreasing long-term concentration trend.

The source of the nitrate is the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds, which were four contiguous, unlined surface impoundments used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric-acid wastes generated at Y-12. The ponds also received periodic shipments of Tc-99 wastes generated at the DOE Savannah River Plant. During RCRA closure of the site in 1988, the ponds were backfilled and covered with a multilayer low-permeability cap (and an asphalt-paved parking lot). Operation of the ponds emplaced a contaminant plume containing a heterogeneous mix of inorganic, organic, and radiological contaminants. With concentrations in excess of 10,000 mg/L, nitrate is the primary inorganic component of the plume and, based on available data from the network of existing monitoring wells, elevated concentrations (>10 mg/L) of nitrate extend at least 5,000 ft east-southeast and west-southwest (parallel with geologic strike) of the former S-3 Ponds, and approximately 1,000 ft south-southwest (across geologic strike) toward the main channel of Bear Creek (DOE 1997). The elongated geometry of the plume reflects the preferred strike-parallel direction of groundwater flow/contaminant transport in BCV.

The gradational decrease in bulk permeability and groundwater flux that occurs with depth (see Section 3.0) has generally limited the vertical (down-dip) extent of the S-3 Ponds contaminant plume, with the very high nitrate concentrations (>1,000 mg/L) evident for the groundwater samples from the deepest sampling port in well GW-134 (sampling port 5) showing that the plume extends at least 750 ft bgs. Additionally, compared to the nitrate concentrations reported for all the sampling ports more than 300 ft bgs (Figure 1), the substantially lower nitrate levels in the groundwater samples from port 33 illustrate how seasonal recharge/discharge cycles more effectively flush contaminants from the shallow flow system (DOE 1997).

5.2 URANIUM

None of the groundwater samples collected to date had a total uranium concentration above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

The following VOCs were detected in each of the groundwater samples collected to date: PCE, TCE, c12DCE, and chloroform. As shown in the following data summary, the highest concentrations were reported in August 1999 for TCE (30 μg/L) and c12DCE (14 μg/L), both of which may be present as a result of the degradation of the parent compound (PCE), with the concentrations of PCE and TCE being above the respective MCLs (5 μg/L).

Date Sampled	Concentration (µg/L)			
	PCE	TCE	c12DCE	Chloroform
08/11/99	10	30	14	3 J

MCL	5	5	70	Not applicable
Note: J = Estimated value below the analytical reporting limit				

All of the VOCs detected in the groundwater samples collected to date are confirmed components of the contaminant plume that originates from the former S-3 Ponds, and their presence in the groundwater from this sampling port indicates vertical (down-dip) transport/migration for at least 100 ft bgs. Nevertheless, compared to the nitrate concentrations in the groundwater samples from this well, the relatively low concentrations of VOCs reflect the much lower volume of organic wastes disposed at the site and the greater attenuation of these compounds relative to that of nitrate (DOE 1997). Additionally, PCE concentrations reported for sampling port 35, which is only 25 ft shallower in the Maynardville Limestone, are much higher than evident in port 36 (Figure 2). As with the similar disparity in the nitrate concentrations in the groundwater from these ports, the difference between PCE levels in each port potentially reflect the strong influence on groundwater flow/contaminant migration exerted by lithologic and/or stratigraphic features in the Maynardville Limestone.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA.

5.5 GROSS BETA ACTIVITY

The groundwater samples collected in August 1999 and August 2004 had gross beta activity of 210 pCi/L and 130 pCi/L, respectively. Both results are substantially above the Safe Drinking Water Act (SDWA) screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). In addition to gross beta activity, the sample collected in August 2004 was analyzed for Tc-99, a beta-emitting radionuclide that is a primary component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. Although the Tc-99 result for this sample (270 pCi/L) is substantially below the SDWA screening level for Tc-99 (3,790 pCi/L), the result confirms that Tc-99 is the primary source of gross beta activity in the groundwater samples from this port. Like nitrate and chlorinated hydrocarbons, the presence of Tc-99 in the water-producing feature(s) providing inflow to sampling port 33 reflect the density-driven vertical (down-dip) migration of the more mobile components of the contaminant plume.

WELL GW-134
Sampling Port 35

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located in Bear Creek Valley (BCV) near the west end of Y-12, approximately 450 ft southeast of the former S-3 Ponds. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 35 to 842 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 35 being 81 ft bgs (Figure 1). Only two samples have been collected from this port, one in August 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 35 yields groundwater from the shallow bedrock interval in the uppermost formation of the Conasauga Group (Maynardville Limestone). The Maynardville Limestone subcrops along the axis of BCV, underlies the main channel of Bear Creek, and dips to the southeast below the Knox Group carbonates that form Chestnut Ridge. The bulk of the groundwater flow in the Maynardville Limestone occurs at shallow depths (<150 ft bgs) in an extensively interconnected network of solution conduits and cavities (shallow karst network). Below the shallow karst network, orthogonal sets of permeable, planar fractures (e.g., bedding plane fractures) form water-producing zones within an essentially impermeable matrix, with preferred flow in directions that parallel geologic strike. Because the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity decreases with depth (Solomon et. al. 1992). Additionally, there are seven stratigraphic zones (number from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et. al. 1995). The more permeable zones are at the bottom (Zone 2) and top (zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater flow in this formation (Goldstrand 1995).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 35 yields nitrate-contaminated, calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 1,540 and 2,180 mg/L;
- pH (field measurements) of 7.0 and 7.25;
- nitrate concentrations above 100 mg/L;
- low molar proportions of chloride, fluoride, potassium, sodium, and sulfate (<10% of total anions/cations);

- elevated total (unfiltered sample) concentrations of strontium (>1 mg/L); and
- total concentrations of trace metals (except strontium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The elevated strontium concentrations may be attributable to natural geochemical processes at depth in the Maynardville Limestone, including: mixing of sulfate-enriched groundwater with brines at depth, which may cause the precipitation of barite ($BaSO_4$) and celestite ($SrSO_4$); upward diffusion of solutes from brines in the deeper bedrock; and matrix diffusion from disseminated minerals in the bedrock (Toran and Saunders 1992).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

The groundwater samples collected in August 1999 and August 2004 had nitrate concentrations of 290.5 mg/L and 160 mg/L, respectively. These nitrate results, which substantially exceed the drinking water MCL for nitrate (10 mg/L), suggest a decreasing long-term concentration trend.

The source of the nitrate is the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds, which were four contiguous, unlined surface impoundments used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric-acid wastes generated at Y-12. The ponds also received periodic shipments of Tc-99 wastes generated at the DOE Savannah River Plant. During RCRA closure of the site in 1988, the ponds were backfilled and covered with a multilayer low-permeability cap (and an asphalt-paved parking lot). Operation of the ponds emplaced a contaminant plume containing a heterogeneous mix of inorganic, organic, and radiological contaminants. With concentrations in excess of 10,000 mg/L, nitrate is the primary inorganic component of the plume and, based on available data from the network of existing monitoring wells, elevated concentrations (>10 mg/L) of nitrate extend laterally at least 5,000 ft east-southeast and west-southwest (parallel with geologic strike) of the former S-3 Ponds, and approximately 1,000 ft south-southwest (across geologic strike) toward the main channel of Bear Creek (DOE 1997). The elongated geometry of the plume reflects the preferred strike-parallel direction of groundwater flow/contaminant transport in BCV.

The gradational decrease in bulk permeability and groundwater flux that occurs with depth (see Section 3.0) has generally limited the vertical (down-dip) extent of the S-3 Ponds contaminant plume, with the very high nitrate concentrations (>1,000 mg/L) evident for the groundwater samples from the deepest sampling port in well GW-134 (sampling port 5) showing that the plume extends at least 750 ft bgs. Additionally, compared to the nitrate concentrations reported for all the sampling ports more than 300 ft bgs (Figure 1), the substantially lower nitrate levels in the groundwater samples from port 35 illustrate how seasonal recharge/discharge cycles more effectively flush contaminants from the shallow flow system (DOE 1997). Moreover, the nitrate concentrations reported for sampling port 35 are significantly higher than the nitrate levels evident in groundwater from sampling port 36, which is only 15 ft shallower in the Maynardville Limestone than port 35 (Figure 1). This suggests that there are significant lithologic and/or stratigraphic controls on the migration/transport of the mobile components of the S-3 Ponds contaminant plume.

5.2 URANIUM

None of the groundwater samples collected to date had a total uranium concentration above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

The following VOCs were detected in each of the groundwater samples collected to date: PCE, TCE, c12DCE, 11DCE, and chloroform. Each of these compounds except 11DCE was detected in each groundwater sample. As shown in the following data summary, the highest concentrations were reported for PCE, TCE, and c12DCE, with the concentrations of PCE and TCE being above the respective MCLs (5 µg/L).

Date Sampled	**Concentration (µg/L)**				
	PCE	**TCE**	**c12DCE**	**111DCE**	**Chloroform**
08/11/99	11	19	13	.	3 J
08/11/04	15	16	10	2 J	2 J
MCL	5	5	70	7	Not applicable
Note: "." = Not detected; J = Estimated value below the analytical reporting limit					

All of the VOCs detected in the groundwater samples collected to date are confirmed components of the contaminant plume that originates from the former S-3 Ponds, and their presence in the groundwater from this sampling port indicates vertical (down-dip) transport/migration for at least 100 ft bgs. Nevertheless, compared to the nitrate concentrations in the groundwater samples from this sampling port, the relatively low concentrations of VOCs reflect the much lower volume of organic wastes disposed at the site and the greater attenuation of these compounds relative to that of nitrate (DOE 1997). Additionally, PCE concentrations reported for sampling port 36 (40 ft shallower) and for sampling port 33 (25 ft deeper) in the Maynardville Limestone are much lower than evident in port 35 (Figure 2). As with the similar disparity between nitrate concentrations in the groundwater samples from these ports, the difference between PCE levels potentially reflect the strong influence on groundwater flow/contaminant migration exerted by lithologic and/or stratigraphic features in the Maynardville Limestone.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA and CE.

5.5 GROSS BETA ACTIVITY

The groundwater samples collected in August 1999 and August 2004 had gross beta activity of 330 pCi/L and 220 pCi/L, respectively. Both results are substantially above the Safe Drinking Water Act (SDWA) screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). In addition to gross beta activity, the sample collected in August 2004 was analyzed for Tc-99, a beta-emitting radionuclide that is a primary component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. Although the Tc-99 result for this sample (370 pCi/L) is substantially below the SDWA screening level for Tc-99 (3,790 pCi/L), the result confirms that Tc-99 is the primary source of gross beta activity in the groundwater samples from this port. Like nitrate and PCE, the presence of Tc-99 in the water-producing feature(s) providing inflow to sampling port 35 reflects the southward (across strike and down-dip) migration of the mobile components of the S-3 Ponds contaminant plume.

WELL GW-134
Sampling Port 36

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located in Bear Creek Valley (BCV) near the west end of Y-12, approximately 450 ft southeast of the former S-3 Ponds. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 35 to 842 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 36 being 41 ft bgs (Figure 1). Only two samples have been collected from this port, one in August 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 36 yields groundwater from the shallow bedrock interval in the uppermost formation of the Conasauga Group (Maynardville Limestone). The Maynardville Limestone subcrops along the axis of BCV, underlies the main channel of Bear Creek, and dips to the southeast below the Knox Group carbonates that form Chestnut Ridge. The bulk of the groundwater flow in the Maynardville Limestone occurs at shallow depths (<150 ft bgs) in an extensively interconnected network of solution conduits and cavities (shallow karst network). Below the shallow karst network, orthogonal sets of permeable, planar fractures (e.g., bedding plane fractures) form water-producing zones within an essentially impermeable matrix, with preferred flow in directions that parallel geologic strike. Because the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity decreases with depth (Solomon et. al. 1992). Additionally, there are seven stratigraphic zones (number from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et. al. 1995). The more permeable zones are at the bottom (Zone 2) and top (zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater flow in this formation (Goldstrand 1995).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 36 yields nitrate-contaminated, calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 791 and 982 mg/L;
- pH (field measurements) of 7.2 and 7.45;
- nitrate concentrations above 50 mg/L;
- low molar proportions of chloride, fluoride, potassium, sodium, and sulfate (<10% of total anions/cations); and

- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

The groundwater samples collected in August 1999 and August 2004 had nitrate concentrations of 72.98 mg/L and 81.8 mg/L, respectively. These nitrate results, which substantially exceed the drinking water MCL for nitrate (10 mg/L), suggest an indeterminate long-term concentration trend.

The source of the nitrate is the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds, which were four contiguous, unlined surface impoundments used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric-acid wastes generated at Y-12. The ponds also received periodic shipments of Tc-99 wastes generated at the DOE Savannah River Plant. During RCRA closure of the site in 1988, the ponds were backfilled and covered with a multilayer low-permeability cap (and an asphalt-paved parking lot). Operation of the ponds emplaced a contaminant plume containing a heterogeneous mix of inorganic, organic, and radiological contaminants. With concentrations in excess of 10,000 mg/L, nitrate is the primary inorganic component of the plume and, based on available data from the network of existing monitoring wells, elevated concentrations (>10 mg/L) of nitrate extend at least 5,000 ft east-southeast and west-southwest (parallel with geologic strike) of the former S-3 Ponds, and approximately 1,000 ft south-southwest (across geologic strike) toward the main channel of Bear Creek (DOE 1997). The elongated geometry of the plume reflects the preferred strike-parallel direction of groundwater flow/contaminant transport in BCV.

The gradational decrease in bulk permeability and groundwater flux that occurs with depth (see Section 3.0) has generally limited the vertical (down-dip) extent of the S-3 Ponds contaminant plume, with the very high nitrate concentrations (>1,000 mg/L) evident for the groundwater samples from the deepest sampling port in well GW-134 (sampling port 5) showing that the plume extends at least 750 ft bgs. Additionally, compared to the nitrate concentrations reported for all the sampling ports more than 300 ft bgs (Figure 1), the substantially lower nitrate levels in the groundwater samples from port 36 illustrate how seasonal recharge/discharge cycles more effectively flush contaminants from the shallow flow system (DOE 1997). Moreover, the nitrate concentrations reported for sampling port 36 are significantly (>50%) lower than the nitrate levels evident in groundwater from sampling port 35, which is only 15 ft deeper in the Maynardville Limestone than port 36 (Figure 1). This suggests that there are significant lithologic and/or stratigraphic controls on the migration/transport of the mobile components of the S-3 Ponds contaminant plume.

5.2 URANIUM

None of the groundwater samples collected to date had a total uranium concentration above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

A low (estimated) concentration of PCE (2 µg/L) was detected in the groundwater sample collected in August 2004. This compound is one of the primary organic components of the S-3 Ponds contaminant plume, and their presence in the shallow groundwater from this sampling port reflects the southward (down-dip) transport toward the headwaters of Bear Creek. Compared to the nitrate concentrations in the groundwater samples from this sampling port, the low concentrations of PCE reflects the much lower volume of organic wastes disposed at the site and the greater attenuation of these compounds relative to that of nitrate (DOE 1997). Additionally, PCE concentrations reported for sampling port 35, which is 40 ft deeper in the Maynardville Limestone, are much higher than evident in port 36 (Figure 2). As with the similar disparity in the nitrate concentrations in the groundwater from these ports, the difference between PCE levels in each port potentially reflect the strong influence on groundwater flow/contaminant migration exerted by lithologic and/or stratigraphic features in the Maynardville Limestone.

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity above the applicable MDA was reported for the groundwater sample collected in August 2004, and this result (4.8 pCi/L) is substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

The groundwater samples collected in August 1999 and August 2004 had gross beta activity of 32 pCi/L and 130 pCi/L, respectively. These results suggest an increasing concentration trend, with the latter value being substantially above the Safe Drinking Water Act (SDWA) screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). In addition to gross beta activity, the sample collected in August 2004 was analyzed for Tc-99, a beta-emitting radionuclide that is a primary component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. Although the Tc-99 result for this sample (230 pCi/L) is substantially below the SDWA screening level for Tc-99 (3,790 pCi/L), the result confirms that Tc-99 is the primary source of gross beta activity in the groundwater samples from this port. Like nitrate and PCE, the presence of Tc-99 in the water-producing feature(s) providing inflow to sampling port 36 reflects the southward (across strike and down-dip) migration of the mobile components of the S-3 Ponds contaminant plume.

WELL GW-135
Sampling Port 03

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located on the crest of Chestnut Ridge near the west end of Y-12, on the east side of Industrial Landfill IV. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 80 to 1,275 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 03 being 1,206 ft bgs, which is approximately 20 ft below sea level (Figure 1). Only two samples have been collected from this port, one in September 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 03 yields groundwater from the deep bedrock interval in the uppermost formation of the Conasauga Group (Maynardville Limestone). The Maynardville Limestone subcrops along the axis of BCV, underlies the main channel of Bear Creek, and dips to the southeast below the Knox Group carbonates that form Chestnut Ridge. The bulk of the groundwater flow in the Maynardville Limestone occurs at shallow depths (<150 ft bgs) in an extensively interconnected network of solution conduits and cavities (shallow karst network). Below the shallow karst network, orthogonal sets of permeable, planar fractures (e.g., bedding plane fractures) form water-producing zones within an essentially impermeable matrix, with preferred flow in directions that parallel geologic strike. Because the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity decreases with depth (Solomon et. al. 1992). Additionally, there are seven stratigraphic zones (number from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et. al. 1995). The more permeable zones are at the bottom (Zone 2) and top (zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater flow in this formation (Goldstrand 1995).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 03 yields extremely mineralized sodium-chloride-bicarbonate groundwater generally characterized by:

- TDS above 40,000 mg/L;
- pH (field measurements) near 6.5;
- extremely high concentrations of calcium (>1,000 mg/L), chloride (>20,000 mg/L), sodium (>10,000 mg/L), and sulfate (>2,000 mg/L); and

- very high total (unfiltered sample) concentrations of arsenic (>1 mg/L), boron (>3 mg/L), lithium (>10 mg/L), selenium (>4 mg/L), and strontium (>30 mg/L).

These geochemical characteristics suggest that this port essentially monitors connate water (brine). Additionally, the elevated trace metal concentrations are attributable to natural geochemical processes at depth in the Maynardville Limestone, including: mixing of sulfate-enriched groundwater with brines at depth, which may cause the precipitation of barite ($BaSO_4$) and celestite ($SrSO_4$); upward diffusion of solutes from brines in the deeper bedrock; and matrix diffusion from disseminated minerals in the bedrock (Toran and Saunders 1992).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

None of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

None of the groundwater samples collected to date had total uranium concentrations above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Benzene concentrations of 13 μg/L and 15 μg/L were detected in the groundwater samples collected in September 1999 and August 2004, respectively. Both results exceed the drinking water MCL for benzene (5 μg/L). In addition to benzene, each sample also contained low (estimated) concentrations of styrene (3 μg/L). Also, ethylbenzene was detected (2 μg/L) in the sample collected in August 2004.

There are several potential sources of the petroleum hydrocarbons in the groundwater samples from this sampling port: (1) residual contamination from installation of the well; (2) contamination from components of the Westbay sampling equipment that are made of or contain petroleum-based materials; (3) contamination of the samples during sampling or handling; and (4) traces of natural hydrocarbons in the low-permeability bedrock.

Residual contamination from installation/construction of the well seems an unlikely source of the hydrocarbons in light of the age of the well (>8 years). Moreover, well installation and construction was closely supervised and controlled to exclude usage of petroleum-based drilling equipment lubricants. Additionally, well installation/construction records do not note any accidental spills/leaks of petroleum-based fluids from the drilling rig or support equipment during installation of the well.

Contamination from components of the Westbay sampling equipment in the well is possible, as several components of the sampling apparatus contain petroleum hydrocarbons. However, it is not known if the hydrocarbons are leachable from these components and repeated sampling since installation of the equipment would be expected to "flush" any leached constituents from the sampling port. Also, such systemic contamination from components of the Westbay sampling equipment would be expected to result in consistent contamination of samples from multiple, if not all, sampling ports. However, only some of the other ports repeatedly yield samples that contain petroleum hydrocarbons. Indeed, these compounds have not been detected consistently in any of the samples collected to date from eight of the sampling ports in the well. In addition, these hydrocarbons have been observed in groundwater samples from some deeper wells that are not instrumented with Westbay sampling equipment.

Contamination of the samples during collection or handling also may be possible, but is not indicated by results for associated quality assurance samples (i.e., petroleum hydrocarbons are not detected in the field or trip blanks). Similarly, data for laboratory blank samples do not support contamination during storage and/or analysis in the laboratory. Also, contamination of the samples during collection at the well head seems very unlikely again because such systemic contamination would result in the detection of petroleum hydrocarbons in the samples collected from all other ports in the well.

Traces of petroleum hydrocarbons naturally present at depth in the low-permeability bedrock may explain the detection of these compounds in the groundwater samples from this port. These hydrocarbons have been observed in groundwater samples from some deeper wells that are not instrumented with Westbay sampling equipment.

Acrylonitrile was detected (13 µg/L) in the groundwater sample collected in September 1999. According to the manufacturer, the Westbay™ sampling system contains several components made with acrylonitrile, and detection of this compound is often an artifact from sampling ports in low permeability zones (Westbay Instruments, Inc. 1999).

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA. Additionally, the sample collected in August 2004 was analyzed for Tc-99, a beta-emitting radionuclide that is a primary component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. The analytical result for Tc-99 is below the MDA, which is consistent with the results for gross beta activity.

WELL GW-135
Sampling Port 06

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located on the crest of Chestnut Ridge near the west end of Y-12, on the east side of Industrial Landfill IV. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 80 to 1,275 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 06 being 1,142 ft bgs (Figure 1). Only two samples have been collected from this port, one in September 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 06 yields groundwater from the deep bedrock interval in the uppermost formation of the Conasauga Group (Maynardville Limestone). The Maynardville Limestone subcrops along the axis of BCV, underlies the main channel of Bear Creek, and dips to the southeast below the Knox Group carbonates that form Chestnut Ridge. The bulk of the groundwater flow in the Maynardville Limestone occurs at shallow depths (<150 ft bgs) in an extensively interconnected network of solution conduits and cavities (shallow karst network). Below the shallow karst network, orthogonal sets of permeable, planar fractures (e.g., bedding plane fractures) form water-producing zones within an essentially impermeable matrix, with preferred flow in directions that parallel geologic strike. Because the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity decreases with depth (Solomon et. al. 1992). Additionally, there are seven stratigraphic zones (number from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et. al. 1995). The more permeable zones are at the bottom (Zone 2) and top (zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater flow in this formation (Goldstrand 1995).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 06 yields sulfate-enriched, sodium-chloride-bicarbonate groundwater generally characterized by:

- TDS above 6,000 mg/L;
- pH (field measurements) near 7.0;
- sulfate concentrations of above 2,000 mg/L; and
- elevated total (unfiltered sample) concentrations of boron (>2 mg/L), lithium (>1 mg/L), and strontium (>5 mg/L).

Elevated trace metal concentrations are probably attributable to natural geochemical processes at depth in the Maynardville Limestone, including: mixing of sulfate-enriched groundwater with brines at depth, which may cause the precipitation of celestite ($SrSO_4$); upward diffusion of solutes from brines in the deeper bedrock; and matrix diffusion from disseminated minerals in the bedrock (Toran and Saunders 1992).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

None of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

One groundwater sample collected to date had a total uranium concentration above the applicable analytical reporting limit, and this result (0.000533 mg/L in September 1999) is substantially below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Benzene concentrations of 2 μg/L and 22 μg/L were reported for the groundwater samples collected in September 1999 and August 2004, respectively; the latter result exceeds the drinking water MCL for benzene (5 μg/L). Also, ethylbenzene was detected (2 μg/L) in the sample collected in August 2004. Considering the depth of water-producing intervals that provide inflow to this sampling port, the detection of these petroleum hydrocarbons in the groundwater samples probably reflects the presence of petroliferous zones at depth in the Maynardville Limestone.

There are several potential sources of the petroleum hydrocarbons in the groundwater samples from this sampling port: (1) residual contamination from installation of the well; (2) contamination from components of the Westbay sampling equipment that are made of or contain petroleum-based materials; (3) contamination of the samples during sampling or handling; and (4) traces of natural hydrocarbons in the low-permeability bedrock.

Residual contamination from installation/construction of the well seems an unlikely source of the hydrocarbons in light of the age of the well (>8 years). Moreover, well installation and construction was closely supervised and controlled to exclude usage of petroleum-based drilling equipment lubricants. Additionally, well installation/construction records do not note any accidental spills/leaks of petroleum-based fluids from the drilling rig or support equipment during installation of the well.

Contamination from components of the Westbay sampling equipment in the well is possible, as several components of the sampling apparatus contain petroleum hydrocarbons. However, it is not known if the hydrocarbons are leachable from these components and repeated sampling since installation of the equipment would be expected to "flush" any leached constituents from the sampling port. Also, such systemic contamination from components of the Westbay sampling equipment would be expected to result in consistent contamination of samples from multiple, if not all, sampling ports. However, only some of the other ports repeatedly yield samples that contain petroleum hydrocarbons. Indeed, these compounds have not been detected consistently in any of the samples collected to date from eight of the sampling ports in the well. In addition, these hydrocarbons have been observed in groundwater samples from some deeper wells that are not instrumented with Westbay sampling equipment.

Contamination of the samples during collection or handling also may be possible, but is not indicated by results for associated quality assurance samples (i.e., petroleum hydrocarbons are not detected in the field or trip blanks). Similarly, data for laboratory blank samples do not support contamination during storage and/or analysis in the laboratory. Also, contamination of the samples during collection at the well head seems very unlikely again because such systemic contamination would result in the detection of petroleum hydrocarbons in the samples collected from all other ports in the well.

Traces of petroleum hydrocarbons naturally present at depth in the low-permeability bedrock may explain the detection of these compounds in the groundwater samples from this port. These hydrocarbons have been observed in groundwater samples from some deeper wells that are not instrumented with Westbay sampling equipment.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA. Additionally, the sample collected in August 2004 was analyzed for Tc-99, a beta-emitting radionuclide that is a primary component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. The analytical result for Tc-99 is below the MDA, which is consistent with the results for gross beta activity.

WELL GW-135
Sampling Port 11

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located on the crest of Chestnut Ridge near the west end of Y-12, on the east side of Industrial Landfill IV. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 80 to 1,275 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 11 being 965 ft bgs (Figure 1). Only two samples have been collected from this port, one in September 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 11 yields groundwater from the deep bedrock interval in the uppermost formation of the Conasauga Group (Maynardville Limestone). The Maynardville Limestone subcrops along the axis of BCV, underlies the main channel of Bear Creek, and dips to the southeast below the Knox Group carbonates that form Chestnut Ridge. The bulk of the groundwater flow in the Maynardville Limestone occurs at shallow depths (<150 ft bgs) in an extensively interconnected network of solution conduits and cavities (shallow karst network). Below the shallow karst network, orthogonal sets of permeable, planar fractures (e.g., bedding plane fractures) form water-producing zones within an essentially impermeable matrix, with preferred flow in directions that parallel geologic strike. Because the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity decreases with depth (Solomon et. al. 1992). Additionally, there are seven stratigraphic zones (number from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et. al. 1995). The more permeable zones are at the bottom (Zone 2) and top (zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater flow in this formation (Goldstrand 1995).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 11 yields chloride-, sulfate-, and sodium-enriched, calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS above 3,000 mg/L;
- pH (field measurements) near 7.0;
- high concentrations of sulfate (>1,500 mg/L) and sodium (>100 mg/L);
- elevated total (unfiltered sample) concentrations of boron (>1 mg/L) and strontium (>7 mg/L); and

- total concentrations of trace metals (except boron and strontium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The elevated boron and strontium concentrations are attributable to natural geochemical processes at depth in the Maynardville Limestone, including: mixing of sulfate-enriched groundwater with brines at depth, which may cause the precipitation of barite ($BaSO_4$) and celestite ($SrSO_4$); upward diffusion of solutes from brines in the deeper bedrock; and matrix diffusion from disseminated minerals in the bedrock (Toran and Saunders 1992).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

None of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

None of the groundwater samples collected to date had total uranium concentrations above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Benzene concentrations of 34 μg/L and 26 μg/L were detected in the groundwater samples collected in September 1999 and August 2004, respectively. Both of these results substantially exceed the drinking water MCL for benzene (5 μg/L). Also, low (estimated) concentrations of ethylbenzene (1 μg/L), toluene (2 μg/L), and styrene (1 μg/L) in the sample collected in August 2004.

There are several potential sources of the petroleum hydrocarbons in the groundwater samples from this sampling port: (1) residual contamination from installation of the well; (2) contamination from components of the Westbay sampling equipment that are made of or contain petroleum-based materials; (3) contamination of the samples during sampling or handling; and (4) traces of natural hydrocarbons in the low-permeability bedrock.

Residual contamination from installation/construction of the well seems an unlikely source of the hydrocarbons in light of the age of the well (>8 years). Moreover, well installation and construction was closely supervised and controlled to exclude usage of petroleum-based drilling equipment lubricants. Additionally, well installation/construction records do not note any accidental spills/leaks of petroleum-based fluids from the drilling rig or support equipment during installation of the well.

Contamination from components of the Westbay sampling equipment in the well is possible, as several components of the sampling apparatus contain petroleum hydrocarbons. However, it is not known if the hydrocarbons are leachable from these components and repeated sampling since installation of the equipment would be expected to "flush" any leached constituents from the sampling port. Also, such systemic contamination from components of the Westbay sampling equipment would be expected to result in consistent contamination of samples from multiple, if not all, sampling ports. However, only some of the other ports repeatedly yield samples that contain petroleum hydrocarbons. Indeed, these compounds have not been detected consistently in any of the samples collected to date from eight of the sampling ports in the well. In addition, these hydrocarbons have been observed in groundwater samples from some deeper wells that are not instrumented with Westbay sampling equipment.

Contamination of the samples during collection or handling also may be possible, but is not indicated by results for associated quality assurance samples (i.e., petroleum hydrocarbons are not detected in the field or trip blanks). Similarly, data for laboratory blank samples do not support contamination during storage and/or analysis in the laboratory. Also, contamination of the samples during collection at the well head seems very unlikely again because such systemic contamination would result in the detection of petroleum hydrocarbons in the samples collected from all other ports in the well.

Traces of petroleum hydrocarbons naturally present at depth in the low-permeability bedrock may explain the detection of these compounds in the groundwater samples from this port. These hydrocarbons have been observed in groundwater samples from some deeper wells that are not instrumented with Westbay sampling equipment.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA. Additionally, the sample collected in August 2004 was analyzed for Tc-99, a beta-emitting radionuclide that is a primary component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. The analytical result for Tc-99 is below the MDA, which is consistent with the results for gross beta activity.

WELL GW-135
Sampling Port 15

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located on the crest of Chestnut Ridge near the west end of Y-12, on the east side of Industrial Landfill IV. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 80 to 1,275 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 15 being 836 ft bgs (Figure 1). Only two samples have been collected from this port, one in September 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 15 yields groundwater from the upper most formation (Maynardville Limestone) of the Conasauga Group, which underlies the axis of Bear Creek Valley (BCV) and dips southeast beneath the overlying Knox Group formations that form Chestnut Ridge. The bulk of the groundwater flow in the Maynardville Limestone occurs at shallow depths (<150 ft bgs) in an extensively interconnected network of solution conduits and cavities (shallow karst network). Below the shallow karst network, orthogonal sets of permeable, planar fractures form water-producing zones within an essentially impermeable matrix. Because the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity decreases with depth. Also, there are seven stratigraphic zones (number from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et. al. 1995). The more permeable zones are at the bottom (Zone 2) and top (zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater flow in this formation (Goldstrand 1995).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 15 yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 243 and 336 mg/L;
- pH (field measurements) of 7.7;
- low molar proportions of chloride, fluoride, potassium, sodium, and sulfate (<10% of total anions/cations); and

- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

None of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

None of the groundwater samples collected to date had total uranium concentrations above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Low (estimated) concentrations of ethylbenzene (1 μg/L) and styrene (2 μg/L) were detected in the groundwater sample collected August 2004. Considering the depth of water-producing intervals that provide inflow to this sampling port, the detection of these petroleum hydrocarbons in the groundwater sample possibly reflects the presence of petroliferous zones at depth in the Maynardville Limestone.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA. Additionally, the sample collected in August 2004 was analyzed for Tc-99, a beta-emitting radionuclide that is a primary component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. The analytical result for Tc-99 is below the MDA, which is consistent with the results for gross beta activity.

WELL GW-135
Sampling Port 19

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located on the crest of Chestnut Ridge near the west end of Y-12, on the east side of Industrial Landfill IV. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 80 to 1,275 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 19 being 731 ft bgs (Figure 1). Only two samples have been collected from this port, one in September 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 19 yields groundwater from the deep bedrock interval in the uppermost formation of the Conasauga Group (Maynardville Limestone). The Maynardville Limestone subcrops along the axis of BCV, underlies the main channel of Bear Creek, and dips to the southeast below the Knox Group carbonates that form Chestnut Ridge. The bulk of the groundwater flow in the Maynardville Limestone occurs at shallow depths (<150 ft bgs) in an extensively interconnected network of solution conduits and cavities (shallow karst network). Below the shallow karst network, orthogonal sets of permeable, planar fractures (e.g., bedding plane fractures) form water-producing zones within an essentially impermeable matrix, with preferred flow in directions that parallel geologic strike. Because the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity decreases with depth (Solomon et. al. 1992). Additionally, there are seven stratigraphic zones (number from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et. al. 1995). The more permeable zones are at the bottom (Zone 2) and top (zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater flow in this formation (Goldstrand 1995).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 19 yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 192 and 317 mg/L;
- pH (field measurements) near 7.5;
- low molar proportions of chloride, fluoride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at

Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

None of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

Total uranium concentrations reported for the groundwater samples collected in September 1999 (0.00101 mg/L) and August 2004 (0.00119 mg/L) exceed the applicable analytical reporting limit, and both results are substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

None of the groundwater samples collected to data contained VOCs.

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity above the applicable MDA was reported for the groundwater samples collected in September 1999 (5.6 pCi/L) and August 2004 (4.3 pCi/L). Both results are substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA. Additionally, the sample collected in August 2004 was analyzed for Tc-99, a beta-emitting radionuclide that is a primary component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. The analytical result for Tc-99 is below the MDA, which is consistent with the results for gross beta activity.

WELL GW-135
Sampling Port 23

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located on the crest of Chestnut Ridge near the west end of Y-12, on the east side of Industrial Landfill IV. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 80 to 1,275 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 23 being 609 ft bgs (Figure 1). Only two samples have been collected from this port, one in September 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 23 yields groundwater from the lower Knox Group (Chepultepec Dolomite), which underlies the steep northern flank of Chestnut Ridge. The Knox Group formations, along with the uppermost formation (Maynardville Limestone) of the underlying Conasauga Group, comprise an aquifer consisting of three vertically gradational subsystems distinguished by groundwater flux, which decreases with depth: (1) the stormflow zone, (2) the vadose zone, and (3) the groundwater zone (Solomon et al. 1992). The stormflow and vadose zones occur at shallow depths within the thick (>100 ft) residuum that has developed on Chestnut Ridge. In the bedrock zone, orthogonal sets of permeable, planar fractures (e.g., bedding plane fractures) form water-producing zones within an essentially impermeable matrix, with preferred flow in directions that parallel geologic strike. Dissolution of carbonates has enlarged fractures and produced an interconnected conduit-flow system characteristic of karst aquifers, but the occurrence of solution features and the frequency, aperture, and connectivity of permeable fractures decrease with depth. Consequently, the bulk hydraulic conductivity is vertically gradational, with the bulk of the groundwater flux occurring within the transitional horizon between residuum and unweathered bedrock and substantially lower flux (and longer solute residence times) at successively greater depths in the bedrock (Solomon et al. 1992).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 23 yields sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS above 3,000 mg/L;
- pH (field measurements) near 7.2;
- sulfate concentrations above 2,000 mg/L along with unusually high concentrations of potassium (>50 mg/L) and sodium (>70 mg/L);

- elevated total (unfiltered sample) concentrations of boron (>2 mg/L), fluoride (>1 mg/L), iron (>1 mg/L), and strontium (>8 mg/L); and
- total concentrations of trace metals (except boron, iron, and strontium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Elevated trace metal concentrations may be attributed to natural geochemical processes, including: mixing of sulfate-enriched groundwater with brines at depth, which may cause the precipitation of celestite ($SrSO_4$); upward diffusion of solutes from brines in the deeper bedrock; and matrix diffusion from disseminated minerals in the bedrock (Saunders and Toran 1992).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

None of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

One of the groundwater samples collected to date had a total uranium concentration above the analytical reporting limit, and this result (0.000668 mg/L in September 1999) is substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Benzene concentrations of 14 µg/L and 19 µg/L were reported for the groundwater samples collected in September 1999 and August 2004, respectively. Both of these results substantially exceed the drinking water MCL for benzene (5 µg/L). Each sample also contained low (estimated) concentrations of ethylbenzene (3 µg/L and 4 µg/L, respectively) and toluene (3 µg/L and 2 µg/L, respectively), and the sample collected in August 2004 had a trace of styrene (2 µg/L).

There are several potential sources of the petroleum hydrocarbons in the groundwater samples from this sampling port: (1) residual contamination from installation of the well; (2) contamination from components of the Westbay sampling equipment that are made of or contain petroleum-based materials; (3) contamination of the samples during sampling or handling; and (4) traces of natural hydrocarbons in the low-permeability bedrock.

Residual contamination from installation/construction of the well seems an unlikely source of the hydrocarbons in light of the age of the well (>8 years). Moreover, well installation and construction was closely supervised and controlled to exclude usage of petroleum-based drilling equipment lubricants. Additionally, well installation/construction records do not note any accidental spills/leaks of petroleum-based fluids from the drilling rig or support equipment during installation of the well.

Contamination from components of the Westbay sampling equipment in the well is possible, as several components of the sampling apparatus contain petroleum hydrocarbons. However, it is not known if the hydrocarbons are leachable from these components and repeated sampling since installation of the equipment would be expected to "flush" any leached constituents from the sampling port. Also, such systemic contamination from components of the Westbay sampling equipment would be expected to result in consistent contamination of samples from multiple, if not all, sampling ports. However, only some of the other ports repeatedly yield samples that contain petroleum hydrocarbons. Indeed, these compounds have not been detected consistently in any of the samples collected to date from eight of the sampling ports in the well. In addition, these hydrocarbons have been observed in groundwater samples from some deeper wells that are not instrumented with Westbay sampling equipment.

Contamination of the samples during collection or handling also may be possible, but is not indicated by results for associated quality assurance samples (i.e., petroleum hydrocarbons are not detected in the field or trip blanks). Similarly, data for laboratory blank samples do not support contamination during storage and/or analysis in the laboratory. Also, contamination of the samples during collection at the well head seems very unlikely again because such systemic contamination would result in the detection of petroleum hydrocarbons in the samples collected from all other ports in the well.

Traces of petroleum hydrocarbons naturally present at depth in the low-permeability bedrock may explain the detection of these compounds in the groundwater samples from this port. These hydrocarbons have been observed in groundwater samples from some deeper wells that are not instrumented with Westbay sampling equipment.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA. Additionally, the sample collected in August 2004 was analyzed for Tc-99, a beta-emitting radionuclide that is a primary component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. The analytical result for Tc-99 is below the MDA, which is consistent with the results for gross beta activity.

WELL GW-135
Sampling Port 26

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located on the crest of Chestnut Ridge near the west end of Y-12, on the east side of Industrial Landfill IV. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 80 to 1,275 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 26 being 554 ft bgs (Figure 1). Only two samples have been collected from this port, one in September 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 26 yields groundwater from the lower Knox Group (Chepultepec Dolomite), which underlies the steep northern flank of Chestnut Ridge. The Knox Group formations, along with the uppermost formation (Maynardville Limestone) of the underlying Conasauga Group, comprise an aquifer consisting of three vertically gradational subsystems distinguished by groundwater flux, which decreases with depth: (1) the stormflow zone, (2) the vadose zone, and (3) the groundwater zone (Solomon et al. 1992). The stormflow and vadose zones occur at shallow depths within the thick (>100 ft) residuum that has developed on Chestnut Ridge. In the bedrock zone, orthogonal sets of permeable, planar fractures form water-producing zones within an essentially impermeable matrix, and dissolution of carbonates has enlarged fractures and produced an interconnected conduit-flow system characteristic of karst aquifers. Because the occurrence of solution features and the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity of the groundwater zone is vertically gradational. Most groundwater flux occurs within the transitional horizon between residuum and unweathered bedrock (water table interval); lower flux (and longer solute residence times) occurs at successively greater depths in the bedrock (Solomon et al. 1992).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 26 yields sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS above 2,500 mg/L;
- pH (field measurements) near 7.1;
- sulfate concentrations above 1,500 mg/L along with unusually high concentrations of potassium (>20 mg/L);

- elevated total (unfiltered sample) concentrations of boron (>1 mg/L), fluoride (>1 mg/L), iron (>4 mg/L), and strontium (>7 mg/L); and
- total concentrations of trace metals (except boron, iron, and strontium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Elevated trace metal concentrations may be attributed to natural geochemical processes, including: mixing of sulfate-enriched groundwater with brines at depth, which may cause the precipitation of celestite ($SrSO_4$); upward diffusion of solutes from brines in the deeper bedrock; and matrix diffusion from disseminated minerals in the bedrock (Saunders and Toran 1992).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

None of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

None of the groundwater samples collected to date had total uranium concentrations above the analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Low (estimated) concentrations of benzene (4 μg/L), ethylbenzene (3 μg/L), and styrene (1 μg/L) were detected in the groundwater sample collected in September 1999. Higher concentrations of benzene (6 μg/L), which slightly exceeds the drinking water MCL (5 μg/L), ethylbenzene (11 μg/L), and styrene (11 μg/L) were detected in the sample collected in August 2004, along with toluene (6 μg/L) and xylenes (5 μg/L).

There are several potential sources of the petroleum hydrocarbons in the groundwater samples from this sampling port: (1) residual contamination from installation of the well; (2) contamination from components of the Westbay sampling equipment that are made of or contain petroleum-based materials; (3) contamination of the samples during sampling or handling; and (4) traces of natural hydrocarbons in the low-permeability bedrock.

Residual contamination from installation/construction of the well seems an unlikely source of the hydrocarbons in light of the age of the well (>8 years). Moreover, well installation and construction was closely supervised and controlled to exclude usage of petroleum-based drilling equipment lubricants. Additionally, well installation/construction records do not note any accidental spills/leaks of petroleum-based fluids from the drilling rig or support equipment during installation of the well.

Contamination from components of the Westbay sampling equipment in the well is possible, as several components of the sampling apparatus contain petroleum hydrocarbons. However, it is not known if the hydrocarbons are leachable from these components and repeated sampling since installation of the equipment would be expected to "flush" any leached constituents from the sampling port. Also, such systemic contamination from components of the Westbay sampling equipment would be expected to result in consistent contamination of samples from multiple, if not all, sampling ports. However, only some of the other ports repeatedly yield samples that contain petroleum hydrocarbons. Indeed, these compounds have not been detected consistently in any of the samples collected to date from eight of the sampling ports in the well. In addition, these hydrocarbons have been observed in groundwater samples from some deeper wells that are not instrumented with Westbay sampling equipment.

Contamination of the samples during collection or handling also may be possible, but is not indicated by results for associated quality assurance samples (i.e., petroleum hydrocarbons are not detected in the field or trip blanks). Similarly, data for laboratory blank samples do not support contamination during storage and/or analysis in the laboratory. Also, contamination of the samples during collection at the well head seems very unlikely again because such systemic contamination would result in the detection of petroleum hydrocarbons in the samples collected from all other ports in the well.

Traces of petroleum hydrocarbons naturally present at depth in the low-permeability bedrock may explain the detection of these compounds in the groundwater samples from this port. These hydrocarbons have been observed in groundwater samples from some deeper wells that are not instrumented with Westbay sampling equipment.

Acrylonitrile was detected (31 µg/L) in the groundwater sample collected in August 2004. According to the manufacturer, the Westbay™ sampling system contains several components made with acrylonitrile, and detection of this compound is often an artifact from sampling ports in low permeability zones (Westbay Instruments, Inc. 1999).

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA. Additionally, the sample collected in August 2004 was analyzed for Tc-99, a beta-emitting radionuclide that is a primary component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. The analytical result for Tc-99 is below the MDA, which is consistent with the results for gross beta activity.

WELL GW-135
Sampling Port 30

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located on the crest of Chestnut Ridge near the west end of Y-12, on the east side of Industrial Landfill IV. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 80 to 1,275 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 30 being 459 ft bgs (Figure 1). Only two samples have been collected from this port, one in September 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 30 yields groundwater from the lower Knox Group (Chepultepec Dolomite), which underlies the steep northern flank of Chestnut Ridge. The Knox Group formations, along with the uppermost formation (Maynardville Limestone) of the underlying Conasauga Group, comprise an aquifer consisting of three vertically gradational subsystems distinguished by groundwater flux, which decreases with depth: (1) the stormflow zone, (2) the vadose zone, and (3) the groundwater zone (Solomon et al. 1992). The stormflow and vadose zones occur at shallow depths within the thick (>100 ft) residuum that has developed on Chestnut Ridge. In the bedrock zone, orthogonal sets of permeable, planar fractures form water-producing zones within an essentially impermeable matrix, and dissolution of carbonates has enlarged fractures and produced an interconnected conduit-flow system characteristic of karst aquifers. Because the occurrence of solution features and the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity of the groundwater zone is vertically gradational. Most groundwater flux occurs within the transitional horizon between residuum and unweathered bedrock (water table interval); lower flux (and longer solute residence times) occurs at successively greater depths in the bedrock (Solomon et al. 1992).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 30 yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 188 and 275 mg/L;
- pH (field measurements) of 7.69 and 7.75;
- low molar proportions of chloride, fluoride, potassium, sodium, and sulfate (<10% of total anions/cations); and

- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Two of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit, and both results (0.0323 mg/L in September 1999 and 0.0606 mg/L in August 2004) are substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Two of the groundwater samples collected to date had total uranium concentrations above the applicable analytical reporting limit, and both results (0.000879 mg/L in September 1999 and 0.000699 mg/L in August 2004) are substantially below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

None of the groundwater samples collected to date contained VOCs.

5.4 GROSS ALPHA ACTIVITY

One of the groundwater samples collected to date had gross alpha activity above the applicable MDA, and this result (11 pCi/L in September 1999) is less than the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA. Additionally, the sample collected in August 2004 was analyzed for Tc-99, a beta-emitting radionuclide that is a primary component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. The analytical result for Tc-99 is below the MDA, which is consistent with the results for gross beta activity.

WELL GW-135
Sampling Port 34

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located on the crest of Chestnut Ridge near the west end of Y-12, on the east side of Industrial Landfill IV. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 80 to 1,275 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 34 being 334 ft bgs (Figure 1). Only two samples have been collected from this port, one in September 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 34 yields groundwater from the lower Knox Group (Chepultepec Dolomite), which underlies the steep northern flank of Chestnut Ridge. The Knox Group formations, along with the uppermost formation (Maynardville Limestone) of the underlying Conasauga Group, comprise an aquifer consisting of three vertically gradational subsystems distinguished by groundwater flux, which decreases with depth: (1) the stormflow zone, (2) the vadose zone, and (3) the groundwater zone (Solomon et al. 1992). The stormflow and vadose zones occur at shallow depths within the thick (>100 ft) residuum that has developed on Chestnut Ridge. In the bedrock zone, orthogonal sets of permeable, planar fractures form water-producing zones within an essentially impermeable matrix, and dissolution of carbonates has enlarged fractures and produced an interconnected conduit-flow system characteristic of karst aquifers. Because the occurrence of solution features and the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity of the groundwater zone is vertically gradational. Most groundwater flux occurs within the transitional horizon between residuum and unweathered bedrock (water table interval); lower flux (and longer solute residence times) occurs at successively greater depths in the bedrock (Solomon et al. 1992).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 34 yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 187 and 194 mg/L;
- pH (field measurements) of 7.49 and 7.55;
- low molar proportions of chloride, fluoride, potassium, sodium, and sulfate (<10% of total anions/cations); and

- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Two of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit, and both results (0.134 mg/L in September 1999 and 0.167 mg/L in August 2004) are substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Two of the groundwater samples collected to date had total uranium concentrations above the applicable analytical reporting limit, and both results (0.00127 mg/L in September 1999 and 0.000889 mg/L in August 2004) are substantially below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

None of the groundwater samples collected to date contained VOCs.

5.4 GROSS ALPHA ACTIVITY

One of the groundwater samples collected to date had gross alpha activity above the applicable MDA, and this result (5.9 pCi/L in September 1999) is less than the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

One of the groundwater samples collected to date had gross beta activity above the applicable MDA, and this result (6.5 pCi/L in September 1999) is less than the Safe Drinking Water Act screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity pCi/L). Additionally, the sample collected in August 2004 was analyzed for Tc-99, a beta-emitting radionuclide that is a primary component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. The analytical result for Tc-99 is below the MDA, which is consistent with the results for gross beta activity.

WELL GW-135
Sampling Port 39

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well is located on the crest of Chestnut Ridge near the west end of Y-12, on the east side of Industrial Landfill IV. The well was converted from a core hole that was drilled as part of a geologic investigation performed at Y-12 during the summer of 1985 (King and Haase 1987), and was included in several subsequent hydrogeologic and geochemical studies (King and Haase 1988; Toran and Saunders 1992; Dreier, Early, and King 1993). The well has nominal 4.5-inch diameter steel (SF25) riser casing above an open-hole interval that extends from a depth of 80 to 1,275 ft bgs. In March 1990, a multiport monitoring system (Westbay™) was installed in the well. This equipment enables the collection of groundwater samples from multiple discreet depth intervals within the open-hole interval (Martin Marietta Energy Systems 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

The Westbay™ multiport monitoring system in the well has been used to obtain groundwater samples from ten sampling ports, with port 39 being 214 ft bgs (Figure 1). Only two samples have been collected from this port, one in September 1999 and one in August 2004. Each sample was obtained by lowering a 250 milliliter non-vented stainless steel sample collection bottle to the sampling port, opening the port valve, allowing the bottle to fill, retrieving the filled bottle to the surface, and decanting the contents into the appropriate laboratory sample bottle(s). The sample collection bottle was lowered, filled, and retrieved as many times as necessary to fill the laboratory sample bottle(s). Groundwater in the first sample collection bottle retrieved from the sampling port was used as a "formation rinse" to obtain field measurements and to condition the sample collection bottle.

3.0 HYDROLOGIC CHARACTERISTICS

Sampling port 39 yields groundwater from the lower Knox Group (Chepultepec Dolomite), which underlies the steep northern flank of Chestnut Ridge. The Knox Group formations, along with the uppermost formation (Maynardville Limestone) of the underlying Conasauga Group, comprise an aquifer consisting of three vertically gradational subsystems distinguished by groundwater flux, which decreases with depth: (1) the stormflow zone, (2) the vadose zone, and (3) the groundwater zone (Solomon et al. 1992). The stormflow and vadose zones occur at shallow depths within the thick (>100 ft) residuum that has developed on Chestnut Ridge. In the bedrock zone, orthogonal sets of permeable, planar fractures form water-producing zones within an essentially impermeable matrix, and dissolution of carbonates has enlarged fractures and produced an interconnected conduit-flow system characteristic of karst aquifers. Because the occurrence of solution features and the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity of the groundwater zone is vertically gradational. Most groundwater flux occurs within the transitional horizon between residuum and unweathered bedrock (water table interval); lower flux (and longer solute residence times) occurs at successively greater depths in the bedrock (Solomon et al. 1992).

4.0 GEOCHEMICAL CHARACTERISTICS

Sampling port 39 yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 149 and 178 mg/L;
- pH (field measurements) of 7.32 and 7.41;
- low molar proportions of chloride, fluoride, potassium, sodium, and sulfate (<10% of total anions/cations); and

- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Two of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit, and both results (0.2616 mg/L in September 1999 and 0.245 mg/L in August 2004) are substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

None of the groundwater samples collected to date had total uranium concentrations above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

None of the groundwater samples collected to date contained VOCs.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples collected to date had gross alpha activity above the applicable MDA.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta activity above the applicable MDA. Additionally, the sample collected in August 2004 was analyzed for Tc-99, a beta-emitting radionuclide that is a primary component of the groundwater contaminant plume emplaced during historical operation of the former S-3 Ponds. The analytical result for Tc-99 is below the MDA, which is consistent with the results for gross beta activity.

WELL GW-141

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in September 1987, completed with a screened monitored interval from 141 to 156 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located on the crest of Chestnut Ridge southwest of the west end of Y-12, about 100 ft directly north (hydraulically downgradient) of Industrial Landfill IV. In operation since 1989, this landfill receives about 12,000 ft^2 per year of nonhazardous and nonradioactive industrial wastes, including cardboard, plastics, rubber, scrap metal, wood, paper, and special wastes generated from DOE operations on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fifty-one groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 37 samples between February 1988 and July 1997, and the low-flow sampling method used to obtain 14 samples between January 1998 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from bedrock in the Knox Group (Copper Ridge Dolomite). Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 90 ft bgs and exhibits moderate seasonal fluctuations (<10 ft).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 160 – 284 mg/L;
- pH (field measurements) of 6.2 – 7.6;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are less than 0.5 mg/L.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for 37 groundwater samples collected from the well since January 1991.

5.1 NITRATE

All but one groundwater sample had nitrate above the applicable analytical reporting limit, with the highest concentration (0.88 mg/L in January 1995) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Three groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.0014 mg/L in January 1997) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected at low levels in three groundwater samples: acetone (9 μg/L) in February 2000, MC (0.89 μg/L) in July 2000, and carbon disulfide (0.64 μg/L) in July 2004. These compounds are common laboratory agents and the results are considered to be outliers.

5.4 GROSS ALPHA ACTIVITY

Six groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the two highest values (16.6 pCi/L in January 1996 and 17 pCi/L in January 1997) being slightly above the MCL for gross alpha activity (15 pCi/L). Alpha activity has been below the applicable MDA in every sample collected since January 1997.

5.5 GROSS BETA ACTIVITY

Seven groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (35 pCi/L in January 1997) being less than the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-142

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1985, completed with an open-hole monitored interval from 248.5 to 295 ft bgs, and constructed with nominal 6.5-inch diameter steel (SF25) riser casing. The well is located on the southern flank of Chestnut Ridge directly south of the east end of Y-12, about 300 ft east (hydraulically upgradient) of Kerr Hollow Quarry (KHQ). KHQ is an inactive, water-filled quarry formerly used for disposal of various hazardous and nonhazardous wastes generated from historical DOE operations on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Ninety-five groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 53 samples between February 1986 and August 1997, and the low-flow sampling method used to obtain 42 samples between November 1997 and October 2003.

An evaluation of the monitoring data available through August 2000 indicated potential bias related to the groundwater sampling method: (unfiltered) samples obtained with the conventional sampling method had substantially higher levels of uranium than samples obtained with the low-flow sampling method (AJA 2001). Results of "paired sampling", when groundwater samples are collected with the low-flow sampling method one day and the conventional sampling method the next day, are needed to determine if the uranium concentrations are biased by the sampling method.

Inherent differences in the manner in which each sampling method induces inflow of groundwater into the well may explain the disparity between the conventional and low-flow sampling results. Conventional sampling involves aggressively purging the well (1-2 gallons per minute), which may substantially lower the water level in the well and induce inflow from water-producing features that may not be proximal to the pump intake. In contrast, low-flow sampling involves purging the well at flow rate low enough (<300 milliliters per minute) to ensure minimal water-level drawdown in the well (<1 ft per quarter hour), which induces groundwater inflow only from the water-producing feature(s) proximal to the well. Thus, the conventional sampling method has much greater local hydrologic influence (particularly in directions parallel with geologic strike) and substantially increases the relative inflow of contaminated groundwater into the well.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the bedrock interval in the Knox Group (Mascot Dolomite). Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 139 ft bgs and exhibit unusually wide (>80 ft) fluctuations (Figure 1). However, the conventional sampling method is associated with the largest apparent water level fluctuations. Purging the well during conventional sampling typically decreases the water level in the well by 40 ft or more, and the water level is very slow to recover to the presampling level (Figure 2). Moreover, the protocol of consecutive daily sampling required for RCRA post-closure detection monitoring at the KHQ was discontinued in part because the water level in this well would not sufficiently recover between sampling events (Bechtel Jacobs Company LLC [BJC] 2001).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- moderate TDS (150 mg/L – 800 mg/L);
- pH (field measurements) of 7.1 – 8.5;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for 76 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Twenty groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (1.9 mg/L in March 1991) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Twenty groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.032 mg/L in August 1993) being slightly above the MCL for uranium (0.03 mg/L). As noted in Section 2.0, uranium concentrations may be significantly higher in conventional samples from this well than in low-flow samples. Uranium concentrations reported for low-flow samples have been either non-detect values or less than 0.005 mg/L, and uranium concentrations reported for conventional samples were commonly above 0.01 mg/L (Figure 3). Furthermore, uranium has been detected in only one semiannual sample (0.004 mg/L in October 2001) since 1999, when the reporting limit increased from 0.0005 mg/L to 0.004 mg/L.

A time-series plot of the uranium concentrations in each sample from well GW-142 shows a generally decreasing trend, which may be skewed by the change to low-flow sampling in October 1997 (Figure 3). Although the well is located hydraulically upgradient of KHQ, the significant drop in water level (> 40 ft) induced by the conventional method (Figure 2) would temporarily establish a fairly strong hydraulic gradient toward the well from the site. If uranium flux was induced toward well GW-142 by the periodic gradient reversals caused by aggressively purging the well for the conventional sampling method, then the low-flow sampling method may effectively keep uranium concentrations low in samples from the well.

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for 61 groundwater samples show non-detect values or false positive results for all of the VOCs that are confirmed groundwater contaminants in the Chestnut Ridge Regime. Low concentrations of PCE were detected in samples collected in March 1991 (0.7 μg/L), August 1991 (0.7 μg/L), November 1991 (0.8 μg/L), May 1992 (2 μg/L), November 1995 (1 μg/L), and April 1997 (1 μg/L). Samples collected in April 1997 also had low levels (1 μg/L) of chloroform. The series of PCE detections between March 1991 and May 1992 generally coincide with the disturbance of wastes in KHQ from efforts to achieve clean closure of site (BJC 2001).

5.4 GROSS ALPHA ACTIVITY

Forty-one groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (16.8 pCi/L in January 1996) being slightly above the MCL for gross alpha activity (15 pCi/L). However, none of the other results for gross alpha activity exceed the MCL, with values below 5 pCi/L reported for each sample collected since November 1997.

5.5 GROSS BETA ACTIVITY

Forty-five of the groundwater samples had gross beta activity above the applicable MDA and/or the corresponding CE, with the highest value (38.8 pCi/L in February 1992) being slightly below the SDWA screening level for gross beta activity (50 pCi/L). However, this result is a suspected outlier because none of the other results for gross beta activity exceed 15 pCi/L and values have been below 10 pCi/L reported for each sample collected since July 1995.

WELL GW-143

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1985, completed with an open-hole monitored interval from 205 to 253 ft bgs, and constructed with nominal 6.5-inch diameter steel (SF25) riser casing. The well forms a cluster with well GW-144 and is located on the southern flank of Chestnut Ridge directly south of the east end of Y-12, about 250 ft south (hydraulically downgradient) of Kerr Hollow Quarry (KHQ). KHQ is an inactive, water-filled quarry formerly used for disposal of various hazardous and nonhazardous wastes generated from historical DOE operations on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Ninety-seven groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 53 samples between March 1986 and August 1997, and the low-flow sampling method used to obtain 44 samples between November 1997 and October 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the bedrock interval in the Knox Group (Mascot Dolomite). The average static groundwater level in the well is about 77 ft bgs. Presampling depth-to-water measurements for the well indicate unusually wide (>100 ft) fluctuations in groundwater surface elevations (Figure 1). However, the conventional sampling method is associated with the largest apparent water level fluctuations. Purging the well during conventional sampling typically decreases the water level in the well by 90 ft or more, and the water level is very slow to recover to the presampling level (Figure 2). Moreover, the protocol of consecutive daily sampling required for RCRA post-closure detection monitoring at the KHQ was discontinued in part because the water level in this well would not sufficiently recover between sampling events, as shown on Figure 1 (Bechtel Jacobs Company LLC [BJC] 2001).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields sulfate-enriched, calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 120 – 300 mg/L;
- pH (field measurements) of 6.9 – 8.5;
- unequal molar proportions of calcium and magnesium;
- concentrations of sulfate (>30 mg/L), sodium (>20 mg/L), chloride (>109 mg/L), and fluoride (>2 mg/L) that are much higher than typical of other wells in the Knox Group; and
- total (unfiltered sample) concentrations of trace metals (except boron and strontium that are substantially higher than evident in other Knox Group wells) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Dissolution of locally disseminated gypsum ($CaSO_4 \cdot 2 H_2O$) may account for the sulfate-enriched geochemistry (Lockheed Martin Energy Systems, Inc. 1999) and enriched levels of other solutes, including boron and strontium, may be a legacy of the sedimentary basin brines that are encountered at depth elsewhere on the ORR (Saunders and Toran 1992).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for 79 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Eight groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.3 mg/L in September 1991) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Forty-one groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.006 mg/L in September 1992) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected in 13 groundwater samples and the summed VOC concentration exceeded 5 μg/L in three of these samples (March 1996, April 1997, and November 1997). None of the VOC concentrations exceeded an applicable MCL. Very low concentrations (2 μg/L or less) of TCE, CT, and/or chloroform were detected in the six samples collected in August 1993, March 1994, and April-May 1997. Similarly low levels of PCE (1 μg/L), ethylbenzene (2 μg/L), total xylene (1 μg/L), bromomethane (4 μg/L), chloromethane (8 μg/L), and TCFM (2 μg/L) were detected in the sample collected in November 1997. These VOCs are known or suspected to have been included in the wastes disposed at KHQ and their repeated detection in the groundwater samples collected from the well during the early and mid-1990s generally coincides with efforts to remove or otherwise stabilize the submerged wastes during RCRA closure of the site.

One sample (April 1997) had 2-butanone (13 μg/L), and acetone was detected in four samples: the highest acetone concentration (100 μg/L) was in April 1997, and most recent detection (1 μg/L) was in December 2002. The results for acetone and 2-butanone are probable artifacts because these compounds are commonly detected in blank samples.

5.4 GROSS ALPHA ACTIVITY

Forty-nine groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (12 pCi/L in October 1994) being slightly below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Sixty-four groundwater samples had gross beta activity above the applicable MDA and the corresponding CE, with the highest value (44 pCi/L in November 1997) being slightly below the SDWA screening level for gross beta activity.

WELL GW-144

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1985, completed with a screened monitored interval from 148 to 195 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and well screen (0.01 slot). The well forms a cluster with well GW-143 on the southern flank of Chestnut Ridge directly south of the east end of Y-12, about 250 ft south (hydraulically downgradient) of Kerr Hollow Quarry (KHQ), which is a closed, water-filled quarry formerly used for disposal of various hazardous and nonhazardous waste generated from historical DOE operations on the ORR. Groundwater monitoring is performed at KHQ in accordance with the requirements of a RCRA post-closure permit issued by the TDEC in 1995 (TDEC 1995).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Ninety-eight groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 54 samples between February 1986 and August 1997, and the low-flow sampling method used to obtain 44 samples between November 1997 and October 2004. Many of these samples were collected in accordance with the replicate sampling protocol associated with RCRA post-closure detection monitoring performed between October 1996 and April 2001, when four samples were collected over consecutive days during each semiannual sampling event.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from bedrock in the Knox Group (Mascot Dolomite); the monitored interval for the well intercepts a water-producing fracture at 170 ft bgs that yields over 20 gallons per minute (BWXT Y-12. 1995). The average static groundwater level in the well is 77 ft bgs. Presampling depth-to-water measurements for the well indicate moderate (<6 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 130 – 240 mg/L, excluding a suspected outlier (104 mg/L) in January 1995;
- pH (field measurements) of 6.5 – 8.2;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion, which is based on the analytical results reported for 78 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Forty-six groundwater samples had nitrate concentrations above the applicable analytical reporting limit, and the historical maximum concentration (6.89 mg/L in April 1998) is below the MCL for nitrate (10 mg/L). As shown on Figure 1, nitrate levels in the well show wide fluctuations, with peak concentrations evident during seasonally high flow (winter and spring). The source of the nitrate may be municipal sewage sludge application sites in hayfields located about 800 ft west-northwest (across geologic strike) of KHQ. In an effort to better determine if downgradient transport from the sludge application site is a source of the nitrate, groundwater samples collected in October 1998 from KHQ wells GW-142, GW-143, GW-144, GW-145, and GW-231 and Outfall 301 were analyzed for ammonia, fecal coliform, nitrate, and total phosphate (as phosphorous). Nitrate was detected only in the sample from Outfall 301 (1.38 mg/L) and trace levels of ammonia were detected in samples from wells GW-145 (0.42 mg/L) and GW-231 (0.22 mg/L); the fecal coliform count and total phosphate level for each sampling location did not exceed respective analytical reporting limits.

5.2 URANIUM

Forty-five groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the historical maximum concentration (0.007 mg/L in August 1995) being slightly above the applicable UTL (0.005 mg/L) and substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected at very low levels in 21 groundwater samples collected from the well since 1991. Acetone (1 μg/L in April 1998) and chloromethane (3 μg/L in April 1999) were each detected in one sample. However, as shown below in Table 1, low concentrations (5 μg/L or less) of PCE, CTET, and/or chloroform were detected in 19 of the samples from the well, most recently in the sample collected in December 2002.

Table 1. VOC data for well GW-144

Sampling Date	Concentration (μg/L)		
	PCE	CTET	Chloroform
06/15/91	1 J	5	FP
09/05/91	2 J	2 J	2 J
11/06/91	1 J	1 J	2 J
05/29/92	.	2 J	.
09/15/92	.	2 J	.
12/01/92	.	5	0.8 J
08/26/93	.	3 J	0.7 J
12/15/93	.	3 J	.
04/19/94	.	2 J	.
01/18/95	1 J	3 J	.
04/25/95	.	3 J	1 J
11/14/95	.	2 J	.
01/22/96	.	3 J	.
04/24/96	.	4 J	.
04/28/97	.	.	1 J
04/29/97	.	2 J	FP
04/30/97	2 J	1 J	FP
05/01/97	1 J	.	FP
12/02/02	0.4 J	.	.

Note: "." = Not detected; J = Estimated concentration; FP = false positive result

These VOCs are known or suspected to have been included in the wastes disposed at KHQ and their repeated detection in the groundwater samples collected from the well during the early and mid-1990s generally coincides with efforts to remove or otherwise stabilize the submerged wastes during RCRA closure of the site.

5.4 GROSS ALPHA ACTIVITY

Forty groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (8.43 pCi/L in October 1994) being below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Thirty of the groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (7.49 pCi/L in October 1994) being substantially below the SDWA screening level for gross beta activity.

WELL GW-145

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1985, completed with a screened monitored interval from 86 to 110 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and well screen (0.01 slot). The well forms a cluster with well GW-146 and is located on the southern flank of Chestnut Ridge directly south of the east end of Y-12, about 150 ft southwest (hydraulically downgradient) of Kerr Hollow Quarry (KHQ). KHQ is an inactive, water-filled quarry formerly used for disposal of various hazardous and nonhazardous wastes generated from historical DOE operations on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Ninety-eight groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 54 samples between March 1986 and August 1997, and the low-flow sampling method used to obtain 44 samples between November 1997 and October 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the bedrock interval in the Knox Group (Mascot Dolomite). Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 3 ft bgs and exhibits unusually wide (>40 ft) fluctuations. However, the conventional sampling method is associated with the largest apparent water level fluctuations (Figure 1). Purging the well during conventional sampling typically decreases the water level in the well by 90 ft or more, and the water in the well recovers very slowly to the presampling level. Moreover, the protocol of consecutive daily sampling required for RCRA post-closure detection monitoring at the KHQ was discontinued in part because the water level in this well would not sufficiently recover between sampling events, as shown on Figure 1 (Bechtel Jacobs Company LLC [BJC] 2001).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields sulfate-enriched, calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 164 – 356 mg/L, excluding an outlier (940 mg/L) from October 5, 2000;
- pH (field measurements) of 6.6 – 8.6;
- unequal molar proportions of calcium and magnesium;
- concentrations of sulfate (>30 mg/L), sodium (>20 mg/L), chloride (>109 mg/L), and fluoride (>2 mg/L) that are much higher than typical of other wells in the Knox Group; and
- total (unfiltered sample) concentrations of trace metals (except boron and strontium that are substantially higher than evident in other Knox Group wells) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Dissolution of locally disseminated gypsum ($CaSO_4 \cdot 2\ H_2O$) may account for the sulfate-enriched geochemistry (Lockheed Martin Energy Systems, Inc. 1999) and enriched levels of other solutes, including boron and strontium, may be a legacy of the sedimentary basin brines that are encountered at depth elsewhere on the ORR (Saunders and Toran 1992).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for 78 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Thirty-three groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.95 mg/L in July 1995) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Seventy-one groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.0223 in October 2000) being slightly below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected at very low levels (<5 μg/L) in five groundwater samples, with the maxium summed VOC concentration (8 μg/L in April 1997) slightly exceeding 5 μg/L. A low concentration (2 μg/L) of PCE was detected in the sample collected in July 1995. Also, similarly low concentrations of PCE (1 μg/L), TCE (2 μg/L), 11DCE (2 μg/L), and chloroform (3 μg/L) were detected in the sample collected in April 1997. Chloromethane was detected at very low levels in the samples collected in April 1999 (3 μg/L) and October 2000 (1 μg/L).

5.4 GROSS ALPHA ACTIVITY

Sixty-seven groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (28 pCi/L) exceeding the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Sixty-two groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (27.9 pCi/L) being below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-151

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1985, completed with a screened monitored interval from 85 to 96.5 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and well screen (0.01 slot). The well forms a cluster with wells GW-150 and GW-220 and is located in Bear Creek Valley near the east end of Y-12, immediately east of the Upper East Fork Poplar Creek (UEFPC) diversion channel on the east side (hydraulically downgradient) of New Hope Pond (NHP)/Lake Reality. Closed in 1988 and covered with a multi-layer, low-permeability cap in 1989, NHP was an unlined surface impoundment constructed in 1963 to regulate the quantity and quality of surface water exiting Y-12 via UEFPC. Lake Reality is a lined surface impoundment that was built in 1988 to replace NHP. During normal operations, flow in UEFPC bypasses Lake Reality and is directed through the concrete-lined diversion channel, which borders the south and east sides of NHP/Lake Reality.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Sixty groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 45 samples between February 1986 and April 1997, and the low-flow sampling method used to obtain 15 samples between February 1998 and August 2004.

An evaluation of the monitoring data available through August 2000 indicated potential bias related to the groundwater sampling method: (unfiltered) samples obtained with the conventional sampling method had substantially lower contaminant (VOC) concentrations than samples obtained with the low-flow sampling method (AJA 2001). Inherent differences in the manner in which each sampling method induces inflow of groundwater into the well may explain the disparity between the conventional and low-flow sampling results for VOCs. Conventional sampling involves purging up to three well volumes of groundwater from the well at about 1-2 gallons per minute, which may substantially lower the water level in the well and induce inflow from water-producing features (i.e., fractures, cavities, conduits) that may not contribute to well recharge under normal conditions. In contrast, low-flow sampling involves purging the well at flow rate low enough (<300 milliliters per minute) to ensure minimal water-level drawdown in the well (<1 ft per quarter hour), which induces groundwater inflow only from the water-producing feature(s) proximal to the monitored interval. Thus, the conventional sampling method has much greater local hydrologic influence (particularly in directions parallel with geologic strike) and may substantially increase the relative inflow of uncontaminated groundwater into the well.

It is possible, however, that the disparity in the VOC concentrations is attributable to an increasing long-term concentration trend (see Section 5.3). Results of "paired" groundwater sampling, with the low-flow sampling method used to collect a sample one day and the conventional sampling method used to collect a sample the next day, are needed to determine if the VOC concentrations are biased by the sampling method.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maynardville Limestone (upper Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 12 ft bgs and exhibits minor (<3 ft) seasonal fluctuations. Presampling groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are about 0.8 ft higher in well GW-151 than well GW-220, which is completed at a shallower depth (45 ft bgs) in the Maynardville Limestone. Based on the distance (52 ft) between the monitored interval midpoint (elevation) in each well, the contemporaneous groundwater elevations indicate upward vertical hydraulic gradients (0.004 - 0.046) during seasonally high and low flow conditions.

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-151 indicate components of flow to the north/northeast toward the UEFPC drainage system and to the east parallel with geologic strike in the Maynardville Limestone. However, a gravel and perforated-pipe underdrain constructed beneath portions of the UEFPC distribution channel (see Section 1.0) substantially influences local groundwater flow directions. Additionally, local groundwater flow patterns near NHP are influenced by the full-time operation of a groundwater extraction and treatment system intended to intercept and contain the VOC-contaminated groundwater in the Maynardville Limestone near the east end of Y-12, as required by the CERCLA Action Memorandum (DOE 1999). Beginning in October 2001, groundwater has been pumped from a well (GW-845) located about 500 ft south-southeast of well GW-151 and is treated on-site to remove particulates, iron, manganese, and VOCs. Long-term operation of the system has generally maintained 15 to 17 ft of drawdown in the immediate vicinity of well GW-845 and has established an elongated zone of influence that extends parallel with geologic strike for at least 900 ft to the east (downgradient) and 600 ft to the west (upgradient) of the pumping well (DOE 2002).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 222 – 394 mg/L;
- pH of 4.9 – 8.3 (field measurements);
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations);
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the respective monitoring data reported for the groundwater samples collected from the well since January 1991, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Thirty-nine groundwater samples had nitrate above the analytical reporting limit, with the highest concentration (8.6 mg/L in August 2000) being slightly below the drinking water MCL for nitrate (10 mg/L). However, this result is a suspected outlier because all other nitrate results are less than 2 mg/L.

5.2 URANIUM

Very low levels of uranium were detected in the groundwater samples collected in February 1994 (0.002 mg/L) and May 1994 (0.002 mg/L). Each concentration is substantially below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample (Table 1): CTET, chloroform, PCE, TCE, 11DCE, 12DCE (c12DCE), 111TCA, and carbon disulfide. These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and UEFPC watersheds. In the UEFPC watershed east of the flow divide, which occurs near the west end of Y-12, the VOC plume in the Maynardville Limestone appears to originate near the Fire Training Facility in the southwestern section of Y-12, extends eastward (parallel with geologic strike) and mixes with VOCs released from several sources in the central and eastern Y-12 areas, and enters Union Valley east of the ORR boundary along Scarboro Road (DOE 1998). In October 2000, full-time operation of a groundwater remediation system began to help intercept and contain the (CTET-dominated) portion of the VOC plume in the Maynardville Limestone near the east end of Y-12, as required by the CERCLA Action Memorandum (DOE 1999). Operation of the system involves pumping groundwater from an extraction well (GW-845) completed in the Maynardville Limestone about 500 ft south-southeast (across geologic strike) of well GW-151; treating the groundwater on-site to remove particulates, iron, manganese, and VOCs; and discharging the effluent into UEFPC.

The principal VOCs in the groundwater samples are CTET and PCE; one or both compounds were detected in each sample, with historical maximum concentrations above 1,000 µg/L and 500 µg/L, respectively (Table 1). Also, the most recent sampling results show that the concentrations of both VOCs remain substantially above respective drinking water MCLs. Secondary compounds in the samples are chloroform, TCE, and 12DCE (c12DCE), at least one of which was detected in all but four of the samples, including each sample collected since December 1995. Historical maximum concentrations exceed 100 µg/L for PCE, 50 µg/L for chloroform, and 25 µg/L for c11DCE, with the most recent sampling results showing that the TCE concentrations substantially exceed the MCL (Table 1). Minor VOCs in the samples are 11DCE, 111TCA, and carbon disulfide. The four most recent samples had traces of 11DCE; 111TCA (1 µg/L in May 1994) and carbon disulfide (5 µg/L in August 2004) were each detected in only one sample.

A time-series plot of summed VOC concentrations reported for the samples obtained with the conventional sampling method between January 1991 and April 1997 shows a seasonally cyclic pattern (Figure 1), with the VOC concentrations in samples obtained during seasonally low flow conditions (summer and fall) typically being higher than VOC concentrations in samples obtained during seasonally high flow conditions (winter and spring). However, similar seasonal concentration fluctuations are not evident from the low-flow sampling results, which instead show a strongly increasing concentration trend that may have stabilized in CY 2003 (Figure 1). Moreover, as illustrated by the data summarized in Table 1, concurrently increasing concentration trends are evident for individual compounds (CTET, chloroform, PCE, TCE, and 12DCE). This suggests an overall increase in the relative flux of dissolved VOCs along the groundwater flow/transport pathways intercepted by the monitored interval in the well. This increase may result from a combination of reduced recharge following closure of NHP and the strong local hydrologic influence of the UEFPC distribution channel underdrain (DOE 1998). The increasing VOC concentration trend may be at least partially attributable to the change in groundwater sampling methods (see Section 2.0 and Figure 1). Notably, the full-time operation of groundwater extraction well GW-845 appears to have influenced CTET and chloroform (chloromethanes) concentrations in the groundwater at this well, but not PCE, TCE, and 12DCE (chloroethenes) concentrations. As shown by a time-series plot of summed chloromethanes, the increasing trend appears to have stabilized from January 2000 through January 2003, then decreased steadily through July 2004. However, the increasing trend in chloroethene concentrations continues uninterrupted (Figure 2). These divergent trends suggest different sources and/or flowpaths for dissolved chloromethanes and chloroethenes intercepted by the monitored interval of the well.

5.4 GROSS ALPHA ACTIVITY

Six of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (4.75 pCi/L in December 1995) being substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Nineteen of the groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (7.12 pCi/L in January 2002) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-153

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1985, completed with a screened monitored interval from 45 to 60 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and well screen (0.01 slot). The well forms a cluster with wells GW-152 and GW-240 and is located in Bear Creek Valley near the east end of Y-12, directly south of the Upper East Fork Poplar Creek (UEFPC) diversion channel on the south side of New Hope Pond (NHP)/Lake Reality. Closed in 1988 and covered with a multi-layer, low-permeability cap in 1989, NHP was an unlined surface impoundment constructed in 1963 to regulate the quantity and quality of surface water exiting Y-12 via UEFPC. Lake Reality is a lined surface impoundment that was built in 1988 to replace NHP. During normal operations, flow in UEFPC is directed through the concrete-lined distribution channel, which borders the south and east sides of NHP/Lake Reality.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-six groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 31 samples between February 1986 and May 1997, and the low-flow sampling method used to obtain 15 samples between December 1997 and November 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maynardville Limestone (upper Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 17 ft bgs and exhibits minor (<3 ft) seasonal fluctuations. Presampling groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are about 0.5 ft higher in well GW-153 than well GW-240, which is completed at a shallower depth (29.5 ft bgs) in the Maynardville Limestone. Based on the distance (28.2 ft) between the monitored interval midpoint (elevation) in each well, the contemporaneous groundwater elevations indicate downward vertical hydraulic gradients (0.011 - 0.024) during seasonally high and low flow conditions.

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-153 indicate components of flow to the north/northeast toward the UEFPC drainage system and to the east parallel with geologic strike in the Maynardville Limestone. However, a gravel and perforated-pipe underdrain constructed beneath portions of the UEFPC distribution channel (see Section 1.0) substantially influences local groundwater flow directions. Additionally, local groundwater flow patterns near NHP are influenced by the full-time operation of a groundwater extraction and treatment system intended to intercept and contain the VOC-contaminated groundwater in the Maynardville Limestone near the east end of Y-12, as required by the CERCLA Action Memorandum (DOE 1999). Beginning in October 2001, groundwater has been pumped from a well (GW-845) located about 450 ft south-southeast (hydraulically downgradient) of well GW-151 and is treated on-site to remove particulates, iron, manganese, and VOCs. Long-term operation of the system has generally maintained 15 to 17 ft of drawdown in the immediate vicinity of well GW-845 and has established an elongated zone of influence that extends parallel with geologic strike for at least 900 ft to the east (downgradient) and 600 ft to the west (upgradient) of the pumping well (DOE 2002).

As part of an aquifer pumping test in well GW-845 in July 1998, eosine dye was injected in well GW-153 and rapid breakthrough of the dye observed in the pumping well, which clearly demonstrated the hydraulic connection between the shallow and intermediate/deep groundwater flowpaths along strike in the Maynardville Limestone. Additionally, confirmed detection of the dye in two shallow wells (GW-220 and GW-832) located about 600 ft northeast (across geologic strike) of the injection well (and about 300 ft northwest of the pumping well) suggests that the degree of hydrologic connection with the UEFPC distribution channel underdrain. This indicates that groundwater movement along dip parallel or conjugate fracture flowpaths in the shallow flow system are strong enough to overcome the hydraulic capture zone in the intermediate to deep flow systems created by extraction of groundwater from well GW-845 (BJC 1998).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS 164 – 366 mg/L;
- pH of 7.2 – 8.6 (field measurements);
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the respective monitoring data reported for the groundwater samples collected from the well since January 1991, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Each groundwater sample had nitrate above the analytical reporting limit, with the highest concentration (1.7 mg/L in August 1995) being substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Uranium concentrations at or above the applicable analytical reporting limit were reported for all but one of the groundwater samples, with the highest value (0.00228 mg/L in November 2004) being below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in all but one of the groundwater samples (Table 1): bromodichloromethane, bromoform, CTET, chloroform, dibromochloromethane, PCE, and TCE. Most of these compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and UEFPC watersheds. In the UEFPC watershed east of the flow divide, which occurs near the west end of Y-12, the VOC plume in the Maynardville Limestone appears to originate near the Fire Training Facility in the southwestern section of Y-12, extends eastward (parallel with geologic strike) and mixes with VOCs released from several sources in the central and eastern Y-12 areas, and enters Union Valley east of the ORR boundary along Scarboro Road (DOE 1998). In October 2000, full-time operation of a groundwater remediation system began to help intercept and contain the (CTET-dominated) portion of the VOC plume in the Maynardville Limestone in the eastern Y-12 area, as required by the CERCLA Action Memorandum (DOE 1999). Operation of the system involves pumping groundwater from an extraction well (GW-845) completed in the Maynardville Limestone about 700 ft east (parallel with geologic strike) of well GW-153; treating the groundwater on-site to remove particulates, iron, manganese, and VOCs; and discharging the effluent into UEFPC.

The primary VOC in the groundwater samples is CTET, which was detected at a concentration of 100 µg/L in all but seven of the groundwater samples (Table 1). Secondary compounds are chloroform and PCE, with one or both compounds detected in each sample collected since November 1999. In contrast, TCE was detected in only one sample since November 1999 (2 µg/L in October 2001). Similarly, bromodichloromethane, bromoform, and dibromochloromethane were detected only in a series of samples collected between December 1998 and April 2001, with the highest concentrations (>10 µg/L) reported for dibromochloromethane. Also, the most recent sampling results show that only the CTET concentrations remain above the applicable drinking water MCL (Table 1).

A time-series plot of summed VOC concentrations for each groundwater sample (Figure 1) shows a widely variable but generally increasing trend between January 1991 (42 µg/L) and October 2000 (299 µg/L), followed by a sharply decreasing trend through October 2003 (58 µg/L). Note that the decreasing trend coincides with full-time operation of groundwater extraction well GW-845. Decreasing concentrations are particularly evident for CTET, with the concentration reported for the groundwater sample collected in October 2003 (51 µg/L) being about 80% lower than the historical maximum CTET concentration (280 µg/L) reported for samples June 1999 and October 2000. However, decreasing concentrations are not evident for all of the VOCs (Table 1), as illustrated by the similar levels of PCE reported for groundwater samples collected before and after operation of the extraction well (e.g., 4 µg/L in November 1994 and April 2001). This pattern suggests different sources and flowpaths for the different VOCs.

5.4 GROSS ALPHA ACTIVITY

Six of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (4 pCi/L in November 1999) being substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Gross beta activity above the MDA and corresponding CE was reported for the groundwater samples collected in May 1991 (4.36 pCi/L), November 1994 (5.44 pCi/L), November 1995 (4.92 pCi/L), and November 2004 (10 pCi/L). These values reflect background levels and are substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-154

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in July 1985, completed with a screened monitored interval from 4.7 to 11.2 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with wells GW-222 and GW-223 and is located in Bear Creek Valley (BCV) at the east end of Y-12, near the former Oil Skimmer Basin (OSB) and immediately west (hydraulically upgradient) of New Hope Pond (NHP)/Lake Reality. The OSB, formerly located near the inlet to NHP, was a 25 x 40 ft sediment-accumulation basin and oil/water separator; visual evidence of a direct hydraulic connection with the OSB was observed during installation of wells GW-154 and GW-223 (Geraghty & Miller, Inc. 1989). Closed in 1988 and covered with a multi-layer, low-permeability cap in 1989, NHP was an unlined surface impoundment constructed in 1963 to regulate the quantity and quality of surface water exiting Y-12 via Upper East Fork Poplar Creek (UEFPC). Lake Reality is a lined surface impoundment that was built in 1988 to replace NHP. During normal operations, flow in UEFPC is directed through a concrete-lined diversion channel bordering the south and east sides of NHP/Lake Reality. Until December 1996 when flow was rerouted to bypass Lake Reality, surface flow in the UEFPC distribution channel discharged into Lake Reality (and exited through a weir in the western berm). Beginning in July 1998, flow in the UEFPC distribution channel was diverted through the Lake Reality spillway, which discharges into the mainstream of UEFPC directly north (downstream) of Lake Reality.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-eight groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 34 samples between February 1986 and September 1997, and the low-flow sampling method used to obtain 14 samples between February 1998 and August 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in thc in the Maynardville Limestone (upper Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 6 ft bgs and exhibits minor (<4 ft) seasonal fluctuations, although a particularly sharp "spike" in the groundwater elevation is indicated by presampling water-level measurement recorded in July 2001 (Figure 1). Also, presampling water-level measurements recorded during contemporaneous sampling events (i.e., within 24 hours) performed after the closure of NHP (and the OSB) show groundwater elevations in well GW-154 being consistently higher than evident in wells GW-222 and GW-223, which are completed at greater depths in the Maynardville Limestone (25 ft and 90 ft bgs, respectively). Based on the distance between the monitored interval midpoint (elevation) in the wells, the relationships between the groundwater elevations indicate: (1) downward vertical hydraulic gradients (0.014 - 0.067) from the water table interval (GW-154) to the shallow bedrock (GW-222) and (2) lesser downward vertical hydraulic gradients (0.001 - 0.008) within the bedrock interval between GW-222 and GW-223. However, presampling groundwater elevations determined from contemporaneous sampling events performed before the closure of NHP show higher groundwater elevations in well GW-223 (and GW-222) relative to well GW-154 and indicate upward hydraulic gradients (Figure 1). Thus, the closure of NHP (and the OSB) and installation of the low-permeability cap at the site appears to have reversed the local vertical hydraulic gradients.

Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-154 indicate east-northeasterly flow toward the UEFPC drainage system. However, a gravel and perforated-pipe underdrain constructed beneath portions of the UEFPC distribution channel (see Section 1.0) substantially influences local groundwater flow directions. Additionally, local groundwater flow patterns near NHP are influenced by the full-time operation of a groundwater extraction and treatment system intended to intercept and contain the VOC-contaminated groundwater in the Maynardville Limestone near the east end of Y-12, as required by the CERCLA Action Memorandum (DOE 1999). Beginning in October 2000, groundwater has been pumped from a well (GW-845) located about 1,200 ft southeast of well GW-154 and is treated on-site to remove particulates, iron, manganese, and VOCs. Long-term operation of the system has generally maintained 15 to 17 ft of drawdown in the immediate vicinity of well GW-845 and has established an elongated zone of influence that extends parallel with geologic strike for at least 900 ft to the east (downgradient) and 600 ft to the west (upgradient) of the pumping well (DOE 2002). Groundwater elevations in well GW-154 do not appear to exhibit any direct response to the operation of well GW-845 (Figure 1).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 334 – 620 mg/L;
- pH (field measurements) of 5.96 – 8.1;
- high concentrations of sulfate (>70 mg/L) compared to other wells of similar depth in the Maynardville Limestone;
- low molar proportions of sodium, potassium, chloride and nitrate (<10% of total anions/cations);
- total concentrations of trace metals (excluding uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on respective monitoring data reported for the groundwater samples collected since January 1991, the principal contaminants present in the groundwater at this well are uranium, gross alpha activity, and gross beta activity.

5.1 NITRATE

Twenty-three groundwater samples had nitrate concentrations above the applicable analytical reporting limit (one sample was not analyzed for nitrate; Table 1), with the highest concentration (3.4 mg/L in July 2001) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Total uranium concentrations reported for 22 groundwater samples (five samples were not analyzed for uranium) exceed the applicable analytical reporting limit (Table 1) and each result is at least an order-of-magnitude above the MCL for uranium (0.03 mg/L). The specific source of the uranium in the shallow groundwater at this well has not been identified, but is probably the former OSB, which is believed to have retained uranium-contaminated oils (DOE 1998), particularly in light of the direct hydraulic connection with the OSB that was observed during installation of the well (see Section 1.0). Considering the relatively neutral pH of the samples, the uranium is probably present as uranyl cations combined with available anions in the groundwater (Fetter 1993), including carbonate dissolved from the Maynardville Limestone, which may greatly increase the relative mobility of uranium in the groundwater flow system.

Uranium concentrations reported for the groundwater samples range between the historical minimum value of 0.2 mg/L in August 1996 and the historical maximum value of 1.37 mg/L in July 2001 (Table 1). Note that the highest and lowest uranium values were reported for samples obtained during seasonally low groundwater flow conditions, which illustrates the lack of any clear and consistent relationship between temporal changes in uranium concentrations and inferred seasonal flow conditions. Also, the uranium concentrations are typically an order-of-magnitude higher than evident in samples of the deeper groundwater from well GW-223 (e.g., 0.0342 mg/L in August 2003). Considering the downward vertical hydraulic gradients indicated by presampling groundwater elevations recorded following closure of NHP (and the former OSB) and installation of the low-permeability cap at the site (see Section 3.0), recharge of uranium-contaminated groundwater from the shallow flow system may help maintain the (elevated) uranium concentrations in the deeper groundwater.

A time-series plot of the uranium concentrations reflects a fairly indeterminate long-term concentration trend that encompasses gaps in the sampling history for the well (April 1991 – November 1994) and the analytical history for uranium (September 1997 – August 1999) (Figure 2). Also, the uranium concentrations exhibit significant short-term variation, with conspicuous temporal "peaks" evident in May 1995 (0.66 mg/L), November 1996 (0.47 mg/L), and July 2001 (1.37 mg/L), the latter result corresponding with a sharp spike in the groundwater elevation in the well (Figure 1). This relationship suggests wide temporal changes in the relative advective flux of uranium along the groundwater flow/transport pathways intercepted by the monitored interval in the well. Moreover, uranium results obtained between July 2001 (1.37 mg/L) and 2003 (0.411 mg/L) show a clearly decreasing concentrations trend, which potentially reflect a response to the full-time operation of groundwater extraction well GW-845 (see Section 3.0), although subsequent sampling result suggest a slight concentration rebound through August 2004 (0.61 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, only trace (estimated) concentrations of PCE (2 µg/L in June 1996) and bromoform (1 µg/L in February 2003) were detected in any of the groundwater samples collected since January 1991, and both of these results are probably sampling or analytical artifacts.

5.4 GROSS ALPHA ACTIVITY

All but two of the groundwater samples collected since January 1991 had gross alpha activity above the applicable MDA and corresponding CE (the sample collected in February 1996 was not analyzed for gross alpha activity; Table 2), and all of these results substantially exceed the MCL for gross alpha activity (15 pCi/L). Uranium isotopes are the source of the elevated gross alpha activity in the groundwater at this well; U-234 and U-238 were detected (i.e., >MDA and

CE) in each of the samples analyzed for these isotopes (Table 2), with activities ranging between 49.9 pCi/L (U-238) and 543 pCi/L (U-234). As with total uranium (see Section 5.2), contamination resulting from historical operation of former OSB is the suspected source of the uranium isotopes in the shallow groundwater at this well (DOE 1998).

Excluding the non-detect gross alpha activity (i.e., <MDA) reported for the groundwater sample collected in November 1995 (Table 2), which is an outlier compared to the other results and is a likely analytical artifact, the other samples define a wide range of gross alpha activity, with the historical maximum value (1,270 pCi/L in August 2003) being about 450% higher than the historical minimum value (271 pCi/L in June 1996). Also, the gross alpha activity reported for each sample is at least an order-of-magnitude higher than reported for samples of the deeper groundwater from well GW-223 (e.g., 11.91 pCi/L in August 2003). Considering the downward vertical hydraulic gradients indicated by presampling groundwater elevations recorded following the closure/capping of NHP (see Section 3.0), the relatively low levels of gross alpha activity in the deeper groundwater suggest limited vertical flux of the uranium isotopes present in the shallow groundwater.

A time-series plot of the gross alpha activity (excluding the non-detect result noted above) encompasses the three-year gap in the sampling history (April 1991 – November 1994) for the well and shows a variable but slightly increasing trend that appears to be skewed upward by a conspicuous "spike" (1,270 pCi/L) in August 2002 (Figure 3). However, unlike a similarly sharp temporal peak in the concentration of total uranium in July 2001 (see Section 5.2), this result for gross alpha activity correlates with a temporal low, rather than temporal high, groundwater elevation (Figure 1). Accordingly, it is not clear if this and other temporal peak values for gross alpha activity (e.g., 685 pCi/L in January 2001) are significant with respect to the relative flux of uranium isotopes in the groundwater. Additionally, the highest values for gross alpha activity, including all but two results that exceed 500 pCi/L, were reported for samples obtained with the low-flow sampling method. This suggests that the increasing trend may be an artifact of the sampling method. Moreover, the close similarity between the gross alpha activity reported for the samples collected in January 1991 (551 pCi/L) and August 2003 (518 pCi/L) suggests a fairly indeterminate long-term trend and indicates minimal overall change in the relative flux of uranium isotopes in the shallow groundwater from this well. This interpretation is supported by the results for uranium isotopes, as illustrated by the similar levels of U-234 reported for the samples collected in January 1991 (451 pCi/L) and February 2003 (428 pCi/L).

5.5 GROSS BETA ACTIVITY

All but two groundwater samples had gross beta activity above the applicable MDA and corresponding CE (the sample collected in February 1996 was not analyzed for gross beta activity; Table 2), and all these results exceed the SDWA screening level (50 pCi/L) for gross beta activity. Elevated gross beta activity in the groundwater at this well is probably attributable to uranium isotopes and related daughter products that emit beta particles and, as noted previously for gross alpha activity, reflects contamination associated with historical operation of the former OSB.

Excluding the non-detect gross beta activity (i.e., <MDA) reported for the groundwater sample collected in November 1995 (Table 2), which is clearly an outlier, results for the other samples define a wide range of gross beta activity, with the historical maximum value (340 pCi/L in January 1991) being about 650% higher than the historical minimum value (51 pCi/L in July 2001). Also, as with gross alpha activity, the available data show that gross beta activity in the shallow groundwater from well GW-154 is consistently higher than evident in the deeper groundwater from well GW-223, as illustrated by the results reported for the samples collected

from each well in January 2003 (165 pCi/L and 15 pCi/L, respectively). This too suggests minimal vertical migration of uranium isotopes (and beta particle-emitting daughter products) into the deeper flow system near these wells.

A time-series plot of the gross beta activity (excluding the non-detect result noted above) encompasses the three-year gap in the sampling history (April 1991 – November 1994) for the well and shows a variable but slightly decreasing trend (Figure 4). As with the gross alpha activity, the temporal peak gross beta result reported for the sample collected in August 2002 (275 pCi/L) correlates with a temporal low, rather than temporal high, presampling groundwater elevation (Figure 1). Accordingly, it is not clear if this and other temporal peak values for gross beta activity (e.g., 144 pCi/L in January 2001) are significant with respect to the relative flux of uranium isotopes (and beta-particle emitting daughter products) in the groundwater.

WELL GW-156

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1985, completed with a screened monitored interval from 145 to 157.6 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and PVC well screen (0.01 slot). The well is located on the crest of Chestnut Ridge southeast of the east end of Y-12, about 100 ft east (hydraulically downgradient) of the Chestnut Ridge Sediment Disposal Basin (CRSDB). The CRSDB is a former sinkhole filled with contaminated sediments generated from remedial actions at Y-12 and covered with a low-permeability, multilayer cap during RCRA closure of the site in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Eighty-nine groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 50 samples between February 1986 and April 1997, and the low-flow sampling method used to obtain 39 samples between October 1997 and October 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the Knox Group. Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 140 ft bgs and exhibit substantial (10 - 25 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 266 – 414 mg/L;
- pH (field measurements) of 6.6 – 7.6;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for 74 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Forty-five groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.71 mg/L) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Forty-three groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.007 mg/L) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs have not been detected in any of the groundwater samples from this well that were analyzed for VOCs (between February 1991 and July 1995).

5.4 GROSS ALPHA ACTIVITY

Nineteen groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (8.48 pCi/L) being below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Twenty groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (14.85 pCi/L) being substantially below the SDWA for gross beta activity (50 pCi/L).

WELL GW-159

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1985, completed with a screened monitored interval from 145 to 157 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and well screen (0.01 slot). The well is located on the crest of Chestnut Ridge southeast of the east end of Y-12, about 100 ft west (hydraulically upgradient) of the Chestnut Ridge Sediment Disposal Basin (CRSDB). The CRSDB is a former sinkhole filled with contaminated sediments generated from remedial actions at Y-12 and covered with a low-permeability, multilayer cap during RCRA closure of the site in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Ninety-three groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 54 samples between February 1986 and April 1997, and the low-flow sampling method used to obtain 39 samples between October 1997 and October 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the Knox Group. Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 115 ft bgs and exhibit unusually wide (>25 ft) water-level fluctuations (Figure 1). However, the conventional sampling method is associated with the largest apparent water level fluctuations. Purging the well during conventional sampling typically decreases the water level in the well by 40 ft or more, and the water level is very slow to recover to the presampling level (Figure 2). Moreover, the protocol of consecutive daily sampling required for RCRA post-closure detection monitoring at the CRSDB was discontinued in part because the water level in this well would not sufficiently recover between sampling events (Bechtel Jacobs Company LLC [BJC] 2001).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 176 – 251 mg/L;
- pH (field measurements) of 7.0 – 8.6;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for 74 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Thirty-five groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.72 mg/L) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Forty-two groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.003 mg/L) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, only acetone has been detected in one of the groundwater samples from this well that were analyzed for VOCs (between February 1991 and July 1995). The sample collected in June 1991 had an acetone concentration of 15 µg/L, and this result is considered to be an outlier.

5.4 GROSS ALPHA ACTIVITY

Eighteen groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (450 pCi/L) being substantially above the MCL for gross alpha activity (15 pCi/L). However, this result was identified as an outlier (none of the other gross alpha results exceed 10 pCi/L) and is a sampling or analytical artifact.

5.5 GROSS BETA ACTIVITY

Twelve groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (535 pCi/L) being substantially above the SDWA for gross beta activity (50 pCi/L). However, this result was identified as an outlier (none of the other gross beta results exceed 15 pCi/L) and is probably a sampling or analytical artifact.

WELL GW-169

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in September 1986, completed with a screened monitored interval from 28.7 to 34.8 ft bgs, and constructed with nominal 2.5-inch diameter PVC (#40) riser casing and well screen (0.01 slot). The well forms a cluster with wells GW-170 and GW-232 and is located in Union Valley east of Y-12, about 1,500 ft east of the ORR boundary along Scarboro Road.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-one groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 21 samples between March 1991 and September 1997, and the low-flow sampling method used to obtain 20 samples between February 1998 and October 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Maynardville Limestone). The average static groundwater level in the well is 28 ft bgs. Presampling depth-to-water measurements for the well indicate substantial (10-25 ft) water level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 105 mg/L – 576 mg/L;
- pH (field measurements) of 5.8 – 7.6;
- high total suspended solids (>1,000 mg/L) commonly reported for samples collected before 1996;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals (excluding artifacts of high suspended solids: aluminum, iron, etc.) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion, which is based on the analytical results reported for 41 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Thirty-eight groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (1.4 mg/L in February 2003) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Ten groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.0052 mg/L in September 1995) being substantially below the MCL for uranium (0.3 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Low levels of PCE (1 – 4 μg/L) were detected in all but one (January 2000) of the groundwater samples collected to date. Also, TCE was detected in 20 of 23 samples collected through February 1999, but none of the samples collected since then, with the highest concentration reported for the initial sample collected in March 1991 (6 μg/L). This is the only result to exceed the MCL for TCE (5 μg/L). Acetone was detected in October of 2004 (2 μg/L), but this result is probably a sampling or analytical artifact and is considered to be an outlier.

5.4 GROSS ALPHA ACTIVITY

Twenty-seven groundwater samples had gross alpha activity above the applicable MDA and corresponding CE. As shown below in Table 1, gross alpha activity reported for seven of the samples collected between November 1991 and September 1995 exceed the MCL for gross alpha activity (15 pCi/L). Much lower (<4 pCi/L) and less widely variable levels of gross alpha activity were reported for the 22 groundwater samples collected since September 1995, with results below the MDA reported for nine of these samples.

Table 1. Gross alpha results for well GW-169 that exceed the MCL

Sampling Date	Gross Alpha Activity (pCi/L)
11/12/91	45.9
11/11/92	40.1
01/23/93	25.6
08/19/93	24.3
11/01/93	72
06/12/95	18.7
09/28/95	17.4

The source of the alpha activity has not been determined. Ten of the groundwater samples collected from the well have been analyzed for uranium isotopes, most recently in February 1998. The highest levels of U-234 (2.23 pCi/L in December 1994) and U-238 (0.929 pCi/L in September 1995) are substantially lower than the gross alpha results summarized in Table 1. The inconsistent detection and widely variable results for gross alpha activity are probably related to analytical interference associated with the very high suspended solids of the (unfiltered) groundwater samples (see Section 4.0).

5.5 GROSS BETA ACTIVITY

Thirty-four groundwater samples had gross beta activity above the applicable MDA and corresponding CE. The gross beta results for samples collected in November 1991 (71 pCi/L, the historical maximum) and November 1993 (65.5 pCi/L) exceed the SDWA screening level for gross alpha activity (50 pCi/L). As with gross alpha activity in the well, much higher gross beta activity was reported for groundwater samples collected through September 1995 (35.8 pCi/L) compared to subsequent samples, all of which had gross beta activity below 10 pCi/L. Also, the source of the beta activity likewise is not known. The lack of uranium isotopes in the well tends to discount uranium daughters as potential sources of beta activity in the well. Also, six of the samples from the well were analyzed for Tc-99, which was detected (i.e., Tc-99 activity >MDA and CE) only in the sample collected in August 1994 (33 pCi/L) and the gross beta activity for this sample is less than the CE.

WELL GW-170

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in April 1986, completed with an open-hole monitored interval from 104 to 156.9 ft bgs, and constructed with nominal 4.5-inch diameter steel (F25) riser casing. The well forms a cluster with wells GW-169 and GW-232 and is located in Union Valley about 1,500 ft east of the ORR boundary along Scarboro Road.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-seven groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 23 samples between June 1990 and September 1997, and the low-flow sampling method used to obtain 24 samples between June 1998 and October 2004.

Groundwater samples from the well exhibit conspicuous geochemical characteristics (see Section 4.0) potentially attributable to localized contamination from cement (grout). Redevelopment of the well before sampling also may be necessary to obtain the most representative (i.e., the least grout-contaminated) groundwater samples.

Note that a Hydrolab™ water quality multiprobe became lodged in well GW-170 in 1996. All attempts to retrieve the probe have failed, and it remains at the bottom of the open-hole interval.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maynardville Limestone (upper Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 32 ft bgs and exhibits moderate (about 7 ft) seasonal fluctuations. Presampling groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are typically more than 5 ft lower in well GW-170 than well GW-169, which is completed at a shallower depth (42 ft bgs) in the Maynardville Limestone. Based on the distance (98 ft) between the monitored interval midpoint (elevation) in each well, the contemporaneous groundwater elevations indicate consistently downward vertical hydraulic gradients (0.001 - 0.09) during seasonally high and low flow conditions. Similarly, the relationship between presampling groundwater elevations and monitored-interval midpoints for wells GW-170 and GW-232, which is completed are a substantially greater depth (341 ft) in the Maynardville Limestone, likewise indicate downward vertical gradients of similar magnitude, but sometimes show slightly upward vertical gradients (0.0003 – 0.006), typically during seasonally low groundwater flow (summer and fall).

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in Union Valley near the east end of Y-12 and the vicinity of well GW-170 indicate components of flow toward unnamed drainage features in Union Valley to the east-southeast of the well (parallel with geologic strike in the Maynardville Limestone).

4.0 GEOCHEMICAL CHARACTERISTICS

Before January 2000, the well produced calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 96 – 310 mg/L;
- pH of 7.2 – 12.2 (field measurements);
- low molar proportions of chloride, potassium, sulfate, and sodium (>10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

As illustrated by the data summarized in Table 1, the groundwater samples obtained since January 2000 exhibit significantly different geochemical characteristics than reported for samples collected previously, including atypical levels of carbonate and bicarbonate, strongly basic pH, and unusually high potassium concentrations. The abrupt change in geochemical characteristics does not appear to be related to the groundwater sampling method because the conventional and low-flow sampling results obtained before January 2000 show similar values for pH, potassium, and TDS. Similar geochemical characteristics evident for other monitoring wells at Y-12 are believed to be the result of localized contamination by cement grout circulated into the surrounding bedrock during their installation and construction. However, grout contamination related to the installation of well GW-170, or the wells with which it is clustered (GW-169 and GW-232), seems unlikely considering their age (19 years) and the lack of any previous evidence of grout contamination in any of the wells (as illustrated by the data in Table 1). Moreover, residual grout contamination from well installation/construction does not explain the apparent sharp decrease in TDS. Low TDS implies short groundwater residence time and, considering the depth to the open-hole monitored interval in the well (>100 ft bgs), potentially indicates a more direct hydraulic connection with the shallower flow system than previously evident. Perhaps construction activities performed during CY 1999 near well GW-170, including the widening of Highway 61 east of the well, which has involved blasting and excavation of the bedrock (Copper Ridge Dolomite), and the construction of an office building to the west of the well, which involved excavation of footings into the bedrock (Maynardville Limestone) and installation of a (concrete) slab-on-grade foundation, in some way altered the groundwater geochemistry and the matrix of groundwater flowpaths (and contaminant transport pathways) intercepted by the well.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the respective monitoring data reported for the groundwater samples collected from the well since March 1991, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Thirty-four groundwater samples had nitrate concentrations above the analytical reporting limit, with the highest concentration (1.2 mg/L in September 1995) being substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Six groundwater samples had uranium concentrations above the analytical reporting limit, with the highest concentration (0.0019 mg/L in September 1995) being substantially below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample (Table 2): acetone, benzene, CTET, chloroform, methylene chloride (MC), PCE, TCE, toluene, and 12DCE. These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and UEFPC watersheds. In the UEFPC watershed east of the flow divide, which occurs near the west end of Y-12, the VOC plume in the Maynardville Limestone appears to originate near the Fire Training Facility in the southwestern section of Y-12, extends eastward (parallel with geologic strike) and mixes with VOCs released from several sources in the central and eastern Y-12 areas, and enters Union Valley east of the ORR boundary along Scarboro Road (DOE 1998). In October 2000, full-time operation of a groundwater remediation system began to help intercept and contain the (CTET-dominated) portion of the VOC plume in the Maynardville Limestone in the eastern Y-12 area, as required by the CERCLA Action Memorandum (DOE 1999). Operation of the system involves pumping groundwater from an extraction well (GW-845) completed in the Maynardville Limestone about 800 ft west of Scarboro Road (about 2,300 ft west of well GW-170); treating the groundwater on-site to remove particulates, iron, manganese, and VOCs; and discharging the effluent into UEFPC.

The primary VOC in the groundwater samples is CTET, which was detected in all but two of the groundwater samples, with concentrations of 100 μg/L or more evident in September 1991, April 1992, October 1992, and November 1994 (Table 2). Secondary VOCs in the samples are benzene, chloroform, PCE, and TCE. Chloroform was detected in all but one of the samples, with concentrations of 50 μg/L or more evident in January 1993, March 1993, February 1994, August 1994, and December 1995. Low levels of PCE and TCE were detected in each sample, with the bulk of the results for both compounds being estimated values below their respective analytical reporting limits (5 μg/L). Benzene was not detected in any of the groundwater samples collected before January 2000, but was detected at estimated concentrations below 5 μg/L in all but two of the samples collected since then. Excluding false positive results, the other VOCs were detected much more sporadically, with low levels (4 μg/L or less) of methylene chloride detected in six samples and traces (1 μg/L or less) of 12DCE detected in four samples. Also, the most recent data show that concentrations of each applicable VOC remain below corresponding drinking water MCLs (Table 2).

A time-series plot of summed VOC (solvent) concentrations for each groundwater sample (Figure 1) shows a widely variable and generally indeterminate trend between March 1991 and July 1998, followed by a decreasing trend through January 2000, with sharply lower concentrations evident thereafter (Figure 1). This is primarily attributable to substantially lower concentrations of CTET evident since January 2000. Also, the repeated detection of benzene, which was not detected in any of the samples collected before January 2000, coincides with the sharply lower concentrations of CTET (Figure 1). An explanation for the decrease in CTET concentrations and the concurrent detection of benzene is not apparent from the monitoring results, especially considering the lack of similarly significant changes in the concentrations of the other VOCs in the well (Table 1), although both coincide with conspicuous changes in the geochemical characteristics of the groundwater samples obtained from the well (see Section 4).

5.4 GROSS ALPHA ACTIVITY

Seventeen groundwater samples had gross alpha activity above the MDA and corresponding CE, with the highest value (7.06 pCi/L in September 1997) being less than the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Twenty-nine groundwater samples had gross beta activity above the MDA and corresponding CE, with the highest value (36.05 pCi/L in July 1998) being slightly below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). The elevated levels of gross beta activity may be related to the elevated potassium concentrations in the grout-contaminated groundwater samples from the well. Potassium-40 (K-40) is a beta-emitting isotope and, based on the natural ratio of K-40 to total K (K-40 = 0.0119% total K; Brownlow 1979), should be present in the groundwater samples. The presence of K-40 would account for the strong correlation between the monitoring results for gross beta activity and total potassium (Figure 2).

WELL GW-171

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in February 1986, completed with a screened monitored interval from 25.8 to 31.2 ft bgs, and constructed with nominal 2.5-inch diameter PVC (#40) riser casing and well screen (0.01 slot). The well forms a cluster with wells GW-172 and GW-230 and is located in Union Valley east of Y-12, about 4,300 ft east of the ORR boundary along Scarboro Road.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-five groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain ten samples between September 1994 and September 1997, and the low-flow sampling method used to obtain 15 samples between February 1998 and August 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Maynardville Limestone). Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 7 ft bgs and exhibit substantial (10 - 25 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 100 – 330 mg/L;
- pH (field measurements) of 5.8 – 7.4;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for the groundwater samples collected from the well since January 1991.

5.1 NITRATE

Eleven groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (1.5 mg/L in August 2000) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

None of the groundwater samples had uranium concentrations above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were not detected in any of the groundwater samples.

5.4 GROSS ALPHA ACTIVITY

Eight groundwater samples had gross alpha activity above the applicable MDA and the corresponding CE, with the highest value (7.96 pCi/L in September 1997) being less than the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Nineteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (27.4 pCi/L in June 1996) being below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-172

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in May 1986, completed with an open-hole monitored interval from 105 to 133.8 ft bgs, and constructed with nominal 4.5-inch diameter steel riser casing. The well forms a cluster with wells GW-171 and GW-230 and is located in Union Valley east of Y-12, about 4,300 ft east of the ORR boundary along Scarboro Road.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-four groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain ten samples between June 1990 and September 1997, and the low-flow sampling method used to obtain 14 samples between February 1998 and August 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the intermediate bedrock interval (>100 ft bgs) in the Conasauga Group (Maynardville Limestone). Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 15 ft bgs and exhibit moderate (about 10 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 219 – 600 mg/L;
- pH (field measurements) of 6.5 – 7.4;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Eight groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (1.4 mg/L in August 2000) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Only the seven groundwater samples collected between September 1994 and February 1996 were analyzed for uranium and two of the samples had concentrations above the applicable analytical reporting limit: 0.00073 mg/L in March 1995 and 0.0089 mg/L in December 1995. Both results are substantially below the MCL for uranium (0.3 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were not detected in any of the groundwater samples.

5.4 GROSS ALPHA ACTIVITY

Eight groundwater samples had gross alpha activity above the applicable MDA and the corresponding CE, with the highest value (3.17 pCi/L in February 1999) being substantially below less than the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Nine groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (30.5 pCi/L in August 2001) being below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-173

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1985, completed with a screened monitored interval from 154 to 165 ft bgs, and constructed nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located on the crest of Chestnut Ridge directly south of Y-12, approximately 200 ft east of the Chestnut Ridge Security Pits (CRSP). The CRSP include two contiguous former waste disposal areas, each consisting of a series of unlined, east-west oriented trenches that were about 8 to 10 ft wide, 10 to 18 ft deep, and 700 to 800 ft long. Beginning in 1973, the disposal trenches at the site received a variety of hazardous waste until December 1984 and nonhazardous wastes until November 1988. All the disposal trenches are covered by a multi-layer low-permeability cap installed during RCRA closure of the site in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-nine groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 27 samples between February 1986 and July 1992, and the low-flow sampling method used to obtain samples in March 2004 and October 2004.

Presampling depth-to-water measurements show that the static water level in the well exhibits substantial (>25 ft) temporal (seasonal) fluctuations (Figure 1). Similarly distinctive groundwater elevation fluctuations also are evident in other wells completed in the Knox Group on Chestnut Ridge, particularly wells located at or near the crest of the ridge, which is both a recharge area and a groundwater flow divide (Solomon et al. 1992).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the Knox Group (Copper Ridge Dolomite). The Knox Group formations, along with the uppermost formation (Maynardville Limestone) of the underlying Conasauga Group, comprise an aquifer consisting of three vertically gradational subsystems distinguished by groundwater flux, which decreases with depth: (1) the stormflow zone, (2) the vadose zone, and (3) the groundwater zone (Solomon et al. 1992). The stormflow and vadose zones occur at shallow depths within the thick (>100 ft) residuum that has developed on Chestnut Ridge. In the bedrock zone, orthogonal sets of permeable, planar fractures form water-producing zones within an essentially impermeable matrix, and dissolution of carbonates has enlarged fractures and produced an interconnected conduit-flow system characteristic of karst aquifers. Because the occurrence of solution features and the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity of the groundwater zone is vertically gradational. Most groundwater flux occurs within the transitional horizon between residuum and unweathered bedrock (water table interval); lower flux (and longer solute residence times) occurs at successively greater depths in the bedrock (Solomon et al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 140 ft bgs. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of the CRSP indicate radial flow directions, with components of flow to the north into BCV; to the east along the axis of the ridge (toward well GW-173), parallel with geologic strike of the bedrock; and south toward drainage features that traverse the broad southern flank of the ridge.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date indicate that this well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 174 – 240 mg/L;
- pH of 6.9 – 7.8 (field measurements);
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite);
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Eight groundwater samples collected to date had nitrate concentrations at or above the applicable analytical reporting limit, with the highest concentration (1.3 mg/L in August 1991 and February 1992) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

None of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in all but one groundwater sample collected to date: PCE, 111TCA, TCFM, and 1,1,2-trichloro-1,2,2-trifluoroethane, which is also known as Freon-113 (F113). These compounds are components of a dissolved plume of VOCs that originates from the CRSP. Historical operation of the former waste disposal trenches at the CRSP emplaced an elongated plume of dissolved VOCs in the groundwater that extends more than 2,500 ft east-northeast along the ridge crest (parallel with geologic strike) and at least 500 ft to the north and south down the ridges flanks. The existing network of monitoring wells at the site shows that 111TCA, 11DCA, and 11DCE are the primary compounds in the groundwater near the western disposal trench area and PCE, TCE, and 12DCE are the principal compounds in the groundwater near the eastern disposal trench area. Some constituents of the VOC plume (e.g., 11DCA and 11DCE) are probably present as a result of the degradation of 111TCA. Elongation of the VOC plume along the axis of the ridge and the distribution of plume constituents indicate primarily west-to-east groundwater flow/contaminant transport via strike-parallel flowpaths in the Knox Group (e.g., bedding-plane fractures). Additionally, low levels of 111TCA detected in several downgradient monitoring wells on the southern flank of the ridge potentially reflect groundwater flow/contaminant transport via "quickflow" conduits that cut across geologic strike (Shevenell 1994). The vertical extent of the VOC plume has not been determined, but based on the existing network of monitoring wells at the site, the plume extends at least 150 ft bgs near the western disposal trenches and 270 ft bgs near the eastern disposal trenches.

Each groundwater sample collected to date contained PCE, with the low (estimated) concentration (4 μg/L) detected in the sample collected most recently (October 2004) being an apparent outlier compared to the other PCE results, which range between 11 and 15 μg/L (Table 1). In contrast, 111TCA was detected in only one sample (0.6 μg/L in May 1991) and low levels of TCFM (3 μg/L) and freon-113 (3 μg/L) were detected in the samples collected in May and October 2004 (analytical results for these VOCs were not reported for samples collected before May 2004). The preponderance of PCE in the groundwater from this well is the likely result of down-dip (i.e., bedding-plane parallel) and strike-parallel (eastward) migration from the eastern disposal trenches at the CRSP. Moreover, none of the groundwater samples collected to date contained PCE degradation products, particularly TCE and 12DCE, indicating that the monitored interval for the well does not intercept groundwater flow/transport pathways where biologically mediated degradation (reductive dechlorination) of PCE occurs.

Excluding the potential outlier result noted above, the PCE results suggest an indeterminate or slightly increasing long-term trend that spans the 12-year gap in the sampling history for the well (Figure 1). Also, the available data suggest that the PCE concentrations do not exhibit strong seasonal fluctuations or consistent correlations with the presampling water level in the well.

5.4 GROSS ALPHA ACTIVITY

Four groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (2.65 pCi/L in October 1991) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Four groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE. Excluding the sample in April 1992 (65.9 pCi/L) which appears to be an outlier, the highest value (9.05 pCi/L in July 1992) is substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-175

1.0 *INSTALLATION, CONSTRUCTION, AND LOCATION*

This well was installed in June 1988, completed with a screened monitored interval from 148 to 167 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located on the crest of Chestnut Ridge directly south of Y-12, approximately 200 ft west of the Chestnut Ridge Security Pits (CRSP). The CRSP include two contiguous former waste disposal areas, each consisting of a series of unlined, east-west oriented trenches that were about 8 to 10 ft wide, 10 to 18 ft deep, and 700 to 800 ft long. Beginning in 1973, the disposal trenches at the site received a variety of hazardous waste until December 1984 and nonhazardous wastes until November 1988. All the disposal trenches are covered by a multi-layer low-permeability cap installed during RCRA closure of the site in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-five groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 31 samples between August 1988 and February 1996, and the low-flow sampling method used to obtain four samples between March 2001 and October 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the Knox Group (Copper Ridge Dolomite). The Knox Group formations, along with the uppermost formation (Maynardville Limestone) of the underlying Conasauga Group, comprise an aquifer consisting of three vertically gradational subsystems distinguished by groundwater flux, which decreases with depth: (1) the stormflow zone, (2) the vadose zone, and (3) the groundwater zone (Solomon et al. 1992). The stormflow and vadose zones occur at shallow depths within the thick (>100 ft) residuum that has developed on Chestnut Ridge. In the bedrock zone, orthogonal sets of permeable, planar fractures form water-producing zones within an essentially impermeable matrix, and dissolution of carbonates has enlarged fractures and produced an interconnected conduit-flow system characteristic of karst aquifers. Because the occurrence of solution features and the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity of the groundwater zone is vertically gradational. Most groundwater flux occurs within the transitional horizon between residuum and unweathered bedrock (water table interval); lower flux (and longer solute residence times) occurs at successively greater depths in the bedrock (Solomon et al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 117 ft bgs and exhibits moderate (about 21 ft) temporal (seasonal) fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of the CRSP indicate radial flow directions, with components of flow to the north into BCV (toward well GW-175); to the east along the axis of the ridge, parallel with geologic strike of the bedrock; and south toward drainage features that traverse the broad southern flank of the ridge.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date indicate that this well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 130 – 298 mg/L;
- pH of 7.3 – 8.5 (field measurements);
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite);
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Twenty-one groundwater samples collected to date had nitrate concentrations at or above the applicable analytical reporting limit, with the highest concentration (0.763 mg/L in November 1995) being substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Ten groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest concentration (0.001 mg/L in August 1991, October 1991, February 1992, July 1992, October 1992, June 1993, and September 1993) being below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected to date: acetone, methylene chloride, PCE, TCE, TCFM, 11DCE, and 111TCA. Each compound except acetone is a confirmed component of the dissolved plume of VOCs that originates from the CRSP. Historical operation of the former waste disposal trenches at the CRSP emplaced an elongated plume of dissolved VOCs in the groundwater that extends more than 2,500 ft east-northeast along the ridge crest (parallel with geologic strike) and at least 500 ft to the north and south down the ridges flanks. The existing network of monitoring wells at the site shows that 111TCA, 11DCA, and 11DCE are the primary compounds in the groundwater near the western disposal trench area and PCE, TCE, and 12DCE are the principal compounds in the groundwater near the eastern disposal trench area. Some constituents of the VOC plume (e.g., 11DCA and 11DCE) are probably present as a result of the degradation of 111TCA. Elongation of the VOC plume along the axis of the ridge and the distribution of plume constituents indicate primarily west-to-east groundwater flow/contaminant transport via flowpaths (e.g., bedding-plane fractures) that parallel the geologic strike of the Knox Group strata. Vertical flow/transport occurs parallel with the dip of the strata, with cross-cutting fractures facilitating contaminant migration to the north and south (Shevenell 1994). The vertical extent of the VOC plume has not been determined, but based on the existing network of monitoring wells at the site, the plume extends at least 150 ft bgs near the western disposal trenches and 270 ft bgs near the eastern disposal trenches.

The VOCs detected most frequently in the groundwater samples are PCE and 111TCA (Table 1). Only eight of the samples contained other VOCs (excluding false positive results) and none of the compounds were detected in more than four samples. Note that TCFM was detected in each of the samples collected since March 2001; however, VOC results reported for previous samples do not include TCFM. Aside from the results for PCE and TCFM, which have historical maximum concentrations of 41 μg/L and 16 μg/L, respectively, the bulk of the results are estimated values below 5μg/L. Also, the most recent sampling results show that PCE concentrations remain above the MCL for drinking water (5 μg/L). The dominance of PCE and 111TCA in the groundwater samples suggest that the monitored interval in the well intercepts groundwater flow/transport pathways for VOCs that originate from both the western and eastern waste disposal trenches at the CRSP. Additionally, the infrequent detection of PCE and 111TCA degradation products in the samples collected to date suggests that the monitored interval in the well does not intercept groundwater flowpaths where biologically mediated degradation of these compounds occurs. Indeed, the lack of 111TCA degradation products (i.e., 11DCA) in the samples indicates that the geochemistry of the groundwater in the well is not especially conducive to abiotic (chemical) degradation of the 111TCA.

A time-series plot of summed concentrations of VOCs detected in the groundwater samples (excluding false positive results) shows a slightly decreasing, widely variable long-term trend that encompasses 5-year (February 1996 - March 2001) and 3-year (August 2001 – May 2004) gaps in the sampling history for the well (Figure 1). The fluctuations in summed VOC concentrations do not appear to exhibit any clear or consistent correlation with seasonal groundwater flow conditions, as illustrated by the temporal "peak" VOC concentrations evident during seasonally high flow (e.g., 91 μg/L in April 1989) and seasonally low flow (e.g., 55 μg/L in August 1991). Additionally, in contrast to other wells near the CRSP, the VOC concentrations in well GW-175 do not show any direct response to the closure of the site in 1988 and installation of the low-permeability cap in 1989, as illustrated by the stable PCE concentrations detected over time (Table 1). This suggests minimal overall change in the relative flux of VOCs along the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

Four groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (4.39 pCi/L in October 1991) being substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

One groundwater sample collected to date had gross beta activity above the applicable MDA and corresponding CE, with the highest value (14.3 pCi/L in June 1993) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-176

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1985, completed with a screened monitored interval from 134 to 145 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located on the crest of Chestnut Ridge directly south of Y-12, approximately 150 ft south of the Chestnut Ridge Security Pits (CRSP). The CRSP include two contiguous former waste disposal areas, each consisting of a series of unlined, east-west oriented trenches that were about 8 to 10 ft wide, 10 to 18 ft deep, and 700 to 800 ft long. Beginning in 1973, the disposal trenches at the site received a variety of hazardous waste until December 1984 and nonhazardous wastes until November 1988. All the disposal trenches are covered by a multi-layer low-permeability cap installed during RCRA closure of the site in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-nine groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 27 samples between February 1986 and July 1992, and the low-flow sampling method used to obtain samples in May 2004 and October 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the Knox Group (Copper Ridge Dolomite). The Knox Group formations, along with the uppermost formation (Maynardville Limestone) of the underlying Conasauga Group, comprise an aquifer consisting of three vertically gradational subsystems distinguished by groundwater flux, which decreases with depth: (1) the stormflow zone, (2) the vadose zone, and (3) the groundwater zone (Solomon et al. 1992). The stormflow and vadose zones occur at shallow depths within the thick (>100 ft) residuum that has developed on Chestnut Ridge. In the bedrock zone, orthogonal sets of permeable, planar fractures form water-producing zones within an essentially impermeable matrix, and dissolution of carbonates has enlarged fractures and produced an interconnected conduit-flow system characteristic of karst aquifers. Because the occurrence of solution features and the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity of the groundwater zone is vertically gradational. Most groundwater flux occurs within the transitional horizon between residuum and unweathered bedrock (water table interval); lower flux (and longer solute residence times) occurs at successively greater depths in the bedrock (Solomon et al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 113 ft bgs and exhibits minor (about 2 ft) temporal (seasonal) fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of the CRSP indicate radial flow directions, with components of flow to the north into BCV; to the east along the axis of the ridge, parallel with geologic strike of the bedrock; and south toward drainage features that traverse the broad southern flank of the ridge.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date indicate that this well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 212 – 346 mg/L;
- pH of 6.7 – 7.0 (field measurements);
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite);
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations);
- total concentrations of trace metals (except boron) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995); and
- boron concentrations of 0.147 - 0.7 mg/L.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Eight groundwater samples collected to date had nitrate concentrations at or above the applicable analytical reporting limit, with the highest concentration (0.6 mg/L in February 1992) being substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Only one groundwater sample collected to date had a uranium concentration at or above the applicable analytical reporting limit, and this result (0.001 mg/L in August 1991) is an order-of-magnitude lower than the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample collected to date: PCE, 11DCE, 11DCA, 12DCA, and 111TCA (Table 1). Each compound is a confirmed component of the dissolved plume of VOCs that originates from the CRSP. Historical operation of the former waste disposal trenches at this site emplaced an elongated plume of dissolved VOCs in the groundwater that extends more than 2,500 ft east-northeast along the ridge crest (parallel with geologic strike) and at least 500 ft to the north and south down the ridges flanks. The existing network of monitoring wells at the site shows that 111TCA, 11DCA, and 11DCE are the primary compounds in the groundwater near the western disposal trench area and PCE, TCE, and 12DCE are the principal compounds in the groundwater near the eastern disposal trench area. Some constituents of the VOC plume (e.g., 11DCA and 11DCE) are probably present as a result of the degradation of 111TCA. Elongation of the VOC plume along the axis of the ridge and the distribution of plume constituents indicate primarily west-to-east groundwater flow/contaminant transport via flowpaths (e.g., bedding-plane fractures) that parallel the geologic strike of the Knox Group strata. Vertical flow/transport occurs parallel with the dip of the strata, with cross-cutting fractures facilitating contaminant migration to the north and south (Shevenell 1994). The vertical extent of the VOC plume has not been determined, but based on the existing network of monitoring wells at the site, the plume extends at least 150 ft bgs near the western disposal trenches and 270 ft bgs near the eastern disposal trenches.

Each groundwater sample contained 11DCA and 111TCA; all but one of the samples had PCE and/or 11DCE; and 12DCA was detected in only two of the samples (Table 1). With maximum historical concentrations above 300 μg/L and 150 μg/L, respectively, 111TCA and 11DCA are the dominant compounds, which suggests that the monitored interval in the well intercepts groundwater flow/contaminant transport pathways for VOCs that originate from the western disposal trenches at the CRSP. The other VOCs were detected at much lower concentrations, with all the results for PCE and 11DCE being less than 10 μg/L and 25 μg/L, respectively, and only trace levels (2 μg/L) of 12DCA. The most recent sampling results (October 2004) show that the concentrations of PCE, 11DCE, and 111TCA remain below respective drinking water MCLs (Table 1).

As noted previously, some of the compounds in the CRSP VOC plume are present as a result of the degradation of related parent compounds. Abiotic degradation of 111TCA, which is the only major chlorinated solvent that can be transformed chemically in groundwater under all likely conditions (McCarty 1996), probably explains the frequent detection and relatively high concentrations of 11DCA and 11DCE in the groundwater samples from well GW-176. This is clearly illustrated by a time-series plot of the proportional distribution of 111TCA, 11DCA, and 11DCE concentrations in each groundwater sample collected to date (Figure 1), whereby a substantial decrease in the relative proportion of 111TCA is accompanied by a concurrent increase in the proportions of 11DCA and 11DCE.

A time-series plot of summed concentrations of VOCs detected in the groundwater samples (excluding false positive results) shows a generally decreasing but widely variable long-term trend that encompasses the 12-year (July 1992 – May 2004) gap in the sampling history for the well (Figure 2). The fluctuations in summed VOC concentrations show a strong correlation with seasonal groundwater flow conditions, with prominent temporal "peak" VOC concentrations evident in samples collected during seasonally high flow, including samples collected in April 1987 (369 μg/L), March 1988 (520 μg/L), April 1989 (583 μg/L), and January 1990 (403 μg/L). This relationship suggests seasonally variable flux of dissolved VOCs along the groundwater flow/transport pathways intercepted by the monitored interval in the well. Additionally, the concentrations of most VOCs decreased rapidly and seasonal fluctuations moderated in response to the closure of the site in 1988 and installation of the low-permeability cap in 1989. For instance, summed VOC concentrations decreased about 43% between February 1986 (319 μg/L) and April 1992 (182 μg/L). Since then, however, summed VOC concentrations have remained fairly unchanged, as illustrated by the nearly equal summed VOC concentrations evident for samples collected in July 1992 (98 μg/L) and October 2004 (92 μg/L).

5.4 GROSS ALPHA ACTIVITY

Four groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (2.92 pCi/L in May 1991) being substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Three groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, with the highest value (5.32 pCi/L in May 1991) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-177

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1985, completed with a screened monitored interval from 130 to 145 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and well screen (0.01 slot). The well is located on the crest of Chestnut Ridge directly south of Y-12, approximately 200 ft west of the Chestnut Ridge Security Pits (CRSP). The CRSP include two contiguous former waste disposal areas, each consisting of a series of unlined, east-west oriented trenches that were about 8 to 10 ft wide, 10 to 18 ft deep, and 700 to 800 ft long. Beginning in 1973, the disposal trenches at the site received a variety of hazardous waste until December 1984 and nonhazardous wastes until November 1988. All the disposal trenches are covered by a multi-layer low-permeability cap installed during RCRA closure of the site in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-nine groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 41 samples between February 1986 and February 1996, and the low-flow sampling method used to obtain 8 samples between March 2001 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the lower Knox Group (Copper Ridge Dolomite), which underlies the steep northern flank of Chestnut Ridge. The Knox Group formations, along with the uppermost formation (Maynardville Limestone) of the underlying Conasauga Group, comprise an aquifer consisting of three vertically gradational subsystems distinguished by groundwater flux, which decreases with depth: (1) the stormflow zone, (2) the vadose zone, and (3) the groundwater zone (Solomon et al. 1992). The stormflow and vadose zones occur at shallow depths within the thick (>100 ft) residuum that has developed on Chestnut Ridge. In the bedrock zone, orthogonal sets of permeable, planar fractures form water-producing zones within an essentially impermeable matrix, and dissolution of carbonates has enlarged fractures and produced an interconnected conduit-flow system characteristic of karst aquifers. Because the occurrence of solution features and the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity of the groundwater zone is vertically gradational. Most groundwater flux occurs within the transitional horizon between residuum and unweathered bedrock (water table interval); lower flux (and longer solute residence times) occurs at successively greater depths in the bedrock (Solomon et al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 115 ft bgs and exhibits moderate (about 11 ft) seasonal fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-177 indicate radial flow directions, with components of flow to the north into BCV, to the east along the axis of the ridge (parallel with geologic strike), and south toward drainage features that traverse the broad southern flank of the ridge.

4.0 GEOCHEMICAL CHARACTERISTICS

This well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 120 – 272 mg/L;
- pH of 7.2 – 8.2 (field measurements);

- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite);
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the respective monitoring data reported for the groundwater samples collected from the well since January 1991, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Fourteen groundwater samples had nitrate concentrations at or above the applicable analytical reporting limit, with the highest concentration (0.847 mg/L in November 1995) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Twenty-one groundwater samples had uranium concentrations at or above the applicable analytical reporting limit, with the highest concentration (0.003 mg/L in April 1992 and June 1993) being an order-of-magnitude lower than the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample: CTET, PCE, 11DCE, 12DCE, 11DCA, and 111TCA. These compounds are components of a dissolved plume of VOCs that originates from the CRSP. Historical operation of the former waste disposal trenches at the CRSP emplaced an elongated plume of dissolved VOCs in the groundwater that extends more than 2,500 ft east-northeast along the ridge crest (parallel with geologic strike) and at least 500 ft to the north and south down the ridges flanks. The existing network of monitoring wells at the site shows that 111TCA, 11DCA, and 11DCE are the primary compounds in the groundwater near the western disposal trench area and PCE, TCE, and 12DCE are the principal compounds in the groundwater near the eastern disposal trench area. Elongation of the VOC plume along the axis of the ridge and the distribution of plume constituents indicate primarily west-to-east groundwater flow/contaminant transport via strike-parallel flowpaths in the Knox Group (e.g., bedding-plane fractures). Nevertheless, the presence of dissolved VOCs in the groundwater at this well indicates that there is a component of groundwater flow/contaminant transport to the west of the CRSP. Additionally, low levels of 111TCA detected in several downgradient monitoring wells on the southern flank of the ridge potentially reflect groundwater flow/contaminant transport via "quickflow" conduits that cut across geologic strike (Shevenell 1994). The vertical extent of the VOC plume has not been determined, but based on the existing network of monitoring wells at the site, the plume extends at least 150 ft bgs near the western disposal trenches and 270 ft bgs near the eastern disposal trenches.

The VOCs detected most frequently in the groundwater samples are 111TCA, 11DCA, and 11DCE (Table 1). Carbon tetrachloride, PCE, and 12DCE were detected only in samples collected in October 1991 (PCE), December 1993 (12DCE), and November 1995 (CTET). As shown in Table 1, the highest concentrations were reported for 111TCA (29 µg/L in December 1993) and 11DCA (25 µg/L in January 2002). Much lower levels are evident for 11DCE (most are estimated values below 5 µg/L), although the historical maximum 11DCE concentration (8 µg/L in January 2002) slightly exceeds the MCL. The preponderance of 111TCA and 11DCA in the well suggests transport of contaminants primarily from the western disposal trenches at the CRSP.

As illustrated by results for 111TCA (Figure 1), the concentrations of VOCs in the groundwater samples often show an inverse correlation with the presampling water level in the well (i.e., concentrations are highest in samples collected when water levels are lowest). This relationship suggests greater dilution of the groundwater samples collected during seasonally (or episodically) high flow conditions. Also, the VOC concentrations decreased sharply immediately after closure of the CRSP in 1988 and installation of the low-permeability cap in 1989, which probably reflects the substantially reduced flux of contaminants from the source areas. Since then, however, the sampling results show a relatively indeterminate long-term concentration trend, as illustrated by the 111TCA concentrations reported for the groundwater samples collected in January 1991 (12 µg/L), February 1996 (10 µg/L), March 2001 (11 µg/L), and January 2004 (8 µg/L).

5.4 GROSS ALPHA ACTIVITY

Sixteen groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (4.72 pCi/L in May 1995) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Eighteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (10.05 pCi/L in February 1991) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-178

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1987, completed with a screened monitored interval from 118 to 133 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located on the crest of Chestnut Ridge directly south of Y-12, approximately 50 ft north of the Chestnut Ridge Security Pits (CRSP). The CRSP include two contiguous former waste disposal areas, each consisting of a series of unlined, east-west oriented trenches that were about 8 to 10 ft wide, 10 to 18 ft deep, and 700 to 800 ft long. Beginning in 1973, the disposal trenches at the site received a variety of hazardous waste until December 1984 and nonhazardous wastes until November 1988. All the disposal trenches are covered by a multi-layer low-permeability cap installed during RCRA closure of the site in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Nineteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 17 samples between March 1988 and February 1992, and the low-flow sampling method used to obtain samples in May and October 2004.

The groundwater samples collected from this well in 2004 had a pink color. Well GW-178 was used as an injection point for two dye trace studies performed in 1990 and 1992. The first study used 10 kilograms of Fluorocene dye, and the second study used 225 pounds of a 20% solution of Rhodamine WT and 246 pounds of a 100% solution of an optical brightener (FB28). The pink color of the groundwater samples shows that at least some of the dye from the second test is still present in the well 14 years after injection.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the Knox Group (Copper Ridge Dolomite). The Knox Group formations, along with the uppermost formation (Maynardville Limestone) of the underlying Conasauga Group, comprise an aquifer consisting of three vertically gradational subsystems distinguished by groundwater flux, which decreases with depth: (1) the stormflow zone, (2) the vadose zone, and (3) the groundwater zone (Solomon et al. 1992). The stormflow and vadose zones occur at shallow depths within the thick (>100 ft) residuum that has developed on Chestnut Ridge. In the bedrock zone, orthogonal sets of permeable, planar fractures form water-producing zones within an essentially impermeable matrix, and dissolution of carbonates has enlarged fractures and produced an interconnected conduit-flow system characteristic of karst aquifers. Because the occurrence of solution features and the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity of the groundwater zone is vertically gradational. Most groundwater flux occurs within the transitional horizon between residuum and unweathered bedrock (water table interval); lower flux (and longer solute residence times) occurs at successively greater depths in the bedrock (Solomon et al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 89 ft bgs and exhibits moderate (about 9 ft) temporal (seasonal) fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of the CRSP indicate radial flow directions, with components of flow to the north into BCV (toward well GW-178); to the east along the axis of the ridge, parallel with geologic strike of the bedrock; and south toward drainage features that traverse the broad southern flank of the ridge.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date indicate that this well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 194 – 446 mg/L;
- pH of 7.1 – 7.7 (field measurements);
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite);
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Six groundwater samples collected to date had nitrate concentrations at or above the applicable analytical reporting limit, with the highest concentration (0.5 mg/L in January 1991, April 1991, and February 1992) being substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

None of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, the VOCs detected in one or more of the groundwater samples collected to date are CTET, chloroform, MC, PCE, 11DCE, 11DCA, and 111TCA. Of these compounds, only 111TCA, 11DCA, 11DCE, and PCE are confirmed components of the dissolved plume of VOCs that originates from the CRSP. Historical operation of the former waste disposal trenches at this site emplaced an elongated plume of dissolved VOCs in the groundwater that extends more than 2,500 ft east-northeast along the ridge crest (parallel with geologic strike) and at least 500 ft to the north and south down the ridges flanks. The existing network of monitoring wells at the site shows that 111TCA, 11DCA, and 11DCE are the primary compounds in the groundwater near the western disposal trench area and PCE, TCE, and 12DCE are the principal compounds in the groundwater near the eastern disposal trench area. Some constituents of the VOC plume (e.g., 11DCA and 11DCE) are probably present as a result of the degradation of 111TCA. Elongation of the VOC plume along the axis of the ridge and the distribution of plume constituents indicate primarily west-to-east groundwater flow/contaminant transport via flowpaths (e.g., bedding-plane fractures) that parallel the geologic strike of the Knox Group strata. Vertical flow/transport occurs parallel with the dip of the strata, with cross-cutting fractures facilitating contaminant migration to the north and south

(Shevenell 1994). The vertical extent of the VOC plume has not been determined, but based on the existing network of monitoring wells at the site, the plume extends at least 150 ft bgs near the western disposal trenches and 270 ft bgs near the eastern disposal trenches.

Each groundwater sample collected to date contained 111TCA and all but three of the samples contained 11DCA (Table 1). Concentrations of 111TCA are all less than 50 µg/L, substantially below the drinking water MCL (200 µg/L), with the most recent sampling results (May and October 2004) showing concentrations below 10 µg/L. Conversely, the most recent sampling results for 11DCA (11 µg/L and 12 µg/L, respectively) are the highest concentrations reported for this compound. Other VOCs were detected less frequently than 111TCA and 11DCA and at much lower concentrations, with low levels (<5 µg/L) of PCE and 11DCE detected about half of the samples and chloroform detected in one sample (excluding false positive results). The dominance of 111TCA and 11DCA in the groundwater at this well suggests that the monitored interval in the well intercepts cross-strike groundwater flow/contaminant transport pathways for VOCs that originate primarily from the western disposal trenches at the CRSP. Indeed, considering that the well is only 50 ft from the closest disposal trench, the relatively modest levels of VOCs in the groundwater at this well suggest that these cross-strike pathways play only a minor role in the overall transport/migration of dissolved VOCs from the CRSP.

As noted previously, some of the compounds in the CRSP VOC plume are present as a result of the degradation of related parent compounds. Abiotic degradation of 111TCA, which is the only major chlorinated solvent that can be transformed chemically in groundwater under all likely conditions (McCarty 1996), probably explains the frequent detection 11DCA in the groundwater samples from well GW-178. This may explain why the long-term decrease in the concentration of 111TCA is accompanied by a concurrent increase in the concentration of 11DCA (Figure 1).

A time-series plot of summed concentrations of VOCs detected in each groundwater sample (excluding false positive results) shows a generally decreasing trend dominated by the 12-year gap (February 1992 – May 2004) in the sampling history for the well (Figure 2). Before the gap, summed VOC concentrations appear to have increased sharply between March 1988 (23 µg/L) and October 1988 (54 µg/L); decreased steadily through July 1990 (26 µg/L), rebounded to a peak level in August 1991 (45 µg/L), and decreased again through February 1992 (29 µg/L). The initial decrease probably reflects reduced flux of VOCs in response to closure of the CRSP and installation of the low-permeability cap over the waste disposal trenches. The significance of the latter temporal peak is not apparent from the available data. The most recent sampling results suggest that the rate of decrease in the concentrations of VOCs in the groundwater has slowed considerably, as indicated by the similar summed concentrations of VOCs detected in the samples collected in February 1992 and October 2004 (23 µg/L).

5.4 GROSS ALPHA ACTIVITY

Only one of the groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, and this result (8.4 pCi/L in October 1991) is below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

None of the groundwater samples collected to date had gross beta concentrations at or above the applicable analytical reporting limit.

WELL GW-179

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in December 1985, completed with a screened monitored interval from 106 to 117 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located on the crest of Chestnut Ridge directly south of Y-12, less than 50 ft north of the Chestnut Ridge Security Pits (CRSP). The CRSP include two contiguous former waste disposal areas, each consisting of a series of unlined, east-west oriented trenches that were about 8 to 10 ft wide, 10 to 18 ft deep, and 700 to 800 ft long. Beginning in 1973, the disposal trenches at the site received a variety of hazardous waste until December 1984 and nonhazardous wastes until November 1988. All the disposal trenches are covered by a multi-layer low-permeability cap installed during RCRA closure of the site in 1989.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-five groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 23 samples between February 1986 and July 1992, and the low-flow sampling method used to obtain samples in May and October 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the Knox Group (Copper Ridge Dolomite). The Knox Group formations, along with the uppermost formation (Maynardville Limestone) of the underlying Conasauga Group, comprise an aquifer consisting of three vertically gradational subsystems distinguished by groundwater flux, which decreases with depth: (1) the stormflow zone, (2) the vadose zone, and (3) the groundwater zone (Solomon et al. 1992). The stormflow and vadose zones occur at shallow depths within the thick (>100 ft) residuum that has developed on Chestnut Ridge. In the bedrock zone, orthogonal sets of permeable, planar fractures form water-producing zones within an essentially impermeable matrix, and dissolution of carbonates has enlarged fractures and produced an interconnected conduit-flow system characteristic of karst aquifers. Because the occurrence of solution features and the frequency, aperture, and connectivity of permeable fractures decrease with depth, the bulk hydraulic conductivity of the groundwater zone is vertically gradational. Most groundwater flux occurs within the transitional horizon between residuum and unweathered bedrock (water table interval); lower flux (and longer solute residence times) occurs at successively greater depths in the bedrock (Solomon et al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 112 ft bgs and exhibits minor (<1 ft) temporal (seasonal) fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of the CRSP indicate radial flow directions, with components of flow to the north into BCV (toward well GW-179); to the east along the axis of the ridge, parallel with geologic strike of the bedrock; and south toward drainage features that traverse the broad southern flank of the ridge.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date indicate that this well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 256 – 294 mg/L;
- pH of 6.5 – 8.6 (field measurements);
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite);
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Nine groundwater samples collected to date had nitrate concentrations at or above the applicable analytical reporting limit, with the highest concentration (0.7 mg/L in February 1991) being substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Four groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit, with the highest concentration (0.001 mg/L in February 1991, May 1991, August 1991, and July 1992) being below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample collected to date: CTET, chloroform, MC, PCE, 11DCE, 12DCE, 11DCA, 111TCA, and TCFM. Only 111TCA, 11DCA, 11DCE, PCE, and TCFM have been detected in the groundwater samples collected since January 1991 and these VOCs are components of a dissolved plume of VOCs that originates from the CRSP. Historical operation of the former waste disposal trenches at this site emplaced an elongated plume of dissolved VOCs in the groundwater that extends more than 2,500 ft east-northeast along the ridge crest (parallel with geologic strike) and at least 500 ft to the north and south down the ridges flanks. The existing network of monitoring wells at the site shows that 111TCA, 11DCA, and 11DCE are the primary compounds in the groundwater near the western disposal trench area and PCE, TCE, and 12DCE are the principal compounds in the groundwater near the eastern disposal trench area. Some constituents of the VOC plume (e.g., 11DCA and 11DCE) are probably present as a result of the degradation of 111TCA. Elongation of the VOC plume along the axis of the ridge and the distribution of plume constituents indicate primarily west-to-east groundwater flow/contaminant transport via flowpaths (e.g., bedding-plane fractures) that parallel the geologic strike of the Knox Group strata. Vertical flow/transport occurs parallel with the dip of the strata, with cross-cutting fractures facilitating contaminant migration to the north and south (Shevenell 1994). The vertical extent of the VOC plume has not been determined, but based on the existing network of monitoring wells at the site, the plume extends at least 150 ft bgs near the western disposal trenches and 270 ft bgs near the eastern disposal trenches.

Each groundwater sample collected to date contained 111TCA, 11DCA, and 11DCE, with PCE detected in all but two of the samples (Table 1). A low level (11 μg/L) of TCFM was detected in the sample collected in October 2004, but this compound was not detected in the May 2004 sample and was not analyzed in historical samples (Table 1). Historical data show the highest concentrations for 111TCA and 11DCA, with respective maximum values of 1,100 μg/L (April 1986) and 300 μg/L (March 1988), and the preponderance of these compounds suggests that the well intercepts groundwater flow/contaminant transport pathways for VOCs that originate primarily from the western disposal trenches at the CRSP. However, the most recent (May and October 2004) sampling results show substantially lower concentrations of both compounds, with 111TCA levels substantially below the drinking water MCL (200 μg/L). Results for 11DCE show a historical maximum value of 77 μg/L (April 1986) and concentrations at or above 50 μg/L in most of the samples collected before February 1991 (Table 2). The most recent samples (May and October 2004) also show that the 11DCE concentrations remain above the MCL (7 μg/L). Although detected in most of the samples, PCE is a secondary compound compared to the other VOCs, with a historical maximum value of 42 μg/L (February 1986) that appears to be an outlier compared to the other PCE results, none of which exceed 15 μg/L, including very low levels (5 μg/L or less) reported for all but one of the samples collected since March 1990.

As noted previously, some of the compounds in the CRSP VOC plume are present as a result of the degradation of related parent compounds. Abiotic degradation of 111TCA, which is the only major chlorinated solvent that can be transformed chemically in groundwater under all likely conditions (McCarty 1996), probably explains the frequent detection and relatively high concentrations of 11DCA and 11DCE in the groundwater samples from well GW-179. This is clearly illustrated by a time-series plot of the proportional distribution of 111TCA, 11DCA, and 11DCE concentrations in each groundwater sample collected to date (Figure 1), whereby a substantial decrease in the relative proportion of 111TCA is accompanied by a concurrent increase in the proportions of 11DCA and 11DCE. In contrast, none of the groundwater samples collected to date contained PCE degradation products, particularly TCE and c12DCE, indicating that the monitored interval for the well does not intercept groundwater flow/transport pathways where biologically mediated degradation (reductive dechlorination) of PCE occurs.

A time-series plot of the summed concentrations of VOCs detected in each groundwater sample (excluding false positive results) generally shows a decreasing long term trend dominated by the nearly 12-year gap (July 1992 – May 2004) in the sampling history for the well (Figure 2). Before the sampling gap, the data show two distinct trends: a widely fluctuating trend evident before the CRSP were closed and capped and a less variable, clearly decreasing trend after the site was closed and capped. The wide concentration fluctuations generally correspond with seasonal groundwater elevations, with higher summed VOC concentration evident for samples collected during winter and spring, which suggests seasonally variable flux of dissolved VOCs along the groundwater flow/transport pathways intercepted by the monitored interval in the well. The steadily decreasing trend segment reflects the substantially reduced flux of VOCs after closure of the site and installation of the low-permeability cap. Nevertheless, the rate of concentration decrease appears to have slowed, with summed VOC concentrations decreasing by about 1,045 μg/L in the four years between March 1988 (1,278 μg/L) and July 1992 (234 μg/L), but only by about 140 μg/L in the 12 years between July 1992 and October 2004 (93 μg/L). This suggests that the bulk of the most contaminated groundwater has been flushed from the flowpaths monitored by the well.

5.4 GROSS ALPHA ACTIVITY

Six groundwater samples collected to date had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (4.19 pCi/L in April 1992) being substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Seven groundwater samples collected to date had gross beta activity above the applicable MDA and corresponding CE, with the highest value (11.16 pCi/L in February 1991) being below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-190

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1989, completed with a screened monitored interval from 8 to 26.2 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (type 304) riser casing and well screen (0.01 slot wire-wound). This well is located in Bear Creek Valley near the west end of Y-12, about 500 ft southeast of the intersection of Bear Creek Road and Old Bear Creek Road.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Eighteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 16 samples between June 1990 and November 1993, and the low-flow sampling method used to obtain samples in April and October 2003.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Nolichucky Shale). The average static groundwater level in the well is 9.3 ft below ground surface. Presampling depth-to-water measurements for the well indicate minor fluctuations (<3 ft) in seasonal groundwater surface elevations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- moderate TDS (200 -300 mg/L);
- pH (field measurements) of 6.3 – 7.3;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion, which is based on the analytical results reported for 15 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Four groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.26 mg/L in March 1991) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Only one groundwater sample had a uranium concentration above the applicable analytical reporting limit and this result (0.001 mg/L in November 1993) is substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected from the well between March 1991 and November 1993: PCE, TCE, 12DCE, 11DCE, VC, 111TCA, and 11DCA. Summed concentrations of the compounds detected in each sample vary widely from a high of 1,559 ug/L in December 1991 to 65 ug/L in November 1993, with maximum concentrations of PCE (170 ug/L), TCE (230 ug/L), 12DCE (1,100 ug/L), and VC (66 ug/L) substantially above respective MCL. These historical VOC results also suggest a seasonally variable but generally indeterminate long-term concentration trend, as illustrated by the PCE concentrations evident in March 1991 (34 μg/L), December 1991 (170 μg/L), March 1992 (41 μg/L), November 1992 (75 μg/L), March 1993 (110 μg/L), and November 1993 (49 μg/L). The source of the VOCs in the groundwater at this well has not been confirmed but is probably one or more of the former waste handling and storage areas within the northern part of the Y-12 Salvage Yard.

The groundwater samples collected from the well in April and October 2003 did not contain VOCs. The apparent lack of VOCs in the groundwater at the well may reflect the combined and cumulative effects of various natural attenuation processes since the last previous sampling event (November 1993). However, this also may be an artifact of the change from conventional sampling to low-flow sampling. Conventional sampling involves collecting groundwater samples after purging at least three well-volumes of groundwater at a pumping rate (1-2 gallons per minute) which may substantially lower the water level in the well (or purge the well dry). Conventional sampling induces groundwater inflow into the well from water-producing features throughout the monitored interval, including features that may not be proximal to the pump intake, and the radius of influence may extend a significant distance from the well, particularly in the direction of geologic strike. Conversely, low-flow sampling involves purging the well at flow rate low enough (<300 milliliters per minute) to induce minimal water-level drawdown in the well (<1 ft per quarter hour) and collecting groundwater samples when field measurements show stable values for selected indicator parameters (e.g., temperature). Low-flow sampling induces groundwater inflow into the well from the water-producing feature(s) proximal to the pump intake, with a much smaller radius of influence compared to that of conventional sampling.

5.4 GROSS ALPHA ACTIVITY

Five groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (2.67 pCi/L in September 1991) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Four groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (5.31 pCi/L in September 1991) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-193

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1989, completed with a screened monitored interval from 5.5 to 18.45 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located on the east side of Bldg. 9201-1, about 300 ft south of Second Street in the east-central section of Y-12.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-two groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 18 samples between June 1990 and August 1997, and the low-flow sampling method used to obtain 14 samples between March 1998 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Maynardville Limestone). The average static groundwater level in the well is about 6 ft bgs. Presampling depth-to-water measurements for the well indicate minor fluctuations (<3 ft) in seasonal groundwater surface elevations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 290 - 580 mg/L, excluding an outlier (1000 mg/L) in February 1999;
- pH of 6.4 – 7.8 (field measurements);
- high sulfate concentrations (>100 mg/L);
- low molar proportions of chloride, potassium, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals (except iron and manganese) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion, which is based on the analytical results reported for 29 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Six groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (1.3 mg/L in September 1993 and January 2001) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Twenty-one groundwater samples had uranium concentrations above the applicable analytical reporting limit. Two of these results exceed the MCL for uranium (0.03 mg/L): 0.086 mg/L in September 1993 and 0.08 mg/L in November 1993. The remaining uranium concentrations are substantially lower, with non-detect results reported for all but two samples collected since

January 2000. A time-series plot of the detected uranium results (Figure 1) shows a slightly decreasing to indeterminate trend dominated by the concentration "spike" in 1993.

5.3 VOLATILE ORGANIC COMPOUNDS

Each groundwater sample collected between March 1991 and November 1993 contained summed concentrations of benzene, toluene, ethylbenzene, and xylene (BTEX) above 4,000 μg/L. These sampling results confirmed the release of petroleum hydrocarbons from Tank 2331-U, a former gasoline underground storage tank (UST) that was excavated and removed in December 1988 (DOE 1998). As shown by a time-series plot of the summed BTEX concentrations (Figure 2), the VOC concentrations in the groundwater at the well have decreased substantially. Only benzene has been detected in three of the samples collected since January 2001, and each result exceeds the MCL for benzene (5 μg/L). Along with the source control actions (i.e., removal of the UST), the substantially reduced levels of BTEX in the groundwater at this well are attributable to various natural attenuation processes because groundwater remedial action was not performed at the site.

5.4 GROSS ALPHA ACTIVITY

Twenty-four groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with results that exceed the MCL (15 pCi/L) reported for samples collected in July 1992 (17.1 pCi/L), June 1993 (15.2 pCi/L), September 1993 (19 pCi/L), November 1993 (42.1 pCi/L), and February 1999 (77.59 pCi/L). The source of the alpha activity in the groundwater at this well has not been conclusively identified, but is suspected to be uranium isotopes, based on the detection of U-234 (4.5 pCi/L) and U-238 (6.93 pCi/L) in the sample collected in November 1996 (the only sample that was analyzed for uranium isotopes).

5.5 GROSS BETA ACTIVITY

Twenty-four groundwater samples had gross beta activity above the applicable MDA and corresponding CE, although none of the results exceed the SDWA screening level for gross beta activity (50 pCi/L). Samples with the highest levels of gross beta activity were collected in November 1992 (24.3 pCi/L), September 1993 (24.9 pCi/L), November 1993 (41.6 pCi/L), and February 1999 (29.69 pCi/L). These results exceed background levels in the groundwater but are below the SDWA screening level for gross beta activity (50 pCi/L). Available data show that Tc-99 is not the source of the beta activity; each groundwater sample collected from the well since November 1996 was analyzed for Tc-99, as required by the RCRA post-closure permit for the East Fork Regime (TDEC 2003), and none of these results exceed the corresponding MDA. Uranium isotopes and associated daughters are the most likely source of the beta activity.

WELL GW-203

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1985, completed with a screened monitored interval from 144 to 156 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and well screen (0.01 slot). The well is located on the crest of Chestnut Ridge directly south of Y-12, about 100 ft south (hydraulically downgradient) of the United Nuclear Corporation Site (UNCS). The UNCS is a closed facility that was used for the disposal of cement-fixed sludge, radiologically-contaminated soils, and demolition debris. A multilayer, low-permeability cap was installed at the site in 1992 in accordance with the CERCLA ROD signed in 1991 (DOE 1991).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fifty-four groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 40 samples between February 1986 and April 1997, and the low-flow sampling method used to obtain 14 samples between November 1997 and August 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the Knox Group (Copper Ridge Dolomite). Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 74 ft bgs and exhibit substantial (10 - 25 ft) water-level fluctuations, which is typical of many Knox Group wells on Chestnut Ridge.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 120 – 228 mg/L, excluding an outlier (78 mg/L) in May 1990;
- pH (field measurements) of 7.0 – 8.4;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for 35 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Thirty-four groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (3.2 mg/L) being below the MCL for nitrate (10 mg/L).

5.2 URANIUM

One groundwater sample had a uranium concentration above the applicable analytical reporting limit, and this result (0.001 mg/L in January 1993) is substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected in only two groundwater samples: ethylbenzene (1 µg/L) was detected in July 1992, and 2-butanone (9 µg/L) was detected in March 1997. These results are considered to be outliers because each compound was detected only once.

5.4 GROSS ALPHA ACTIVITY

Eleven of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (20.1 pCi/L in January 1993) exceeding the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Sixteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (49.58 pCi/L in February 1999) being slightly below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-204

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1989, completed with a screened monitored interval from 6.5 to 17.3 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (type 304) riser casing and well screen (0.01 slot spiral wound). This well, located in Bear Creek Valley on the east side of Bldg. 9204-2 in the central section of the Y-12 complex, was installed in the pit from which a petroleum fuel underground storage tank (UST) was excavated and removed in August 1988.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 18 samples between June 1990 and November 2003, and the low-flow sampling method used to obtain 12 samples between September 1999 and October 2004. Note that the six-year gap in the sampling history for the well spans the change in groundwater sampling methods.

An evaluation of the monitoring data available through August 2000 indicated potential bias related to the groundwater sampling method: (unfiltered) samples obtained with the conventional sampling method had substantially higher uranium concentrations than samples obtained with the low-flow sampling method (AJA 2001). Results of "paired sampling" performed during seasonally high (May 2003) and seasonally low (November 2003) groundwater flow conditions, with the low-flow method used the first day and the conventional sampling method used the next, confirm the apparent sampling-method bias. As shown below in the summary of results for selected analytes, the unfiltered samples obtained with low-flow and conventional sampling methods exhibit substantial differences for some analytes (e.g., REDOX and dissolved oxygen) and minimal difference for other analytes (e.g., pH and chloride).

Table 1. Consecutive daily sampling results for uranium and other selected analytes, May and November 2003

Analyte	Units	May 2003		November 2003	
		Low-Flow Sampling	Conventional Sampling	Low-Flow Sampling	Conventional Sampling
pH	St. units	7.65	7.61	7.29	7.32
Dissolved Oxygen	ppm	1.41	2.85	0.1	6.07
REDOX	mV/L	-14	226	92	194
Dissolved Solids	mg/L	172	190	247	265
Suspended Solids	mg/L	3	90	5	181
Calcium	mg/L	47.5	50.2	59.1	96.5
Chloride	mg/L	3.05	2.86	2.28	2.17
Aluminum	mg/L	0.331	6.4	0.359	30.9
Iron	mg/L	0.212	4.21	0.279	38
Uranium	mg/L	0.0478	0.0535	0.0678	0.124

These results also show that the unfiltered groundwater samples obtained with the conventional method contain substantially more suspended solids than the unfiltered samples obtained with the low-flow method; the preservation of these turbid samples (i.e., reducing the pH below 2) explains the extremely high levels of aluminum and iron (and calcium). Unfiltered samples obtained with the conventional method likewise appear to have higher total uranium concentrations than unfiltered samples obtained with the low-flow method.

3.0 HYDROLOGIC CHARACTERISTICS

The former UST pit in which the well was installed is within the subcrop area of the Conasauga Group about 350 ft north of the geologic contact between the Nolichucky Shale and Maynardville Limestone. Note that the large monitored (screened) interval in the well is intended to straddle the water table during seasonally high and low flow conditions and facilitate detection of light non-aqueous phase liquids (LNAPL). The average static groundwater level in the well is about 7 ft bgs and presampling depth-to-water measurements for the well indicate minor (<4 ft) water-level fluctuations.

Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-204 indicate southeasterly flow toward the Maynardville Limestone and the Upper East Fork Poplar Creek (UEFPC) drainage system. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and original main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred flow in directions that parallel geologic strike (i.e., bedding-plane fractures), which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 143 mg/L – 532 mg/L;
- pH of 6.3 – 7.8 (field measurements);
- elevated sulfate concentrations (>25 mg/L);
- low molar proportions of chloride, potassium, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion, which is based on the analytical results reported for the 26 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Twelve groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (1.28 mg/L in May 2001) being significantly below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Uranium was detected in each groundwater sample (Table 2) and the concentration reported for each sample, which range from 0.0316 mg/L (November 2001) to 0.71 mg/L (June 1991), exceeds the MCL for uranium (0.03 mg/L). Note that the uranium concentrations show no response to the excavation and removal of Tank 0134-U (August 1988); the source of the uranium has not been determined, but may be associated with Bldg. 9204-2 (DOE 1998). Based on available data, the uranium levels show a variable but decreasing long-term concentration trend (Figure 1). As described in Section 2, results of "paired" sampling in CY 2003 confirmed the suspected sampling-method bias: samples obtained with the conventional sampling method have substantially higher uranium concentrations than samples obtained with the low-flow sampling method. Thus, the decreasing long-term trend for uranium may be largely an artifact of the change in sampling methods. Considered separately, uranium results obtained with each sampling method show indeterminate concentration trends, as illustrated by the uranium levels evident from conventional sampling in September 1993 (0.126 mg/L) and November 2003 (0.124 mg/L) and the uranium levels evident from low-flow sampling in June 2000 (0.0665 mg/L) and November 2003 (0.0678 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Each groundwater sample collected between March 1991 and September 1993 contained summed concentrations of benzene, toluene, ethylbenzene, and xylene (BTEX) above 200 μg/L (Table 2). These sampling results confirmed the release of petroleum hydrocarbons from Tank T0134-U. The BTEX levels dropped below respective analytical reporting limits in December 1991, with low levels of individual compounds detected in August 1992 (xylene = 12μg/L), March 1993 (ethylbenzene = 2 μg/L), and November 1993 (xylene = 2μg/L and ethylbenzene = 2 μg/L), and non-detect values reported for each sample collected since September 1999 (Table 2 and Figure 2). Along with the source control actions (i.e., removal of the UST), the substantially reduced levels of BTEX in the groundwater at this well are attributable to various natural attenuation processes because groundwater remedial action was not performed at the site.

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity above the applicable MDA and corresponding CE was reported for all but two of the groundwater samples (Table 2) and all but one of these results exceed the MCL for gross alpha activity (15 pCi/L), with the highest values evident in June 1993 (102 pCi/L), October 2000 (71 pCi/L), and May 2001 (74 pCi/L). Radiological analyses of the samples collected during CY 2001 and CY 2002 confirm that the alpha radioactivity is from uranium isotopes (U-234 and U-238), with the highest levels of these isotopes reported for the samples collected in May 2001 (U-234 = 33 pCi/L and U-238 = 29 pCi/L) and May 2002 (U-234 = 21 pCi/L and U-238 = 16 pCi/L). Considering the relatively limited mobility of uranium isotopes in the groundwater with the neutral pH evident in the well, the source(s) of the isotopes may be proximal to the well, including Bldg. 9204-2 (DOE 1998).

Available data indicate an indeterminate long-term trend for gross alpha activity, as illustrated by the gross alpha results reported for the samples collected in September 1991 (22 pCi/L), March 1993 (31 pCi/L), June 2000 (28 pCi/L), and May 2003 (47 pCi/L). Additionally, the consecutive daily sampling results obtained during May and November 2003 (see Section 2.0) suggest that samples obtained with the conventional sampling method had somewhat higher alpha activity than samples obtained with the low-flow sampling method (Figure 3). However, the higher alpha activity reported for the conventional method samples (Table 2) may be related to analytical interference associated with the higher suspended solids of the groundwater samples (see Table 1).

5.5 GROSS BETA ACTIVITY

Gross beta activity above the applicable MDA and corresponding CE was reported for all but two of the groundwater samples (Table 2). The historical maximum value for gross beta activity (238 pCi/L in March 1992) exceeds the SDWA screening level (50 pCi/L) but is considered an outlier because the remaining gross beta results are all less than 45 pCi/L. Uranium isotopes and associated daughters are the most likely source of the beta activity in the groundwater at the well. Excluding the historical maximum as an outlier, the available data show that the levels of gross beta activity may have increased slightly in the early 1990s, but since then exhibit a fairly indeterminate long-term trend, as illustrated by the gross beta results reported for the samples collected in June 1993 (36.8 pCi/L), October 2000 (34 pCi/L), May 2003 (39 pCi/L) Additionally, the consecutive daily sampling results obtained during May and November 2003 (see Section 2) suggest slightly lower gross beta results obtained with the low-flow method than the conventional sampling method (Table 2). However, the higher beta activity reported for the conventional method samples may be related to analytical interference associated with the higher suspended solids of the groundwater samples (see Table 1).

WELL GW-205

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1985, completed with a screened monitored interval from 152 to 164 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and well screen (0.01 slot). The well is located on the crest of Chestnut Ridge south of Y-12, about 100 ft southwest (hydraulically downgradient) of the United Nuclear Corporation Site (UNCS). The UNCS is a closed facility that was used for the disposal of cement-fixed sludge, radiologically-contaminated soils, and demolition debris. A multilayer, low-permeability cap was installed at the site in 1992 in accordance with the CERCLA ROD signed in 1991 (DOE 1991).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fifty-four groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 40 samples between February 1986 and April 1997, and the low-flow sampling method used to obtain 14 samples between November 1997 and August 2004.

Groundwater samples from the well exhibit conspicuous geochemical characteristics (see Section 4.0) attributable to contamination from the cement (grout) lost into the surrounding bedrock during installation of the well. To ensure collection of representative groundwater samples, the well may need to be redeveloped before the low-flow sampling method is used or the conventional sampling method should be used.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the Knox Group (Copper Ridge Dolomite). The average static groundwater level in the well is about 72 ft bgs. Presampling depth-to-water measurements for the well indicate substantial (10-20ft) water-level fluctuations, which is typical of many Knox Group wells.

4.0 GEOCHEMICAL CHARACTERISTICS

As noted in Section 2.0, this atypical geochemistry probably is a consequence of localized grout contamination. Moreover, as shown in Figure 1, the low-flow sampling method tends to obtain the more grout-contaminated groundwater samples from the well (i.e., samples with more basic pH levels and higher concentrations of potassium and sodium). This suggests that the conventional sampling method induces greater inflow of "fresh" groundwater into the well, which effectively dilutes the grout-contaminated groundwater entering the well; thus buffering the pH and lowering the concentrations of potassium and sodium. Nevertheless, considering that the well was installed in 1985, the persistent grout contamination in the well is a chronic problem with respect to obtaining representative groundwater samples. Before CY 1999, the well produced calcium-magnesium-bicarbonate groundwater typical of the Knox Group in the Chestnut Ridge Regime. However, since February 1999 the well has yielded groundwater generally characterized by:

- TDS of 150 - 660 mg/L;
- pH of 9.3 – 10.4 (field measurements);
- low molar proportion of calcium (<5% of total cations);
- high molar proportions of carbonate alkalinity and potassium (>50% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion, which is based on the analytical results reported for 35 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Twenty-nine groundwater samples had nitrate concentrations above the analytical reporting limit. None of the results exceed the MCL for nitrate (10 mg/L), with concentrations below 1 mg/L reported for all but two of the samples: 6.3 mg/L in April 1995 and 8.4 mg/L in August 2000. These results are considered to be outliers.

5.2 URANIUM

Eighteen groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.001 mg/L) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected at low levels in two of the 21 groundwater samples analyzed for VOCs between January 1991 and April 1997: PCE (1 μg/L) in January 1991 and 2-butanone (13 μg/L) in October 1992. These results may be sampling or analytical artifacts and are considered to be outliers.

5.4 GROSS ALPHA ACTIVITY

Fourteen groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (6.64 pCi/L in November 1995) being below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Nineteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (84.85 pCi/L) exceeding the SDWA screening level for gross beta activity (50 pCi/L). Although the UNCS may be a source of beta-emitting radionuclides to the groundwater hydraulically upgradient of the well, it is also possible that the elevated gross beta activity reported for this well is a consequence of the elevated potassium concentrations in the grout-contaminated groundwater samples form the well. Potassium-40 (K-40) is a beta-emitting isotope and, based on the natural ratio of K-40 to total K (K-40 = 0.0119% total K; Brownlow 1979), the groundwater samples collected from the well in February 2000 (total K = 79 mg/L) and July 2002 (total K = 78 mg/L) each contained nearly 1 mg/L of K-40. Furthermore, the sample collected in July 2002 was analyzed for K-40 activity and the result was about 90 pCi/L. The presence of K-40 in the well would account for the strong correlation between the monitoring results for gross beta activity and total potassium (Figure 2). Thus, elevated gross beta activity may be an artifact of the grout contamination in well. Consequently, this well is not ideally suited for groundwater quality monitoring designed to detect or monitor a release of beta-emitting radiological contaminants from the UNCS.

WELL GW-207

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in September 1985, completed with an open-hole monitored interval from 100 to 109.6 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing. The well forms a cluster with wells GW-208 and GW-816 and is located near Scarboro Road northeast of Y-12, about 50 ft east of the section of Upper East Fork Poplar Creek that passes through a gap in Pine Ridge.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-three groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 28 samples between June 1990 and April 1997, and the low-flow sampling method used to obtain 15 samples between December 1997 and November 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from intermediate bedrock interval (>100 ft bgs) in the Rome Formation. The average static groundwater level in the well is 2.1 ft above the ground surface, indicating artesian conditions. Presampling depth-to-water measurements for the well indicate moderate fluctuations (<7 ft) in seasonal groundwater surface elevations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 310 – 438 mg/L;
- pH (field measurements) of 6.9 – 7.8;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for 40 groundwater samples collected from the well since January 1991.

5.1 NITRATE

One groundwater sample had a nitrate concentration above the applicable analytical reporting limit, and this result (0.04 mg/L in September 1996) is substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

None of the groundwater samples had uranium concentrations above the analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected at very low levels in two groundwater samples: 4-methyl-2-pentanone (4 μg/L) in January 1992 and methylene chloride (4 μg/L) in June 1995. These results are considered to be outliers because each compound was detected only once.

5.4 GROSS ALPHA ACTIVITY

Ten groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (4.48 pCi/L in November 1995) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Twelve groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (7.1 pCi/L in October 2001) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-208

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in May 1986, completed with an open-hole monitored interval from 404 to 412.8 ft bgs, and constructed with nominal 4.5-inch diameter steel riser casing. The well forms a cluster with wells GW-207 and GW-816 and is located near Scarboro Road northeast of Y-12, about 50 ft east of the section of Upper East Fork Poplar Creek that passes through a gap in Pine Ridge.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-four groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 29 samples between June 1990 and April 1997, and the low-flow sampling method used to obtain 15 samples between December 1997 and November 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the deep bedrock interval (>400 ft bgs) in the Rome Formation. The average static groundwater level in the well is 0.02 ft above the ground surface, indicating artesian conditions. Presampling depth-to-water measurements for the well indicate moderate (<7 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 372 – 498 mg/L;
- pH (field measurements) of 6.9 – 8.0;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for 40 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Four groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.827 mg/L in December 1995) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Two groundwater samples had uranium concentrations above the analytical reporting limit and the maximum result (0.004 mg/L in May 1994) is substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected at low levels in three groundwater samples: 1,2-dichloropropane (2 μg/L) and chloroform (7 μg/L) in January 1992, 2-butanone (4 μg/L) in December 1997, and acetone (9 μg/L) in June 1998. These results are considered outliers because these compounds are common laboratory reagents that were detected only once.

5.4 GROSS ALPHA ACTIVITY

Seven groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (102 pCi/L in January 1992) being substantially above the MCL for gross alpha activity (15 pCi/L). However, this gross alpha result was identified as an outlier (none of the other results exceed 10 pCi/L) and is probably an analytical artifact.

5.5 GROSS BETA ACTIVITY

Seventeen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (17 pCi/L in January 1992) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-217

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1987, completed with a screened monitored interval from 165 to 180 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). This well is located on the crest of Chestnut Ridge southwest of the west end of Y-12, about 100 ft directly east (hydraulically downgradient) of the unlined portion (about 22,500 ft^2) of the eastern end of Industrial Landfill IV. This landfill began operating in 1989 in accordance with a permit issued by the TDEC-DSWM that allows for the disposal of nonhazardous, nonradioactive industrial wastes (including cardboard, plastics, rubber, scrap metal, wood, and paper) and special wastes (e.g., asbestos and beryllium oxide) generated from DOE operations at Y-12 and elsewhere on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-eight groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 33 samples between February 1988 and July 1997, and the low-flow sampling method used to obtain 15 samples between January 1998 and July 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the Knox Group (Copper Ridge Dolomite). The average static groundwater level in the well is 107 ft bgs. Presampling depth-to-water measurements for the well indicate substantial (10-25ft) water-level fluctuations. However, the difference between the presampling groundwater elevations may be at least partially attributable to the hydraulic performance of the well. Whenever the conventional sampling method is used, the well typically purges dry and the water level is very slow to recover back to the presampling level. Slow recovery of the water level suggests that the monitoring interval intercepts groundwater flowpaths with relatively low hydraulic conductivity. The average result of several falling head permeability tests performed in well GW-217 (Jones 2004) indicates that the hydraulic conductivity of the bedrock near the well is about 1.2×10^{-5} cm/s (0.034 ft/day).

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 106 – 200 mg/L;
- pH (field measurements) of 5.2 – 8.6;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals (except boron) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Also, as noted in Section 4.0, elevated boron concentrations potentially reflect groundwater contamination. The following discussion of contaminant concentrations in the well is based on the analytical results reported for 37 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Thirty-six groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (1.1 mg/L in January 1995) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Four groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.001 mg/L in July 1991, October 1991, and January 1993) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected in five groundwater samples. Acetone was detected in samples collected from the well in July 1991 (18 μg/L), January 1998 (120 μg/L), and February 2000 (9.4 μg/L). A trace of xylene (0.51 μg/L) was reported for the sample collected in July 2003. The acetone and xylene results are probably analytical artifacts and are considered to be outliers. Trace levels of PCE (0.47 μg/L), TCE (0.41 μg/L), and c12DCE (0.49 μg/L) were detected in the sample collected from the well in January 2004. The significance of these results is questionable because the compounds were not detected in the subsequent sample (July 2004).

5.4 GROSS ALPHA ACTIVITY

Eight groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (5.61 pCi/L in October 1991) being below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Eighteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (45.1 pCi/L in April 1992) being slightly below the SDWA screening level for gross beta activity (50 pCi/L). However, the historical maximum gross beta activity is clearly an outlier value (none of the other gross beta results exceed 16 pCi/L).

5.6 Other

Historical monitoring results show that total boron concentrations in the groundwater at the well consistently exceeded the boron UTL (0.028 mg/L) for groundwater in the Knox Group (HSW 1995) and were more than an order-of-magnitude higher than evident in most wells in the Knox Group. Available data show that boron concentrations in the well steadily increased through October 1994 (0.22 mg/L) and slowly decreased thereafter, dropping below 0.1 mg/L in July 2000 for the first time since January 1993 (Figure 1). This pattern suggests a "pulse" of elevated boron transported via the groundwater flowpaths intercepted by the well. This well is hydraulically down gradient along geologic strike from the eastern (unlined) section of Industrial Landfill IV and groundwater in the Knox Group exhibits preferred flow along strike-parallel flowpaths. Because boron solute species are uncharged, they are probably not extensively absorbed onto mineral surfaces and are, therefore, highly mobile in groundwater (Hem 1985). Also, results of falling head permeability tests in the well (see Section 3.0) support advective transport of boron to the well within the time period between initial disposal of wastes in the landfill (October 1989) and a conspicuous concentration "spike" (0.69 mg/L) in January 1992. Moreover, historical data show that three of the four lowest boron concentrations (≤0.0074 mg/L) were reported for groundwater samples collected from the well before mid-1989, when the Industrial Landfill IV began receiving waste.

WELL GW-219

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in July 1987, completed with a screened monitored interval from 4.3 to 11.3 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley (BCV) at the northeast corner of the Bldg. 9418-3 Uranium Vault, which is in the south-central section of Y-12, adjacent to Upper East Fork Poplar Creek (UEFPC) near the intersection of Chromium Drive and Third Street. Constructed of concrete, the subsurface vault is 16 ft wide, 4 ft deep, and 20 ft long, with a 3-ft square floor drain in one corner and a pair of 2-ft diameter manholes in the concrete cap. Between 1960 and 1964, the vault was filled with an estimated 224 tons of uranium oxide dross (DOE 1998).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fourteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain samples in March and April 1997, and the low-flow sampling method used to obtain 12 samples between September 1998 and November 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Maynardville Limestone (upper Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements for the well show that the static groundwater level in the well occurs at an average depth of about 6 ft bgs and exhibits seasonal fluctuations of about 4 ft. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-219 indicate flow primarily to the east, parallel with geologic strike in the Maynardville Limestone. Additionally, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local groundwater flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 275 - 375 mg/L;
- pH (field measurements) of 6.7 – 7.4;
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and

- total concentrations trace metals (except uranium) that are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The Y-12 GWPP requested biological testing to assess microbial activity in groundwater at this well in April 2004. The results (shown below) are qualitative counts of bacterial colonies of four specific bacteria types, estimates based on the appearance of the sample after an eight- to ten-day growth period.

Date Sampled	Bacteria Activity (colony forming units/milliliter)			
	Heterotrophic Aerobic	Iron-Related	Slime Forming	Sulfate- Reducing
04/27/04	1,000	5,000	1,000	1,000

These results indicate the presence of various bacteria in the groundwater at this well.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the respective monitoring data reported for the groundwater samples collected from the well since January 1991, uranium, gross alpha, and gross beta are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Five of the groundwater samples had nitrate (as N) at or above the analytical reporting limit, with all of the results being less than 1 mg/L and substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Each groundwater sample had total uranium concentrations above the applicable analytical reporting limit (Table 1), with ten of the results, including the historical maximum concentration (0.6 mg/L in November 1991), being more than an order-of-magnitude above the MCL for total uranium (0.03 mg/L). The most likely source of the uranium in the groundwater at this well is the Bldg. 9418-3 Uranium Vault (DOE 1998). Also, under the neutral pH of the groundwater samples, uranium tends to complex with inorganic anions (e.g., carbonate) which may facilitate transport in the groundwater system (Fetter 1993).

A time-series plot of the uranium results for each groundwater sample shows a fairly indeterminate long term trend (Figure 1), as illustrated by the uranium concentrations reported for the samples collected in December 1999 (0.599 mg/L) and November 2004 (0.525 mg/L). The indeterminate trend for uranium in the well suggests long-term and continued influx from an active source of uranium. Also, the uranium concentrations exhibit proportionally large temporal fluctuations, as illustrated by the 65% concentration increase between May 2002 (0.359 mg/L) and November 2002 (0.584 mg/L), followed by the 50% concentration decrease through June 2003 (0.285 mg/L), a 70% concentration increase through November 2003 (0.485 mg/L), and a 30% concentration decrease through April 2004 (0.338 mg/L). Assuming advective transport of uranium (complexes) in the groundwater, the temporal changes in uranium concentrations potentially reflect corresponding changes in the relative flux of the uranium along the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.3 VOLATILE ORGANIC COMPOUNDS

Very low (estimated) concentrations of acetone (3 µg/L), PCE (0.3 µg/L), and TCE (2 µg/L) were detected in the samples collected in March 1997, September 1997, and May 2001, respectively; these results are probably sampling or analytical artifacts.

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity above the applicable MDA and corresponding CE was reported for each groundwater sample (Table 1), and all of these gross alpha results exceed the MCL for gross alpha activity (15 pCi/L). Most of the results exceed 100 pCi/L, with the historical maximum (585 pCi/L in March 1997) and historical minimum (26 pCi/L in October 2000) values being suspected outliers compared to the other gross alpha results, which range between about 80 and 200 pCi/L. Historical data indicate that uranium isotopes (U-234 and U-238) are the likely source of the gross alpha activity in the groundwater (Table 1).

A time-series plot of gross alpha activity for each groundwater sample shows a fairly indeterminate long term trend (Figure 2), as illustrated by the results reported for the samples collected in June 2000 (100 pCi/L) and November 2004 (110 pCi/L). The indeterminate trend for gross alpha activity suggests long-term and continued flux of uranium isotopes via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.5 GROSS BETA ACTIVITY

Gross beta activity above the applicable MDA and corresponding CE was reported for each groundwater sample (Table 1), and all but two of these results exceed the SDWA screening level (50 pCi/L) for a 4 millirem dose equivalent (the MCL for gross beta activity). Most of the results exceed 100 pCi/L, with the historical maximum value (837 pCi/L in March 1997) and historical minimum value (24 pCi/L in October 2000) being suspected outliers compared to the other gross beta results. Uranium isotopes (U-234 and U-238) and related decay products are the primary source of the gross beta activity in the groundwater samples (Table 1). In addition to uranium isotopes, five of the samples were analyzed for technetium-99 (Tc-99), which also is a beta-emitting radionuclide, with the Tc-99 activity below the MDA for three samples and slightly above the MDA for two samples.

A time-series plot of gross beta activity for each groundwater sample shows an indeterminate long-term trend (Figure 2), as illustrated by the results reported for the samples collected in June 2000 (89 pCi/L) and November 2004 (97 pCi/L). Relatively unchanged levels of gross beta activity support long-term and continued flux of uranium isotopes via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

WELL GW-220

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1985, completed with a screened monitored interval from 31 to 45.2 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and well screen (0.01 slot). This well forms a cluster with wells GW-150 and GW-151 and is located in Bear Creek Valley near the east end of Y-12, immediately east of the Upper East Fork Poplar Creek (UEFPC) distribution channel on the east side (hydraulically downgradient) of New Hope Pond (NHP). Closed in 1988 and covered with a multi-layer, low-permeability cap in 1989, NHP was an unlined surface impoundment constructed in 1963 to regulate the quantity and quality of surface water exiting Y-12 via UEFPC. Lake Reality is a lined surface impoundment that was built in 1988 to replace NHP. During normal operations, flow in UEFPC bypasses Lake Reality and is directed through the concrete-lined distribution channel,, which borders the south and east sides of NHP/Lake Reality.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Sixty-five groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 45 samples between February 1986 and May 1997, and the low-flow sampling method used to obtain 20 samples between December 1997 and November 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maynardville Limestone (upper Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 12 ft bgs and exhibits seasonal fluctuations of 4 to 14 ft. Also, presampling groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are about 0.8 ft lower in well GW-220 than well GW-151, which is completed at a greater depth (95 ft bgs) in the Maynardville Limestone. Based on the distance (52 ft) between the monitored interval midpoint (elevation) in each well, the contemporaneous groundwater elevations indicate upward vertical hydraulic gradients (0.004 - 0.046) during seasonally high and low flow conditions.

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-220 indicate components of flow to the north/northeast toward the UEFPC drainage system and to the east parallel with geologic strike in the Maynardville Limestone. However, a gravel and perforated-pipe underdrain constructed beneath portions of the UEFPC distribution channel (see Section 1.0) substantially influences local groundwater flow directions. Additionally, local groundwater flow patterns near NHP are influenced by the full-time operation of a groundwater extraction and treatment system intended to intercept and contain the VOC-contaminated groundwater in the Maynardville Limestone near the east end of Y-12, as required by the CERCLA Action Memorandum (DOE 1999). Beginning in October 2001, groundwater has been pumped from a well (GW-845) located about 500 ft south-southeast of well GW-220 and is treated on-site to remove VOCs, particulates, iron, and manganese. Long-term operation of the system has generally maintained 15 to 17 ft of drawdown in the immediate vicinity of well GW-845 and has established an elongated zone of influence that extends parallel with geologic strike for at least 900 ft to the east (downgradient) and 600 ft to the west (upgradient) of the pumping well (DOE 2002).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 190 – 366 mg/L;
- pH of 4.0 – 7.8 (field measurements);
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the respective monitoring data reported for the groundwater samples collected from the well since January 1991, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Nitrate was detected in 42 groundwater samples (three samples were not analyzed for nitrate), with the highest concentration (3.3 mg/L in August 2000) being substantially below the drinking water MCL for nitrate (10 mg/L). Moreover, the historical maximum nitrate concentration appears to be an outlier because only two of the remaining nitrate values exceed 1 mg/L.

5.2 URANIUM

Only six groundwater samples had uranium concentrations at or above the applicable analytical reporting limit, with the highest values (0.001 mg/L in April 1991, April 1993, November 1993, and May 1994) being an order-of-magnitude lower than the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in 42 groundwater samples (Table 1): CTET, chloroform, PCE, TCE, trichlorofluoromethane (TCFM), 12DCE, and 11DCE. These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and UEFPC watersheds. In the UEFPC watershed east of the flow divide, which occurs near the west end of Y-12, the VOC plume in the Maynardville Limestone appears to originate near the Fire Training Facility in the southwestern section of Y-12, extends eastward (parallel with geologic strike) and mixes with VOCs released from several sources in the central and eastern Y-12 areas, and enters Union Valley east of the ORR boundary along Scarboro Road (DOE 1998). In October 2000, full-time operation of a groundwater remediation system began to help intercept and contain the (CTET-dominated) portion of the VOC plume in the eastern Y-12 area, as required by the CERCLA Action Memorandum (DOE 1999). Operation of the system involves pumping groundwater from an extraction well (GW-845) completed in the Maynardville Limestone about 500 ft south-

southeast (across geologic strike) of well GW-220; treating the groundwater on-site to remove particulates, iron, manganese, and VOCs; and discharging the effluent into UEFPC.

The primary compound in each groundwater sample is CTET (Table 1), with a concentration of 1,000 μg/L or more reported for seven of the samples collected since August 2000. Secondary constituents are PCE, TCE, and chloroform. The most recent (low-flow sampling) results for TCE and chloroform show concentrations above 100 μg/L and 50 μg/L, respectively. Concentrations of 12DCE remain below 50 μg/L and only trace levels (2 μg/L or less) of TCFM have been detected. Also, the most recent sampling results show that the concentrations of CTET, PCE, and TCE substantially exceed respective drinking water MCLs (Table 1).

A time-series plot of summed VOC concentrations for each groundwater sample shows a cyclic but clearly increasing long-term trend (Figure 1). Monitoring (conventional sampling) results obtained through May 1997 show cyclic temporal fluctuations in VOC concentrations, with the highest concentrations typically detected in samples obtained during seasonally low groundwater flow conditions (summer and fall). Similar temporal fluctuations are less evident from subsequent (low-flow sampling) VOC results, which instead show a steadily increasing concentration trend that appears to continue in response to the full-time operation of groundwater extraction well GW-845 (Figure 1). Also, concurrently increasing concentration trends are evident for each individual VOC (except TCFM), which suggests an overall increase in the relative flux of dissolved VOCs via the groundwater flow/transport pathways intercepted by the monitored interval for the well.

5.4 GROSS ALPHA ACTIVITY

Eight groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (4.55 pCi/L in August 1991) being substantially below the drinking water MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Sixteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (36.9 pCi/L in August 1992) being less than the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). Furthermore, this result is a suspected outlier because all but one (18.8 pCi/L in April 1993) of the other detected results are less than 10 pCi/L.

WELL GW-221

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1985, completed with a screened monitored interval from 146 to 158 ft bgs, and constructed with 4.5-inch diameter PVC (#40) riser casing and screen (0.01 slot). The well is located on the crest of Chestnut Ridge south of Y-12, about 100 ft southeast (hydraulically downgradient) of the United Nuclear Corporation Site (UNCS). The UNCS is a closed facility that was used for the disposal of cement-fixed sludge, radiologically-contaminated soils, and demolition debris. A multilayer, low-permeability cap was installed at the site in 1992 in accordance with the CERCLA ROD signed in 1991 (DOE 1991).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fifty-five groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 41 samples between February 1986 and April 1997, and the low-flow sampling method used to obtain 14 samples between November 1997 and August 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the Knox Group. Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 75 ft bgs and exhibit substantial (10 - 25 ft) water-level fluctuations, which is typical of many Knox Group wells on Chestnut Ridge.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 106 – 270 mg/L;
- pH (field measurements) of 6.0 – 8.0;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for 36 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Thirty-four groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (2.4 mg/L in August 2000) being below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Three groundwater samples had uranium concentrations above the applicable analytical reporting limit, and results for each sample (0.001 mg/L) is substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were not detected in any of the 21 groundwater samples analyzed for VOCs between January 1991 and April 1997.

5.4 GROSS ALPHA ACTIVITY

Eight groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (13.31 pCi/L in August 2004) being slightly below the MCL for gross alpha activity (15 pCi/L). This result may be an outlier because the next highest value (4.42 pCi/L in October 1992) is much lower.

5.5 GROSS BETA ACTIVITY

Eleven groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (10.5 pCi/L in October 1992) being substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-222

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1985, completed with a screened monitored interval from 18 to 25 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and well screen (0.01 slot). The well forms a cluster with wells GW-154 and GW-223 and is located in Bear Creek Valley (BCV) at the east end of Y-12, near the former Oil Skimmer Basin (OSB) immediately west (hydraulically upgradient) of the New Hope Pond (NHP)/Lake Reality. Located near the inlet to NHP, the OSB was a 25 x 40 ft sediment-accumulation basin and oil/water separator; visual evidence of a direct hydraulic connection with the OSB was observed during installation of wells GW-154 and GW-223 (Geraghty & Miller, Inc. 1989). Closed in 1988 and covered with a multi-layer, low-permeability cap in 1989, NHP was an unlined surface impoundment constructed in 1963 to regulate the quantity and quality of surface water exiting Y-12 via Upper East Fork Poplar Creek (UEFPC). Lake Reality is a lined surface impoundment that was built in 1988 to replace NHP. During normal operations, flow in UEFPC is directed through a concrete-lined diversion channel bordering the south and east sides of NHP/Lake Reality. Until December 1996 when flow was rerouted to bypass Lake Reality, surface flow in the UEFPC distribution channel discharged into Lake Reality (and exited through a weir in the western berm). Beginning in July 1998, flow in the UEFPC distribution channel was diverted through the Lake Reality spillway, which discharges into the mainstream of UEFPC directly north (downstream) of Lake Reality.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-four groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 30 samples between February 1986 and November 1996, and the low-flow sampling method used to obtain four samples between June 2000 and November 2004. This sampling history encompasses three time gaps when samples were not collected from the well: May 1991 – November 1994; November 1996 – June 2000; and October 2000 – June 2004.

The well infrequently yields slightly turbid unfiltered groundwater samples containing elevated total (unfiltered sample) iron concentrations compared to other wells, which suggests that groundwater sampling activities disturb silt, clay, and other similarly fine-grained material distributed within the filter pack surrounding the well screen and/or settled onto the bottom of the well. The filter pack may be the source of the suspended material because the low-flow sampling procedure would not typically be expected to disturb sediments on the bottom of the well. However, the intake for the sampling pump in this well is located about 1.5 ft from the bottom of the screen, and collection of samples with elevated iron concentrations may reflect sediment from the bottom of the well.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maynardville Limestone (upper Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 7 ft bgs and does not exhibit wide seasonal fluctuations (<2 ft since 1991). Also, presampling water-level measurements recorded during contemporaneous sampling events (i.e., within 24 hours) performed before NHP was closed and capped show that groundwater elevations in well GW-222 were consistently higher than evident in well GW-154, which is completed at a shallower depth in the Maynardville Limestone (11 ft bgs), and were usually slightly lower than evident in well GW-223, which is completed deeper (90.5 ft bgs) in the Maynardville Limestone (Figure 1). The relationships between the groundwater elevations before closure of NHP indicate strongly upward vertical hydraulic gradients from the bedrock interval (GW-222 and GW-223) to the water table interval (GW-154). In contrast, the presampling groundwater elevations determined from contemporaneous sampling events performed after the NHP was closed and capped show groundwater elevations in well GW-154 being consistently higher than evident in wells GW-222 and GW-223 (Figure 1). The relationships between these groundwater elevations reflect downward gradients (0.014 – 0.067) from the water table interval (GW-154) to the shallow bedrock interval (GW-222) and lesser downward vertical hydraulic gradients (0.001 - 0.008) within the bedrock interval from GW-222 to GW-223. Thus, the closure of NHP (and the OSB) and installation of the low-permeability cap at the site appears to have reversed the local vertical hydraulic gradients in the Maynardville Limestone.

Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-222 indicate east-northeasterly flow toward the UEFPC drainage system. However, a gravel and perforated-pipe underdrain constructed beneath portions of the UEFPC distribution channel (see Section 1.0) substantially influences local groundwater flow directions. Additionally, local groundwater flow patterns are influenced by the full-time operation of a groundwater extraction and treatment system intended to intercept and contain the VOC-contaminated groundwater in the Maynardville Limestone near NHP, as required by the CERCLA Action Memorandum (DOE 1999). Beginning in October 2000, groundwater has been pumped from a well (GW-845) located about 1,200 ft southeast of well GW-222 and is treated on-site to remove particulates, iron, manganese, and VOCs. Long-term operation of the system has generally maintained 15 to 17 ft of drawdown in the immediate vicinity of well GW-845 and has established an elongated zone of influence that extends parallel with geologic strike for at least 900 ft to the east (downgradient) and 600 ft to the west (upgradient) of the pumping well (DOE 2002). However, there are insufficient data to determine if groundwater elevations in well GW-222 show any response to the operation of well GW-845.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples collected to date show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 248 – 652 mg/L, excluding a suspected outlier (130 mg/L) in March 1996;
- pH (field measurements) of 6.8 – 7.4;
- strongly negative oxidation-reduction potential (REDOX) and low dissolved oxygen (DO) indicative of reducing conditions (e.g., REDOX = -132 mV and DO = 0.12 ppm in November 2004);
- elevated concentrations of chloride (>20 mg/L), sodium (>20 mg/L), and sulfate (>30 mg/L) compared to other wells of similar depth in the Maynardville Limestone;
- low molar proportions of fluoride, nitrate, and potassium (<10% of total anions/cations);
- unusually high total iron concentrations (e.g., 5.15 mg/L in November 2004); and
- total concentrations of other trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

It is not clear if the elevated chloride, sodium, and sulfate concentrations typical of the groundwater samples indicate contamination from one or more sources hydraulically upgradient of the well or if they reflect the range natural geochemical variability in the Maynardville Limestone. Also, the groundwater from this well contains a mixture of chlorinated hydrocarbons (see Section 5.3) and elevated chloride concentrations in the groundwater samples may be a consequence of the biologically mediated degradation (reductive dechlorination) of these compounds (Hinchee et al. 1995). In any case, the sampling results reflect a general reduction in TDS that is primarily attributable to substantially reduced levels of chloride and sulfate, as illustrated by the chloride results reported for the groundwater samples collected in October 1990 (141 mg/L), August 1995 (55 mg/L), October 2000 (29.7 mg/L), and November 2004 (13 mg/L).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, the principal contaminants present in the groundwater at this well are uranium, VOCs, and gross alpha activity.

5.1 NITRATE

Seven of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.71 mg/L in February 1995) being substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

All of the groundwater samples collected to date had uranium concentrations above the applicable analytical reporting limit (Table 1), with results for 21 of the samples being greater than or equal to the drinking water MCL for uranium (0.03 mg/L). The specific source of the uranium in the groundwater at this well has not been identified, but is probably the former OSB, which is believed to have retained uranium-contaminated oils (DOE 1998). Considering the fairly neutral pH of the groundwater in the well, the uranium is probably present as uranyl cations combined with available anions in the groundwater (Fetter 1993), including carbonate dissolved from the Maynardville Limestone.

Total uranium concentrations reported for the groundwater samples collected to date range between the historical minimum value of 0.009 mg/L in October 1987 and April 1999, and the historical maximum value of 0.364 mg/L in August 1990 (Table 1). However, there is a clear distinction between the uranium results reported for samples collected before and after NHP (and the OSB) was closed and capped. Indeed, all of the uranium concentrations that are less than the drinking water MCL were reported for groundwater samples collected before closure of the site. After closure of NHP, the uranium concentrations are higher, most being above the MCL, and the uranium results show substantially greater temporal variation (Figure 2), with notably sharp concentration "spikes" indicated by results for the samples collected in May 1990 (0.354 mg/L), August 1990 (0.364 mg/L), February 1995 (0.26 mg/L), and March 1996 (0.28 mg/L). Also, the increased uranium concentrations evident after closure of NHP generally coincide with the concurrent change from an upward vertical hydraulic gradient to a downward vertical hydraulic gradient (see Section 3.0).

Total uranium concentrations detected in unfiltered groundwater samples from well GW-222 typically are higher than reported for samples of the deeper groundwater from well GW-223 (e.g., 0.0412 mg/L in February 2004), but are lower than uranium concentrations reported for the samples of the shallower groundwater in well GW-154 (e.g., 0.477 mg/L in February 2004). Considering the downward vertical hydraulic gradients indicated by presampling groundwater elevations recorded following closure of NHP (and the former OSB) and installation of the low-permeability cap at the site (see Section 3.0), increased recharge of uranium-contaminated groundwater from the shallow flow system may help maintain the (elevated) uranium concentrations in the deeper groundwater.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample collected to date (Table 2): CTET, chloroform (CLF), PCE, TCE, 12DCE (c12DCE) and VC. These compounds are components of an essentially contiguous commingled plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide separating the Bear Creek and UEFPC watersheds. East of the flow divide in the UEFPC watershed, the VOC plume in the Maynardville Limestone appears to originate near the Fire Training Facility in the southwestern section of Y-12, extends eastward (parallel with geologic strike) and mixes with VOCs released from several sources in the central and eastern Y-12 areas, and enters Union Valley east of the ORR boundary along Scarboro Road (DOE 1998). As noted in Section 3.0, full-time operation of a groundwater extraction and treatment system began in October 2000 to intercept and contain the (CTET-dominated) portion of the VOC plume in the Maynardville Limestone near NHP.

Historical data show CTET, PCE, and 12DCE as the primary VOCs in the groundwater samples, with each compound having at least one concentration above 100 μg/L (Table 2). However, the most recent data (June and November 2004) show substantially lower concentrations of these and other VOCs, with the highest concentration (5 μg/L) reported for PCE and c12DCE. These results confirm the sharp decrease in VOC concentrations indicated by the VOC levels detected in the sample collected in October 2000. The recent decrease in VOC concentrations in the groundwater samples from this well coincides with the full-time operation of groundwater extraction well GW-845 (see Section 3.0).

Historical data show that VOCs are not present in the shallow groundwater at well GW-154 and, as illustrated by the selected data summarized below, similar levels of VOCs are evident in the groundwater at wells GW-222 and GW-223.

VOC	Concentration (µg/L)					
	June 2000		October 2000		Nov. 2004	Aug.2004
	GW-222	GW-223	GW-222	GW-223	GW-222	GW-223
PCE	110	110	6	25	5	18
TCE	29	31	3 J	13	2 J	9
12DCE	45	38	15	95	5	39
CTET	28	.	.	.	.	
CLF	5	.	.	.	.	
VC	.	.	1 J	3 J	2 J	25
Summed VOCs	217	178	25	136	14	91

Note: "." = Not detected; J = Estimated value below analytical reporting limit

The lack of VOCs in the shallow groundwater from well GW-154 essentially eliminates the OSB as a likely source of the VOCs and shows that the presence of VOCs in the deeper groundwater from wells GW-222 and GW-223 does not result from local vertical infiltration of VOC-contaminated groundwater from the shallow flow system. Instead, the VOCs in the groundwater from these wells probably result from lateral migration from upgradient sources (west of the well) via strike-parallel groundwater flow/transport pathways in the Maynardville Limestone.

A time-series plot of the summed concentrations of VOCs detected in the groundwater samples, which includes a combination of quarterly and semiannual sampling results and encompasses several gaps in the sampling history for the well (see Section 2.0), shows an indeterminate long-term concentration trend dominated by wide temporal concentration fluctuations (Figure 3). Summed VOC concentrations were below 50 µg/L before closure of NHP but increased above 500 µg/L immediately after closure. Since that time, concentrations have varied, possibly showing an overall decrease with the lowest summed VOC concentration in the June 2004 sample (Table 2).

5.4 GROSS ALPHA ACTIVITY

All of the groundwater samples collected since January 1990 had gross alpha activity above the applicable MDA and corresponding CE; with values above the drinking water MCL (15 pCi/L) reported for each of these samples (Table 1). Comparable levels of gross alpha activity were reported for samples collected before January 1990, but these results are considered qualitative because the sample-specific MDA and corresponding CE are not available for these samples. Uranium isotopes are the source of the elevated gross alpha activity, as indicated by analytical results for seven of the samples collected from the well to date, which show U-234 and U-238 levels ranging between from less than 5 pCi/L to slightly above 100 pCi/L (Table 1). As with total uranium (see Section 5.2), contamination associated with the historical operation of the OSB is the suspected source of the uranium isotopes in the shallow groundwater at this well (DOE 1998).

Analytical results for the groundwater samples collected since January 1990 show gross alpha activity ranging between the 18 pCi/L and 118 pCi/L (Table 1), with the most recent values for gross alpha activity (e.g., 30 pCi/L in November 2004) exceeding the drinking water MCL. Also, the samples from this well typically have levels of gross alpha activity that are substantially lower than reported for samples of the shallower groundwater in well GW-154 (e.g., 698 pCi/L in August 2004), but are generally higher than typically evident in samples of the deeper groundwater in GW-223 (e.g., 21 pCi/L in August 2004). With the downward vertical hydraulic gradients evident since the closure of NHP (and the former OSB), these results suggest somewhat limited vertical flux of the uranium isotopes present in the shallow groundwater (water table interval) in the Maynardville Limestone.

A time-series plot of the gross alpha activity reported for groundwater samples collected since January 1990 (i.e., excluding the qualitative results noted above) encompasses several significant gaps in the sampling history for the well (see Section 2.0) and shows an indeterminate trend dominated by wide temporal fluctuations (Figure 4). Because the gross alpha activity of samples collected before 1990 are not shown, the impact from closuring the NHP (and the former OSB) and reversal of the vertical horizontal gradient are unknown. However, the gross alpha concentration trend since 1990 generally mirrors the total uranium trend (Figure 2), and the gross alpha activity trend before 1990 is most likely similar to the uranium trend before 1990.

5.5 GROSS BETA ACTIVITY

All but one of the groundwater samples collected since January 1990 had gross beta activity above the applicable MDA and corresponding CE (Table 1); with results for five samples exceeding the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity). Note, that gross beta activity results for samples collected before January 1990 are qualitative (the sample-specific MDA and CE are not available). As with gross alpha activity, uranium isotopes released from the former OSB are the source of the gross beta activity in the shallow groundwater at this well.

Analytical results for the groundwater samples collected since January 1990 show gross beta activity ranging between the 10 pCi/L and 116 pCi/L (Table 1), with the most recent sampling results (e.g., 41 pCi/L in November 2004) being slightly below the SDWA screening level. Also, as noted previously with gross alpha activity, the samples from this well typically have levels of gross beta activity that are substantially lower than reported for samples of the shallower groundwater in well GW-154 (e.g., 288 pCi/L in August 2004), but are generally higher than typically evident in samples of the deeper groundwater in GW-223 (e.g., 18 pCi/L in August 2004). These results support the similar results for gross alpha activity and reflect the fairly limited vertical flux of the uranium isotopes present in the shallow groundwater (water table interval) in the Maynardville Limestone. A time-series plot of the gross beta activity reported for groundwater samples collected since January 1990 (i.e., excluding the qualitative results noted above) mirrors that of gross alpha activity (Figure 4).

WELL GW-223

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1985, completed with a screened monitored interval from 79 to 90.5 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and well screen (0.01 slot). The well forms a cluster with wells GW-154 and GW-222 and is located in Bear Creek Valley (BCV) at the east end of Y-12, near the former Oil Skimmer Basin (OSB) immediately west (hydraulically upgradient) of the New Hope Pond (NHP)/Lake Reality. Located near the inlet to NHP, the OSB was a 25 x 40 ft sediment-accumulation basin and oil/water separator; visual evidence of a direct hydraulic connection with the OSB was observed during installation of wells GW-154 and GW-223 (Geraghty & Miller, Inc. 1989). Closed in 1988 and covered with a multi-layer, low-permeability cap in 1989, NHP was an unlined surface impoundment constructed in 1963 to regulate the quantity and quality of surface water exiting Y-12 via Upper East Fork Poplar Creek (UEFPC). Lake Reality is a lined surface impoundment that was built in 1988 to replace NHP. During normal operations, flow in UEFPC is directed through a concrete-lined diversion channel bordering the south and east sides of NHP/Lake Reality. Until December 1996 when flow was rerouted to bypass Lake Reality, surface flow in the UEFPC distribution channel discharged into Lake Reality (and exited through a weir in the western berm). Beginning in July 1998, flow in the UEFPC distribution channel was diverted through the Lake Reality spillway, which discharges into the mainstream of UEFPC directly north (downstream) of Lake Reality.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-one groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 30 samples between February 1986 and November 1996, and the low-flow sampling method used to obtain 11 samples between September 1999 and August 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the bedrock interval in the Maynardville Limestone (upper Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 7 ft bgs and exhibits minor (<3 ft) seasonal fluctuations, although a particularly sharp "spike" in the groundwater elevation is indicated by presampling water-level measurement recorded in July 2001 (Figure 1). Also, presampling water-level measurements recorded during contemporaneous sampling events (i.e., within 24 hours) performed after the closure of NHP (and the OSB) show groundwater elevations in well GW-223 being consistently lower than evident in well GW-154 and GW-222, which are completed at shallower depths in the Maynardville Limestone (11 ft and 25 ft bgs, respectively). Based on the distance between the monitored interval midpoint (elevation) in the wells, the relationships between the groundwater elevations indicate: (1) downward vertical hydraulic gradients (0.014 - 0.067) from the water table interval (GW-154) to the shallow bedrock (GW-222) and (2) lesser downward vertical hydraulic gradients (0.001 - 0.008) within the bedrock interval between GW-222 and GW-223. Presampling groundwater elevations determined from contemporaneous sampling events performed before the closure of NHP show higher groundwater elevations in well GW-223 (and GW-222) relative to well GW-154 and indicate upward hydraulic gradients (Figure 1). Thus, the closure of NHP (and the OSB) and installation of the low-permeability cap at the site appears to have reversed local vertical hydraulic gradients.

Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-223 indicate east-northeasterly flow toward the UEFPC drainage system. However, a gravel and perforated-pipe underdrain constructed beneath portions of the UEFPC distribution channel (see Section 1.0) substantially influences local groundwater flow directions. Additionally, local groundwater flow patterns are influenced by the full-time operation of a groundwater extraction and treatment system intended to intercept and contain the VOC-contaminated groundwater in the Maynardville Limestone near NHP, as required by the CERCLA Action Memorandum (DOE 1999). Beginning in October 2000, groundwater has been pumped from a well (GW-845) located about 1,200 ft southeast of well GW-223 and is treated on-site to remove particulates, iron, manganese, and VOCs. Long-term operation of the system has generally maintained 15 to 17 ft of drawdown in the immediate vicinity of well GW-845 and has established an elongated zone of influence that extends parallel with geologic strike for at least 900 ft to the east (downgradient) and 600 ft to the west (upgradient) of the pumping well (DOE 2002). Groundwater elevations in well GW-223 do not appear to exhibit any direct response to the operation of well GW-845 (Figure 1).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 303 – 510 mg/L;
- pH (field measurements) of 6.13 – 7.31, excluding a suspected outlier (5) in August 1996;
- elevated concentrations of sulfate (>30 mg/L) and chloride (>20 mg/L) compared to other wells of similar depth in the Maynardville Limestone;
- low molar proportions of sodium, potassium, and nitrate (<10% of total anions/cations);
- total concentrations of trace metals (excluding uranium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

It is not clear if the elevated sulfate and chloride concentrations typical of the groundwater samples reflect natural geochemical characteristics in the Maynardville Limestone, or if the elevated concentrations are the result of contamination from one or more sources hydraulically upgradient of the well. Also, the groundwater contains a mixture of chlorinated hydrocarbons (see Section 5.3) and elevated chloride concentrations in the groundwater samples may be a consequence of the biologically mediated degradation (dechlorination) of these compounds (Hinchee et al. 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on respective monitoring data reported for the groundwater samples collected from the well since January 1991, the principal contaminants present in the groundwater at this well are uranium, VOCs, and gross alpha activity.

5.1 NITRATE

Only five of the groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (0.35 mg/L in November 1994) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

All but one of the groundwater samples had uranium concentrations above the applicable analytical reporting limit (Table 1); including seven results that slightly exceed the MCL for uranium (0.03 mg/L). The specific source of the uranium in the groundwater at this well has not been identified, but is probably the former OSB, which is believed to have retained uranium-contaminated oils (DOE 1998), particularly in light of the direct hydraulic connection observed during installation of the well (see Section 1.0). Considering the relatively neutral pH of the samples, the uranium is probably present as uranyl cations combined with available anions in the groundwater (Fetter 1993), including carbonate dissolved from the Maynardville Limestone, which may greatly increase the relative mobility of uranium in the groundwater flow system.

Excluding the non-detect result reported for the groundwater sample collected in November 1994, total uranium concentrations range between the historical minimum value of 0.005 mg/L in February 1991 and the historical maximum value of 0.0465 mg/L in August 2004 (Table 1). Indeed, all of the uranium concentrations that exceed the MCL have been reported for groundwater samples collected since July 2001 (0.0353 mg/L). These results also illustrate the clearly increasing long-term concentration trend for uranium in the well since closure of NHP (Figure 2). The increasing trend may reflect a corresponding increase in the relative flux of uranium along the groundwater flow/transport pathways intercepted by the monitored interval in the well, possibly in response to the testing and full-time operation of groundwater extraction well GW-845 (see Section 3.0). Additionally, uranium concentrations detected in samples from well GW-223 typically are an order-of-magnitude lower than reported for samples of the shallower groundwater from well GW-154 (e.g., 0.411 mg/L in August 2003). Considering the downward vertical hydraulic gradients indicated by presampling groundwater elevations recorded following closure of NHP (and the former OSB) and installation of the low-permeability cap at the site (see Section 3.0), increased recharge of uranium-contaminated groundwater from the shallow flow system may help maintain the (elevated) uranium concentrations in the deeper groundwater.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in each groundwater sample (Table 2): CTET, chloroform (CLF), PCE, TCE, 12DCE (c12DCE) and VC. These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide separating the Bear Creek and UEFPC watersheds. East of the flow divide in the UEFPC watershed, the VOC plume in the Maynardville Limestone appears to originate near the Fire Training Facility in the southwestern section of Y-12, extends eastward (parallel with geologic strike) and mixes with VOCs released from several sources in the central and eastern Y-12 areas, and enters Union Valley east of the ORR boundary along Scarboro Road (DOE 1998). As noted in Section 3.0, full-time operation of a groundwater extraction and treatment system began in October 2000 to intercept and contain the (CTET-dominated) portion of the VOC plume in the Maynardville Limestone near NHP.

The primary VOCs in the groundwater samples are PCE, TCE, and 12DCE (c12DCE), each of which were detected in each sample (Table 2), with the most recent sampling results (February and August 2004) showing PCE and TCE concentrations above respective MCLs (5 µg/L).

Historical maximum concentrations of PCE (420 µg/L in November 1996), TCE (110 µg/L in November 1996), and 12DCE (95 µg/L in October 2000) substantially exceed the highest concentrations of secondary VOCs in the samples; CTET (30 µg/L in May 1991), CLF (11 µg/L in August 1996), and VC (6 µg/L in January 2001). Also, the secondary VOCs are detected infrequently, with CTET and CLF detected (excluding false positive results) in only one of the samples collected since September 1999 and June 1996, respectively, and VC detected only in samples collected since October 2000 (3 µg/L), including the sample collected most recently (2 µg/L in August 2004). The bulk of the results for the secondary VOCs are estimated values below 5 µg/L, although the low levels of VC equal or slightly exceed the MCL (2 µg/L).

As illustrated by the selected data summarized below, none of the VOCs detected in the groundwater samples from well GW-223 have been detected in samples of the shallower groundwater from well GW-154, which does not yield VOC-contaminated groundwater.

VOC	Concentration (µg/L)					
	August 1991		August 1996		August 2004	
	GW-154	GW-223	GW-154	GW-223	GW-154	GW-223
PCE	.	190	.	170	.	18
TCE	.	42	.	37	.	9
12DCE	.	30	.	29	.	39
CTET	.	26	.	16	.	.
CLF	.	FP	.	FP	.	.
VC	.	.	.	.	.	2 J
Summed VOCs	0	288	0	252	0	68
Note: "." = Not detected; J = Estimated value below analytical reporting limit						

The lack of VOCs in the shallow groundwater from well GW-154 essentially eliminates the OSB as a likely source of the VOCs and shows that the presence of VOCs in the deeper groundwater from well GW-223 does not result from local vertical infiltration of VOC-contaminated groundwater from the shallow flow system. Instead, the VOCs in the samples from well GW-223 indicate lateral migration from upgradient sources (west of the well) via strike-parallel groundwater flow/transport pathways at depth in the Maynardville Limestone.

A time-series plot of the summed concentrations of VOCs detected in the groundwater samples encompasses the gaps in the sampling history for the well (May 1991 – November 1994 and November 1996 – September 1999) and shows a clearly decreasing long-term concentration trend (Figure 2). Continued reductions in the levels of PCE and TCE account for the bulk of the concentration decrease, as illustrated by the data summarized above, although the 12DCE levels remain relatively unchanged over the same time period. Note that the decreasing levels of PCE and TCE predate the full-time operation of groundwater extraction well GW-845. Thus, decreasing levels of VOCs probably correspond with an overall reduction in the relative flux of VOCs along the groundwater flow/transport pathways intercepted by the monitored interval in the well. Additionally, decreasing concentrations may be attributable to biologically mediated degradation (sequential dechlorination) of PCE and TCE by anaerobic methanotropic organisms in the groundwater. Selected results for some of the indicator parameters, particularly the very low REDOX conditions (Table 3), suggest that the geochemical conditions in the groundwater at this well are within the optimum range for biotic degradation (dechlorination) of chlorinated hydrocarbons. Degradation of PCE and TCE may account for both the decreasing concentrations of these compounds and the relatively unchanged levels of 12DCE, because the REDOX conditions do not suggest the strongly reducing (methanongenic) conditions necessary to transform 12DCE to VC (Chapelle 1996).

5.4 GROSS ALPHA ACTIVITY

All but one of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE (Table 1), including two results that are slightly above the MCL for gross alpha activity (15 pCi/L). Uranium isotopes are the source of the gross alpha activity in the groundwater at this well; each of the samples collected between January 2001 and August 2004 had U-234 and U-238 levels ranging between 3.53 pCi/L and 15.84 pCi/L (Table 1). As with total uranium (see Section 5.2), contamination associated with the historical operation of the OSB is the suspected source of the uranium isotopes in the shallow groundwater at this well (DOE 1998).

Excluding the non-detect gross alpha activity (i.e., <MDA) reported for the groundwater sample collected in March 1996 (Table 1), the other samples define a fairly limited range of gross alpha activity, with the historical maximum value of 24.09 pCi/L in February 2004 and a historical minimum value of 2.05 pCi/L in August 1995. Also, the gross alpha activity reported for each sample is at least an order-of-magnitude lower than reported for samples of the shallower groundwater from well GW-154 (e.g., 698 pCi/L in August 2004). Considering the downward vertical hydraulic gradients indicated by presampling groundwater elevations recorded following closure of NHP (and the former OSB), the relatively low levels of gross alpha activity in the deeper groundwater suggest limited vertical flux of the uranium isotopes present in the shallow groundwater.

A time-series plot of the gross alpha activity (excluding the non-detect result noted above) encompasses the previously mentioned gaps in the sampling history for the well and shows a variable but generally increasing trend (Figure 4). Concurrent increases in U-234 and U-238 levels support this trend (Table 1). This suggests an increase in the relative flux of uranium isotopes via the groundwater flow/transport pathways intercepted by the monitored interval in the well, perhaps in response to the full-time operation of groundwater extraction well GW-845.

5.5 GROSS BETA ACTIVITY

Sixteen of the groundwater samples collected since January 1991 had gross beta activity above the applicable MDA and corresponding CE (Table 1), with the historical maximum value (17.92 pCi/L in August 2004) being substantially below the SDWA screening level (50 pCi/L) for gross beta activity. Although below the screening level, the results for gross beta activity indicate an increasing long-term trend (Table 1), which generally corresponds with the trends for gross alpha activity and uranium isotopes.

WELL GW-225

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1985, completed with an open-hole monitored interval from about 150 to 200 ft bgs, and constructed with nominal 4.5-inch diameter steel (SF25) riser casing. The well is paired with well GW-226 and is located in Bear Creek Valley (BCV) approximately 5,000 ft west of Y-12, on the south side of the main channel of Bear Creek, about 100 ft directly south of Sanitary Landfill I and the Oil Landfarm waste management area (WMA).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-eight groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 30 samples between January 1986 and August 2003, and the low-flow sampling method used to obtain eight samples between March 2001 and July 2004.

An evaluation of the monitoring data available through August 2000 indicated potential bias related to the groundwater sampling method: (unfiltered) samples obtained with the conventional sampling method had substantially higher nitrate concentrations than samples obtained with the low-flow sampling method (AJA 2001). However, results of "paired sampling" performed during March and August 2003, when groundwater samples were collected with the low-flow sampling method one day and the conventional sampling method the next day, do not confirm the apparent sampling-method bias (Table 1). The samples obtained with the conventional sampling method had higher, but not substantially higher summed nitrate concentrations than the samples obtained with the low-flow sampling method. Also, as illustrated by the data summarized on Table 1, there is little if any difference between the conventional and low-flow sampling results for other analytes (e.g., calcium and strontium). Thus, the apparent difference between the historical conventional sampling results for nitrate and the more recent low-flow sampling results for nitrate probably reflect an overall decrease in the relative nitrate concentration in the groundwater at this well (see Section 5.1).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the intermediate bedrock interval in the Maynardville Limestone (Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 11 ft bgs and exhibits seasonal fluctuations up to about 18 ft. Also, measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in well GW-225 are typically equal to or slightly higher than evident in well GW-226, which is completed at a shallower depth (55 ft bgs) in the Maynardville Limestone. Based on the distance between the monitored interval midpoint (elevation) in each well (about 125 ft), the contemporaneous groundwater elevations indicate very slightly upward vertical hydraulic gradients (0.0003 – 0.005) from the deeper bedrock (GW-225) to the shallow bedrock interval (GW-226) during seasonally high and low flow conditions.

Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV and on Chestnut Ridge, groundwater elevation isopleths in the vicinity of well GW-225 indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields chloride- and sodium-enriched, nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 216 – 792 mg/L;
- pH of 6 – 7.35 (field measurements);
- nitrate concentrations above 25 mg/L;
- elevated concentrations of chloride, (>70 mg/L), strontium (>1 mg/L), and sulfate (>40 mg/L) relative to other wells completed at shallower depths in the Maynardville Limestone;
- low molar proportions of potassium and sodium (<10% of total anions/cations); and
- total concentrations of trace metals (except strontium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

It is not clear if the chloride, strontium, and sulfate concentrations typical of the groundwater samples reflect localized geochemical characteristics, or if the elevated concentrations are the result of contamination from one or more sources upgradient of the well.

The relative percent difference (RPD) between respective summed millequivalent concentrations determined from the analytical results for the principal anions and cations (i.e., the ion charge-balance) reported for the groundwater sample obtained with the conventional sampling method in March 2003 (RPD = +54.4%) does not meet the data quality objective (RPD < 20%). The source of the charge-balance error is probably the unusually low nitrate concentration (0.213 mg/L) reported for this sample (see Section 5.1). Because of the charge-balance error, this nitrate result (and the results for all the major anions and cations) is considered qualitative.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, nitrate, uranium, and VOCs are the contaminants present at elevated levels in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected since January 1986 had nitrate concentrations above the analytical reporting limit (Table 2), and all but two of these samples had concentrations above the MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds, which are unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988. Located about 4,500 ft east-northeast of well GW-225, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984. The groundwater contaminant plume originating from the site contains a heterogeneous mixture of inorganic, organic, and radiological contaminants. Nitrate, a principal component of the plume, enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale and recharge of nitrate-contaminated surface water in Bear Creek (DOE 1997). Nitrate is chemically stable and highly mobile in groundwater and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells, the extent of nitrate contamination in the Maynardville Limestone in BCV west of Y-12, as defined by concentrations above 10 mg/L, is generally characterized by: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for about 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) and is significantly influenced by hydrologic interactions with surface water in Bear Creek.

As noted previously, all but two of the groundwater samples collected since January 1986 had nitrate concentrations above the MCL (Table 2), including the historical maximum value (105 mg/L in November 1990), with no apparent difference between the results for samples obtained with the conventional or low-flow sampling method (see Section 2.0). The lowest nitrate concentrations, 3.1 mg/L in November 1988 and 0.213 mg/L in March 2003, clearly are outliers (too low); the latter result is considered qualitative because of the ion charge-balance error determined for this sample (see Section 4.0). Also, the temporal fluctuations in concentration of nitrate show a somewhat inconsistent relationship with seasonal groundwater flow conditions, although six of the nine highest nitrate values (i.e., >80 mg/L) were reported for samples collected during seasonally low flow (summer and fall). This suggests seasonal (and episodic) recharge of less nitrate-contaminated groundwater along the flowpaths intercepted by the monitored interval in the well.

A time series plot of the nitrate concentrations reported for the groundwater samples collected since January 1986 (excluding the suspected outliers noted above) spans the nearly 10-year gap in the sampling history for the well (November 1992 – March 2001) and shows: (1) a widely variable, increasing trend between January 1986 (48.1 mg/L) and November 1990 (105 mg/L); (2) a widely variable, decreasing trend through September 1992 (72 mg/L); and (3) after the sampling gap, a fairly indeterminate trend at much lower concentrations, as illustrated by the nearly equal nitrate concentrations reported for the samples collected with the low-flow sampling method in March 2001 (35.4 mg/L) and February 2004 (34.2 mg/L). Substantially reduced flux of nitrate following the closure of the former S-3 Ponds in 1984 and installation of the low-permeability cap in 1989 probably explains the long-term decrease in nitrate concentrations in the groundwater at this well.

5.2 URANIUM

All of the groundwater samples collected since February 1991 had uranium concentrations at or above the applicable analytical reporting limit (Table 1), with the historical maximum value (0.00372 mg/L) being almost an order-of-magnitude lower than the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Based on the VOC results reported for the groundwater samples collected since February 1991 (previous VOC results generally do not meet all applicable data quality objectives), one or more of the following compounds were detected (excluding false positive results) in at least one of the samples (Table 3): CTET, chloroform, PCE, TCE, 11DCA, 11DCE, 12DCE (isomers), and 111TCA. These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. In the

Bear Creek watershed west of the flow divide, the VOC plume in the Maynardville Limestone appears to originate near Spoil Area I and to extend several thousand feet westward (parallel with geologic strike) down the axis of BCV, with influx of various VOCs from several different downgradient source areas. The distribution of VOCs within the plume reflects the relative contributions from the source areas and commingling during downgradient transport. Plume constituents in the upper part of BCV are TCE, c12DCE, and PCE; source areas include Spoil Area I and the former S-3 Ponds. Farther downstream (west), TCE becomes the primary contaminant in the plume, with major inputs of VOCs from the Rust Spoil Area or a nearby source in the Bear Creek floodplain; the Oil Landfarm waste management area (WMA), including the former Boneyard/Burnyard (BYBY), the former Hazardous Chemical Disposal Area (HCDA), and Sanitary Landfill I; and inflow of VOC-contaminated groundwater and surface water that discharges from a northern tributary of Bear Creek (NT-7) that traverses the Bear Creek Burial Grounds WMA. The highest VOC concentrations within the Maynardville Limestone exceed 300 µg/L and occur in the deeper groundwater directly south (down dip) of the former HCDA, about 500 ft east-northeast (hydraulically upgradient) of well GW-225. These high concentrations coincide with downward vertical hydraulic gradients in the Maynardville Limestone in this area and a major losing reach of the main channel of Bear Creek (DOE 1997).

TCE is the principal VOC in the groundwater samples, with concentrations above 100 reported for each sample, a historical maximum concentration of 400 µg/L in February 1991, and the most recent sampling results (February and July 2004) showing that the concentrations remain above 200 µg/L. Secondary compounds in the samples are chloroform, CTET, PCE, 11DCA, 11DCE, 12DCE (c12DCE), and 111TCA; one or more of which were detected in all but one of the samples (Table 3). Historical maximum values for each of these compounds are less than 10 µg/L, with most of the results being estimated values below 5 µg/L. The remaining VOCs were detected infrequently (only one or two samples) with most of the results being estimated values of 1 µg/L or less; these results are probably analytical artifacts.

As noted in Section 2.0, the results of "paired" sampling do not indicate substantial differences between the concentrations of VOCs in the groundwater samples obtained with the conventional sampling and low-flow sampling methods. This is illustrated by the data summarized below, which show equal or nearly equal concentrations of all VOCs except TCE, with the samples obtained with the conventional method each having 50 µg/L more TCE than the corresponding samples obtained with the low-flow method.

VOC	Concentration (µg/L)			
	Low-Flow Sampling March 24, 2003	**Conventional Sampling March 25, 2003**	**Low-Flow Sampling August 12, 2003**	**Conventional Sampling August 13, 2003**
PCE	.	2 J	2 J	2 J
TCE	230	280	200	250
c12DCE	3 J	3 J	2 J	3 J
11DCE	3 J	2 J	3 J	3 J
CTET	5 J	7	4 J	6
Chloroform	2 J	2 J	2 J	1 J
Summed VOCs	243	297	213	265

Assuming a heterogeneous mixture of dissolved VOCs in the groundwater at the well, it is not clear why the sampling method would only influence the concentration of TCE.

A time-series plot of TCE concentrations reported for the groundwater samples obtained with the low-flow sampling method shows an indeterminate long-term trend dominated by clearly seasonal concentration fluctuations (Figure 3), with temporal peak concentrations consistently evident during seasonally high groundwater flow conditions (winter and spring). This trend suggests seasonally (and episodically) variable movement of TCE along the groundwater flow/transport pathways intercepted by the monitored interval in the well (and proximal to the sampling pump intake). As shown by the data summarized in Table 3, however, the concentrations of other VOCs detected in the samples do not exhibit similarly wide temporal fluctuations, as illustrated by the equal concentrations of chloroform reported for the samples collected in February 2004 (2 μg/L) and July 2004 (2 μg/L).

5.4 GROSS ALPHA ACTIVITY

Eight of the groundwater samples collected since February 1991 (previous results for gross alpha activity do not meet applicable data quality objectives) had gross alpha activity above the applicable MDA and corresponding CE, with the historical maximum value (16.7 pCi/L in September 1992) being slightly above the MCL for gross alpha activity (15 pCi/L). This result appears to be an outlier, all of the other results for gross alpha activity are less than 8 pCi/L.

5.5 GROSS BETA ACTIVITY

All but two of the groundwater samples collected since February 1991 (previous results for gross beta activity do not meet applicable data quality objectives) had gross beta activity above the applicable MDA and corresponding CE (Table 4), and all of these results are less than the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the MCL for gross beta activity).

WELL GW-226

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1985, completed with an open-hole monitored interval from about 45 to 55 ft bgs, and constructed with nominal 4.5-inch diameter steel (SF25) riser casing. The well is paired with well GW-225 and is located in Bear Creek Valley (BCV) approximately 5,000 ft west of Y-12, on the south side of the main channel of Bear Creek, about 100 ft directly south of Sanitary Landfill I and the Oil Landfarm waste management area (WMA).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-nine groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 25 samples between January 1986 and August 2003, and the low-flow sampling method used to obtain 14 samples between March 1998 and July 2004.

An evaluation of the monitoring data available through August 2000 indicated potential bias related to the groundwater sampling method: samples obtained with the conventional sampling method had substantially lower VOC concentrations than samples obtained with the low-flow sampling method (AJA 2001). Results of "paired sampling" performed during May and August 2003, when groundwater samples were collected with the low-flow sampling method one day and the conventional sampling method the next day, confirm the apparent sampling-method bias (Table 1); summed concentrations of VOCs detected in the samples obtained with the low-flow method are about 20 to 40% higher than the corresponding summed VOC concentrations for the samples obtained with the conventional sampling method. Conversely, the conventional sampling method appears to yield samples with higher levels of gross alpha activity and gross beta activity (Table 1). Also, the conventional sampling method appears to promote the inflow of more mineralized groundwater into the well, as illustrated by the higher calcium concentrations and TDS evident for both conventional sampling events, although samples obtained with either method have similar nitrate concentrations (Table 1).

Inherent differences in the manner in which each sampling method induces flow of groundwater into the well may explain the disparity between the conventional and low-flow sampling results for VOCs. Conventional sampling involves purging up to three well volumes of groundwater from the well at about 1-2 gallons per minute, which may substantially lower the water level in the well and induce flow from water-producing features (i.e., fractures, cavities, conduits) that may not contribute to well recharge under normal conditions. Conventional sampling also appears to disturb fine-grained particles in the bottom of the well or in the fractures intercepted by the open-hole interval, which frequently results in the collection of unfiltered samples with significant levels of total suspended solids (TSS), as illustrated by the extremely high TSS reported for the (unfiltered) samples collected in March 2003 (864 mg/L) and August 2003 (719 mg/L). In contrast, low-flow sampling involves purging the well at flow rate low enough (<300 milliliters per minute) to ensure minimal water-level drawdown in the well (<1 ft per quarter hour), which induces groundwater inflow only from the water-producing feature(s) proximal to the monitored interval. Thus, the conventional sampling method appears to induce inflow of more mineralized groundwater (with lower VOC concentrations) from water-producing features that are not proximal to the monitored interval, whereas low-flow sampling appears to primarily induce inflow of VOC-contaminated groundwater from the water producing feature(s) close to the well.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maynardville Limestone (Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995). Additionally, well GW-226 is located along a reach of the main channel of Bear Creek south of Sanitary Landfill I that loses substantial flow to the Maynardville Limestone and greatly facilitates the transfer of surface-water contaminants into Maynardville Limestone (DOE 1997).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 11 ft bgs and exhibits seasonal fluctuations up to about 13 ft. Also, measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in well GW-226 are typically equal to or slightly lower than evident in well GW-225, which is completed deeper (200 ft bgs) in the Maynardville Limestone. Based on the distance between the monitored interval midpoint (elevation) in each well (about 125 ft), the contemporaneous groundwater elevations indicate very slightly upward vertical hydraulic gradients (0.0003 – 0.005) from the deeper bedrock (GW-225) to the shallow bedrock interval (GW-226) during seasonally high and low flow conditions.

Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV and on Chestnut Ridge, groundwater elevation isopleths in the vicinity of well GW-226 indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields chloride- and sodium-enriched, nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 216 – 792 mg/L;
- pH of 6 – 7.35 (field measurements);
- aluminum and iron (total) concentrations that sporadically exceed 50 mg/L;
- elevated concentrations of chloride (>60 mg/L) and sulfate (>30 mg/L) relative to other wells completed at shallower depths in the Maynardville Limestone;
- low molar proportions of potassium and sodium (<10% of total anions/cations); and
- total concentrations of trace metals (except aluminum and iron) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

It is not clear if the chloride and sulfate concentrations typical of the groundwater samples reflect localized geochemical characteristics, or if the elevated concentrations are the result of contamination from one or more sources upgradient of the well. Also, the unusually high total aluminum and iron concentrations show a direct correlation with TSS, and are probable artifacts of the preservation of the unfiltered samples (i.e., acidification below a pH of 2).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on sampling results obtained since February 1991, three of these contaminants (nitrate, uranium, and VOCs) are present at elevated levels in the groundwater at this well.

5.1 NITRATE

Seventeen groundwater samples had nitrate concentrations at or above the analytical reporting limit (Table 2) and most of these samples had concentrations above the drinking water MCL for nitrate (10 mg/L). The source of the nitrate is the former S-3 Ponds, which are unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988. Located about 4,500 ft east-northeast of well GW-226, the former S-3 Ponds were used for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12 between 1951 and 1984. The groundwater contaminant plume originating from the site contains a heterogeneous mixture of inorganic, organic, and radiological contaminants. Nitrate, a principal component of the plume, enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale and recharge of nitrate-contaminated surface water in Bear Creek (DOE 1997). Nitrate is chemically stable and highly mobile in groundwater and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds (and elsewhere in BCV). Based on the existing network of monitoring wells, the extent of nitrate contamination in the Maynardville Limestone in BCV west of Y-12, as defined by concentrations above 10 mg/L, is generally characterized by: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for about 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) and is significantly influenced by hydrologic interactions with surface water in Bear Creek.

As noted previously, eleven of the groundwater samples had nitrate concentrations above the MCL (Table 2), including the historical maximum value (32.3 mg/L in February 2004), with no apparent difference between the results for samples obtained with the conventional or low-flow sampling method (see Section 2.0). Also, with high nitrate concentrations evident for samples collected during seasonally high flow (e.g., 28.6 mg/L in March 1999) and seasonally low flow (e.g., 19.1 mg/L in September 2000), there does not appear to be any consistent relationship between nitrate levels and seasonal groundwater flow conditions. Figure 1 is a time-series plot of the nitrate results, which shows an indeterminate trend with wide concentration fluctuations from March 1998 through March 2001, followed by a much less variable and increasing trend through February 2004, with a sharp concentration decrease in July 2004 (20.9 mg/L).

5.2 URANIUM

All of the groundwater samples had uranium concentrations at or above the applicable analytical reporting limit (Table 1), with the results for eight samples exceeding the drinking water MCL for uranium (0.03 mg/L). There are several sources of uranium in BCV hydraulically upgradient of well GW-226, including the contaminant plume originating from the former S-3 Ponds and inflow of uranium-contaminated surface water in Bear Creek. Nevertheless, the CERCLA remedial investigation identified the former Boneyard/Burnyard (BYBY) as the primary source of uranium in groundwater from the Maynardville Limestone hydraulically downgradient (west) of the site (DOE 1997), which is about 550 ft east-northeast of the well. Uranium-bearing wastes disposed at the BYBY were below the seasonally high water table and the limestone bedrock served as a source of dissolved carbonate, which combined with uranyl cations leached from the wastes and greatly increased what would otherwise be relatively limited mobility, considering the neutral pH groundwater in the Maynardville Limestone (DOE 1997). As a major source area for uranium, the BYBY was prioritized for CERCLA remedial action, which was completed in May 2003 and involved: (1) the excavation and on-site consolidation/off-site disposal of about 81,000 yd^3 of waste materials; (2) construction of a multi-layer low-permeability cap over waste materials consolidated on site; and (3) reconstruction of a northern tributary of Bear Creek (NT-3) that drains the site (BJC 2004).

As noted previously, total uranium concentrations reported for most of the groundwater samples, do not exceed the MCL (0.03 mg/L), with the most recent result (0.00694 in July 2004) being the lowest concentration reported for any groundwater sample collected since November 1988 (0.003 mg/L). Additionally, all of the samples with uranium concentrations above the MCL, including the historical maximum value (0.092 mg/L in October 1990), were obtained with the conventional sampling method. This suggests that the conventional sampling method tends to induce greater inflow of uranium-contaminated groundwater into the well, a finding supported by the results of paired low-flow and conventional sampling (see Section 2.0). If so, it is not clear which sampling method provides the most representative sampling results for total uranium.

A time-series plot of uranium concentrations reported for the groundwater samples collected since February 1998 (including the conventional sampling results obtained in 2003) shows an indeterminate trend (Figure 3), as illustrated by the similarity between the uranium concentrations evident in March 1998 (0.016 mg/L) and February 2004 (0.0125 mg/L). However, the uranium concentrations exhibit a clear correlation with seasonal flow conditions, with temporal peak concentrations reported for samples collected during seasonally high groundwater flow conditions (winter and spring), and temporal low concentrations reported for samples collected during seasonally low flow conditions (summer and fall). This suggests seasonal (and episodic) changes in advective flux of uranium via the groundwater flow/transport pathways intercepted by the monitored interval in the well. Also, recent low-flow sampling data potentially reflect a decreasing concentration trend, with the uranium concentration evident in July 2004 being about 56% lower than evident in August 2001 (0.0157 mg/L), which may be attributable to the CERCLA remedial action at the BYBY.

5.3 VOLATILE ORGANIC COMPOUNDS

Based on the VOC results reported for the groundwater samples collected since February 1991 (previous VOC results generally do not meet all applicable data quality objectives), one or more of the following compounds were detected in one or more of the samples (Table 3): benzene, CTET, chloroethane, chloroform, chloromethane, TCE, 11DCA, 11DCE, and 12DCE (isomers). These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. In the Bear Creek watershed west of the flow divide, the VOC plume in the Maynardville Limestone appears to originate near Spoil Area I and to extend several thousand feet westward (parallel with geologic strike) down the axis of BCV, with influx of various VOCs from several different downgradient source areas. The distribution of VOCs within the plume reflects the relative contributions from the source areas and commingling during downgradient transport. Plume constituents in the upper part of BCV are TCE, c12DCE, and PCE; source areas include Spoil Area I and the former S-3 Ponds. Farther downstream (west), TCE becomes the primary contaminant in the plume, with major inputs of VOCs from the Rust Spoil Area or a nearby source in the Bear Creek floodplain; the Oil Landfarm waste management area (WMA), including the former Boneyard/Burnyard (BYBY), Hazardous Chemical Disposal Area (HCDA), and Sanitary

Landfill I; and inflow of VOC-contaminated groundwater and surface water that discharges from a northern tributary of Bear Creek (NT-7) that traverses the Bear Creek Burial Grounds WMA. The highest VOC concentrations within the Maynardville Limestone exceed 300 µg/L and occur in the deeper groundwater directly south (down dip) of the former HCDA, about 500 ft east-northeast (hydraulically upgradient) of well GW-226.

The primary VOCs in the groundwater samples are TCE and 12DCE (c12DCE), both of which was detected in each sample (Table 3). The dominant compound is TCE, which has been detected in each sample, with concentrations above 100 µg/L reported for most of these samples, including the historical maximum concentration of 210 µg/L (March 1999 and February 2004). Conversely, most of the 12DCE concentrations are less than 10 µg/L and the historical maximum value (36 µg/L in February 1991) is substantially below the MCL (70 µg/L). Secondary compounds in the samples are chloroform, CTET, 11DCA, and 11DCE, which were detected in a total of twelve samples, but only three of the samples collected since August 1999 (Table 3). The remaining VOCs were detected infrequently (only one or two samples) with most of the results being estimated values below 5 µg/L.

As noted in Section 2.0, the summed concentrations of VOCs detected in the groundwater samples obtained with the conventional sampling method are lower than the summed VOC concentrations for samples obtained with the low-flow sampling methods. As illustrated by the "paired" sampling results summarized below, this is primarily attributable to substantial differences in the concentrations of TCE.

VOC	Concentration (µg/L)			
	Low-Flow Sampling March 24, 2003	**Conventional Sampling March 25, 2003**	**Low-Flow Sampling August 12, 2003**	**Conventional Sampling August 13, 2003**
TCE	200	110	160	120
c12DCE	8	10	7	9
11DCE	3 J	2 J	1 J	.
11DCA	1 J	.	.	.
CTET	.	.	2 J	2 J
Chloroform	.	1 J	1 J	1 J
Chloromethane	.	4 J	.	.
Summed VOCs	212	127	171	132

Aside from TCE, however, the respective sampling results do not show any significant difference between the concentrations of the other VOCs detected in the samples. Assuming a heterogeneous mixture of dissolved VOCs in the groundwater at the well, it is not clear why the sampling method influences the concentrations of some compounds and not others. Nevertheless, these findings suggest that the VOC results reflect the apparent tendency for the conventional sampling method to induce inflow of (nitrate- and uranium-contaminated) groundwater from water-producing features that are not proximal to the well (i.e., further into the formation), whereas low-flow sampling appears to primarily induce inflow of TCE-contaminated groundwater from the water producing feature(s) close to the well.

A time-series plot of TCE concentrations reported for the groundwater samples obtained with the low-flow sampling method shows an indeterminate long-term trend dominated by clearly seasonal concentration fluctuations (Figure 3), with temporal peak concentrations consistently evident during seasonally high groundwater flow conditions (winter and spring). This trend suggests seasonally (and episodically) variable advective flux of TCE along the groundwater flow/transport pathways intercepted by the monitored interval in the well. As shown by the data summarized in Table 3, however, the concentrations of other VOCs detected in the samples do not exhibit similarly wide temporal fluctuations, as illustrated by the nearly equal concentrations of c12DCE reported for the samples collected in March 2003 (8 µg/L) and August 2003 (7 µg/L).

5.4 GROSS ALPHA ACTIVITY

All but four of the groundwater samples collected since February 1991 (previous results for gross alpha activity do not meet applicable data quality objectives) had gross alpha activity above the applicable MDA and corresponding CE, and four of these results exceed the drinking water MCL for gross alpha activity (Table 2). Uranium isotopes are the source of the gross alpha activity, as indicated by the analytical results for the samples collected in March 1998 (U-234 = 3.2 pCi/L and U-238 = 5 pCi/L), May 2001 (U-234 = 3.2 pCi/L and U-238 = 4.5 pCi/L), and August 2001 (U-234 = 3.4 pCi/L and U-238 = 5.2 pCi/L). The contaminant plumes originating from the former S-3 Ponds and the BYBY are primary sources of uranium isotopes in groundwater and surface water in BCV west of Y-12, with the latter site being the closest and most likely source of the uranium isotopes in the groundwater at the well GW-226 (DOE 1997). As with total uranium (see Section 5.2), U-234 and U-238 ions leached from wastes disposed at the BYBY probably combined with carbonate dissolved from the limestone bedrock, which greatly increased their relatively limited mobility in the neutral pH groundwater in the Maynardville Limestone (DOE 1997).

As noted in Section 2.0, the conventional sampling method appears to induce inflow of groundwater with elevated gross alpha activity, and all of the results that exceed the MCL were reported for samples obtained with this sampling method (Table 2). Additionally, seasonal fluctuations in gross alpha activity are generally indicated, with the highest values reported for the samples collected during seasonally high groundwater flow conditions in May 1991 (33.86 pCi/L) and March 2003 (33 pCi/L). Substantially lower gross alpha activity was reported for the samples obtained with the low-flow sampling method, although like the conventional sampling results, the highest value was reported for a sample collected during seasonally high flow conditions (11 pCi/L in March 2003). These results suggest seasonally (and episodically) variable flux of alpha-emitting radionuclides (uranium isotopes) via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.5 GROSS BETA ACTIVITY

All but one of the groundwater samples collected since February 1991 (previous results for gross beta activity do not meet applicable data quality objectives) had gross beta activity above the applicable MDA and corresponding CE (Table 4). Although uranium isotopes and related daughter products contribute to the gross beta activity in the groundwater at this well, Tc-99 may be another source, as indicated by the relatively low levels of this beta-emitting radionuclide detected (i.e., >MDA and CE) in samples collected March 1998 (28 pCi/L) and February 2001 (16 pCi/L). Technetium-99 is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, the only site at Y-12 which received wastes that contained Tc-99 (DOE 1998). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in BCV west of Y-12, the distribution of elevated gross beta activity suggests that the groundwater transport of Tc-99 in the Maynardville Limestone closely mirrors that of nitrate.

Gross beta activity results that exceed the MDA and corresponding CE range between 8.5 pCi/L (July 2004) and 45 pCi/L (August 2003), and are all less than the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the MCL for gross beta activity).

The highest values reported for the groundwater samples obtained with the conventional sampling method in February 1991 (41.44 pCi/L) and August 2003 (45 pCi/L). These results suggest, as noted in Section 2.0, that the conventional sampling method induces greater relative inflow of contaminated groundwater.

WELL GW-227

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in November 1985, completed with an open-hole monitored interval from 30 to 40 ft bgs, and constructed with nominal 4.5-inch diameter steel riser casing. The well is paired with well GW-228 and is located in Bear Creek Valley (BCV) approximately 4,500 ft west of Y-12, south of the main channel of Bear Creek approximately 100 ft directly south of the Oil Landfarm waste management area (WMA). The Oil Landfarm WMA encompasses several closed waste management facilities, including the Oil Landfarm, Boneyard/Burnyard (BYBY), Hazardous Chemical Storage Area (HCDA), and Sanitary Landfill I.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-one groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 29 samples between January 1986 and September 1992, and the low-flow sampling method used to obtain samples in March and September 2005. The sampling history includes a quarterly sampling frequency, followed by a nearly 13-year period (September 1992 – March 2005) when no samples were collected from the well.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maynardville Limestone (Conasauga Group), which trends northeast-southwest along the axis of BCV, dips southeast at an angle of 45º - 55º, and underlies the main channel of Bear Creek. The Maynardville Limestone exhibits the hydrologic characteristics typical of karst aquifers, with most of the groundwater flow occurring at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (shallow karst network). Hydrologic interaction between Bear Creek and the shallow karst network provides the principal exit-pathway for contaminants released from source areas within the Bear Creek watershed west of Y-12. Deeper in the subsurface, below the shallow karst network, fractures provide the primary groundwater flowpaths, and the bulk permeability generally decreases with depth because of decreased fracture aperture and increased fracture spacing (Solomon et. al. 1992). Also, distinct lithologic and hydrologic characteristics differentiate seven hydrostratigraphic zones (numbered from bottom to top) in the Maynardville Limestone (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

The static water level in the well occurs at an average depth of about 13 ft bgs and exhibits maximum seasonal fluctuations of approximately 8 ft. Also, depth-to-water measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in well GW-227 are typically lower than those evident in well GW-228, which is completed deeper (100 ft bgs) in the Maynardville Limestone. Based on the distance between the monitored interval midpoint (elevation) in each well (55 ft), the contemporaneous groundwater elevations indicate upward vertical hydraulic gradients (0.011 – 0.048) within the shallow bedrock interval (from GW-228 to GW-227) during both seasonally high and low flow conditions.

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-227 indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone. Additionally, the well is located along a reach of Bear Creek south of Sanitary Landfill I that loses substantial flow to the shallow karst network in the Maynardville Limestone and is believed to greatly facilitate the recharge of contaminated surface water into the groundwater flow system downgradient (south and west) of the Oil Landfarm WMA (DOE 1997).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples collected to date show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 368 – 578 mg/L;
- pH of 6.48 – 7.1 (field measurements);
- elevated levels of chloride (>25 mg/L) and sulfate (>35 mg/L) compared to other wells completed at similarly shallow depths in the Maynardville Limestone;
- low molar proportions of potassium and sodium (<10% of total anions/cations);
- conspicuously high concentrations of iron (>2 mg/L) and manganese (>1 mg/L); and
- total concentrations of other trace metals, except for boron and uranium, that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Many geochemical characteristics of the shallow groundwater in this well differ substantially from those indicated for the groundwater from the deeper flowpaths intercepted by the monitored interval in well GW-228, as illustrated by the following summary of selected field measurements and laboratory analytes reported for groundwater samples collected on contemporaneous dates in March and September 2005. Considering the vertically upward hydraulic gradients noted in Section 3.0, upward migration from the deeper flow system may at least partially account for the elevated levels of chloride in the shallow groundwater, but not the elevated levels of boron and sulfate. Note also the substantial difference between total iron and manganese concentrations reported for the samples from each well. Both wells have steel riser casing and open-hole monitored intervals, and static water levels in each well typically occur within the casing. Thus, the disparity between the iron and manganese concentrations does not appear to be an artifact of well construction, but instead is probably a function of the unusually high levels of dissolved oxygen in the shallower groundwater.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that each of the principal contaminants except VOCs are present at elevated concentrations in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected to date had nitrate concentrations at or above the analytical reporting limit (Table 1) and most of these samples had concentrations above the drinking water MCL for nitrate (10 mg/L). Elevated nitrate concentrations in the samples indicate that the monitored interval in the well intercepts water-producing features that are hydraulically connected with the heterogeneous plume of inorganic, organic, and radiological contaminants originating from the former S-3 Ponds. Located hydraulically upgradient approximately 4,300 ft east-northeast of the well, these unlined surface impoundments received several million gallons of nitric-acid wastes generated at Y-12 between 1951 and 1984, and were filled and covered with a low-permeability cap during RCRA closure of the site in 1989. Nitrate is a principal component of the contaminant plume, is chemically stable and highly mobile in groundwater, and is believed to effectively delineate the primary groundwater flow/contaminant transport pathways in the Maynardville Limestone (DOE 1997).

Nitrate concentrations detected in all but two of the groundwater samples collected between January 1986 (66.5 mg/L) and September 1992 (35 mg/L), including the historical maximum concentration (77 mg/L in September 1987), substantially exceed the drinking water MCL for nitrate (Table 1). Note that the nitrate result reported for the sample collected in February 1991 (18 mg/L) is considered qualitative because of the ion charge balance error (i.e., the percent difference between respective summed milliequivalent concentrations of the major cations and anions exceeds 20%). Also, the historical data show wide fluctuations in nitrate concentrations, with the highest levels typically observed during seasonally low-flow conditions (summer and fall), as illustrated by the “peak” concentrations evident in September 1987 (77 mg/L; the historical maximum value), July 1988 (61 mg/L), and November 1991 (45 mg/L). This relationship suggests that the changes in nitrate concentrations reflect the seasonal (and episodic) recharge of uncontaminated (or less nitrate-contaminated) groundwater via the flowpaths intercepted by the monitored interval in the well, which is consistent with the low nitrate concentrations evident in March 1987 (36.4 mg/L), February 1990 (9.4 mg/L), and March 1992 (9.77 mg/L). Note, however, that not only are the nitrate concentrations detected in the samples collected most recently (3.56 mg/L in March 2005 and 3.26 mg/L in September 2005) substantially lower than indicated by the previous sampling results, but these concentrations do not suggest substantial seasonal variation.

As noted previously, well GW-227 is paired with well GW-228 and, as illustrated by the selected sampling results summarized below, historical data show that nitrate concentrations were typically lower in the deeper groundwater flow/transport pathways intercepted by the monitored interval in well GW-228, although more recent sampling results show nearly equal concentrations for each well. Thus, considering the upward vertical hydraulic gradients indicated by contemporaneous presampling groundwater elevations in each well, as noted in Section 4.0, nitrate concentrations in the shallower groundwater at well GW-227 do not appear to have been significantly influenced by upward migration of nitrate from the deeper flow system in the Maynardville Limestone.

Nitrate (mg/L)			
GW-227 (30-40 ft bgs)		GW-228 (80-100 ft bgs)	
01/14/86	66.5	01/14/86	19.2
06/23/87	43.8	06/23/87	22.5
04/27/88	45	04/27/88	24
07/27/89	27	07/28/89	27
02/08/90	9.4	02/02/90	37
03/21/05	3.53	03/21/05	2.47

A time-series plot of nitrate concentrations detected in the groundwater samples collected to date shows a widely variable but clearly decreasing long-term trend that spans the nearly 13-year (September 1992 – March 2005) gap in the sampling history for the well (Figure 1). Also, note the decreasing concentrations evident in the deeper groundwater at well GW-228, as illustrated by the data summarized above. The overall decrease from the historical nitrate concentrations is directly attributable to the substantially reduced flux of nitrate in the Maynardville Limestone following the closure/capping of the former S-3 Ponds. Nevertheless, the rate of concentration decrease appears to have slowed considerably, with the most recent sampling results noted above suggesting that the nitrate concentrations may have reached asymptotic levels in the groundwater at this well.

5.2 URANIUM

All of the groundwater samples had uranium concentrations above the applicable analytical reporting limit (Table 1), with the results for all but one of the samples being at or above the drinking water MCL for uranium (0.03 mg/L). There are several sources of uranium in BCV hydraulically upgradient of the well, including the groundwater contaminant plume originating from the former S-3 Ponds and inflow of uranium-contaminated surface water in Bear Creek. Additionally, the CERCLA remedial investigation identified the former BYBY, which is located approximately 550 ft east-northeast of the well, as the primary source of uranium in Maynardville Limestone hydraulically downgradient (west) of the Oil Landfarm WMA (DOE 1997). Uranium-bearing wastes in the subsurface at the BYBY were below the seasonally high water table and carbonate dissolved from the limestone bedrock combined with uranyl cations leached from the wastes and greatly increased what would otherwise be relatively limited uranium mobility, considering the neutral pH groundwater in the Maynardville Limestone (DOE 1997). As a major source area for uranium, the BYBY was prioritized for CERCLA remedial action, which was completed in May 2003 and involved: (1) the excavation and on-site consolidation/off-site disposal of about 81,000 yd^3 of waste materials; (2) construction of a multi-layer low-permeability cap over waste materials consolidated on site (above the seasonally high water table); and (3) reconstruction of a northern tributary of Bear Creek (NT-3) that drains the site.

Aside from the historical minimum value (0.024 mg/L in November 1991), uranium concentrations reported for all the other groundwater samples collected to date meet or exceed the drinking water MCL (0.03 mg/L), although the historical maximum value (1.66 mg/L in March 1987) is a suspected outlier compared to the other uranium results (Table 1). The uranium concentrations also exhibit significant short-term variability, although the concentration fluctuations do not exhibit any consistent relationship with seasonal flow conditions, as illustrated by the low uranium concentrations reported for samples collected during seasonally high flow (e.g., 0.03 mg/L in February 1990) and seasonally low flow (e.g., 0.098 mg/L in July 1988). Interestingly, the fluctuations in uranium levels often exhibit an inverse relationship with concurrent changes in nitrate concentrations, as illustrated by the selected data summarized below, whereby a short-term increase in uranium is mirrored by a short-term decrease in nitrate. This relationship suggests that there are separate sources for the uranium and nitrate transported via the groundwater flow/transport pathways intercepted by the monitored interval in the well, with the BYBY the presumed principal source of the uranium and the former S-3 Ponds the sole source of nitrate.

Sampling Date	Nitrate (mg/L)	% Change	Uranium (mg/L)	% Change
10/30/87	68	.	0.078	.
04/27/88	45	-34%	0.205	+162%
07/08/88	61	+36%	0.098	-52%
11/11/88	49	-34%	0.238	+143%

As illustrated by the selected sampling results summarized below, total uranium concentrations are substantially lower in the deeper groundwater flow/transport pathways intercepted by the monitored interval in well GW-228. Thus, considering the upward vertical hydraulic gradients noted previously, the elevated concentrations of uranium in the shallower groundwater at well GW-227 probably do not result from upward migration of uranium from the deeper flow system in the Maynardville Limestone. Moreover, the lack of elevated uranium levels in the deeper groundwater, in light of the elevated nitrate concentrations indicated by historical data, again indicates that the uranium and nitrate in the shallow groundwater at well GW-227 do not share a common source area.

Uranium (mg/L)			
GW-227 (30-40 ft bgs)		GW-228 (80-100 ft bgs)	
05/20/86	0.07	05/20/86	0.003
04/27/88	0.205	04/27/88	0.005
02/08/90	0.03	02/02/90	0.005
03/21/05	0.0496	03/21/05	0.00056

A time-series plot of the uranium concentrations (excluding the suspected outlier) shows a decreasing long-term trend dominated by wide temporal fluctuations and the prolonged gap in the sampling history for the well (Figure 2). Additionally, compared to the uranium concentrations evident in June (0.038 mg/L) and September 1992 (0.033 mg/L), the uranium results reported for the samples collected in March (0.0496 mg/L) and September 2005 (0.056 mg/L) suggest a 30 to 70% increase. Assuming the higher concentrations correlate with increased flux of uranium, these results are in direct contrast to the decreasing levels of nitrate, which reflect substantially reduced flux, as noted in Section 5.1, and are somewhat surprising considering that bulk of the uranium-bearing wastes were excavated and removed from the BYBY during the CERCLA remedial action described above. Divergent trends in the relative flux of these contaminants may be at least partially attributable to differential transport in the Maynardville Limestone, but also indicates that the uranium and nitrate probably do not share a common source area.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected to date (Table 2): acetone, benzene, CTET, chloroethane, chloroform, ethylbenzene, methylene chloride (MC), styrene, PCE, toluene, TCE, vinyl acetate, xylenes, 12DCE, 111TCA, and 4-methyl-2-pentaone (4M2P). The presence of VOCs in the samples indicates that the monitored interval in the well intercepts groundwater flow/transport pathways for VOCs released from one or more upgradient sources that contribute to an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. Available data for the network of wells completed in the Maynardville Limestone west of the flow divide indicate that VOC-contaminated groundwater, as defined by individual or summed VOC concentrations above 5 µg/L, appears to originate near Spoil Area I and to extend hydraulically downgradient for several thousand feet westward (parallel with geologic strike) down the axis of BCV. The apparent distribution of VOCs within the plume reflects the relative influx from multiple source areas, commingling during downgradient groundwater transport, and hydraulic communication with Bear Creek (DOE 1997). In the upper part of BCV, hydraulically upgradient (east) of the well, the primary VOCs are TCE, c12DCE, and PCE and the confirmed or suspected source areas include Spoil Area I, the contaminant plume emplaced during historical operation of the former S-3 Ponds, and the Rust Spoil Area. Farther downgradient, additional influx of VOCs into the Maynardville Limestone occurs from several potential sources within the Oil Landfarm WMA, including the Oil Landfarm, HCDA, and Sanitary Landfill I (DOE 1997); each of these potential source areas is hydraulically upgradient of well GW-227.

Based on frequency of detection and concentration magnitude, the primary VOC in the groundwater samples is TCE, which is the only VOC detected in all of the samples collected to date (Table 2). All but two of the TCE results exceed the drinking water MCL (5 µg/L) and, excluding a suspected outlier reported for the sample collected in June 1992 (88 µg/L), the results for three samples, including the historical maximum value (82 µg/L in September 1987), exceed 50 µg/L (Table 2). Secondary VOCs detected in the samples are CTET, chloroform, MC, PCE, and 12DCE; of these, only PCE and 12DCE were detected in the samples collected most recently (March and September 2005). The bulk of the analytical results for these compounds, most of which were detected only in the series of samples collected between December 1986 and December 1989, are estimated concentrations below 5 µg/L (Table 2). The remaining compounds were detected in no more than three of the samples, none of which were collected after November 1990, with the bulk of these results being estimated concentrations below 3 µg/L.

As illustrated by the selected sampling results summarized below, TCE concentrations are substantially higher in the deeper groundwater flow/transport pathways intercepted by the monitored interval in well GW-228. Thus, considering the upward vertical hydraulic gradients indicted by the presampling groundwater elevations (see Section 3.0), the concentration of TCE in the shallower groundwater may be at least partially attributable to upward migration of TCE from the deeper flow system in the Maynardville Limestone. Also, the sampling results for these wells indicate that a greater proportional decrease in TCE levels has occurred in the shallower groundwater, which suggests that the most contaminated groundwater has been flushed from the shallow flow system in the Maynardville Limestone.

TCE (µg/L)			
GW-227 (30-40 ft bgs)		**GW-228 (80-100 ft bgs)**	
05/20/86	34	05/20/86	82
04/27/88	22	04/27/88	76
02/08/90	14	02/02/90	78
03/21/05	16	03/21/05	63

Several of the VOCs detected in the groundwater samples collected to date, particularly 11DCA, 11DCE, and 12DCE isomers, are probably present in the groundwater as a result of biologically mediated degradation (sequential dechlorination) of related parent compounds (PCE and 111TCA). However, as illustrated by the data summarized in Table 3, results for selected indicator parameters (particularly dissolved oxygen) suggest that geochemical characteristics of the groundwater in this well generally are not within the optimum range for biotic degradation of chlorinated hydrocarbons. Instead, considering the upward vertical hydraulic gradients noted previously, the presence of the VOC-degradation products in the groundwater at this well may be at least partially attributable to upward migration from the deeper flow system, where geochemical conditions may promote more effective anaerobic degradation, as indicated by the low dissolved oxygen and REDOX values reported for the most recent samples collected from well GW-228 (see data summary included in Section 4.0).

A time-series plot of TCE concentrations detected in the groundwater samples collected to date (excluding the suspected outlier noted above) shows an indeterminate long-term trend dominated by "peak" concentrations in September 1987 (82 µg/L) and July 1988 (68 µg/L) and the prolonged gap in the sampling history for the well (Figure 2). Note that both these TCE results were reported for samples collected during seasonally low flow conditions (summer and fall), whereas low TCE concentrations, such as those reported for the samples collected in March 1987 (10 µg/L) and March 1989 (13 µg/L), often correlate with seasonally high flow conditions (winter and spring). This relationship suggests seasonally variable flux of TCE via the groundwater flow/transport pathways intercepted by the monitored interval in the well. Interestingly, the concentrations of other VOCs detected in the samples do not show any similar fluctuations, as illustrated by the nearly equal PCE concentrations reported for the samples collected in September 1987 (2 µg/L) and March 1989 (1 µg/L). Moreover, the TCE concentrations detected in the samples collected in March 2005 (16 µg/L) and September 2005 (17 µg/L) are the highest since December 1989 (excluding the suspected outlier noted above) and suggest an overall increase from the historical minimum TCE concentration (3 µg/L) evident in February and May 1990 (Figure 3). Assuming a heterogeneous mixture of dissolved VOCs in the groundwater from the shallow karst network in the Maynardville Limestone, it is unclear why the VOC concentrations exhibit such divergent trends. Perhaps the TCE is not well mixed with other VOCs in the groundwater system, but instead occurs within separate, discreet transport pathways intercepted by the monitored interval in the well. As noted in Section 5.2 regarding the suspected sources of nitrate and uranium, the divergent VOC concentration trends potentially reflect separate transport of compounds from different upgradient source areas.

5.4 GROSS ALPHA ACTIVITY

All of the groundwater samples collected since February 1990 (previous results for gross alpha activity do not meet applicable DQOs) had gross alpha activity above the applicable MDA and corresponding CE, and all but four of these results exceed the drinking water MCL for gross alpha activity (Table 1). Uranium isotopes are the source of the gross alpha activity, as indicated by the analytical results for the samples collected in March 2005 (U-234 = 12 pCi/L and U-238 = 17 pCi/L) and September 2005 (U-234 = 11 pCi/L and U-238 = 16 pCi/L). The contaminant plumes originating from the former S-3 Ponds and the BYBY are primary sources of uranium isotopes in groundwater and surface water in BCV west of Y-12, with the latter site being the closest and most likely source of the uranium isotopes in the groundwater samples from this well (DOE 1997). As with total uranium (see Section 5.2), U-234 and U-238 ions leached from wastes disposed at the BYBY probably combined with carbonate dissolved from the limestone bedrock, which greatly increased their relatively limited mobility in the neutral pH groundwater typical of the Maynardville Limestone (DOE 1997).

Most of the results for gross alpha activity that meet applicable DQOs exceed the drinking water MCL (15 pCi/L), including the historical maximum value (52 pCi/L in October 1990) and the most recent results reported for the samples collected in March (23 pCi/L) and September 2005 (28 pCi/L). Additionally, considering the inherent analytical variability commonly associated with the measurement of gross alpha activity, the results do not suggest wide temporal fluctuations or any consistent relationship with seasonal groundwater flow conditions, although most of the lowest levels of gross alpha activity were reported for samples collected during seasonally low flow conditions (e.g., 8.21 pCi/L in July 1991).

A time-series plot of these results shows a fairly indeterminate long-term trend dominated by the temporal "peak" levels evident in October 1990 (52 pCi/L) and March 1992 (26 pCi/L) and the 13-year gap in the sampling history for the well (Figure 4). Also, as with total uranium concentrations discussed in Section 5.2, the most recent sampling results show higher levels of gross alpha activity than evident during the early 1990s and likewise may indicate an increase in the relative flux of U-234 and U-238 via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.5 GROSS BETA ACTIVITY

All of the groundwater samples collected since February 1990 (previous results for gross beta activity do not meet applicable data quality objectives) had gross beta activity above the applicable MDA and corresponding CE, and about half of these results (six samples) exceed SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity) (Table 1). Uranium isotopes and associated daughters are the most likely source of the beta activity in the groundwater at the well, as indicated by the U-234 and U-236 results for the samples collected in March and September 2005 (Table 1). Note that the analytical results for several of the samples, including the samples collected in March and September 2005, indicate that Tc-99 may not be present in the groundwater flow/transport pathways intercepted by the monitored interval in the well. This is somewhat surprising in light of the elevated nitrate concentrations indicated by historical data for the well, as discussed in Section 5.1, because Tc-99, a beta-emitting radionuclide, is a "signature" component of the contaminant plume emplaced during operation of the former S-3 Ponds. Also, under the neutral pH conditions typical of groundwater in the Maynardville Limestone, the Tc-99 probably occurs as the pertechnetate anion (TcO_4^-) which, like nitrate, is highly soluble and mobile in the subsurface (Gee et al. 1983).

As noted above, about half of the results for gross beta activity that meet applicable DQOs exceed the SDWA screening level (50 pCi/L), including the historical maximum value (150 pCi/L in October 1990), which appears to be an outlier compared to the other results (Table 1). Also, the most recent results reported for the samples collected in March (16 pCi/L) and September 2005 (15 pCi/L) show substantially lower gross beta activity significantly below the SDWA screening level. A time-series plot of the results for gross beta activity, excluding the suspected outlier noted above, is similar to that of gross alpha activity but shows a decreasing long-term trend dominated by the temporal "peak" levels evident in February 1991 (80 pCi/L) and June 1992 (65 pCi/L) and the nearly 13-year gap in the sampling history for the well (Figure 5).

WELL GW-228

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1985, completed with an open-hole monitored interval from 80 to 100 ft bgs, and constructed with nominal 4.5-inch diameter steel riser casing. The well is paired with well GW-227 and is located in Bear Creek Valley (BCV) approximately 4,500 ft west of Y-12, south of the main channel of Bear Creek approximately 100 ft directly south of the Sanitary Landfill I and the Oil Landfarm waste management area (WMA), which encompasses several closed waste management facilities, including the Oil Landfarm, Boneyard/Burnyard (BYBY), Hazardous Chemical Storage Area (HCDA), and Sanitary Landfill I.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-one groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 18 samples between January 1986 and September 1995, and the low-flow sampling method used to obtain three samples between September 1999 and September 2005. The sampling history includes a quarterly sampling frequency followed by 5-year (February 1990 – September 1995) and 6-year (September 1999 – March 2005) periods when no samples were collected from the well.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maynardville Limestone (Conasauga Group), which trends northeast-southwest along the axis of BCV, dips southeast at an angle of 45º - 55º, and underlies the main channel of Bear Creek. The Maynardville Limestone exhibits the hydrologic characteristics typical of karst aquifers, with most of the groundwater flow occurring at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (shallow karst network). Hydrologic interaction between Bear Creek and the shallow karst network provides the principal exit-pathway for contaminants released from source areas within the Bear Creek watershed west of Y-12. Deeper in the subsurface, below the shallow karst network, fractures provide the primary groundwater flowpaths, and the bulk permeability generally decreases with depth because of decreased fracture aperture and increased fracture spacing (Solomon et. al. 1992). Also, distinct lithologic and hydrologic characteristics differentiate seven hydrostratigraphic zones (numbered from bottom to top) in the Maynardville Limestone (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

The static water level in the well occurs at an average depth of 12 ft bgs and exhibits maximum seasonal fluctuations of approximately 12 ft. Also, depth-to-water measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in well GW-228 are typically higher than those evident in well GW-227, which is completed shallower (40 ft bgs) in the Maynardville Limestone. Based on the distance between the monitored interval midpoint (elevation) in each well (55 ft), the contemporaneous groundwater elevations indicate upward vertical hydraulic gradients (0.011 – 0.048) within the shallow bedrock interval (from GW-228 to GW-227) during seasonally high and low flow conditions.

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-228 indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone. Additionally, the well is located along a reach of Bear Creek south of Sanitary Landfill I that loses substantial flow to the shallow karst network in the Maynardville Limestone and is believed to greatly facilitate the recharge of contaminated surface water into the groundwater flow system downgradient (south and west) of the Oil Landfarm WMA (DOE 1997).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples collected to date show distinctly different geochemical characteristics coincident with the change from conventional sampling to low-flow sampling. As illustrated by the selected data summarized below, analytical results for the groundwater samples obtained with the conventional sampling method indicate that the well yields moderately mineralized (TDS >500 mg/L) and nitrate-contaminated calcium-magnesium-bicarbonate groundwater with the neutral pH common of most wells completed in the Maynardville Limestone. However, analytical results for the samples subsequently obtained with the low-flow sampling method indicate that the well yields substantially less mineralized groundwater with higher pH and substantially lower calcium, magnesium, and bicarbonate concentrations, but similar concentrations of other major ions, such as chloride and sodium, compared to the conventional sampling results. Moreover, the low TDS of the most recent samples indicates relatively low residence time for the groundwater and implies inflow from highly permeable flowpaths directly connected with shallow karst network in the Maynardville Limestone.

Sampling Method/Date	pH (st. units)	Concentration (mg/L)					
		TDS	Calcium	Magnesium	Bicarbonate	Chloride	Sodium
Conventional Sampling							
02/02/90	7	666	150	42	341	<100	17
09/17/95	7.8	668	110	40	230	43	19
Low-Flow Sampling							
09/09/99	9.16	262	11.7	14.4	26	37.44	18.9
03/21/05	9.48	124	9.44	12.4	52.8	36.8	17.7
09/08/05	9.59	142	8.77	11.3	62.2	37.7	17.7

It is not clear from the available data what may have caused the change in groundwater chemistry. Perhaps the difference in geochemical characteristics is related to inherent differences in the manner in which each sampling method induces flow of groundwater into the well. Conventional sampling involves purging up to three well volumes of groundwater from the well at about 1-2 gallons per minute, which may substantially lower the water level in the well and induce greater relative inflow from water-producing features (i.e., fractures, cavities, conduits) that may not be proximal to the intake for the dedicated sampling pump in the well. In contrast, low-flow sampling involves purging the well at flow rate low enough (<300 milliliters per minute) to ensure minimal water-level drawdown in the well (<1 ft per quarter hour), which induces groundwater inflow only from the water-producing feature(s) proximal to the pump intake, which is located near the midpoint of the open-hole interval in the well. Thus, the low-flow sampling method may induce proportionally greater inflow from highly permeable flowpaths nearest to the pump intake, whereas conventional sampling may induce proportionally greater inflow of more mineralized groundwater from less permeable flowpaths intercepted throughout the monitored (open-hole) interval.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that nitrate and VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected to date had nitrate concentrations at or above the analytical reporting limit (Table 1) and most of these samples had concentrations above the drinking water MCL for nitrate (10 mg/L). Elevated nitrate concentrations in the samples indicate that the monitored interval in the well intercepts water-producing features that are hydraulically connected with the heterogeneous plume of inorganic, organic, and radiological contaminants originating from the former S-3 Ponds. Located hydraulically upgradient approximately 4,300 ft east-northeast of the well, these unlined surface impoundments received several million gallons of nitric-acid wastes generated at Y-12 between 1951 and 1984, and were filled and covered with a low-permeability cap during RCRA closure of the site in 1989. Nitrate is a principal component of the contaminant plume, is chemically stable and highly mobile in groundwater, and is believed to effectively delineate the primary groundwater flow/contaminant transport pathways in the Maynardville Limestone (DOE 1997).

Nitrate concentrations detected in all but two of the groundwater samples collected between January 1986 (19.2 mg/L) and September 1995 (40 mg/L; the historical maximum concentration) exceed the drinking water MCL for nitrate (Table 1). Indeed, the only two nitrate results that are below the MCL, reported for samples collected in December 1986 (5.4 mg/L) and November 1987 (1.29 mg/L, the historical minimum concentration), appear to be outliers compared to preceding and subsequent sampling results. Also, aside from these outlier results, the lowest nitrate concentrations were reported for samples obtained using the low-flow sampling method; all previous samples were collected using the conventional sampling method. Thus, the difference between the historical and more recent nitrate concentrations may be attributable to the manner in which each sampling method induces flow of groundwater into the well, as noted for major ions (calcium, magnesium, and bicarbonate) in Section 4.0, rather than a corresponding change in the relative flux of nitrate via the groundwater flowpaths intercepted by the open-hole interval in the well.

As noted previously, well GW-228 is paired with well GW-227 and, as illustrated by the selected sampling results summarized below, historical data show that nitrate concentrations were typically lower in the deeper groundwater flow/transport pathways intercepted by the monitored interval in well GW-228, although more recent sampling results show nearly equal concentrations for each well. Thus, considering the upward vertical hydraulic gradients indicated by contemporaneous presampling groundwater elevations in each well, as noted in Section 4.0, nitrate concentrations in the shallower groundwater at well GW-227 do not appear to have been significantly influenced by upward migration of nitrate from the deeper flow system in the Maynardville Limestone.

Nitrate (mg/L)			
GW-227 (30-40 ft bgs)		**GW-228 (80-100 ft bgs)**	
01/14/86	66.5	01/14/86	19.2
06/23/87	43.8	06/23/87	22.5
04/27/88	45	04/27/88	24
07/27/89	27	07/28/89	27
02/08/90	9.4	02/02/90	37
03/21/05	3.53	03/21/05	2.47

A time-series plot of the nitrate concentrations reported for the groundwater samples collected to date, excluding the suspected outliers noted previously, shows a generally increasing trend between January 1986 (19.2 mg/L) and September 1995 (40 mg/L), with substantially lower concentrations evident after the long gaps in the sampling history for the well (Figure 1). Interestingly, the nitrate concentrations apparently increased for several years after the former S-3 Ponds were closed and capped, whereas nitrate levels in the shallow flow system exhibit more direct responses to the closure/capping of the site (as illustrated by the nitrate results for well GW-227), which probably reflects the substantially higher permeability compared to the groundwater flowpaths in the deeper flow system

5.2 URANIUM

All of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit (Table 1), with highest value (0.01 mg/L in January 1986) being less than the drinking water MCL for uranium (0.03 mg/L). Moreover, the most recent results show uranium concentrations only slightly above (0.00056 mg/L in March 2005) or below the analytical reporting limit (September 2005).

As illustrated by the selected sampling results summarized below, total uranium concentrations are substantially lower in the deeper groundwater flow/transport pathways intercepted by the monitored interval in well GW-228. Thus, considering the upward vertical hydraulic gradients noted previously, the elevated concentrations of uranium in the shallower groundwater at well GW-227 probably do not result from upward migration of uranium from the deeper flow system in the Maynardville Limestone. Moreover, the lack of elevated uranium levels in the deeper groundwater, in light of the elevated nitrate concentrations indicated by historical data, again indicates that the uranium and nitrate in the shallow groundwater at well GW-227 do not share a common source area.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected to date (Table 2): acetone, CTET, chloroethane, chloroform, ethylbenzene, methylene chloride (MC), styrene, PCE, toluene, TCE, vinyl acetate, xylenes, 11DCE, 11DCA, 12DCA, 12DCE, 111TCA, and 4-methyl-2-pentaone (4M2P). The presence of VOCs in the samples indicates that the monitored interval in the well intercepts groundwater flow/transport pathways for VOCs released from one or more upgradient sources that contribute to an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. Available data for the network of wells completed in the Maynardville Limestone west of the flow divide indicate that VOC-contaminated groundwater, as defined by individual or summed VOC concentrations above 5 µg/L, appears to originate near Spoil Area I and to extend hydraulically downgradient for several thousand feet westward (parallel with geologic strike) down the axis of BCV. The apparent distribution of VOCs within the plume reflects the relative influx from multiple source areas, commingling during downgradient groundwater transport, and hydraulic communication with Bear Creek (DOE 1997). In the upper part of BCV, hydraulically upgradient (east) of the well, the primary VOCs are TCE, c12DCE, and PCE and the confirmed or suspected source areas include Spoil Area I, the contaminant plume emplaced during historical operation of the former S-3 Ponds, and the Rust Spoil Area. Farther downgradient, additional influx of VOCs into the Maynardville Limestone occurs from several potential sources within the Oil Landfarm WMA, including the Oil Landfarm, HCDA, and Sanitary Landfill I (DOE 1997); each of these potential source areas is hydraulically upgradient of well GW-228.

Based on frequency of detection and concentration magnitude, the primary VOC in the groundwater samples is TCE, which is the only VOC that was detected in all of the samples collected to date (Table 2). All but one of the analytical results for TCE exceed 50 µg/L and the most recent results reported for samples collected in March (63 µg/L) and September 2005 (60 µg/L) show that the TCE concentrations remain substantially above the drinking water MCL (5 µg/L). Also, apparent fluctuations in TCE concentrations do not exhibit any clear correlation with seasonal groundwater flow conditions, although many of the lowest TCE concentrations, including the historical minimum concentration (28 µg/L in September 1995), were reported for samples collected during seasonally low flow conditions (summer and fall). However, this may be an artifact of the sampling history for the well, which includes a greater proportion of samples collected during summer and fall. Moreover, both the historical minimum (28 µg/L in September 1995) and maximum (160 µg/L in January 1986) TCE concentrations are suspected outliers compared to the other TCE results, which range between 55 µg/L (September 1995) and 98 µg/L (March 1987).

As shown by the selected sampling results summarized below, historical and recent TCE concentrations detected in the groundwater samples collected to date are substantially higher than evident in the shallower groundwater flow/transport pathways intercepted by the monitored interval in well GW-227. Thus, considering the upward vertical hydraulic gradients indicted by the presampling groundwater elevations, as noted in Section 4.0, the presence of TCE in the shallower groundwater may be at least partially attributable to upward migration of TCE from the deeper flow system in the Maynardville Limestone.

TCE (µg/L)			
GW-227 (30-40 ft bgs)		**GW-228 (80-100 ft bgs)**	
05/20/86	34	05/20/86	82
04/27/88	22	04/27/88	76
02/08/90	14	02/02/90	78
03/21/05	16	03/21/05	63

Secondary VOCs detected in the groundwater samples collected to date, listed in order of decreasing detection frequency, are 12DCE, PCE, 11DCA, chloroform, and 111TCA; of these, only PCE and 12DCE were detected in the samples collected most recently (Table 2). Concentrations of 12DCE are all less than 20 µg/L, although the most recent results (16 µg/L in March and September 2005) show concentrations just slightly below the historical maximum (17 µg/L in July 1988) and demonstrate that the concentrations of 12DCE generally do not exhibit wide seasonal variations. All but seven of the analytical results for chloroform, PCE, 11DCA, and 111TCA are estimated values below 5 µg/L, with the historical maximum concentration of PCE (36 µg/L in January 1986) an obvious outlier compared to the other PCE results (Table 2). The remaining compounds were detected in at least one of a series of samples collected between December 1986 and September 1988, with the bulk of these results being estimated concentrations less than 5 µg/L.

Several of the VOCs detected in the groundwater samples collected to date, particularly 11DCA and 12DCE isomers, are probably present in the groundwater as a result of biologically mediated degradation (sequential dechlorination) of related parent compounds (PCE and 111TCA). As illustrated by the data summarized in Table 3, results for several indicator parameters (particularly the very low dissolved oxygen and negative REDOX conditions) suggest that geochemical characteristics of the groundwater in this well are generally within the optimum ranges for biotic degradation of chlorinated hydrocarbons. Thus, considering the upward vertical hydraulic gradients noted previously, upward migration from the deeper flow system, where geochemical conditions promote more effective anaerobic degradation, is indicated by the low dissolved oxygen and REDOX values reported for the most recent samples collected from well GW-228 (see data summary included in Section 4.0).

A time-series plot of TCE concentrations detected in the groundwater samples collected to date, excluding the suspected outlier results noted above, shows a slightly decreasing long-term concentration trend (Figure 2). Interestingly, other compounds detected in groundwater samples from the well show little change (e.g., PCE) or a slight increase (12DCE) in concentrations over time (Table 2). Assuming a heterogeneous mixture of dissolved VOCs in the groundwater from the shallow karst network in the Maynardville Limestone, it is unclear why the VOC concentrations exhibit divergent trends. Perhaps the TCE is not well mixed with other VOCs in the groundwater system, but instead occurs within separate, discreet transport pathways intercepted by the monitored interval in the well. As noted in Section 5.2 regarding the suspected sources of nitrate and uranium, the somewhat divergent VOC concentration trends potentially reflect separate transport of compounds from different upgradient source areas

5.4 GROSS ALPHA ACTIVITY

Two groundwater samples collected since February 1990 (previous results do not meet applicable data quality objectives) had gross alpha activity above the applicable MDA and corresponding CE, and both of these results (6.36 pCi/L in February 1990 and 7.11 pCi/L in September 1995) are below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Two groundwater samples collected February 1990 (previous results do not meet applicable data quality objectives) had gross beta activity above the applicable MDA and corresponding CE, with these results (48.01 pCi/L in February 1990 and 33.6 pCi/L in September 1995) being below the SDWA screening level (50 pCi/L) for a 4 millirem per year dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-229

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1985, completed with an open-hole monitored interval from 40 to 55 ft bgs, and constructed with nominal 4.5-inch diameter steel (SF25) riser casing. The well is located in Bear Creek Valley (BCV) approximately 5,500 ft west of Y-12, near the southwest corner of Sanitary Landfill I and the Oil Landfarm waste management area (WMA), about 100 ft north of the main channel of Bear Creek.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-six groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 20 samples between January 1986 and July 2004, and the low-flow sampling method used to obtain six samples between March 2002 and July 2004. Note the two substantial gaps in the sampling history: a five and one-half year gap between May 1990 and November 1995 and a six and one half-year gap between November 1995 and March 2002.

Monitoring data obtained through August 2003 indicated that groundwater samples obtained with the low-flow sampling method had substantially higher concentrations of several contaminants compared to groundwater samples obtained previously with the conventional sampling method. The higher contaminant concentrations indicated by the more recent low-flow sampling results could reflect a long-term increasing concentration trend (i.e., increased contaminant flux via the groundwater flow/transport pathways intercepted by the monitored interval in the well), but also potentially reflect the relative influence (bias) of each sampling method. In order to confirm if the higher contaminant concentrations are attributable to sampling method bias, "paired sampling" was performed during consecutive days in February and July 2004, whereby samples were collected one day using the low-flow sampling method and the next day using the conventional sampling method. These sampling results show little if any significant difference between conventional and low-flow sampling results for indicator parameters (e.g., pH), major ions, trace metals, and radioanalytes, along with substantial but conflicting differences between summed VOC concentrations (Table 1). Based on review of these results, including the VOC data (see Section 5.3), the higher contaminant concentration now evident in groundwater samples from the well do not appear to be an artifact of the change from conventional sampling to low-flow sampling.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maynardville Limestone (Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995). Additionally, well GW-229 is located northwest of a reach of the main channel of Bear Creek south of Sanitary Landfill I that loses substantial flow to the Maynardville Limestone and greatly facilitates the transfer of surface-water contaminants into Maynardville Limestone (DOE 1997).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 18 ft bgs and exhibits seasonal fluctuations up to about 18 ft. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV and on

Chestnut Ridge, groundwater elevation isopleths in the vicinity of well GW-226 indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields chloride- and sodium-enriched, calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 618 – 976 mg/L;
- pH of 6.43 – 6.65 (field measurements, excluding an outlier of 4.38 in February 2003);
- unusually high concentrations of several trace metals, notably barium (>1 mg/L), boron (>4 mg/L), iron (>25 mg/L), manganese (>7 mg/L);
- elevated concentrations of chloride (>100 mg/L) and sodium (>75 mg/L) relative to other wells completed at similarly shallow depths in the Maynardville Limestone;
- low molar proportions of potassium and sulfate (<10% of total anions/cations); and
- total concentrations of other trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

It is not clear if the chloride and sodium concentrations typical of the groundwater samples reflect localized geochemical characteristics, or if the elevated concentrations are the result of contamination from one or more sources upgradient of the well. Also, the elevated chloride levels may be at least partially attributable to the biologically mediated degradation of chlorinated solvents in the groundwater (Hinchee et. al. 1995). Additionally, the unusually high iron and manganese concentrations frequently show a direct correlation with total suspended solids (TSS) in the corresponding samples; these results may be artifacts of the preservation (i.e., acidification below a pH of 2) of turbid unfiltered samples. Indeed, considering the extremely high total iron concentrations reported for several samples (e.g., 27.1 mg/L in February 2003), suspended materials in the unfiltered samples probably include rust particles from the corrosion of the steel riser casing in the well.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, uranium, VOCs, gross alpha activity, and gross beta activity are the contaminants present at elevated levels in the groundwater at this well.

5.1 NITRATE

None of the groundwater samples collected from the well since January 1986 had nitrate concentrations at or above the analytical reporting limit.

5.2 URANIUM

All of the groundwater samples had uranium concentrations above the applicable analytical reporting limit (Table 2), with the results for nine samples, including the samples collected most recently (February and July 2004), substantially exceeding the drinking water MCL for uranium (0.03 mg/L). There are several sources of uranium in BCV hydraulically upgradient of the well, including the contaminant plume originating from the former S-3 Ponds and recharge of uranium-contaminated surface water in Bear Creek. Nevertheless, the CERCLA remedial investigation identified the former Boneyard/Burnyard (BYBY) as the primary source of uranium in groundwater from the Maynardville Limestone hydraulically downgradient (west) of the site (DOE 1997), which is about 1,200 ft east-northeast of the well. Uranium-bearing wastes disposed at the BYBY were below the seasonally high water table and the limestone bedrock provided a source of dissolved carbonate, which combined with uranyl cations leached from the wastes and greatly increased what would otherwise be relatively limited mobility in the neutral pH groundwater in the Maynardville Limestone (DOE 1997). As a major source area, the BYBY was prioritized for CERCLA remedial action, which was completed in May 2003 and involved: (1) the excavation and on-site consolidation/off-site disposal of about 81,000 yd^3 of waste materials; (2) construction of a multi-layer low-permeability cap over waste materials consolidated on site; and (3) reconstruction of a northern tributary of Bear Creek (NT-3) that drains the site (BJC 2004).

Total uranium concentrations reported for all but one of the groundwater samples collected between January 1986 and September 1995 (all of which were obtained with the conventional sampling method) are less than the MCL (0.03 mg/L), ranging from 0.01 mg/L in March 1989 to 0.026 mg/L in August 1987 (Table 2). Conversely, all of the samples obtained since March 2002 (0.238 mg/L), including samples obtained with the conventional sampling method in February and July 2004, substantially exceed the MCL. However, as noted in Section 2.0, the "paired sampling" results do not indicate any significant difference between uranium concentrations in samples obtained with low flow or conventional sampling methods. Thus, the higher uranium concentrations do not appear to be an artifact of the change from conventional sampling to low-flow sampling, but instead may reflect a long-term increase in the relative flux of uranium via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

A time-series plot of the uranium results obtained since September 1995 spans a long gap in the sampling history (see Section 2.0), with a long-term increase in uranium concentrations reflected by the conventional sampling results (Figure 1), although the low-flow sampling results suggest a generally downward trend after the historical maximum concentration in August 2002 (0.266 mg/L). Decreasing concentrations of uranium in the groundwater at this well may be a direct response to the CERCLA remedial actions at the BYBY.

5.3 VOLATILE ORGANIC COMPOUNDS

One or more of the following compounds were detected in all of the groundwater samples collected since January 1986 (Table 3): acetone, benzene, chlorobenzene (CB), chloroethane, PCE, TCE, trichlorofluoromethane (TCFM), VC, 111TCA, 11DCA, 11DCE, 12DCE (isomers), 1,4-dichlorobenzene (14DCB), and 1,1,2-trichloro-1,2,2-trifluoroethane, which is also known as Freon-113 (F113). These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. In the Bear Creek watershed west of the flow divide, the VOC plume in the Maynardville Limestone appears to originate near Spoil Area I and to extend several thousand feet westward (parallel with geologic strike) down the axis of BCV, with influx of various VOCs from several different downgradient source areas. The distribution of VOCs within the plume reflects the relative contributions from the source areas and commingling during downgradient transport. Major plume constituents in the upper part of BCV are acetone, TCE, c12DCE, and PCE. Source areas include Spoil Area I and the former S-3 Ponds. Farther downstream (west), TCE becomes the primary contaminant in the plume, with major inputs of VOCs from the Rust Spoil Area or a nearby source in the Bear Creek floodplain; the Oil Landfarm waste management area (WMA), including the former Boneyard/Burnyard (BYBY), Hazardous Chemical Disposal Area (HCDA), and Sanitary Landfill I; and inflow of VOC-contaminated groundwater and surface water that discharges from a northern tributary of Bear Creek (NT-7) that traverses the Bear Creek Burial Grounds WMA. The highest VOC concentrations within the Maynardville Limestone exceed 300 μg/L and occur in the deeper groundwater directly south (down dip) of the HCDA, about

1,000 ft east-northeast (hydraulically upgradient) of well GW-229. These high concentrations coincide with downward vertical hydraulic gradients in the Maynardville Limestone in this area and a major losing (influent) reach of the main channel of Bear Creek (DOE 1997).

The primary VOCs in the groundwater samples are 12DCE (c12DCE) and VC. Both compounds have been detected the most frequently and at the highest concentrations, with respective historical maximum concentrations of 280 μg/L and 42 μg/L (Table 3). Moreover, the most recent (February and July 2004) sampling results show that concentrations of c12DCE and VC remain substantially above their drinking water MCLs (70 μg/L and 2 μg/L, respectively). Secondary compounds in the samples are benzene, CB, 14DCB, chloroethane, 11DCA, TCE, and 11DCE, which have been detected in all of the samples collected since March 2002. Of these compounds, the highest concentrations have been reported for 11DCE (41 μg/L), TCE (16 μg/L) and CB (14 μg/L), with the most recent sampling results show benzene and 11DCE concentrations above respective MCLs (5 μg/L and 7 μg/L). Other VOCs, including PCE, TCFM, and 111TCA have been detected infrequently and most of the results are estimated values below 5 μg/L (Table 3). Additionally, the most recent sampling results indicate that F113 is present in the groundwater, with three of the four samples analyzed for this compound showing concentrations as high as 44 μg/L.

Biologically mediated degradation (sequential dechlorination) of PCE and TCE by anaerobic methanotropic organisms in the groundwater probably explains the dominance of c12DCE and VC in the groundwater samples from this well. As illustrated by the data summarized in Table 4, results for several indicator parameters suggest that the geochemical conditions in the groundwater at this well are within the optimum range for biotic degradation (dechlorination) of chlorinated hydrocarbons. The REDOX conditions, for instance, suggest the reducing (methanogenic) conditions necessary to transform 12DCE to VC (Chapelle 1996). Additionally, dissolved hydrocarbons (e.g., benzene) in the groundwater may serve as electron donors necessary to co-metabolic transformation of the chlorinated hydrocarbons in the groundwater (McCarty 1996).

As noted in Section 2.0, "paired" sampling results obtained during February and July 2004 show large proportionate differences between the summed concentrations of VOCs detected in the groundwater samples obtained with the conventional and low-flow sampling methods. As shown in the following data summary, this is primarily attributable to the concentrations of c12DCE, with the highest concentration reported for the sample obtained with the low-flow sampling method in February 2004 and the conventional sampling method in July 2004.

VOC	Concentration (µg/L)			
	Low-Flow Sampling February 11, 2004	Conventional Sampling February 12, 2004	Low-Flow Sampling July 28, 2004	Conventional Sampling July 29, 2004
PCE	.	.	1 J	1 J
TCE	6	3 J	10	16
c12DCE	130	67	140	280
t12DCE	.	.	.	1 J
11DCE	13	6	24	41
VC	42	23	31	18
111TCA	.	.	1 J	6
11DCA	7	4 J	9	8
Chloroethane	2 J	1 J	.	2 J
Benzene	7	9	7	8
Chlorobenzene	13	14	14	11
14DCB	3 J	3 J	4 J	3 J
Acetone	.	.	3	7
F113	6	2 J	15	44
TCFM	6	3 J	.	.
Summed VOCs	235	135	259	446

Note that the "paired" sampling results for other VOCs, with the possible exception of F113, show similar concentrations in samples obtained with low-flow and conventional sampling methods. Assuming a heterogeneous mixture of dissolved VOCs in the groundwater, it is not clear why the sampling method does not similarly influence the concentrations of all VOCs. Moreover, there are insufficient data to ascertain which sampling method provides the most representative monitoring results for VOCs. Nevertheless, the relatively high summed VOC concentrations indicated by the "paired" sampling results confirm the substantial increase from VOC levels evident during the mid-1980s and are primarily attributable to the order-of-magnitude increase in the concentration of 12DCE (Table 3). This suggests a corresponding increase in the relative flux of 12DCE (isomers) via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

Although limited by the intermittent sampling history for this well (see Section 2.0) and the large differences between conventional sampling and low-flow sampling results for 12DCE, respective time-series plots of summed VOC concentrations show increasing trends (Figure 2). Also, the low-flow sampling results do not appear to show any clear response to the CERCLA remedial actions at the BYBY, with the increasing concentration trend evident before and after the remedial actions.

5.4 GROSS ALPHA ACTIVITY

Available data for gross alpha activity, excluding results reported for the groundwater samples collected before September 1995, which do not meet applicable data quality objectives (the MDAs and corresponding CEs were not reported for these results), indicate elevated levels that exceed the drinking water MCL for gross alpha activity (15 pCi/L). Radiochemical results for samples collected in February and July 2004 confirm that uranium isotopes are the most likely source of the gross alpha activity in the groundwater at this well (Table 2). The contaminant plumes originating from the former S-3 Ponds and the BYBY are primary sources of uranium isotopes in groundwater and surface water in BCV west of Y-12, with the latter site being the closest and most likely source of the uranium isotopes in the groundwater at the well GW-229

(DOE 1997). As with total uranium (see Section 5.2), U-234 and U-238 ions leached from wastes disposed at the BYBY probably combined with carbonate dissolved from the limestone bedrock, which greatly increased their relatively limited mobility in the neutral pH groundwater in the Maynardville Limestone (DOE 1997).

Results for gross alpha activity that exceed the applicable MDA and corresponding CE range between the historical minimum of 6.13 pCi/L in September 1995 and the historical maximum of 150 pCi/L in February 2003 (Table 2). Also, the "paired" sampling results from February and July 2004 do not indicate any consistent and significant difference between the gross alpha activity detected in samples collected with the conventional and low-flow sampling methods (see Section 2). Additionally, the results for gross alpha activity suggest significant temporal (seasonal) fluctuations, with the lowest values (including the historical minimum) reported for samples collected during seasonally high groundwater flow conditions (winter and spring) and the highest values (including the historical maximum) reported for samples collected during seasonally low groundwater flow (summer and fall). This suggests seasonally increased flux of uranium isotopes along the groundwater flow/transport pathways intercepted by the monitored interval in the well.

A time-series plot of the results for gross alpha activity reported for samples collected since September 1995 is similar to that for total uranium (see Section 5.2): the trend spans a long gap in the sampling history with the conventional sampling results demonstrating the overall increase in gross alpha activity and the low-flow sampling results indicating a general decrease from the historical maximum value in February 2003 (Figure 3). Decreasing levels of gross alpha activity potentially correspond to the reduced flux of uranium isotopes as a result of the CERCLA remedial actions at the BYBY.

5.5 GROSS BETA ACTIVITY

There are limited data for gross beta activity because the applicable MDAs and corresponding CEs were not reported for the samples collected before September 1995 (Table 2). Of the nine results for gross beta activity that meet DQOs, five exceed the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the MCL for gross beta activity). Results of radiological analyses of the groundwater samples collected in February and July 2004 (Table 2) confirm that uranium isotopes (and related beta-emitting daughter products) are the source of the elevated gross beta activity, with the BYBY being the closest and most likely source area. These sampling results also indicate that Tc-99, which is a beta particle-emitting radionuclide considered the "signature" component of the contaminant plume emplaced during operation of the former S-3 Ponds (DOE 1997), is not present in the groundwater at this well (Tc-99 levels were below the applicable MDA for each sample). This is consistent with the lack of nitrate in the groundwater samples from the well (see Section 5.1) because available data indicate that nitrate and Tc-99 from the former S-3 Ponds share similar transport characteristics and nearly identical distribution patterns the Maynardville Limestone west of Y-12 (DOE 1997).

Results for gross beta activity that exceed the applicable MDA and corresponding CE range between the historical minimum of 11 pCi/L in September 1995 and the historical maximum of 120 pCi/L in February 2003 (Table 2). Also, the "paired" sampling results from February and July 2004 do not indicate any consistent and significant difference between the gross beta activity detected in samples collected with the conventional and low-flow sampling methods (see Section 2). Additionally, the results for gross beta activity suggest significant temporal (seasonal) fluctuations that generally mirror those evident for gross alpha activity, with the lowest values (including the historical minimum) reported for samples collected during seasonally high groundwater flow conditions (winter and spring) and the highest values (including the historical maximum) reported for samples collected during seasonally low groundwater flow (summer and fall). This relationship suggests seasonally increased flux of uranium isotopes along the groundwater flow/transport pathways intercepted by the monitored interval in the well.

A time-series plot of the results for gross beta activity reported for samples collected since September 1995 generally mirrors that for gross alpha activity (Figure 3): the trend spans a long gap in the sampling history, with the conventional sampling results demonstrating the an overall increase in gross beta activity and the low-flow sampling results suggesting a general decrease from the historical maximum value in February 2003. Decreasing levels of gross beta activity likewise may correspond to the reduced flux of uranium isotopes as (and beta particle-emitting daughter products) a result of the CERCLA remedial actions at the BYBY.

WELL GW-230

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in May 1986, completed with an open-hole monitored interval from 341 to about 406 ft bgs, and constructed with nominal 5.5-inch diameter steel (SF25) riser casing. The well forms a cluster with wells GW-171 and GW-172 and is located in Union Valley east of Y-12, about 4,300 ft east of the ORR boundary along Scarboro Road.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-four groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain ten samples between June 1990 and April 1997, and the low-flow sampling method used to obtain 14 samples between February 1998 and August 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the deep bedrock interval in the Conasauga Group (Maynardville Limestone). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 12 ft bgs and exhibits moderate (<14 ft) seasonal fluctuations. Presampling groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are typically less than 1 to 4 ft lower in well GW-230 than in wells GW-171 and GW-172, both of which are completed at shallower depths (31 ft bgs and 105 ft bgs, respectively) in the Maynardville Limestone. Based on the distance between the monitored interval midpoint (elevation) in each well, the contemporaneous groundwater elevations indicate primarily downward vertical hydraulic gradients (0.01 - 0.05) during seasonally high and low flow conditions.

There are insufficient monitoring wells located in the vicinity of well GW-230 to ascertain the groundwater flow direction(s). Local topography and the characteristics of groundwater flow in the Maynardville Limestone suggest flow towards drainage features located east and west of the well.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields chloride-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 380 – 649 mg/L;
- pH of 6.2 – 7.4 (field measurements);
- high chloride concentrations (>100 mg/L);
- low molar proportions of potassium, sulfate, and sodium (<10% of total anions/cations); and

- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Considering the depth of the well, the high chloride concentrations in the groundwater samples may reflect the natural geochemical changes related to greater residence time as a consequence of increased fracture spacing and decreased fracture aperture at depth (Solomon et al. 1992). Additionally, the elevated chloride levels may be at least partially attributable to biologically mediated degradation (dechlorination) of dissolved chlorinated hydrocarbons in the groundwater (Hinchee et al. 1995). Moreover, as illustrated by the most recent monitoring data summarized in Table 1, several indicator parameters suggest that the geochemical characteristics of the groundwater, particularly the REDOX conditions, are conducive to biotic degradation of VOCs (see Section 5.3).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the respective monitoring data reported for the groundwater samples collected from the well since January 1991, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Ten groundwater samples had nitrate concentrations at or above the applicable analytical reporting limit, with the highest concentration (1.7 mg/L in August 2000) being substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Only eight of the groundwater samples were analyzed for uranium; none had concentrations above the analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in at least one of the groundwater samples: acetone, benzene, bromomethane, chloromethane, total xylene, toluene, chlorobenzene, 12DCE (total), c12DCE, and VC (Table 2). Most of these compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and UEFPC watersheds. In the UEFPC watershed east of the flow divide, which occurs near the west end of Y-12, the VOC plume in the Maynardville Limestone appears to originate near the Fire Training Facility in the southwestern section of Y-12, extends eastward (parallel with geologic strike) and mixes with VOCs released from several sources in the central and eastern Y-12 areas, and enters Union Valley east of the ORR boundary along Scarboro Road (DOE 1998). In October 2000, full-time operation of a groundwater remediation system began to help intercept and contain the (CTET-dominated) portion of the VOC plume in the eastern Y-12 area, as required by the CERCLA Action Memorandum (DOE 1999). Operation of the system involves pumping groundwater from an extraction well (GW-845) completed in the Maynardville Limestone about 800 ft west of Scarboro Road; treating the groundwater on-site to remove particulates, iron, manganese, and VOCs; and discharging the effluent into UEFPC.

The principal VOCs in the groundwater samples are c12DCE and VC; one or both compounds were detected in all but one of the samples since 1994 (Table 2). Relatively low concentrations of both compounds have been reported, with historical maximum values of only 22 μg/L for (total) 12DCE and 7 μg/L for VC. Also, the most recent monitoring results show that the c12DCE concentrations remain substantially below the drinking water MCL, and VC was detected only once (2 μg/L in February 2004) in the last four samples (Table 2). Secondary VOCs include chlorobenzene and petroleum hydrocarbons (benzene, total xylene, and toluene). Trace levels (1 μg/L) have been detected in 5 samples, including the most recent samples. Petroleum hydrocarbons have been detected in seven of the samples; all results for the petroleum hydrocarbons are estimated values below analytical reporting limits. The persistent detection of these compounds in the groundwater samples is surprising because petroleum hydrocarbons are not principal components of the dissolved VOC plume in the Maynardville Limestone hydraulically upgradient (west) of the well. Also, residual contamination during installation and construction of the well may be a source of the petroleum hydrocarbons, but this seems somewhat unlikely considering the age of the well and the likelihood for residual contamination to have been "flushed" from the well during subsequent well development and sampling.

A plot of the summed concentrations of VOCs detected each groundwater sample shows a fluctuating, indeterminate trend (Figure 1). This indeterminate trend probably reflects limited flux at this depth (>400 ft bgs) in Maynardville Limestone.

5.4 GROSS ALPHA ACTIVITY

One groundwater sample had gross alpha activity above the applicable MDA and corresponding CE, and this result (46.34 pCi/L in August 2002) exceeds the drinking water MCL for gross alpha activity (15 pCi/L). However, gross alpha activity reported for this sample is considered to be an outlier. The inconsistent detection of gross alpha activity may be related to analytical interference associated with the very high TDS of the (unfiltered) groundwater samples (see Section 4.0)

5.5 GROSS BETA ACTIVITY

Fourteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, and the results for two of these samples (57.5 pCi/L in August 2001 and 2,560 pCi/L in August 2002) exceed the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). However, the gross beta activity reported for these samples are suspected outliers compared to the other gross beta results, only one of which exceeds 10 pCi/L. As with the gross alpha activity, the inconsistent detection and widely variable results for gross beta activity may be related to analytical interference associated with the high TDS of the (unfiltered) groundwater samples (see Section 4.0)

WELL GW-231

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1985, completed with a screened monitored interval from 22.8 to 35 ft bgs, and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and screen (0.01 slot). The well forms a cluster with well GW-147 and is located on the southern flank of Chestnut Ridge directly south of the east end of Y-12, about 100 ft west-northwest (hydraulically upgradient) of Kerr Hollow Quarry (KHQ). KHQ is an inactive, water-filled quarry formerly used for disposal of various hazardous and nonhazardous wastes generated from historical DOE operations on the ORR.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Ninety-seven groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 53 samples between March 1986 and August 1997, and the low-flow sampling method used to obtain 44 samples between November1997 and October 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from bedrock in the Knox Group (Mascot Dolomite). Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 12 ft bgs and exhibit moderate (<10 ft) water level fluctuations. Also, presampling groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are typically higher in well GW-231 than in well GW-147, which is completed at a greater depth (69 ft bgs) in the Knox Group. Based on the distance (30 ft) between the monitored interval midpoint (elevation) in each well, the contemporaneous groundwater elevations indicate downward vertical hydraulic gradients (0.004 – 0.033) from well GW-231 to GW-147 during seasonally high and low flow conditions.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 90 – 322 mg/L;
- pH (field measurements) of 6.4 – 8.1;
- equal or nearly equal calcium:magnesium ratios (which is characteristic of water in contact with dolomite) and low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for 78 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Forty-two groundwater samples collected between March 1991 and April 1999 had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (1.79 mg/L in April 1996) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Seven groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.004 mg/L in October 2001) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected at low levels in three groundwater samples: 2-butanone (10 μg/L) in November 1995, TCE (3 μg/L) in April 1998, and chloromethane (1 μg/L) in October 2000. These results are considered outliers because each compound was detected only once.

5.4 GROSS ALPHA ACTIVITY

Twelve groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (5.45 pCi/L in October 2000) being below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Twenty-four groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (7.53 pCi/L in October 2003) being substantially below the SDWA for gross beta activity (50 pCi/L).

WELL GW-232

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in March 1986, completed with an open-hole monitored interval from 401 to 411.7 ft bgs, and constructed with nominal 4.5-inch diameter steel riser casing. The well forms a cluster with wells GW-169 and GW-170, and is located in Union Valley east of Y-12, about 1,500 ft east of the ORR boundary along Scarboro Road.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-six groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 22 samples between June 1990 and April 1997, and the low-flow sampling method used to obtain 24 samples between February 1998 and October 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the deep bedrock interval (>400 ft bgs) in the Conasauga Group (Maynardville Limestone). Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 31 ft bgs and exhibit moderate (<10 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields sulfate-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 430 – 620 mg/L, excluding a suspected outlier (176 mg/L) in August 1994;
- pH (field measurements) of 8.1 – 11.7;
- low molar proportions of chloride, potassium, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for 45 groundwater samples collected from the well since January 1991.

5.1 NITRATE

Nine groundwater samples had nitrate concentrations above the applicable analytical reporting limit, with the highest concentration (1.6 mg/L in August 2000) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Two groundwater samples had uranium concentrations above the applicable analytical reporting limit and both results (0.001 mg/L in August 1993 and February 1994) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were detected at low levels in three groundwater samples: acetone (45 μg/L) in May 1991, toluene (0.6 μg/L) in November 2002, and acetone (2 μg/L) in October 2004. These VOCs are common laboratory reagents and the results are considered to be outliers.

5.4 GROSS ALPHA ACTIVITY

Nine groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (81.3 pCi/L in November 2001) being substantially above the MCL for gross alpha activity (15 pCi/L). However, this gross alpha result is considered an outlier (none of the other results exceed 10 pCi/L) and is probably an analytical artifact.

5.5 GROSS BETA ACTIVITY

Sixteen groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (365.61 pCi/L in November 2001) being substantially above the SDWA screening level for gross beta activity (50 pCi/L). However, this gross beta result is considered an outlier (none of the other results exceed 15 pCi/L) and is probably an analytical artifact.

WELL GW-236

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in October 1985, completed with a screened monitored interval from 10 to about 19 ft bgs, and constructed with nominal 4.5-inch outside diameter PVC (#40) riser casing and well screen (0.01 slot spiral-wound). The well is located in Bear Creek Valley (BCV) west of Y-12, on the north side of Bear Creek approximately 1,700 ft west-southwest of the former S-3 Ponds. This site consists of four unlined surface impoundments that were filled and covered with a multilayer low-permeability cap (and an asphalt-paved parking lot) during RCRA closure of the site in 1988. The surface impoundments were used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12, which emplace a large heterogeneous mixture of inorganic, organic, and radiological contaminants in the subsurface that remains one of the primary sources of groundwater and surface water contamination in BCV.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Eleven groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain eight samples between April 1988 and September 1995, and the low-flow sampling method used to obtain samples in September 1999, March 2004, and August 2004. The sampling history includes quarterly, semiannual, and annual sampling frequencies that encompass three extended non-sampling periods: March 1990 – September 1995; October 1995 – September 1999; and October 1999 – March 2004.

Low pH is a distinguishing characteristic of the groundwater samples from this well (see Section 4.0) and (along with elevated nitrate concentrations) are a consequence of contamination associated with historical operation of the former S-3 Ponds (see Section 5.0).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Maynardville Limestone (Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995). Based on the depth of the well and its location relative to the (projected) geologic contact between the Maynardville Limestone and the underlying Nolichucky Shale, the monitored interval in the well potentially intercepts groundwater flow/transport pathways within the highly permeable zone near the bottom of the formation.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 8 ft bgs and exhibits minor seasonal fluctuations (<4 ft). Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV and on Chestnut Ridge, groundwater elevation isopleths in the vicinity of the well indicate flow to the west, parallel with geologic strike of the Maynardville Limestone and the main channel of Bear Creek.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the samples collected from the well indicate that the well yields acidic, moderately mineralized, nitrate- and sulfate-enriched (contaminated) calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 422 – 1476 mg/L;
- pH (field measurements) of 4.2 – 5.6;
- elevated concentrations of nitrate and sulfate (e.g., 63.5 and 83 mg/L, respectively, in March 2004);
- low molar proportions of chloride, potassium, and sodium (<15% of total anions/cations);
- unusually high total concentrations of manganese (>2 mg/L);
- total concentrations of other trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, nitrate and gross beta activity are principal contaminants currently in the groundwater at this well.

5.1 NITRATE

All of the groundwater samples collected to date had nitrate concentrations above the applicable analytical reporting limit (Table 1). Concentrations above 300 mg/L were reported for all but one of the samples collected between April 1986 (1,470 mg/L) and April 1991 (421 mg/L). Note that the latter result is qualitative because of an unacceptably high charge balance error (-36.4%), as determined by the percent difference between the summed millequivalent concentrations of the primary anions and cations. The source of the nitrate is the contaminant plume emplaced during historical operation of the former S-3 Ponds. Nitrate, a principal component of the plume, enters the Maynardville Limestone via direct inflow of nitrate-contaminated groundwater from the Nolichucky Shale and recharge of nitrate-contaminated surface water in Bear Creek (DOE 1997). Nitrate is chemically stable and highly mobile in groundwater and effectively traces the primary groundwater flow/transport pathways followed by other similarly mobile contaminants originating from the former S-3 Ponds. Based on the existing network of monitoring wells in the Maynardville Limestone in BCV west of Y-12, the extent of elevated nitrate concentrations (i.e., >10 mg/L) in the groundwater indicate: (1) a relatively contiguous plume of nitrate in the fracture-dominated groundwater flow/transport pathways at depth (>100 ft bgs) in the bedrock that extends from south (down-dip) of the former S-3 Ponds westward for about 10,000 ft along geologic strike (i.e., bedding plan fractures) and (2) a more discontinuous plume of nitrate in the shallow karst network, which receives substantially greater recharge (i.e., dilution) than the deeper bedrock and is significantly influenced by hydrologic interactions with surface water in Bear Creek.

Nitrate concentrations in the groundwater samples range from the historical maximum value (1,470 mg/L), which was reported for the initial groundwater sample collected from the well in April 1988, and the historical minimum value (33 mg/L in March 1989), which appears to be an outlier compared to the nitrate concentrations reported samples collected in November 1988 (362 mg/L) and May 1989 (805 mg/L). Additionally, the nitrate results reflect a clearly decreasing long-term concentration trend, with a significant decrease evident between March 1990 (421 mg/L [qualitative]) and September 1995 (65 mg/L) and fairly stable concentrations since September 1995 (Table 1). The decreasing trend follows installation of the low-permeability cap at the former S-3 Ponds during RCRA closure of the site in 1988, and reflects the substantial reduction in the relative flux of nitrate along the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.2 URANIUM

All but one of the groundwater samples collected to date had uranium concentrations at or above the applicable analytical reporting limit (Table 1), with four results, including the historical maximum concentration (0.051 mg/L in June 1988), being above the MCL for uranium (0.03 mg/L). Elevated levels of uranium in the groundwater samples from this well result from downgradient migration/transport of uranium from the contaminant plume emplaced during historical operation of the former S-3 Ponds. Uranium was entrained in the nitric acid wastes disposed at the site and is a primary component of the S-3 Ponds contaminant plume. The extent of uranium migration/transport from the plume is largely controlled by the pH of the groundwater. Within the acidic groundwater near the former surface impoundments, uranium is probably present as uranyl cations that tend to form complexes with a wide variety of inorganic anions (Fetter 1993). This well yields groundwater samples with low pH (see Section 4.0), and the pH has generally increased since the late 1980s. For example, the lowest value (3.8, field measurement) was obtained in September and November 1988 and the range of pH in the CY 2004 samples was 5.16 to 5.57.

As with the nitrate, the uranium results have shown a clearly decreasing long-term trend, with a significant decrease evident between March 1990 (0.045 mg/L) and September 1995 (0.0096 mg/L) and fairly stable concentrations since September 1995 (Table 1). None of the samples collected since March 1990 have exceeded the MCL for uranium. The decreasing trend reflects the substantial reduction in the relative flux of uranium along the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected to date: PCE, toluene, 11DCA, 11DCE, and 111TCA (Table 2). These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and Upper East Fork Poplar Creek watersheds. In the Bear Creek watershed west of the flow divide, the VOC plume in the Maynardville Limestone appears to originate near Spoil Area I and to extend several thousand feet westward (parallel with geologic strike) down the axis of BCV, with influx of various VOCs from several different downgradient source areas. The distribution of VOCs within the plume reflects the relative contributions from the several source areas and commingling during downgradient transport. Plume constituents in the upper part of BCV, where well GW-236 is located, are TCE, c12DCE, and PCE. Potential source areas of the VOCs in groundwater at the well include Spoil Area I and the former S-3 Ponds.

Based on the frequency of detection and concentration magnitude, the primary VOCs in the groundwater samples are PCE, 11DCA, and 111TCA (Table 2), although only trace levels of PCE and 11DCA have been detected since September 1999 and 111TCA has not been detected in samples collected after March 1990. Toluene was detected in only the sample collected in March 1989 (0.3 μg/L) and 11DCE was detected only in the samples collected in March 1989 (5 μg/L) and March 1990 (1 μg/L). None of the sampling results for toluene, PCE, 11DCE, or 111TCA exceed the respective drinking water MCL (Table 2). Also, the VOCs results reflect a clearly decreasing long-term concentration trend that appears to have reached somewhat asymptotic levels, as illustrated by the summed concentrations of VOCs detected in the samples collected in September 1988 (41 μg/L), September 1995 (7 μg/L), September 1999 (2 μg/L), and August 2004 (3 μg/L). The overall decrease in VOC concentrations suggests a corresponding reduction in the relative flux of dissolved VOCs via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

Two of the groundwater samples collected since March 1990 had gross alpha activity above the applicable MDA and corresponding CE: the sample collected in September 1995 (3.26 pCi/L) and the sample collected in September 1999 (5.9 pCi/L). Both results are substantially below the drinking water MCL for gross alpha activity (15 pCi/L). Gross alpha activity results reported for previous samples are qualitative (the sample-specific MDA and CE are not available). Low levels of gross alpha activity in the groundwater at this well are supported by the similarly low levels of U-234 (<2 pCi/L) and U-238 (<5 pCi/L) that were detected (i.e., >MDA and CE) in the samples collected in March and August 2004.

5.5 GROSS BETA ACTIVITY

Four of the groundwater samples collected since March 1990 had gross beta activity above the applicable MDA and corresponding CE (Table 1), and all of these results exceed the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the MCL for gross beta activity). The source of the gross beta activity in the groundwater at this well is Tc-99, which is a beta particle-emitting radionuclide that was detected (i.e., >MDA and CE) in the samples collected in March 2004 (88 pCi/L) and August 2004 (79 pCi/L). Note that these Tc-99 concentrations are substantially less than the corresponding SDWA screening level (3,790 pCi/L) for a 4 mrem/yr dose equivalent. Tc-99 is considered a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds, which is the only site at Y-12 that received wastes that contained Tc-99 (DOE 1998). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-), which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in BCV west of Y-12, the distribution of elevated gross beta activity (i.e., >50 pCi/L) in the Maynardville Limestone suggest that the transport of Tc-99 in the groundwater closely mirrors that of nitrate.

As shown on Table 1, the highest levels of gross beta activity were reported for the groundwater samples collected before September 1995, including the historical maximum value (923 pCi/L in September 1988), although these results are considered qualitative. Gross beta activity reported for the samples collected since September 1995 are less than 100 pCi/L, with the sample collected in August 2004 having the lowest gross beta activity (52 pCi/L) evident since November 1988 (49 pCi/L). The overall decrease in gross beta activity is attributable to the reduced flux of Tc-99 from the former S-3 Ponds following closure of the site and installation of the low-permeability cap.

WELL GW-237

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in November 1985, completed with a screen monitored interval from 6.5 to 13.7 ft bgs, and constructed with nominal 2.5-inch stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley (BCV) west of Y-12, approximately 200 ft northeast of the confluence of the main channel of Bear Creek and a northern tributary (NT) of the creek (NT-6) that drains the eastern sections of the Bear Creek Burial Grounds (BCBG) waste management area (WMA). The BCBG includes numerous hazardous and nonhazardous waste disposal units that received a mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. Liquid wastes included oils, machine coolants, and borax waste water, all or most of which may have contained varying amounts of radioisotopes (primarily uranium isotopes). In 1989, the waste-disposal units in the BCBG waste-management area were covered with multi-layer, low-permeability caps installed during RCRA closure of the site.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Three groundwater samples have been collected to date, with the conventional sampling method used to collect a sample in April 1988 and the low-flow sampling method used to obtain samples in March and September 2004.

Unusually low levels of TDS (<150 mg/L) are a distinguishing characteristic of the groundwater samples from this well (see Section 4.0). The low TDS of the samples suggests relatively low residence time for the groundwater in the well, which indicates that the monitored interval for the well intercepts highly permeable groundwater flowpaths.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Maynardville Limestone (Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths and groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995). The depth of the well and its location relative to the geologic contact between the Maynardville Limestone and the underlying Nolichucky Shale suggest that the monitored interval is completed within Zone 6.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 8 ft bgs and exhibits minimal (<1 ft) seasonal fluctuations. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-237 indicate westerly flow directions, parallel with geologic strike (i.e., bedding-plane fractures) in the Maynardville Limestone.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the groundwater samples collected to date indicate that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- unusually low TDS of 115 – 135 mg/L;
- pH (field measurements) of 6 – 6.2;

- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that none of the principal contaminants are present at elevated concentrations in the groundwater at this well.

5.1 NITRATE

Each groundwater sample had nitrate concentrations above the applicable analytical reporting limit, and the results are all less than 1 mg/L and are substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

None of the groundwater samples had uranium concentrations above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, VOCs were not detected in any of the groundwater samples.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples had gross beta activity above the applicable MDA and corresponding CE.

WELL GW-242

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in November 1985, completed with a screened monitored interval from 9 to 17 ft bgs, and constructed with nominal 2.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located on the southern flank of Pine Ridge west of Y-12, immediately east of Burial Ground-D in the Bear Creek Burial Grounds (BCBG) waste management area. The BCBG includes numerous hazardous and nonhazardous waste disposal units that received a mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. Liquid wastes included oils, machine coolants, and borax waste water, all or most of which may have contained varying amounts of radioisotopes (primarily uranium isotopes). In 1989, most of the waste-disposal units in the BCBG waste management area were covered with multi-layer, low-permeability caps installed during RCRA closure of the site.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fifteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain ten samples between November 1987 and February 1990, and the low-flow sampling method used to obtain five samples between June 1998 and October 2005. This sampling history includes an eight-year period (February 1990 to June 1998) and a six-year period (March 1999 to June 2005) when no groundwater samples were collected from the well.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Pumpkin Valley Shale). The bulk of the groundwater flow in the Conasauga Group occurs within the water table interval, which is a highly permeable zone that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek that traverse the Pumpkin Valley Shale and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow toward the Maynardville Limestone, a highly permeable (karst) formation that subcrops along the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 3 ft bgs and exhibits seasonal fluctuations of about 1 ft. Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-242 indicate flow to the south and southwest toward the Maynardville Limestone and the main channel of Bear Creek. However, groundwater flow in the Pumpkin Valley Shale is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Consequently, the direction(s) of groundwater flow in the vicinity of well GW-242 may be primarily eastward (parallel with geologic strike) toward discharge areas in NT-7.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 214 – 237 mg/L;
- pH of 6.12 – 6.6 (field measurements);
- low molar proportions of chloride, sulfate, potassium, and sodium (<15% of total anions/cations);
- elevated total concentrations of iron (>5 mg/L) and manganese (> 2mg/L); and
- total concentrations of other trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

One groundwater sample had nitrate concentrations above the analytical reporting limit, with that concentration (0.045 mg/L in March 1999) being substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Eight groundwater samples collected to date had uranium concentrations above the analytical reporting limit, with the highest concentration (0.012 mg/L in April 1988) being below the drinking water MCL for uranium (0.03 mg/L). Notably, uranium concentrations have been below the reporting limits in all groundwater samples collected from the well since February 1990.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples (Table 2): PCE, TCE, 12DCE, VC, 111TCA, 11DCA, dichlorodifluoromethane (DCFM), and 1,1,2-trichloro-1,2,2-trifluoroethane, which is also known as freon-113 (Table 1). Waste disposal sites within Burial Ground (BG)-C East or BG-D are the likely source of the dissolved VOCs in the shallow groundwater at this well.

The primary compounds in the groundwater samples are 12DCE and VC, which have been detected in nearly every sample and have historical maximum concentrations that exceed 50 µg/L (Table 1). These primary compounds are probably present in the groundwater as a consequence of the biotic degradation of PCE and TCE (Wilson et al. 1996); most of the geochemical characteristics of the groundwater in the well are conducive to anaerobic biotic degradation (Table 2). Secondary compounds in the samples are PCE, TCE, and 11DCA, which generally have historical maximum values below 10 µg/L. The historical maximum concentrations of PCE, TCE, c12DCE, and VC have exceeded respective drinking water MCLs, and the most recent results (June and October 2005) show that only VC concentrations continue to exceed the MCL (Table 1).

A time-series plot of the summed VOC concentrations shows a highly variable, indeterminate long-term trend that encompasses the two time gaps (February 1990–June 1998 and March 1999–June 2005) in the sampling history for the well (Figure 1). The indeterminate trend, also evident in concentration trends of the individual VOCs (Table 1), suggests little long-term change in the relative flux of dissolved VOCs along the shallow groundwater flowpaths intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

Three groundwater samples collected from the well since February 1990 had gross alpha activity above the applicable MDA and corresponding CE, with the historical maximum (23.04 pCi/L in June 1998) exceeding the drinking water MCL for gross alpha activity (15 pCi/L). However, the historical maximum value is an outlier compared to the other results for gross alpha activity, none of which exceed 4 pCi/L. Results reported for samples obtained before 1990 do not meet applicable data quality objectives because the sample specific MDA and/or CE are not available for these samples.

5.5 GROSS BETA ACTIVITY

Four groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the maximum level (44.54 pCi/L in June 1998) being below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). As with gross alpha activity, the historical maximum value is an outlier compared to the other gross beta results, none of which exceeded 8 pCi/L. Results reported for samples obtained before 1990 do not meet applicable data quality objectives because the sample specific MDA and/or CE are not available for these samples.

WELL GW-244

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during March 1986, completed with a screened monitored interval from 43 to 77 ft bgs, and constructed with nominal 6.5-inch diameter PVC (#40) riser casing and screen (0.03 slot). The well is one of a series of wells completed at similar depths along the western (GW-243 and GW-244) and southern (GW-245, GW-246, and GW-247) boundaries of the former S-3 Ponds (hereafter referenced as the S-3 Site), with well GW-244 being approximately 100 ft northwest of the southwest corner of the site. The S-3 Site, which is located near the western end of Y-12, directly north of the headwaters of Bear Creek, encompasses four contiguous, above-grade, unlined surface impoundments, each with a surface area of approximately 400 x 400 ft and an average total depth of approximately 15 ft. The ponds were used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12, and were closed in 1988 in accordance with requirements of the RCRA regulations applicable to hazardous waste landfills. Closure of the site was completed in 1989 and included the neutralization and removal of liquid wastes and stabilization of neutralization sludge remaining in each pond, which were then filled with crushed limestone and covered with a multilayer low-permeability cap (completed with an asphalt-paved parking lot). Historical operation of the S-3 Site emplaced a heterogeneous mixture of inorganic, organic, and radiological contaminants in the subsurface that remains a primary source of groundwater and surface water contamination in BCV.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fifteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 13 samples between March 1987 and January 1990 and the low-flow sampling method used to obtain samples in June and October 2005. The sampling history includes almost two years of quarterly sampling, followed by a 15-year period (January 1990 – June 2005) when no groundwater samples were collected from the well.

Extremely high total dissolved solids (TDS) is a distinguishing characteristics of the groundwater samples from this well (see Section 4.0), and is a direct consequence of contamination resulting from historical operation of the S-3 Site (see Section 5.0).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Nolichucky Shale (Conasauga Group), which trends northeast-southwest along the northern slope of BCV, dips to the southeast at an angle of 45º-55º, and is bordered on the southeast by the overlying Maynardville Limestone, a highly permeable karst aquifer that provides the principal pathway for subsurface contaminant migration in BCV. The water table interval is a highly permeable zone that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock and transmits the bulk of the groundwater in the Nolichucky Shale. Moreover, it is suspected that the highly acidic wastes from the S-3 Site dissolved carbonate strata interbedded within the Nolichucky Shale and greatly enhanced the relative permeability of these strata-bound flowpaths within several hundred feet of the site.

Groundwater flow in the water table interval in the Nolichucky Shale is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek, which traverse the Nolichucky Shale from northeast to southwest throughout BCV west of Y-12 and are numbered in ascending order downstream from the headwaters of the creek. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et al. 1992). Groundwater flow in the bedrock intervals

(shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone.

The static water level in the well occurs at an average depth of approximately 12.5 ft bgs and exhibits minor (<1 ft) seasonal fluctuations. As indicated by groundwater elevation isopleths determined from contemporaneous depth-to-water measurements from nearby monitoring wells, directions of groundwater flow near the S-3 Site are to the west, parallel with the trend (strike) of bedding in Nolichucky Shale, and to the south-southwest, across geologic-strike toward the Maynardville Limestone and the main channel of Bear Creek. However, as noted previously, the Nolichucky Shale exhibits strongly anisotropic flow via strike-parallel flowpaths (i.e., bedding-plane fractures) that may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Also, possible dissolution of carbonate strata by the acidic seepage from the S-3 Site may locally enhance strata-bound groundwater flow/contaminant transport in directions parallel with geologic strike and dip. Additionally, directions of groundwater flow (and contaminant transport) now evident are undoubtedly different from the flow patterns that occurred during historical operations of the S-3 Site, which created a local "mound" in the water table that enabled groundwater flow (and contaminant transport) to the east of the hydrologic divide separating the Bear Creek and Upper East Fork Poplar Creek watersheds.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples collected in June and October 2005 show that the well yields acidic, highly mineralized and contaminated groundwater from the Nolichucky Shale beneath the S-3 Site that is generally characterized by:

- TDS of 26,300 –27,200 mg/L;
- pH (field measurements) of 5.5 – 5.6;
- very high concentrations of calcium (>5,000 mg/L), nitrate (>4,000 mg/L), magnesium (>800 mg/L), sodium (>400 mg/L), chloride (>250 mg/L), potassium (>40 mg/L), and fluoride (>4 mg/L) relative to other wells;
- very high total concentrations of several trace metals, notably aluminum (>10 mg/L), barium (>130 mg/L), cadmium (>1 mg/L), manganese (>170 mg/L), nickel (>2 mg/L), and strontium (>15 mg/L), that are orders of magnitude above corresponding background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

Note that some of the inorganic compounds and trace metals in the groundwater at this well, such as nitrate and uranium, were entrained in the acidic wastes disposed at the S-3 Site, whereas other inorganics, such as calcium and barium, were dissolved from bedrock minerals by the highly acidic seepage from the site. Also, the very high concentrations of TDS and specific trace metals (e.g., aluminum) may cause analytical interferences for some laboratory analytes, including trace metals, gross alpha activity, and gross beta activity.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, nitrate, VOCs, and gross beta activity are the principal contaminants of the groundwater at this well. Note, however, that the bulk of the historical the analytical results for VOCs, gross alpha activity, and gross beta activity do not meet all applicable DQOs. The QA/QC sample data needed to identify false positive VOC results are not available for groundwater samples collected before January 1991. Similarly, gross alpha activity and gross beta activity reported for the groundwater samples collected before January 1990 are considered unusable because the sample-specific MDA and CE are not available for these analytes.

5.1 NITRATE

Eight of the groundwater samples collected to date were analyzed for nitrate and all of these results exceed 4,000 mg/L, with the nitrate concentration detected in the sample collected most recently (4,290 mg/L in October 2005) being the lowest detected in the well (Table 1). Nitrate is a primary component of the contaminant plume emplaced during historical operations of the S-3 Site, is chemically stable and mobile in groundwater, and effectively traces the groundwater transport pathways followed by other similarly mobile components of the contaminant plume (DOE 1997).

A time-series plot of the nitrate concentrations detected in the groundwater samples collected to date is dominated by the long gap in the sampling history for the well, but shows a generally decreasing long-term trend (Figure 1). As illustrated by the data summarized below, this decreasing trend is generally mirrored by the decreasing nitrate concentration trends indicated by the data for other wells (GW-245, GW-246, and GW-247) located adjacent to the S-3 Site. These data also show that wells GW-243 and GW-244, both of which are located on the west side of the site (parallel with geologic strike), monitor groundwater with the highest levels of nitrate, as indicated by both the historic and the most recent sampling results for each well.

Well No./Monitored Interval Depth (ft bgs)		**Nitrate (mg/L)**				**% Change**
		June 1988	**August 2002**	**August 2004**	**June 2005**	
GW-243	62 – 77	6,160	8,840	.	.	+ 44%
GW-244	43 – 77	6,200	.	.	4,350	-37%
GW-245	25 – 76	3,660	.	.	2,210	-40%
GW-246	34 – 76	5,590	.	2,850	.	-49%
GW-247	31 – 78	3,500	.	.	3,260	-7%
Note: "." = Not sampled						

The decreasing nitrate concentration trend evident for well GW-244 (and wells GW-245, GW-246, and GW-247) suggest a corresponding decrease in the relative flux of nitrate in the shallow groundwater flow system in the Nolichucky Shale nearest to the S-3 Site. Decreased flux of nitrate via the groundwater flowpaths intercepted by the monitored interval in these wells occurred in response to the closure of the site and the subsequent installation of the low-permeability cap. Conversely, the increasing concentration trend indicated by the nitrate data for well GW-243 seems conspicuous relative to the decreasing trends evident for the other wells and may be an artifact of one or more inaccurate sampling results. Also, a relatively minimal decrease in the flux of nitrate is indicted by the sampling results for well GW-247, which may be completed in a comparably less permeable interval in the Nolichucky Shale than well GW-244 (and wells GW-245 and GW-246).

5.2 URANIUM

Seven of the 11 groundwater samples collected to date that were analyzed for uranium had concentrations above the applicable analytical reporting limit (Table 1), including one value (0.111 mg/L in June 1987) that exceeds the drinking water MCL for uranium (0.03 mg/L). However, this maximum result is a suspected outlier because all other results are below 0.02 mg/L. As noted previously, uranium was entrained in the wastewaters disposed at the S-3 Site, and the uranium in the acidic seepage probably occurred as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble complexes with a variety of inorganic anions (Fetter 1993). Consequently, elevated concentrations of uranium are generally restricted to the acidic groundwater in the Nolichucky Shale within approximately 500 ft of the S-3 Site (DOE 1987).

As shown in the following data summary, the uranium concentrations evident in the groundwater at this well do not appear to ever have been significantly elevated and are substantially lower than evident in the other wells located along the southern boundary of the S-3 Site (GW-245, GW-246, and GW-247), with the highest uranium concentrations evident for wells GW-243 and GW-246, which appear to monitor the most acidic groundwater. Considering that uranium was entrained in the wastewaters disposed throughout the operation of the site, the relatively low levels of uranium in the groundwater from of well GW-244 is somewhat surprising.

Well No. / Monitored Interval Depth (ft bgs)		**June 1988**		**August 2002**		**August 2004**		**June 2005**	
		Total U	**pH**	**Total U**	**pH**	**Total U**	**pH**	**Total U**	**pH**
GW-243	62 - 77	60.5	3.6	0.653	5.42	.	.	.	.
GW-244	43 – 77	<0.001	5.5	.	.	.		0.00209	5.5
GW-245	25 – 76	0.115	5.3	.	.	.		0.0478	6.01
GW-246	34 – 76	0.661	4.8	.	.	0.591	4.63	.	.
GW-247	31 – 78	0.036	6.0	.	.	.		0.0241	5.93
Note: "." = Not sampled; Total uranium concentrations in mg/L; pH from field measurements (in standard pH units)									

Interestingly, the groundwater in well GW-244 has never been especially acidic and the pH appears to have changed very little since the S-3 Site was closed and capped, as illustrated by the results summarized above. Perhaps the monitored interval in this well is completed within a stratigraphic section of the Nolichucky Shale that contains proportionally more carbonate than shale. Dissolution of the carbonate by the acidic seepage during the operation of the S-3 Site would buffer the pH of the groundwater, increase the hydraulic conductivity of the permeable flowpaths (e.g., enlarge bedding-plane fractures), and provide dissolved carbonate available to complex with any uranyl cations in the groundwater.

5.3 VOLATILE ORGANIC COMPOUNDS

One or more of the following VOCs was detected in each of the groundwater samples collected to date: acetone, chloroform, ethylbenzene, MC, PCE, TCE, toluene, 2-hexanone, and 12DCE (Table 2). Chlorinated solvents and organic chemicals were not substantial components of the waste stream for the S-3 Site and, consequently, VOCs are fairly minor constituents within the contaminant plume emplaced during historical operation of the site and are typically present at substantially lower concentrations compared to inorganic components of the plume (e.g., nitrate).

Based on frequency of detection and maximum concentration, chloroform and MC are the primary VOCs in the groundwater samples collected to date (Table 2). Both compounds were detected in all but one sample, with a historical maximum concentration of 24 µg/L for chloroform and 10 µg/L for MC. The maximum value for chloroform, which was reported for the sample collected in June 2005, is substantially below the drinking water MCL for total trihalomethanes (80 µg/L). Of the other compounds, only PCE was detected in any sample collected since February 1989, with the highest concentrations reported for acetone (e.g., 32 µg/L in March 1987), and the results for several compounds (e.g., 2-hexanone) being likely analytical artifacts (see Section 5.0). Also, although PCE has been detected infrequently, but the most recent sampling result (6 µg/L in October 2005) indicates concentrations slightly above the MCL for PCE (5 µg/L).

A time-series plot of the summed concentrations of VOCs detected in the groundwater samples collected to date (excluding false positive results) spans the prolonged gap in the sampling history for the well, with the VOC results reported for the samples collected in June and October 2005 suggesting an indeterminate or slightly increasing long-term VOC concentration trend (Figure 2). This trend is attributable to higher PCE and chloroform concentrations, fairly stable MC concentrations, and lower acetone concentrations compared to historical levels. For instance, the concentration of chloroform increased from 14 µg/L in June 1987 to 24 µg/L in June 2005, while acetone concentrations decreased from 21 µg/L to below the detection limit (Table 2). It is not clear from the available data if the divergent concentration trends for individual compounds are significant with regard to the corresponding flux of VOCs via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

As illustrated by the chloroform (CLF) and summed (Tot.) VOC concentrations shown in the following data summary, VOC levels in the groundwater at this well are generally comparable to respective levels detected in groundwater samples from each of the other wells located adjacent to the S-3 Site except wells GW-243 and GW-246. Both of these wells monitor groundwater with substantially higher PCE concentrations than evident in well GW-244, with the most recent sampling results for each well showing PCE levels above 3,000 µg/L and 100 µg/L, respectively.

Well No. / Monitored Interval Depth (ft bgs)		**June 1988**		**Aug. 2002**		**Aug. 2004**		**June 2005**

These data also illustrate the divergent long-term trends in the concentrations of VOCs in the groundwater from the other wells, which appear to have remained fairly unchanged (GW-244 and GW-247), decreased (GW-245), or increased (GW-243 and GW-246) in response to the closure/capping of the S-3 Site. However, considering the relatively low concentrations of the VOCs in most of the wells, it is not clear from the available data if the various long-term concentrations trends are significant with respect to the overall flux of dissolved VOCs through the shallow groundwater flow system in the Nolichucky Shale nearest to the site.

5.4 GROSS ALPHA ACTIVITY

As noted in Section 5.0, only the gross alpha activity reported for the groundwater samples collected from the well since January 1990 meet applicable DQOs, and these results are considered qualitative because of inherent analytical interferences associated with the very high TDS levels in the samples (see Section 4.0). Nevertheless, none of these samples had gross alpha activity above the applicable MDA and/or corresponding CE (Table 1). Low levels of gross alpha activity (i.e., <15 pCi/L drinking water MCL) are supported by analytical results for the primary alpha-emitting radionuclides entrained in the wastes disposed at the S-3 Site, U-234 and U-238, which were detected (i.e., >MDA and CE) at low levels in the groundwater samples collected most recently (Table 1).

5.5 GROSS BETA ACTIVITY

As noted in Section 5.0, only the gross beta activity reported for the groundwater samples since January 1990 meet applicable DQOs, and these results are considered qualitative because of analytical interferences associated with the high TDS of the samples (see Section 4.0). Although considered qualitative, the gross beta activity detected in the samples collected in January 1990 (3,240 pCi/L), June 2005 (3,700 pCi/L), and October 2005 (9,000 pCi/L) substantially exceed the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

Uranium decay products (e.g., Th-234) and other beta-emitting radionuclides known to be included in the waste stream for the S-3 Site (e.g., Np-237) probably contribute to the high level of gross beta activity in the groundwater from this well. However, technetium-99 (Tc-99) is the principal source of beta activity and is the “signature” component of the contaminant plume emplaced during historical operation of the S-3 Site, which is the only site at Y-12 known to have received significant volumes of waste that contained Tc-99 (DOE 1997). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-) which is soluble and highly mobile in groundwater (Gee et al. 1983). Consequently, the distribution of Tc-99 in the groundwater downgradient of the S-3 Site, as indicated by the extent of elevated gross beta activity (>50 pCi/L) defined by the network of wells to the south and west (and east) of the site, closely mirrors that of nitrate from the site, which is also highly mobile in groundwater.

The Tc-99 activity reported for the samples collected in January 1990 (5,000 pCi/L), June 2005 (9,400 pCi/L), and October 2005 (9,000 pCi/L) substantially exceed the SDWA screening level (900 pCi/L) for a 4 mrem/yr dose equivalent from Tc-99. Although there are insufficient data to adequately characterize the long-term trend for Tc-99 activity, the most recent sampling results suggest a significant increase from the Tc-99 levels evident shortly after the installation of the low-permeability cap over the S-3 Site. This may reflect a corresponding increase in the relative flux of Tc-99 via the groundwater flow/transport pathways intercepted by the monitored interval in the well. However, considering that the mobility of Tc-99 is similar to that of nitrate, and the nitrate concentrations in the well decreased substantially since the S-3 Site was closed and capped, it is possible that difference between the historical and recent sampling results for Tc-99 is attributable to inherent analytical variability.

As illustrated by the following summary of results for gross beta (GB) and Tc-99 activity, comparable levels of both analytes are evident in the groundwater from each of the other wells located adjacent to the S-3 Site except wells GW-243 and GW-246, which appear to monitor groundwater with substantially higher levels of gross beta and Tc-99 activity.

WELL GW-245

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during March 1986, completed with a screened monitored interval from 25.3 to 76 ft bgs, and constructed with nominal 6.5-inch diameter PVC (#40) riser casing and screen (0.03 slot wire-wound). The well is one of a series of wells completed at similar depths along the western (GW-243 and GW-244) and southern (GW-245, GW-246, and GW-247) boundaries of the former S-3 Ponds (hereafter referenced as the S-3 Site), with well GW-245 being near the southwest corner of the site. The S-3 Site, which is located near the western end of Y-12, directly north of the headwaters of Bear Creek, encompasses four contiguous, above-grade, unlined surface impoundments, each with a surface area of approximately 400 x 400 ft and an average total depth of approximately 15 ft. The ponds were used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12, and were closed in 1988 in accordance with requirements of the RCRA regulations applicable to hazardous waste landfills. Closure of the site was completed in 1989 and included the neutralization and removal of liquid wastes and stabilization of neutralization sludge remaining in each pond, which were then filled with crushed limestone and covered with a multilayer low-permeability cap (completed with an asphalt-paved parking lot). Historical operation of the S-3 Site emplaced a heterogeneous mixture of inorganic, organic, and radiological contaminants in the subsurface that remains a primary source of groundwater and surface water contamination in BCV.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirteen groundwater samples have been collected from the well, with the conventional sampling method used to obtain 11 samples between March 1987 and January 1990 and the low-flow sampling method used to obtain samples in June and October 2005. The sampling history includes almost two years of quarterly sampling, followed by a 15-year period (January 1990 – June 2005) when no groundwater samples were collected from the well.

Extremely high total dissolved solids (TDS) is a distinguishing characteristic of the groundwater samples from this well (see Section 4.0), and is a direct consequence of contamination resulting from historical operation of the S-3 Site (see Section 5.0.).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Nolichucky Shale (Conasauga Group), which trends northeast-southwest along the northern slope of BCV, dips to the southeast at an angle of 45º-55º, and is bordered on the southeast by the overlying Maynardville Limestone, a highly permeable karst aquifer that provides the principal pathway for subsurface contaminant migration in BCV. The water table interval is a highly permeable zone that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock and transmits the bulk of the groundwater in the Nolichucky Shale. Moreover, it is suspected that the highly acidic wastes from the S-3 Site dissolved carbonate strata interbedded within the Nolichucky Shale and greatly enhanced the relative permeability of these strata-bound flowpaths within several hundred feet of the site.

Groundwater flow in the water table interval in the Nolichucky Shale is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek, which traverse the Nolichucky Shale from northeast to southwest throughout BCV west of Y-12 and are numbered in ascending order downstream from the headwaters of the creek. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et al. 1992). Groundwater flow in the bedrock intervals

(shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone.

The static water level in the well occurs at an average depth of approximately 12 ft bgs and exhibits minor (<1 ft) seasonal fluctuations. As indicated by groundwater elevation isopleths determined from contemporaneous depth-to-water measurements from nearby monitoring wells, directions of groundwater flow near the well are to the west, parallel with the trend (strike) of bedding in Nolichucky Shale, and to the south-southwest, across geologic-strike toward the Maynardville Limestone and the main channel of Bear Creek. However, as noted previously, the Nolichucky Shale exhibits strongly anisotropic flow via strike-parallel flowpaths (i.e., bedding-plane fractures) that may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Also, possible dissolution of carbonate strata by the acidic seepage from the S-3 Site may locally enhance strata-bound groundwater flow/contaminant transport in directions parallel with geologic strike and dip. Additionally, directions of groundwater flow (and contaminant transport) now evident are undoubtedly different from the flow patterns that occurred during historical operations of the S-3 Site, which created a local “mound” in the water table that enabled groundwater flow (and contaminant transport) to the east of the hydrologic divide separating the Bear Creek and Upper East Fork Poplar Creek watersheds.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples collected in June and October 2005 show that the well yields highly contaminated groundwater from the Nolichucky Shale beneath the S-3 Site that is generally characterized by:

- TDS of 14,000 –15,968 mg/L;
- pH (field measurements) of 6 – 6.19;
- extremely high concentrations of calcium (>2,700 mg/L), chloride (>250 mg/L), magnesium (>430 mg/L), nitrate (>2,100 mg/L), and sodium (>180 mg/L);
- low molar proportions of sulfate and potassium (<10% of total anions/cations);
- high concentrations of several trace metals, notably barium (>10 mg/L), cadmium (>0.01 mg/L), manganese (>10 mg/L), nickel (>0.2 mg/L), strontium (>10 mg/L), and uranium (>0.04 mg/L), that are significantly above corresponding background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995)

Note that some of the inorganic compounds and trace metals in the groundwater at this well, such as nitrate and uranium, were entrained in the acidic wastes disposed at the S-3 Site, whereas other inorganics, such as calcium and barium, were dissolved from bedrock minerals by the highly acidic seepage from the site. Also, the high levels of TDS may cause analytical interferences for some laboratory analytes, including gross alpha activity and gross beta activity.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, all of these principal contaminants except gross alpha activity are present in the groundwater at this well. Note, however, that the bulk of the historical the analytical results for VOCs, gross alpha activity, and gross beta activity do not meet all applicable DQOs. The QA/QC sample data needed to identify false positive VOC results are not available for groundwater samples collected before January 1991. Similarly, gross alpha activity and gross beta activity reported for the groundwater samples collected before January 1990 are considered unusable because the sample-specific MDA and CE are not available for these analytes.

5.1 NITRATE

Nine of the groundwater samples collected to date were analyzed for nitrate and all had nitrate concentrations that exceed 2,000 mg/L (Table 1), including the samples collected most recently (June and October 2005), which confirm the nitrate levels in the shallow groundwater near the S-3 Site remain several orders-of-magnitude above the drinking water MCL for nitrate (10 mg/L). Nitrate is the principal component of the contaminant plume emplaced during historical operations of the site, is chemically stable and mobile in groundwater, and is believed to effectively trace the groundwater transport pathways followed by other similarly mobile components of the contaminant plume (DOE 1997).

Excluding the historical maximum nitrate concentration evident in January 1990 (4,240 mg/L), which is considered qualitative because of the ion charge balance error (i.e., the percent difference between respective summed milliequivalent concentrations of the major cations and anions exceeds 20%), a time-series plot of the nitrate concentrations detected in the groundwater samples collected to date shows a generally decreasing long-term trend (Figure 1). This trend spans the long gap in the sampling history for the well and, as illustrated by the data summarized below, generally is mirrored by the concentration trends for other wells located adjacent to the S-3 Site. These data also show that wells GW-243 and GW-244, both of which are located on the west side of the site (parallel with geologic strike), monitor groundwater with the highest levels of nitrate, as indicated by both the historic and the most recent sampling results for each well.

Well No./Monitored Interval Depth (ft bgs)		Nitrate (mg/L)				% Change
		June 1988	August 2002	August 2004	June 2005	
GW-243	62 – 77	6,160	8,840	.	.	+ 44%
GW-244	43 – 77	6,200	.	.	4,350	-37%
GW-245	25 – 76	3,660	.	.	2,210	-40%
GW-246	34 – 76	5,590	.	2,850	.	-49%
GW-247	31 – 78	3,500	.	.	3,260	-7%
Note: "." = Not sampled						

The decreasing nitrate concentration trend evident for well GW-245 (and wells GW-244, GW-246, and GW-247) suggest a corresponding decrease in the relative flux of nitrate in the shallow groundwater flow system in the Nolichucky Shale near to the S-3 Site. Decreased flux of nitrate via the groundwater flowpaths intercepted by the monitored interval in these wells occurred in response to the closure of the site and the subsequent installation of the low-permeability cap. Conversely, the increasing concentration trend indicated by the nitrate data for well GW-243 seems conspicuous relative to the decreasing trends evident for the other wells and may be an artifact of one or more inaccurate sampling results. Also, a relatively minimal decrease in the flux of nitrate is indicted by the sampling results for well GW-247, which may be completed in a comparably less permeable interval in the Nolichucky Shale than well GW-245 (and wells GW-244 and GW-246).

5.2 URANIUM

All but one of the groundwater samples collected to date had uranium concentrations above the MCL for uranium (0.03 mg/L), with the historical maximum concentration (0.188 mg/L) evident in March 1988 (Table 1). As noted previously, uranium was entrained in the wastewaters disposed at the S-3 Site, and the uranium in the acidic seepage probably occurred as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble complexes with a variety of inorganic anions (Fetter 1993). Consequently, elevated concentrations of uranium are generally restricted to the acidic groundwater in the Nolichucky Shale within approximately 500 ft of the site (DOE 1987).

A time-series plot of the uranium results reported for the groundwater samples collected to date shows a variable but generally increasing concentration trend between March 1987 (0.07 mg/L) and May 1989 (0.161 mg/L), with a subsequently decreasing trend spanning the prolonged gap in the sampling history for the well (Figure 2). The overall decrease in uranium concentrations is generally mirrored by the uranium data for the other wells completed in the Nolichucky Shale adjacent to the S-3 Site, as illustrated by the data summarized below, which also indicates that the highest uranium concentrations have been reported for wells GW-243 and GW-246, which appear to monitor the most acidic groundwater.

Well No. / Monitored Interval Depth (ft bgs)		**June 1988**		**August 2002**		**August 2004**		**June 2005**	
		Total U	**pH**	**Total U**	**pH**	**Total U**	**pH**	**Total U**	**pH**
GW-243	62 - 77	60.5	3.6	0.653	5.42	.	.	.	.
GW-244	43 – 77	<0.001	5.5	.	.	.		0.00209	5.5
GW-245	25 – 76	0.115	5.3	.	.	.		0.0478	6.01
GW-246	34 – 76	0.661	4.8	.	.	0.591	4.63	.	.
GW-247	31 – 78	0.036	6.0	.	.	.		0.0241	5.93

Note: "." = Not sampled; Total uranium concentrations in mg/L; pH from field measurements (in standard pH units)

The lower concentrations of uranium indicated by the most recent sampling results probably reflect a corresponding reduction in the relative flux of uranium via the groundwater transport at shallow depths in the Nolichucky Shale nearest the S-3 Site. Additionally, the total concentration of uranium within the groundwater flowpaths intercepted by the monitored interval in this well may have decreased in response to the concurrent increase in the pH of the groundwater, as indicated by the data summarized above, which would be expected to promote sorption of uranyl cations, as noted above.

5.3 VOLATILE ORGANIC COMPOUNDS

One or more of the following VOCs was detected in each of the groundwater samples collected to date: acetone, chloroform, MC, PCE, toluene, xylenes, 2-hexanone, and 111TCA (Table 2). Chlorinated solvents and organic chemicals were not substantial components of the waste stream for the S-3 Site (DOE 1997). Consequently, VOCs are fairly minor constituents within the contaminant plume emplaced during historical operation of the site, and are typically present at substantially lower concentrations compared to other plume constituents (e.g., nitrate).

Based on the frequency of detection and relative concentrations, the primary VOCs in the groundwater samples are chloroform, MC, PCE, and 111TCA (Table 2). Historical data show the highest concentrations for PCE, with the historical maximum concentration (19 µg/L) evident in January 1990, but the most recent sampling results show PCE concentrations are now below the drinking water MCL (5 µg/L). Both chloroform and MC were detected in each sample collected to date, with maximum concentrations of 11 µg/L and 9 µg/L, respectively. Trace levels of 111TCA (3 µg/L or less) were detected in all but four of the samples collected through January 1990. Other VOCs were not detected in any of the samples collected after February 1989 (Table 2), with the highest concentrations reported for acetone (e.g., 14 µg/L in March 1987) and many of these historical results are probably analytical artifacts (see Section 5.0).

A time-series plot of the summed concentrations of VOCs detected in each groundwater sample collected to date is dominated by the prolonged gap in the sampling history for the well, although the most recent sampling results (June and October 2005) suggest a long-term decreasing concentration trend (Figure 3). The decreasing trend is primarily attributable to the reduced levels of PCE, as illustrated by the PCE concentrations evident in March 1987 (12 µg/L) and October 2005 (1 µg/L). Conversely, the most recent sampling results suggest minimal long-term change in the concentrations of other VOCs, as illustrated by the equal concentrations of MC detected in the samples collected in March 1987 (5 µg/L) and October 2005 (5 µg/L). It is not clear from the available data if the divergent concentration trends for individual compounds are significant relative to the corresponding flux of VOCs via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

As illustrated by the chloroform (CLF) and summed (Tot.) VOC concentrations shown in the following data summary, VOC levels in the groundwater at this well are generally comparable to respective levels detected in groundwater samples from each of the other wells located adjacent to the S-3 Site except wells GW-243 and GW-246. Both of these wells monitor groundwater with substantially higher PCE concentrations than evident in well GW-244, with the most recent sampling results for each well showing PCE levels above 3,000 µg/L and 100 µg/L, respectively.

Well No. / Monitored Interval Depth (ft bgs)		**June 1988**		**August 2002**		**August 2004**		**June 2005**

GW-244	43 – 77	13	33	.	.	.	.	24	36
GW-245	25 – 76	8	30.9	.	.	.	.	7	18
GW-246	34 – 76	20	76	.	.	30	177	.	.
GW-247	31 – 78	7	19	.	.	.	.	10	25
Note: "." = Not sampled; All results in µg/L									

These data also illustrate the divergent long-term trends in the concentrations of VOCs in the groundwater from the other wells, which appear to have remained fairly unchanged (GW-244 and GW-247) or increased (GW-243 and GW-246) in response to the closure/capping of the S-3 Site. However, considering the relatively low concentrations of the VOCs in most of the wells, it is not clear from the available data if the various long-term concentration trends are significant with respect to the overall flux of dissolved VOCs through the shallow groundwater flow system in the Nolichucky Shale nearest to the site.

5.4 GROSS ALPHA ACTIVITY

As noted in Section 5.0, only the gross alpha activity reported for the groundwater samples since January 1990 meet applicable DQOs, and these results are considered qualitative because of inherent analytical interferences associated with the very high TDS levels in the samples (see Section 4.0). Nevertheless, none of these samples had gross alpha activity above the applicable MDA and/or corresponding CE (Table 1). Low levels of gross alpha activity (i.e., <15 pCi/L drinking water MCL) are supported by analytical results for the primary alpha-emitting radionuclides entrained in the wastes disposed at the S-3 Site, U-234 and U-238, which were detected (i.e., >MDA and CE) at low levels in the groundwater samples collected most recently (Table 1).

5.5 GROSS BETA ACTIVITY

As noted in Section 5.0, only the gross beta activity reported for the groundwater samples since January 1990 meet applicable DQOs, and these results are considered qualitative because of analytical interferences associated with the high TDS of the samples (see Section 4.0). Although considered qualitative, the gross beta activity detected in the samples collected in January 1990 (1,680 pCi/L), June 2005 (1,200 pCi/L), and October 2005 (890 pCi/L) substantially exceed the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

Uranium decay products (e.g., Th-234) and other beta-emitting radionuclides known to be included in the waste stream for the S-3 Site (e.g., Np-237) probably contribute to the high level of gross beta activity in the groundwater from this well. However, Tc-99 is the principal source of beta activity and is the "signature" component of the contaminant plume emplaced during historical operation of the S-3 Site, which is the only site at Y-12 known to have received significant volumes of waste that contained Tc-99 (DOE 1997). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-) which is soluble and highly mobile in groundwater (Gee et al. 1983). Consequently, the distribution of Tc-99 in the groundwater downgradient of the S-3 Site, as indicated by the extent of elevated gross beta activity (>50 pCi/L) defined by the network of wells to the south and west (and east) of the site, closely mirrors that of nitrate from the site, which is also highly mobile in groundwater.

The Tc-99 activity reported for the groundwater samples collected in January 1990 (4,580 pCi/L) and June 2005 (2,800 pCi/L) substantially exceed the SDWA screening level (900 pCi/L) for a 4 mrem/yr dose equivalent from Tc-99, and the Tc-99 activity reported for the sample collected in and October 2005 (860 pCi/L) is slightly below the SWDA screening level. Compared to the much higher Tc-99 level evident in June 2005 (and January 1990), it is not clear from the available data if the much lower level evident in October 2005 reflects natural temporal variability, or if the latter result is an analytical artifact. Also, there are insufficient data to adequately characterize the long-term trend for Tc-99, although the more recent sampling results suggest a general decrease from the activities evident shortly after the installation of the low-permeability cap over the S-3 Site. Considering that the mobility of Tc-99 is similar to that of nitrate and the substantially reduced nitrate concentrations in the well reflect a corresponding reduction in the overall flux of nitrate after the S-3 Site was closed and capped, the lower levels of Tc-99 likewise probably reflect a corresponding decrease in the relative flux of Tc-99 via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

As illustrated by the following summary of results for gross beta (GB) and Tc-99 activity, comparable levels of both analytes are evident in the groundwater from each of the other wells located adjacent to the S-3 Site except wells GW-243 and GW-246, which appear to monitor groundwater with substantially higher levels of gross beta and Tc-99 activity.

WELL GW-246

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during March 1986, completed with a screened monitored interval from 34 to 76 ft bgs, and constructed with nominal 6.5-inch diameter PVC (#40) riser casing and screen (0.01 slot wire-wound). The well is located in Bear Creek Valley (BCV) west of Y-12, adjacent to the southwest corner of the former S-3 Ponds. This site consists of four contiguous, unlined surface impoundments that were filled and covered with a multilayer low-permeability cap during RCRA closure of the site in 1988 and completed with an asphalt-paved parking lot. The surface impoundments were used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12. Operation of the ponds created a large mound in the water table that dissipated after the site was closed and capped, and emplaced a large, heterogeneous reservoir of inorganic, organic, and radiological contaminants in the subsurface that remains a primary source of groundwater and surface water contamination in BCV.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirteen groundwater samples have been collected from the well, with the conventional sampling method used to obtain eleven samples between March 1987 and January 1990 and the low-flow sampling method used to obtain samples in March and August 2004. The sampling history includes quarterly, semiannual, and annual sampling frequencies and, as indicated by the sampling dates noted above, a 14-year period (January 1990 – March 2004); when no groundwater samples were collected from the well.

High total dissolved solids (TDS) and acidic pH (<5.5) are distinguishing characteristics of the groundwater samples from this well (see Section 4.0) and are a direct consequence of contamination resulting from historical operation of the former S-3 Ponds (see Section 5.0.).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Nolichucky Shale (Conasauga Group). The water table interval is a highly permeable zone that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock and transmits the bulk of the groundwater in the Nolichucky Shale. Also, the highly acidic wastes from the former S-3 Ponds dissolved carbonate strata interbedded within the Nolichucky Shale and greatly enhanced the relative permeability of these flowpaths. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek, which traverse the Nolichucky Shale from northeast to southwest throughout BCV west of Y-12 and are numbered in ascending order downstream from the headwaters of the creek. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that stratigraphically overlies the Nolichucky Shale and subcrops beneath the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 10 ft bgs and exhibits minor (<2 ft) seasonal fluctuations. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-246 and the former S-3 Ponds indicate westward (strike-parallel) components of flow in Nolichucky Shale and cross-strike components of flow to the south-south west toward the Maynardville Limestone and the main channel of Bear Creek. However, as noted previously, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred strike-parallel flow directions that may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Dissolution of carbonate strata by the acidic seepage from the site also locally enhanced strata-bound groundwater flow/contaminant transport in directions parallel with geologic strike and dip. Moreover, present groundwater flow patterns differ substantially from those evident during the historical operations of the former S-3 Ponds, when the local mound created in the water table enabled groundwater flow to the east of the hydrologic divide near the west end of Y-12 that now separates the Bear Creek and Upper East Fork Poplar Creek drainage basins.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples collected to date show that the well yields acidic, highly contaminated groundwater from the Nolichucky Shale beneath the former S-3 Ponds that is generally characterized by:

- TDS of 17,552 –19,100 mg/L;
- pH (field measurements) of 4.4 – 4.7;
- extremely high concentrations (>2,500 mg/L) of nitrate and calcium;
- low molar proportions of chloride, sulfate, potassium, and sodium (<10% of total anions/cations);
- very high concentrations of several trace metals in the most recent sample (August 2004), notably aluminum (67.8 mg/L), barium (10.2 mg/L), manganese (103 mg/L), nickel (4.18 mg/L), and strontium (11.1 mg/L).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, all of these principal contaminants are in the groundwater at this well.

5.1 NITRATE

All but three of the groundwater samples collected to date had nitrate concentrations above 2,500 mg/L (nitrate results were not reported for three samples). As noted previously, nitrate is a primary inorganic component of the contaminant plume emplaced during historical operations of the former S-3 Ponds. Nitrate is a primary component of the plume, is chemically stable and mobile in groundwater, and effectively traces the groundwater transport pathways followed by other similarly mobile components of the contaminant plume (e.g., Tc-99). Based on the existing network of monitoring wells in the Nolichucky Shale west of the former S-3 Ponds, the extent of elevated nitrate concentrations (i.e., >10 mg/L) in the groundwater suggest: (1) transport/migration in the unconsolidated zone (water table interval) directly south toward the headwaters of Bear Creek; (2) westward transport/migration via shallow (<30 ft bgs) strike-parallel flowpaths (i.e., bedding-plane fractures) that terminate in the northern tributaries of Bear Creek located about 1,500 ft (NT-1) and 2,500 ft (NT-2) west of the former S-3 Ponds; (3) downward vertical migration driven by the greater density of the highly mineralized and acidic wastewater and the hydraulic head created by the surface impoundments; and (4) substantially slower migration via much longer and less permeable strike-parallel flowpaths deeper in the bedrock, with upward hydraulic gradients promoting upwelling of nitrate-contaminated groundwater into the shallow flow system near NT-1 and NT-2 (DOE 1997). Nitrate results reported for groundwater samples from this well are representative of concentrations within strike- and dip-parallel flowpaths in the Nolichucky Shale that, considering the location and depth of the well and assuming local geologic dip between 45° – 55°, potentially subcrop beneath the southwestern pond at the site.

The historical maximum nitrate concentration reported for the groundwater sample collected in May 1989 (10,800 mg/L) appears to be an outlier compared to the other nitrate results, all but two of which are less than 5,000 mg/L (Table 1). Also, the nitrate concentration (2,850 mg/L) reported for the sample collected most recently (August 2004) is slightly below the historical minimum value reported of the sample collected in November 1987 (2,860 mg/L). These "bookend" results reflect a generally indeterminate long-term concentration trend illustrated by a time-series plot of the nitrate concentrations (Figure 1), excluding the suspected outlier noted above. This trend spans the long gap in the sampling history for the well and shows a modest decrease in nitrate concentrations following installation of the low-permeability cap over the former S-3 Ponds, but does not indicate any significant overall reduction in the relative flux of nitrate along the groundwater flow/transport pathways intercepted by the monitored interval in the well, which seems unusual considering that wastewater disposal at the site ceased more than 20 years ago. The relatively steady nitrate concentrations over time probably reflect matrix diffusion from the reservoir of contaminants emplaced during operation of the site (see Section 1.0).

5.2 URANIUM

All of the groundwater samples collected to date had uranium concentrations at least an order-of-magnitude above the MCL for uranium (0.03 mg/L), with concentrations above 0.5 mg/L reported for all but one of the samples (Table 1). As noted previously, the acidic groundwater in the Nolichucky Shale near the former S-3 Ponds contains elevated concentrations of numerous trace metals, some that were entrained in the wastewaters disposed at the site (e.g., uranium) and others that were dissolved from carbonate minerals in the bedrock underlying the site (e.g., barium). The uranium in the groundwater probably occurs as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble complexes with a variety of inorganic anions (Fetter 1993). Thus, elevated uranium concentrations in the Nolichucky Shale near the former S-3 Ponds occurs primarily in the low-pH groundwater within about 500 ft of the site (DOE 1997).

As shown by the analytical results summarized on Table 1, widely variable uranium concentrations were reported for the groundwater samples collected between March 1987 (0.464 mg/L) and February 1989 (0.703 mg/L), including the historical maximum concentration (0.893 mg/L in March 1988), whereas more stable uranium concentrations are indicated by results reported for the samples obtained between May 1989 (0.534 mg/L) and August 2004 (0.591 mg/L). As with nitrate concentrations in the samples, these uranium results define an indeterminate long-term concentration trend spanning the long gap in the sampling history for the well and showing an initial concentration decrease at some time after installation of the low-permeability cap at the site (Figure 2). However, the close similarity between the uranium results reported for the groundwater samples collected since then suggests minimal long-term change in the relative flux of uranium via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected to date: acetone, chloroform, ethylbenzene (ETB), xylenes, methylene chloride, PCE, TCE, 11DCE, 111TCA and 1,1,2-trichloro-1,2,2-trifluoroethane, which is also known as freon-113 (Table 2). These compounds are components of the contaminant plume originating from the former S-3 Ponds, but are typically present at substantially lower concentrations compared to other components of the plume (e.g., nitrate). This is because wastewaters that contained chlorinated solvents and other organic chemical were not extensively disposed at the site (DOE 1997).

Based on the frequency of detection and relative concentrations, the primary VOCs in the groundwater samples are PCE, chloroform, and methylene chloride (Table 1). Each of these compounds was detected in all but two of the samples, with maximum historical maximum concentrations PCE (120 µg/L), chloroform (39 µg/L), and methylene chloride (21 µg/L) reported for the sample collected in March 2004 (i.e., the first sample collected from the well since January 1990). Note that the most recent sampling results show PCE concentrations at least an order-of-magnitude above the drinking water MCL (5 µg/L). The other VOCs have been detected more sporadically (e.g., acetone) and/or at very low levels, most results being estimated values of 2 µg/L or less, and only the historical maximum concentrations of acetone (15 µg/L in March 1987) and xylenes (16 µg/L in February 1989) exceed 5 µg/L (Table 2). Additionally, none of the VOC concentrations detected in the samples collected to date suggest the potential presence of DNAPL in the subsurface near the well.

A time-series plot of the summed concentrations of VOCs detected in the groundwater samples collected to date spans the 14-year gap in the sampling history for the well, with the most recent sampling results (March and August 2004) suggesting a long-term increase in VOC concentrations (Figure 3). This increasing trend is primarily attributable to sharply higher concentrations of PCE compared to historical levels. For instance, the PCE concentration reported for the sample collected in March 2004 (120 µg/L) is nearly three times higher than the previous historical maximum (48 µg/L in May 1989). Note that the samples collected most recently were obtained with the low-flow sampling method, whereas all previous samples were collected with the conventional sampling method, which suggests that the higher PCE concentrations may be an artifact of the change to the low flow sampling method. However, concentrations of other VOCs detected in the samples, including compounds that are significantly more soluble and mobile in the groundwater (e.g., chloroform) as well as compounds (e.g., TCE) with solubility/mobility comparable to that of PCE, do not appear to reflect any similar bias (higher or lower) coincident with the change in the sampling method. Perhaps the higher PCE concentrations reflect a corresponding change in the composition of organic wastes disposed at the former S-3 Ponds, whereby the volume and/or proportion of PCE-bearing organic wastewater increased over time relative to that of the other VOCs in the wastewater, such as chloroform.

5.4 GROSS ALPHA ACTIVITY

Only a few of the results for gross alpha activity reported for the samples collected to date are suitable for evaluation because sampling results obtained before January 1990 do not meet applicable data quality objectives (DQOs) (the sample specific MDA and CE are not available for these samples). Moreover, all gross alpha activity results for subsequent samples are considered qualitative because of inherent analytical interferences associated with the very high TDS levels in the samples. In any case, the sampling results for January 1990 (143 pCi/L) and March 2004 (430 pCi/L) show levels of gross alpha activity that exceed the drinking water MCL (15 pCi/L). The CY 2004 sample results show that uranium isotopes are the source of the gross alpha activity (Table 3). Other alpha-particle emitting radionuclides, such as americium-241, were included in the wastes disposed at the former S-3 Ponds and may be additional sources of gross alpha activity in the groundwater at this well (DOE 1997).

5.5 GROSS BETA ACTIVITY

As with gross alpha activity, few of the analytical results for gross beta activity reported for the groundwater samples collected to date meet DQOs and recent sampling results are considered qualitative because of analytical interferences associated with the high TDS of the groundwater samples. As shown on Table 3, radiological results for the three samples collected since January 1990 show gross beta activity substantially above the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). The most recent sampling results (March and August 2004) show that the primary source of the beta activity is Tc-99, with possible contributions from beta-emitting uranium decay products (e.g., thorium-234). Note that Tc-99 is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds because this was the only site at Y-12 to receive wastes that contained Tc-99. The concentrations of Tc-99 reported for these samples (33,000 pCi/L and 26,000 pCi/L) substantially exceed SDWA screening level (3,790 pCi/L) for a 4 mrem/yr dose equivalent from Tc-99. Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-) which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in Nolichucky Shale west of the former S-3 Ponds, the extent of elevated (>50 pCi/L) gross beta activity in the groundwater suggests that the distribution of Tc-99 closely mirrors that of nitrate, with transport in the water table interval south toward Bear Creek and more westward (strike-parallel) transport in the bedrock intervals toward discharge areas in NT-1 and NT-2 (DOE 1997).

WELL GW-247

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during March 1986, completed with a screened monitored interval from 31.5 to 78 ft bgs, and constructed with nominal 6.5-inch diameter PVC (#40) riser casing and screen (0.01 slot wire-wound). The well is one of a series of wells completed at similar depths along the western (GW-243 and GW-244) and southern (GW-245, GW-246, and GW-247) boundaries of the former S-3 Ponds (hereafter referenced as the S-3 Site), with well GW-247 being on the southern side, approximately 200 ft east of the southwest corner of the site. The S-3 Site, which is located near the western end of Y-12, directly north of the headwaters of Bear Creek, encompasses four contiguous, above-grade, unlined surface impoundments, each with a surface area of approximately 400 x 400 ft and an average total depth of approximately 15 ft. The ponds were used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12, and were closed in 1988 in accordance with requirements of the RCRA regulations applicable to hazardous waste landfills. Closure of the site was completed in 1989 and included the neutralization and removal of liquid wastes and stabilization of neutralization sludge remaining in each pond, which were then filled with crushed limestone and covered with a multilayer low-permeability cap (completed with an asphalt-paved parking lot). Historical operation of the S-3 Site emplaced a heterogeneous mixture of inorganic, organic, and radiological contaminants in the subsurface that remains a primary source of groundwater and surface water contamination in BCV.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 11 samples between March 1987 and January 1990 and the low-flow sampling method used to obtain samples in June and October 2005. The sampling history includes almost two years of quarterly sampling, followed by a 15-year period (January 1990 – June 2005) when no groundwater samples were collected from the well.

Extremely high total dissolved solids (TDS) is a distinguishing characteristics of the groundwater samples from this well (see Section 4.0), and is a direct consequence of contamination resulting from historical operation of the S-3 Site (see Section 5.0.).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Nolichucky Shale (Conasauga Group) which trends northeast-southwest along the northern slope of BCV, dips to the southeast at an angle of 45º-55º, and is bordered on the southeast by the overlying Maynardville Limestone, a highly permeable karst unit that provides the principal pathway for subsurface contaminant migration in BCV. The water table interval is a highly permeable zone that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock and transmits the bulk of the groundwater in the Nolichucky Shale. Moreover, it is suspected that the highly acidic wastes from the S-3 Site dissolved carbonate strata interbedded within the Nolichucky Shale and greatly enhanced the relative permeability of these strata-bound flowpaths within several hundred feet of the site.

Groundwater flow in the water table interval in the Nolichucky Shale is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek, which traverse the Nolichucky Shale from northeast to southwest throughout BCV west of Y-12 and are numbered in ascending order downstream from the headwaters of the creek. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone.

The static water level in the well occurs at an average depth of approximately 12.5 ft bgs and exhibits minor (<1 ft) seasonal fluctuations. As indicated by groundwater elevation isopleths determined from contemporaneous depth-to-water measurements from nearby monitoring wells, directions of groundwater flow near the well are to the west, parallel with the trend (strike) of bedding in Nolichucky Shale, and to the south-southwest, across geologic-strike toward the Maynardville Limestone and the main channel of Bear Creek. However, as noted previously, the Nolichucky Shale exhibits strongly anisotropic flow via strike-parallel flowpaths (i.e., bedding-plane fractures) that may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Also, possible dissolution of carbonate strata by the acidic seepage from the S-3 Site may locally enhance strata-bound groundwater flow/contaminant transport in directions parallel with geologic strike and dip. Additionally, directions of groundwater flow (and contaminant transport) now evident are undoubtedly different from the flow patterns that occurred during historical operations of the S-3 Site, which created a local "mound" in the water table that enabled groundwater flow (and contaminant transport) to the east of the hydrologic divide separating the Bear Creek and Upper East Fork Poplar Creek watersheds.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples collected in June and October 2005 show that the well yields slightly acidic, highly contaminated groundwater from the Nolichucky Shale beneath the S 3 Site that is generally characterized by:

- TDS of 19,040 –20,000 mg/L;
- pH (field measurements) of 5.93 – 6;
- high concentrations of calcium (>3,700 mg/L), chloride (>230 mg/L), magnesium (>690 mg/L), nitrate (>3,200 mg/L), and sodium (>240 mg/L);
- low molar proportions of chloride, sodium, sulfate, and potassium (<10% of total anions/cations);
- high molar proportions of nitrate (>90% of total anions/cations);
- high concentrations of several trace metals, notably barium (>40 mg/L), cadmium (>0.01 mg/L), manganese (>20 mg/L), nickel (>0.3 mg/L), strontium (>10 mg/L), and uranium (>0.02 mg/L), that are significantly above corresponding background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995)

Note that some of the inorganic compounds and trace metals in the groundwater at this well, such as nitrate and uranium, were entrained in the acidic wastes disposed at the S-3 Site, whereas other inorganics, such as calcium and barium, were dissolved from bedrock minerals by the highly acidic seepage from the site. Also, the high levels of TDS may cause analytical interferences for some laboratory analytes, including gross alpha activity and gross beta activity.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, all of these principal contaminants except gross alpha activity are present in the groundwater at this well. Note, however, that the bulk of the historical the analytical results for VOCs, gross alpha activity, and gross beta activity do not meet all applicable DQOs. The QA/QC sample data needed to identify false positive VOC results are not available for groundwater samples collected before January 1991. Similarly, gross alpha activity and gross beta activity reported for the groundwater samples collected before January 1990 are considered unusable because the sample-specific MDA and CE are not available for these analytes.

5.1 NITRATE

All of the groundwater samples collected to date that were analyzed for nitrate (nine samples), had nitrate concentrations that exceed 3,000 mg/L (Table 1), including the samples collected most recently (June and October 2005). These results show that nitrate concentrations in the shallow groundwater nearest the S-3 Site remain several orders-of-magnitude above the drinking water MCL for nitrate (10 mg/L). Nitrate is the principal component of the contaminant plume emplaced during historical operations of the site, is chemically stable and mobile in groundwater, and is believed to effectively trace the groundwater transport pathways followed by other similarly mobile components of the contaminant plume (DOE 1997).

A time-series plot of the nitrate concentrations reported for the groundwater samples collected to date shows an indeterminate or slightly decreasing long-term trend (Figure 1). Note that the historic maximum (7,380 mg/L in January 2000) and minimum (1,900 mg/L in February 1989) results are excluded from the trend because these results are considered qualitative (Table 1): the ion charge balance error (i.e., the percent difference between respective summed milliequivalent concentrations of the major cations and anions) for these samples exceeds 20%. The nitrate trend spans the long gap in the sampling history for the well and, as illustrated by the data summarized below, contrasts with the more clearly decreasing nitrate concentrations indicated by the data for wells GW-244, GW-245 and GW-246. The increasing trend indicated for well GW-243 is conspicuous and may be an artifact of one or more inaccurate nitrate results. These data also show that wells GW-243 and GW-244, both of which are located on the west side of the site (parallel with geologic strike), monitor groundwater with the highest levels of nitrate, as indicated by both the historic and the most recent sampling results for each well.

Well No./Monitored Interval Depth (ft bgs)		Nitrate (mg/L)				% Change
		June 1988	August 2002	August 2004	June 2005	
GW-243	62 – 77	6,160	8,840	.	.	+ 44%
GW-244	43 – 77	6,200	.	.	4,350	-37%
GW-245	25 – 76	3,660	.	.	2,210	-40%
GW-246	34 – 76	5,590	.	2,850	.	-49%
GW-247	31 – 78	3,500	.	.	3,260	-7%
Note: "." = Not sampled						

5.2 URANIUM

All of the groundwater samples collected to date had uranium concentrations above the corresponding reporting limit (Table 1), although only two concentrations exceed the drinking water MCL for uranium (0.03 mg/L). As noted previously, uranium was entrained in the nitric-acid wastewaters disposed at the S-3 Site, and uranium in the acidic seepage probably occurred as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble complexes with a variety of inorganic anions (Fetter 1993). Consequently, elevated concentrations of uranium in the Nolichucky Shale near the S-3 Site are generally restricted to the acidic groundwater within approximately 500 ft of the S-3 Site (DOE 1987).

The groundwater in well GW-247 has never been especially acidic, surprisingly, which may explain the relatively low levels of uranium in the well. Also, the pH of the groundwater appears to have changed very little since the S-3 Site was closed and capped, as illustrated by the results summarized below. These results also show that the highest levels of uranium occur in the wells adjacent to the S-3 Site that monitor more acidic groundwater, particularly well GW-243.

Well No. / Monitored Interval Depth (ft bgs)		June 1988		August 2002		August 2004		June 2005	
		Total U	pH	Total U	pH	Total U	pH	Total U	pH
GW-243	62 - 77	60.5	3.6	0.653	5.42	.	.	.	.
GW-244	43 – 77	<0.001	5.5	.	.	.		0.00209	5.5
GW-245	25 – 76	0.115	5.3	.	.	.		0.0478	6.01
GW-246	34 – 76	0.661	4.8	.	.	0.591	4.63	.	.
GW-247	31 – 78	0.036	6.0	.	.	.		0.0241	5.93
Note: "." = Not sampled; Total uranium concentrations in mg/L; pH from field measurements (in standard pH units)									

Perhaps the monitored interval in well GW-247 is completed within a stratigraphic section of the Nolichucky Shale that contains proportionally more carbonate than shale. The carbonate would tend to buffer the acidic seepage during the operation of the S-3 Site, although dissolution of the carbonate would be expected to increase the hydraulic conductivity of the permeable flowpaths (e.g., enlarge bedding-plane fractures).

A time-series plot of the uranium results reported for the groundwater samples collected to date is dominated by the prolonged gap in the sampling history for the well (Figure 2), and shows a variable but generally increasing concentration trend between March 1987 (0.026 mg/L) and June 1988 (0.036 mg/L), with a subsequently decreasing trend through October 2005 (0.0243 mg/L). Moreover, as shown in the preceding data summary, the overall decrease in uranium concentrations is generally mirrored by the uranium data for the other wells located adjacent to the S-3 Site, particularly well GW-243. The lower concentrations of uranium indicated by the most recent sampling results for these wells reflect the corresponding reduction in the relative flux of uranium via the shallow groundwater flow system in the Nolichucky Shale nearest the S-3 Site.

5.3 VOLATILE ORGANIC COMPOUNDS

One or more of the following VOCs was detected in each of the groundwater samples collected to date: acetone, chloroform, ethylbenzene, MC, PCE, toluene, and 2-hexanone (Table 2). Chlorinated solvents and organic chemicals were not substantial components of the waste stream for the S-3 Site and, consequently, VOCs are fairly minor constituents within the contaminant plume emplaced during historical operation of the site, and are typically present at substantially lower concentrations compared to other plume constituents (e.g., nitrate).

Based on the frequency of detection and relative concentrations, the primary VOCs detected in the groundwater samples collected to date are PCE, chloroform, and MC (Table 2). All of these compounds were detected in each of the samples, with the highest concentrations reported for chloroform (10 µg/L) and MC (11 µg/L). Also, the most recent sampling results (June and October 2005) show PCE and MC concentrations above the respective drinking water MCL (5 µg/L). Aside from the primary VOCs, other compounds were not detected in samples collected after February 1989 (Table 2).

A time-series plot of the summed concentrations of VOCs detected in the groundwater samples collected to date is dominated by the prolonged gap in the sampling history for the well and shows an indeterminate long-term VOC concentration trend (Figure 3). Additionally, data for individual compounds show divergent concentration trends. For instance, MC concentrations changed very little between June 1987 (8 µg/L) and June 2005 (7 µg/L), whereas PCE concentrations increased between March 1987 (2 µg/L) and October 2005 (8 µg/L). It is not clear from the available data if the divergent concentration trends for individual compounds are significant relative to the corresponding flux of VOCs via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

As illustrated by the chloroform (CLF) and summed (Tot.) VOC concentrations shown in the following data summary, VOC levels in the groundwater at this well are generally comparable to respective levels detected in groundwater samples from each of the other wells located adjacent to the S-3 Site except wells GW-243 and GW-246. Both of these wells monitor groundwater with substantially higher PCE concentrations than evident in well GW-247, with the most recent sampling results for each well showing PCE levels above 3,000 µg/L and 100 µg/L, respectively.

Well No. / Monitored Interval Depth (ft bgs)		**June 1988**		**Aug. 2002**		**Aug. 2004**		**June 2005**	
		CLF	**Tot. VOC**	**CLF**	**Tot. VOC**	**CLF**	**Tot. VOC**	**CLF**	**Tot. VOC**
GW-243	62 - 77	27	2,153	29	4,076	.	.	.	.
GW-244	43 – 77	13	33	.	.	.	.	24	36
GW-245	25 – 76	8	30.9	.	.	.	.	7	18
GW-246	34 – 76	20	76	.	.	30	177	.	.
GW-247	31 – 78	7	19	.	.	.	.	10	25
Note: "." = Not sampled; All results in µg/L									

These data also illustrate the divergent long-term trends in the concentrations of VOCs in the groundwater from the other wells, which appear to have remained fairly unchanged (GW-244), decreased (GW-245), or increased (GW-243 and GW-246) in response to the closure/capping of the S-3 Site. However, considering the relatively low concentrations of the VOCs in most of the wells, it is not clear from the available data if the various long-term concentrations trends are significant with respect to the overall flux of dissolved VOCs through the shallow groundwater flow system in the Nolichucky Shale nearest to the site.

5.4 GROSS ALPHA ACTIVITY

Only a few of the results for gross alpha activity reported for the samples collected to date are suitable for evaluation because sampling results obtained before January 1990 do not meet applicable data quality objectives (DQOs) (the sample specific MDA and CE are not available for these samples). None of the groundwater samples collected since January 1990 had gross alpha activity above the applicable MDA and corresponding CE (Table 1). Note that these gross alpha activity results are considered qualitative because of inherent analytical interferences associated with the very high TDS levels in the samples (Section 4.0). However, the low levels of U-234 and U-238 (the primary alpha emitting isotopes) reported for the most recent samples collected from the well support the presence of low levels of gross alpha activity (Table 1).

5.5 GROSS BETA ACTIVITY

As with gross alpha activity, few of the analytical results for gross beta activity reported for the groundwater samples collected to date meet DQOs and recent sampling results are considered qualitative because of analytical interferences associated with the high TDS of the groundwater samples. As shown on Table 1, radiological results for the three samples collected since January 1990 show gross beta activity substantially above the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

Uranium decay products (e.g., Th-234) and other beta-emitting radionuclides known to be included in the waste stream for the S-3 Site (e.g., Np-237) probably contribute to the high level of gross beta activity in the groundwater from this well. However, Tc-99 is the principal source of beta activity and is the "signature" component of the contaminant plume emplaced during historical operation of the S-3 Site, which is the only site at Y-12 known to have received significant volumes of waste that contained Tc-99 (DOE 1997). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-) which is soluble and highly mobile in groundwater (Gee et al. 1983). Consequently, the distribution of Tc-99 in the groundwater downgradient of the S-3 Site, as indicated by the extent of elevated gross beta activity (>50 pCi/L) defined by the network of wells to the south and west (and east) of the site, closely mirrors that of nitrate from the site, which is also highly mobile in groundwater.

The Tc-99 activity reported for the samples collected in January 1990 (8,800 pCi/L), June 2005 (9,100 pCi/L), and October 2005 (9,100 pCi/L) substantially exceed the SDWA screening level (900 pCi/L) for a 4 mrem/yr dose equivalent from Tc-99. Although there are insufficient data to adequately characterize the long-term trend for Tc-99, the most recent sampling results suggest a slight increase from the Tc-99 activity evident shortly after the installation of the low-permeability cap over the S-3 Site. This may reflect a corresponding increase in the relative flux of Tc-99 via the groundwater flow/transport pathways intercepted by the monitored interval in the well. However, considering that Tc-99 and nitrate share similar mobility in the groundwater, the lack of a concurrent increase in nitrate concentrations (which decreased slightly) suggests that the higher levels of Tc-99 indicated by the more recent results may simply reflect inherent analytical variability.

As illustrated by the following summary of results for gross beta (GB) activity and Tc-99, comparable levels of both analytes are evident in the groundwater from each of the other wells located adjacent to the S-3 Site except wells GW-243 and GW-246, which appear to monitor groundwater with substantially higher levels of gross beta activity and Tc-99.

WELL GW-251

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in April 1986, completed with a screened monitored interval from 35 to 51 ft bgs, and constructed with nominal 4.5-inch diameter PVC (Schedule 40) riser casing and well screen (0.01 slot). The well is located near the base Chestnut Ridge in the southwest section of Y-12, about 50 ft west of the S-2 Site. The S-2 Site originally consisted of an unlined waste pit excavated into the northern flank of Chestnut Ridge. With an estimated capacity of 200,000 gallons, the S-2 Site was used from 1943 to 1951 for disposal of an unknown quantity of corrosive and toxic aqueous waste, primarily acidic solutions containing nitrates of heavy metals such as copper, nickel, and chromium (DOE 1998). When closed sometime in 1954, the wastes remaining in the S-2 Site were chemically neutralized and the site was backfilled, covered with topsoil, and seeded with grass.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fifty-nine groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 42 samples between June 1986 and May 1997, and the low-flow sampling method used to obtain 17 samples between November 1997 and October 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the shallow bedrock interval in the Maynardville Limestone (upper Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements for the well show that the static groundwater level in the well occurs at an average depth of about 15 ft bgs and exhibits substantial (>15 ft) seasonal fluctuations. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-251 indicate easterly flow, parallel with geologic strike in the Maynardville Limestone. Additionally, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local groundwater flow directions in the Maynardville Limestone may be strongly influenced by subsurface process lines, utilities, and storm sewers (DOE 1998).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 325 - 815 mg/L;
- pH (field measurements) of 5.7 – 7.1;
- high concentrations of nitrate (>50 mg/L) and fluoride (>1 mg/L) compared to other wells of similar depth in the Maynardville Limestone;
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and

- elevated total concentrations of several trace metals, particularly manganese (>2 mg/L), that substantially exceed the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the respective monitoring data reported for the groundwater samples collected from the well since January 1991, nitrate and VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Thirty-three of the groundwater samples were analyzed for nitrate (as N), with concentrations above the analytical reporting limit detected in all but four of the samples, and the most recent sampling results showing concentrations substantially above the MCL for nitrate (Table 1). The mass of inorganic contaminants emplaced in the Maynardville Limestone during historical operation of the S-2 Site is the source of the nitrate in the groundwater at this well. Also, sludge and soil backfill in the former waste pit contain metals, nitrate, and inorganic compounds (e.g., cyanide), are below the saturated zone, and the site is not covered with a low-permeability cap; these conditions effectively promote vertical leaching of contaminants directly into the shallow karst network in the Maynardville Limestone (DOE 1998).

Nitrate concentrations below 100 mg/L were reported for most of the groundwater samples (Table 1), with the recent sampling results showing that concentrations remain near 50 mg/L and substantially above the MCL (10 mg/L). The range of nitrate results encompass conspicuous non-detect results (<0.02 mg/L) for samples collected in December 1994 and February 1995; both results are probably sampling or analytical artifacts. Additionally, the nitrate results reported for the samples collected in July 1991, January 1992, September 1993, and August 1994 are considered qualitative because of the ion charge balance errors (i.e., the relative percent difference between respective summed millequivalent concentrations of the major cations and anions exceeds 20%);

A time-series plot of the nitrate results (excluding the non-detect values and qualitative results noted above) show a generally decreasing long-term concentration trend dominated by wide temporal fluctuations (Figure 1), although the "seesaw" fluctuations indicated by data obtained since May 1997 appear to be an artifact of the change from a quarterly to a semiannual sampling frequency. The slowly decreasing nitrate concentrations, as illustrated by the nitrate results reported for the samples collected in January 1991 (92 mg/L), May 1997 (80.2 mg/L), and April 2004 (61.9 mg/L), suggest an overall decrease in the flux from the source of the nitrate. The temporal concentration fluctuations correlate with seasonal groundwater flow conditions, with the highest nitrate concentrations reported for samples obtained during seasonally high flow and the lowest nitrate concentrations reported for samples obtained during seasonally low flow. This relationship suggests seasonally variable flux of nitrate along the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.2 URANIUM

Thirty-nine groundwater samples were analyzed for total uranium and concentrations at or above the applicable analytical reporting limit were detected in all but one of the samples (Table 1). Total uranium concentrations reported for the samples range from 0.003 mg/L to 0.01 mg/L and are all less than the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, each groundwater sample contained one or more of the following VOCs (Table 2): CTET, chloroform, dibromochloromethane, PCE, TCE, and 12DCE (c12DCE). These compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and UEFPC watersheds. In the UEFPC watershed east of the flow divide, which occurs near the west end of Y-12, the VOC plume appears to originate near the Fire Training Facility in the southwestern section of Y-12, extends eastward (parallel with geologic strike) and mixes with VOCs released from several sources within Y-12, including the S-2 Site, and enters Union Valley east of the ORR boundary along Scarboro Road (DOE 1998).

The primary VOCs in the groundwater samples are PCE and TCE (Table 2), which were detected in each sample and have respective historical maximum concentrations above 600 μg/L and 240 μg/L. Also, the most recent sampling results show that PCE and TCE concentrations remain substantially above respective MCLs (5 μg/L). Secondary VOCs in the groundwater samples are CTET, chloroform, and 12DCE (Table 2), at least one of which was detected (excluding false positive results) in all but one of the samples. Respective maximum historical concentrations for these VOCs are less than 20 μg/L, with several results for each compound being estimated values below 5 μg/L, and the most recent sampling results showing CTET and c12DCE concentrations below corresponding MCLs (5 μg/L and 70 μg/L).

The relatively low concentrations of c12DCE suggest that the geochemical conditions in the groundwater at this well are not especially conducive to the anaerobic methanotropic organisms that are typically associated with the degradation (sequential dechlorination) of PCE and TCE. This is illustrated by the most recent results for several indicator parameters (Table 3), with the REDOX values in particular indicating that the groundwater does not exhibit the geochemical (methanogenic) conditions necessary for biotic degradation of chlorinated hydrocarbons.

A time-series plot of the summed concentrations of VOCs detected in each groundwater sample shows an indeterminate long-term concentration trend dominated by wide temporal fluctuations (Figure 1), although the "seesaw" fluctuations indicated by data obtained since May 1997 appear to be an artifact of the change from a quarterly to a semiannual sampling frequency. The indeterminate trend, illustrated by the similar summed VOC concentrations for the samples collected in January 1992 (327 mg/L), November 1996 (310 mg/L), and May 2003 (319 mg/L), potentially reflects continued influx from the source(s) of VOCs, which may include DNAPL (DOE 1998). The wide temporal concentration fluctuations closely correlate with seasonal groundwater flow conditions, with the highest summed VOC concentrations in samples obtained during seasonally high flow and the lowest summed concentrations in samples obtained during seasonally low flow. This relationship suggests seasonally variable flux of dissolved VOCs along the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

Thirty-two groundwater samples had gross alpha activity above the applicable MDA and corresponding CE (Table 1), including results for five samples that exceed the MCL for gross alpha activity (15 pCi/L). The highest values for gross alpha activity were reported for samples collected in the early 1990s; none of the samples collected since November 1997 had gross alpha activity above 10 pCi/L. Uranium isotopes (U-234 and U-238) are the suspected source of the gross alpha activity in the groundwater and were detected (i.e., >MDA) in groundwater samples collected in March 1998 (U-234 = 10.81 pCi/L and U-238 = 2.32 pCi/L) and July 1998 (U-234 = 10.79 pCi/L and U-238 = 3.34 pCi/L).

A time-series plot of applicable results for gross alpha activity (i.e., results that exceed the MDA and corresponding CE) shows a generally decreasing long-term concentration trend that exhibits substantially less temporal fluctuations compared to nitrate and VOCs (Figure 3). Also, the gross alpha results obtained since November 1997 show generally steady levels below 10 pCi/L.

5.5 GROSS BETA ACTIVITY

Twenty-three groundwater samples had gross beta activity above the applicable MDA and corresponding CE (Table 1), with the highest value (39.6 pCi/L in April 1992) being less than the SDWA screening level (50 pCi/L) for a 4 millirem dose equivalent (the MCL for gross beta activity). Also, gross beta activity above the applicable MDA was reported only for three of the samples collected since May 1996, with the most recent result (15 pCi/L in May 2000) being substantially below the SDWA screening level.

WELL GW-253

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in April 1986, completed with a screened monitored interval from about 36 to 50 ft bgs, and constructed with nominal 4.5-inch diameter. The well is located near the base of Chestnut Ridge in the southwest section of Y-12, about 30 ft east of the S-2 Site. The S-2 Site originally consisted of an unlined waste pit excavated into the northern flank of Chestnut Ridge. With an estimated capacity of 200,000 gallons, the S-2 Site was used from 1943 to 1951 for disposal of an unknown quantity of corrosive and toxic aqueous waste, primarily acidic solutions containing nitrates of heavy metals such as copper, nickel, and chromium (DOE 1998). When closed sometime in 1954, the wastes remaining in the S-2 Site were chemically neutralized and the site was backfilled, covered with topsoil, and seeded with grass.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-one groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 18 samples between June 1986 and June 1996, and the low-flow sampling method used to obtain 13 samples between June 1998 and October 2003.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Maynardville Limestone (upper Conasauga Group). Most groundwater flow in the Maynardville Limestone occurs at shallow depths (i.e., <100 ft bgs) in an extensively interconnected network of solution conduits and cavities (karst network). Below the shallow karst network, fractures provide the primary flowpaths. Also, there are seven stratigraphic zones (numbered from bottom to top) in the Maynardville Limestone that are differentiated by distinct lithologic and hydrologic characteristics (Shevenell et al. 1995). The more permeable zones are at the bottom (Zone 2) and top (Zone 6) of the formation, but Zone 6 is the most permeable interval and probably transmits the bulk of the groundwater in the formation (Goldstrand 1995).

Presampling depth-to-water measurements for the well show that the static groundwater level in the well occurs at an average depth of about 8 ft bgs, with a series of unusually large (>25 ft) water-level fluctuations evident between August 1999 and May 2002 (Figure 1). Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of the well indicate southeasterly flow, parallel with geologic strike in the Maynardville Limestone. Additionally, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local groundwater flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers (DOE 1998).

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 2,650 – 6,250 mg/L;
- pH (field measurements) of 4.8 – 5.8;
- very high concentrations of several inorganic contaminants, chloride (>100 mg/L), nitrate (>500 mg/L), sodium (>100 mg/L), and sulfate (>50 mg/L);
- ion charge balance errors (i.e., the relative percent difference between respective summed milliequivalent concentrations of major cations and anions) that often exceed 20%; and

- very high (total) concentrations of several trace metals, particularly aluminum (>3 mg/L), cadmium (>3 mg/L), copper (>40 mg/L), manganese (>40 mg/L), nickel (>2 mg/L), strontium (>1 mg/L), and zinc (>5 mg/L), that substantially exceed the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

In addition to the acidic pH and high levels of TDS, the most recent monitoring results for several indicator parameters, particularly the REDOX values (Table 1), suggest that the geochemical conditions in the well are not especially conducive to biologically mediated degradation (dechlorination) of the chlorinated hydrocarbons in the groundwater (see Section 5.3).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, which are based on the respective monitoring data reported for the 16 groundwater samples collected from the well since January 1991, nitrate, VOCs, and gross alpha activity are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Fifteen of the groundwater samples were analyzed for nitrate (as N), with concentrations above 500 mg/L reported for all but one of the samples (Table 2). The mass of inorganic contaminants emplaced in the Maynardville Limestone during historical operation of the S-2 Site is the source of the nitrate in the groundwater at this well. Also, the site is not covered with a low-permeability cap and the sludge/soil backfill in the former waste pit contains nitrate, metals, and other inorganic compounds (e.g., cyanide) and is below the saturated zone during seasonally high and low groundwater flow conditions; these conditions effectively promote vertical leaching of contaminants directly into the shallow karst network in the Maynardville Limestone (DOE 1998).

Nitrate concentrations below 1,000 mg/L were reported for most of the groundwater samples, with the recent sampling results showing that concentrations remain substantially above the MCL (Table 2). However, the nitrate results reported for the samples collected in January 1991, April 1991, June 1996, May 2000, November 2000, November 2002, and October 2003 are considered qualitative because of unacceptably high ion charge balance errors (see Section 4.0).

A time-series plot of the nitrate concentrations (excluding the suspected outlier and qualitative results noted above) suggests an indeterminate concentration trend (Figure 2). However, the significance of the indeterminate trend is questionable because of the limited number of quantitative data points.

5.2 URANIUM

Thirteen groundwater samples were analyzed for total uranium and concentrations at or above the applicable analytical reporting limit were detected in only three samples, with the highest concentration (0.01 mg/L in January 1991) being less than the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, each groundwater sample contained one or more of the following VOCs (Table 3): acetone, benzene, bromomethane, CT, chloroform, chloromethane, bromochloromethane, PCE, TCE, toluene, VC, xylenes, 11DCE, and 12DCE (c12DCE and t12DCE). Most of these compounds are components of an essentially contiguous plume of dissolved VOCs that occurs in the Maynardville Limestone on either side of the topographic and hydrologic divide between the Bear Creek and UEFPC watersheds. In the UEFPC watershed east of the flow divide, which occurs near the west end of Y-12, the VOC plume appears to originate near the Fire Training Facility in the southwestern section of Y-12, extends eastward (parallel with geologic strike) and mixes with VOCs released from several sources within Y-12, including the S-2 Site, and enters Union Valley east of the ORR boundary along Scarboro Road (DOE 1998).

The primary VOCs in the groundwater samples are PCE, TCE, and 12DCE (c12DCE), which were detected in each sample and have historical maximum concentrations of 890 μg/L, 960 μg/L, and 280 μg/L, respectively. Also, the most recent sampling results show that the concentrations of each of these compounds remain substantially above respective MCLs (Table 3). Secondary VOCs in the groundwater samples are CT, chloroform, and VC, all three of which were detected in all but two of the samples. Respective maximum historical concentrations for these compounds exceed 50 μg/L, with and the most recent sampling results showing CT and VC concentrations substantially above corresponding MCLs (5 μg/L and 2 μg/L). Other VOCs were each detected in no more than two of the samples and the bulk of the results for these compounds are estimated values below 5 μg/L.

Biologically mediated degradation (sequential dechlorination) of PCE and TCE by anaerobic methanotropic organisms in the groundwater may explain the presence and relatively high concentrations of c12DCE and VC in the groundwater samples from this well. However, as noted in Section 4.0, results for several indicator parameters suggest that the geochemical conditions in the groundwater at this well are not within the optimum range for biotic degradation of chlorinated hydrocarbons. For instance, the REDOX values for the groundwater samples (see Table 1) do not indicate the strongly reducing (methanogenic) conditions necessary to transform 12DCE isomers to VC (Chapelle 1996). Perhaps the monitored interval in the well intercepts groundwater flow/transport pathways for dissolved VOCs transported from a source (DNAPL) where conditions are better suited for biodegradation.

A time-series plot of the summed concentrations of VOCs detected in each groundwater sample shows a slightly increasing long-term trend (Figure 3), which is of questionable significance considering that only three samples were collected from the well between January 1991 and June 1998. The subsequent (low-flow sampling) results show concurrently fluctuating concentrations of dissolved chloroethenes (Figure 4) and chloromethanes (Figure 5) that exhibit indeterminate long-term trends. Additionally, neither concentration trend shows corresponding responses to the series of unusually wide water-level fluctuations in the well (Figure 1). These trends suggest minimal changes in the relative flux of dissolved VOCs via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity above the applicable MDA and corresponding CE was reported for each groundwater sample (Table 2), and all of these gross alpha results exceed the MCL for gross alpha activity (15 pCi/L). All but two of the results are less than 100 pCi/L, with the historical maximum value (231 pCi/L in April 1991) being a suspected outlier, and the historical minimum value (17 pCi/L) reported for a recently collected sample (November 2003). Analytical results for samples obtained between June 1996 and May 2002 show that uranium isotopes (U-234 and U-238) are a source of the gross alpha activity in the groundwater (Table 2), although the summed activity of these isotopes is usually much less than the corresponding gross alpha activity.

A time-series plot of applicable results for gross alpha activity (i.e., results that exceed the MDA and corresponding CE) shows a generally decreasing long-term concentration trend that is skewed downward by the historical maximum and minimum values (Figure 6). Nevertheless, the decreasing trend for gross alpha activity suggests a corresponding decrease in the relative flux of uranium isotopes, which is supported by the data shown in Table 2.

5.5 GROSS BETA ACTIVITY

Gross beta activity above the applicable MDA and corresponding CE was reported for each groundwater sample (Table 2), with results for the samples collected in January 1991 (93 pCi/L), April 1991 (72 pCi/L), and October 2001 (66 pCi/L) exceeding the SDWA screening level (50 pCi/L) for a 4 millirem dose equivalent (the MCL for gross beta activity). As with the gross alpha activity, the uranium isotopes (and related decay products) are the source of the gross beta activity in the samples.

WELL GW-257

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in March 1987, completed with a screened monitored interval from 19 to 34 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-248 and is located in Bear Creek Valley (BCV), about 100 ft directly west of a northern tributary (NT) of Bear Creek (NT-7) that traverses the west-central section of the Bear Creek Burial Grounds (BCBG) waste management area. The BCBG includes numerous hazardous and nonhazardous waste disposal units that received a mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. Liquid wastes included oils, machine coolants, and borax waste water, all or most of which may have contained varying amounts of radioisotopes (primarily uranium isotopes). In 1989, most of the waste-disposal units in the BCBG waste management area were covered with multi-layer, low-permeability caps installed during RCRA closure of the site.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Eight groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain six samples between May 1988 and August 1995, and the low-flow sampling method used to obtain samples in March and August 2004.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Maryville Limestone (the Conasauga Group). The bulk of the groundwater flow in the Maryville Limestone occurs within this highly permeable zone, which occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek that traverse the Maryville Limestone and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 26 ft bgs and exhibits minor seasonal fluctuations (<3 ft). Also, measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in well GW-257 are typically lower than evident in well GW-248, which is completed at a greater depth (62 ft bgs) in the Maryville Limestone. Based on the distance between the monitored interval midpoint (elevation) in each well (29.6 ft), the contemporaneous groundwater elevations indicate an upward vertical hydraulic gradient (0.002) from the shallow bedrock interval (GW-248) to the water table interval (GW-257).

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-257 indicate south and southwesterly flow toward the Maynardville Limestone and the main channel of Bear Creek. However, groundwater flow in the Maryville Limestone is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Consequently, the direction(s) of groundwater flow in the vicinity of well GW-257 may be primarily eastward (parallel with geologic strike) toward discharge areas in NT-7, which flows northeast-southwest across the BCBG approximately 100 ft east of the well.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 130 – 187 mg/L;
- pH of 6.32 – 6.6 (field measurements);
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations);
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Three groundwater samples had nitrate concentrations above the analytical reporting limit, with the highest concentration (0.36 mg/L in August 1995) being substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Two groundwater samples collected to date had uranium concentrations above the analytical reporting limit, with the highest concentration (0.01 mg/L in August 1989) being below the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Each groundwater sample that was analyzed for VOCs contained PCE, with trace levels (<1 μg/L) of TCE detected in two of the samples and chloromethane (8μg/L) detected in one sample (Table 1). The well is located approximately 350 ft east-southeast of the former BCBG Walk-In Pits (WIP), which are the source of a distinct plume of dissolved VOCs in the groundwater that is dominated by PCE. Historical data for other wells near the WIP show that PCE concentrations within the plume exceed 2000 μg/L, which is about 1% of maximum PCE solubility and possibly indicates that the PCE is present as DNAPL in the subsurface near this site (DOE 1997).

The PCE concentration detected in each groundwater sample generally decreased between June 1989 (210 μg/L) and March 1990 (130 μg/L) and subsequently increased through August 2004 (210 μg/L). These sampling results suggest little if any long-term change in the relative flux of PCE via the groundwater flow/transport pathways intercepted by the monitored interval in the well. Moreover, the persistent lack of TCE and other PCE degradation products (e.g., c12DCE) in the samples suggest that there is minimal biotic or abiotic degradation of the PCE in the groundwater at this well. Conversely, data for other wells that monitor VOC-contaminated groundwater with similar geochemical characteristics elsewhere at the BCBG indicate active biotic degradation of PCE and related degradation products. It is not clear from the available data why similarly active biotic degradation of PCE apparently does not occur in the groundwater at this well, downgradient of the WIP.

5.4 GROSS ALPHA ACTIVITY

One of the groundwater samples collected since March 1990 had gross alpha activity above the applicable MDA and corresponding CE, and this result (1.62 pCi/L in August 1995) is substantially below the drinking water MCL for gross alpha activity (15 pCi/L). Gross alpha activity results reported for samples obtained before 1990 are qualitative (the sample-specific MDA and CE are not available) and show similarly low levels of gross alpha activity.

5.5 GROSS BETA ACTIVITY

One of the groundwater samples collected since March 1990 had gross beta activity above the applicable MDA and corresponding CE, and this result (6.51 pCi/L in August 1995) is substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). Gross beta activity results reported for samples before 1990 are qualitative (the sample-specific MDA and CE are not available) and show similarly low levels of gross beta activity.

WELL GW-269

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during June 1986, completed with a screened monitored interval from 21.9 to 30 ft bgs and constructed with nominal 4.5-inch diameter PVC (#40) riser casing and well screen (0.02 slot). The well is located in Bear Creek Valley (BCV) near the west end of Y-12, on the east side of the Salvage Yard Oil/Solvent Drum Storage Area (OSDSA). The OSDSA includes two separate (East and West) gravel-covered areas within the northern section of the Y-12 Salvage Yard that were used from 1976 until 1989 for drummed storage of about 88,000 gallons of waste oils and solvents. Closure of the OSDSA was completed in stages, with the western area completed in 1986 and the eastern area completed in 1991, and involved excavation and removal of contaminated soils and replacement with clean backfill; the eastern area also was covered with an impermeable polyethylene membrane (DOE 1998).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fifteen groundwater samples have been collected from the well, with the conventional sampling method used to obtain thirteen samples between October 1996 and March 1997 and the low-flow sampling method used to obtain samples in May and October 2003.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Maryville Limestone (Conasauga Group). The bulk of the groundwater flow in the Maryville Limestone occurs within a highly permeable zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 14 ft bgs and exhibits minimal (<3 ft) seasonal fluctuations. Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-269 indicate southeasterly flow toward the Maynardville Limestone and the Upper East Fork Poplar Creek (UEFPC) drainage system. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and original main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, the low-permeability formations of the Conasauga Group, including the Maryville Limestone, exhibit strongly anisotropic groundwater flow patterns, with preferred flow in directions that parallel geologic strike (i.e., bedding-plane fractures), which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields chloride-enriched calcium-magnesium-bicarbonate groundwater generally characterized by:

- unusually low TDS of 60 – 135 mg/L, which suggests short groundwater residence time and indicates that the monitored interval in the well intercepts hydraulically active flowpaths;
- pH of 6 – 6.5 (field measurements);

- unusually high chloride concentrations (>70 mg/L) compared to other wells completed at similar depths in the Maryville Limestone;
- low molar proportions of potassium, sodium, and sulfate (<10% of total anions/cations); and
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

It is not clear if the unusually high chloride concentrations typical of the groundwater samples reflect natural geochemical characteristics or if the elevated concentrations are the result of contamination from one or more sources hydraulically upgradient of the well. Also, the groundwater contains a mixture of dissolved hydrocarbons (see Section 5.3) and elevated chloride concentrations in the groundwater samples may be a consequence of the biologically mediated degradation (dechlorination) of these compounds (Hinchee et al. 1995). Aside from the REDOX conditions, recent monitoring data suggest that the geochemical characteristics of the groundwater are conducive to biotic degradation of VOCs (Table 1).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Each groundwater samples had nitrate concentrations at or above the applicable analytical reporting limit, with the highest concentration (0.569 mg/L in May 2003) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

None of the groundwater samples had uranium concentrations at or above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, at least one or more of the following VOCs was detected in each groundwater sample (Table 2): benzene, chloroform, ethylbenzene, toluene, PCE, TCE, trichlorofluoromethane (TCFM), VC, xylenes (total), 11DCA, 11DCE, 12DCE (c12DCE), and 111TCA. These compounds are components of a plume of dissolved VOCs in the groundwater that is believed to originate from one or more sources in the northern section of the Y-12 Salvage Yard, including the OSDSA and the Oil Storage Tank. Additionally, (soluble) contaminants leached from subsurface soils at both sites, which contain chlorinated hydrocarbons along with other organic and inorganic contaminants, continue to enter the shallow flow system (DOE 1998). Based on the characteristics of groundwater flow at shallow depths in the Maryville Limestone in BCV and the network of existing monitoring wells, the dissolved VOCs from the OSDSA that enter the groundwater are probably transported eastward, parallel with geologic strike, toward discharge areas for the shallow flow system, including buried storm drains and utilities, building basement sumps, and the buried northern tributaries of UEFPC (DOE 1998).

The primary VOCs in the groundwater samples are 11DCE, PCE, 12DCE (c12DCE) and 111TCA, which were detected in each sample and have historical maximum concentrations of 270 μg/L, 62 μg/L, 70 μg/L, and 56 μg/L respectively (Table 2). Note that the highest concentrations of these compounds (except 111TCA) were detected in groundwater samples collected with the low-flow sampling method since March 1997. Also, the most recent concentrations of 11DCE, PCE, and 12DCE (c12DCE) are substantially higher than indicated by the conventional sampling results obtained through March 1990, whereas there is little if any difference between recent and historical concentrations of other compounds (e.g., TCE = 4 μg/L in October 1986 and 4 μg/L in October 2003). Aside from the primary VOCs, other compounds (including TCE) are detected infrequently and typically at much lower concentrations, with the bulk of the results being estimated values below 5 μg/L (Table 2). Also, petroleum hydrocarbons were detected in each sample collected between March 1986 and March 1988, but only one of the samples collected since then (benzene = 3 μg/L in March 1997).

Biologically mediated degradation (sequential dechlorination) of PCE and TCE by anaerobic methanotropic organisms in the groundwater may explain the presence and high concentrations of 11DCE. However, the REDOX values for the groundwater samples (see Table 1) do not indicate the reducing (methanogenic) conditions necessary to transform parent compounds to DCE isomers (Chapelle 1996). Also, as noted in Section 4.0, the low TDS in the samples suggests relatively short residence time for groundwater produced from the flowpaths intercepted by the monitored interval in the well. Perhaps the monitored interval intercepts groundwater flow/transport pathways for dissolved VOCs transported from a source where conditions are better suited for biodegradation of chlorinated hydrocarbons, possibly involving co-metabolic degradation with petroleum hydrocarbons.

A time-series plot of the summed concentrations of VOCs detected in each groundwater sample spans two gaps in the sampling history (March 1990 – March 1997 and March 1997 – May 2003) and shows a clearly increasing long-term trend (Figure 1) attributable primarily to the large increases in the concentrations of 11DCE, PCE, and 12DCE (Table 2). Although the samples collected since March 1997 were obtained with the low-flow sampling method, the higher VOC concentrations do not appear to be an artifact of change from the conventional sampling method because, as noted previously, equivalent concentrations of individual VOCs (e.g., TCE) were detected in samples obtained with each method. Also, not all of the individual compounds exhibit increasing concentration trends. Assuming a heterogeneous mixture of VOCs from common source(s), it is not clear why the concentrations of individual compounds exhibit such divergent concentration trends or if the trends are significant with respect to the relative flux of VOCs along the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

Gross beta activity above the applicable MDA and corresponding CE was reported for two groundwater samples, with the highest value (19.4 pCi/L in March 1997) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem dose equivalent (the MCL for gross beta activity).

WELL GW-270

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in June 1986, completed with a screened monitored interval from 11 to 18.5 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-271 and is located in Bear Creek Valley near the west end of Y-12. The well is within the Y-12 Salvage Yard about 750 ft directly east of the former S-3 Ponds. The S-3 Ponds site is a major source of groundwater contamination at Y-12 that was closed and capped in accordance with a RCRA closure plan in 1988. The S-3 site originally consisted of four unlined and contiguous surface impoundments that were used from 1951 to 1984 primarily for percolation/evaporation of nitric acid effluent (with depleted uranium in solution) discharged into the ponds via a pipeline (the Abandoned Nitric Acid Pipeline) connected to process buildings in the central Y-12 area. Operation of the site emplaced a heterogeneous plume of inorganic, organic, and radiological contaminants into the Conasauga Group (Nolichucky Shale) and created a mound in the water table (which dissipated after disposal of wastes in the ponds ceased) that enabled transport/migration of contaminants into areas that now lie east and west of the hydrologic divide separating the Bear Creek and Upper East Fork Poplar Creek watersheds.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Sixteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 14 samples between October 1986 and December 1989, and the low-flow sampling method used to obtain samples in April and October 2003.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the shallow bedrock interval in the Conasauga Group (Nolichucky Shale). The average static groundwater level in the well is 0.3 ft above the ground surface, which indicates slightly artesian conditions. Presampling depth-to-water measurements for the well indicate minimal (<1 ft) water-level fluctuations. Also, presampling groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are lower in well GW-270 than in well GW-271, which is completed at a greater depth (56 ft bgs) in the Nolichucky Shale. Based on the distance (35.25 ft) between the monitored interval midpoint (elevation) in each well, the contemporaneous groundwater elevations indicate upward vertical hydraulic gradients (0.038-0.039) from the shallow bedrock to the water table interval during seasonally high and low flow conditions.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- high TDS (>1, 000 mg/L);
- pH (field measurements) of 7.3 – 7.5;
- atypically high molar proportions of chloride, potassium, sulfate, and sodium (>10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals (except strontium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Nitrate concentrations reported for samples obtained with the conventional sampling method all exceed 100 mg/L, with concentration "spikes" evident in October 1986 (549 mg/L), September 1988 (407 mg/L), and May 1989 (723 mg/L). A substantially lower nitrate concentration was evident from low-flow sampling in April 2003 (34.5 mg/L), but the nitrate level evident from low-flow sampling in October 2003 (112 mg/L) is comparable to the conventional sampling results (Figure 1). It is not clear from the available data if the lower nitrate concentrations evident from low-flow sampling during CY 2003 are an artifact of the sampling method or if they reflect a reduction in nitrate concentrations (and flux) in the groundwater transport/migration pathways intercepted by the monitored interval in the well. The source of the nitrate in the groundwater at this well is the contaminant plume emplaced in the Nolichucky Shale during historical operations of the former S-3 Ponds. Nitrate is chemically stable, does not readily partition to soils, is highly mobile in groundwater, and effectively traces the principal migration pathways followed by other (mobile) components of the plume. The pattern of elevated nitrate levels indicated by the network of wells in the Nolichucky Shale east of the site suggest two principal migration pathways: (1) relatively rapid migration along fairly short, shallow pathways (<30 ft bgs) that typically terminate in storm drains or other utilities, building sumps, and the buried tributaries and original mainstem of Upper East Fork Poplar Creek; and (2) substantially slower migration along much longer strike-parallel pathways deeper in the bedrock toward basement sumps in Bldgs. 9204-4, 9201-5, and 9204-2 (DOE 1998).

5.2 URANIUM

Uranium concentrations above the applicable analytical reporting limit were reported for all but two of the groundwater samples, with the highest value (0.012 mg/L) being less than the MCL for uranium (0.03 mg/L). Also, the available data show an indeterminate long-term concentration trend, with no distinct difference between conventional and low-flow sampling results for uranium, as illustrated by the similarity between the uranium levels reported for samples obtained with the conventional sampling method in March 1988 (0.001 mg/L) and April 2003 (0.0011 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for the groundwater samples collected in CY 2003 show non-detect values for all VOCs analyzed.

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity reported for the groundwater sample collected in October 2003 (5.2 pCi/L) exceeds the MDA and corresponding CE, but is substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Gross beta activity reported for the groundwater sample collected in April 2003 (15 pCi/L) exceeds the MDA and corresponding CE, but is substantially below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-271

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in June 1986, completed with a screened monitored interval from 43.9 to 56.3 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-270 and is located in Bear Creek Valley near the west end of Y-12. The well is within the Y-12 Salvage Yard about 750 ft directly east of the former S-3 Ponds, which are a primary source of groundwater contamination in Bear Creek Valley. Located at the headwaters of Bear Creek, the S-3 Ponds consisted of four unlined surface impoundments, each with a 2.5 million gallon capacity, that were used between 1951 and 1984 for the disposal of acidic, radioactive liquid wastes generated primarily at Y-12. The S-3 Ponds were covered with a multi-layer, low permeability cap (including asphalt paving) during RCRA closure of the site in 1988.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Sixteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 14 samples between October 1986 and January 1990, and the low-flow sampling method used to obtain samples in April and October 2003.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the shallow bedrock interval in the Conasauga Group (Nolichucky Shale). The average static groundwater level in the well is -1.5 ft above the ground surface, indicating artesian conditions. Presampling depth-to-water measurements for the well indicate minimal (<0.05 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- moderate TDS (>150 mg/L<800 mg/L);
- pH (field measurements) of 7.2 – 7.9;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion. Contaminant concentrations in the well are based on the analytical results reported for the groundwater samples collected during 2003.

5.1 NITRATE

None of the groundwater samples had nitrate concentrations above the applicable analytical reporting limit.

5.2 URANIUM

None of the groundwater samples had uranium concentrations above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for each groundwater sample show non-detect values or false positive results for all of the VOCs that are confirmed groundwater contaminants in the East Fork Regime.

5.4 GROSS ALPHA ACTIVITY

One groundwater sample had gross alpha activity above the applicable MDA and corresponding CE, and this result (2.2 pCi/L in April 2003) is substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Two groundwater samples had gross beta activity above the applicable MDA and corresponding CE, and both results (13 pCi/L in April 2003 and 36 pCi/L in October 2003) are below the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-272

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in June 1986, completed with a screened monitored interval from 8.8 to 16.2 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley near the west end of Y-12, within the northeastern section of the Y-12 Salvage Yard, about 1,300 ft directly east of the former S-3 Ponds, a major source of groundwater contamination at Y-12 that was closed and capped in accordance with a RCRA closure plan in 1988. The S-3 site originally consisted of four unlined and contiguous surface impoundments that were used from 1951 to 1984 primarily for percolation/evaporation of nitric acid effluent (with depleted uranium in solution) discharged into the ponds via a pipeline (the Abandoned Nitric Acid Pipeline) connected to process buildings in the central Y-12 area. Operation of the site emplaced a heterogeneous plume of inorganic, organic, and radiological contaminants into the Conasauga Group (Nolichucky Shale) and created a mound in the water table (which dissipated after disposal of wastes in the ponds ceased) that enabled transport/migration of contaminants into areas that now lie east of the hydrologic divide separating the Bear Creek and Upper East Fork Poplar Creek watersheds. Additionally, the Y-12 Salvage Yard encompasses several former waste management units that are known sources of groundwater contamination (e.g., Salvage Yard Drum Deheader).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-two groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 20 samples between October 1986 and January 1990, and the low-flow sampling method used to obtain samples in May and October 2003.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Nolichucky Shale). The average static groundwater level in the well is 4.4 ft below ground surface. Presampling depth-to-water measurements for the well indicate minor (<2 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields nitrate contaminated, calcium-magnesium-bicarbonate groundwater generally characterized by:

- high TDS (>1,200 mg/L);
- pH (field measurements) of 6.8 – 7.1;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals (except barium) that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Nitrate concentrations above the applicable analytical reporting limit were detected in each groundwater sample (Figure 1). Concentrations below the MCL for nitrate (10 mg/L) were reported for each sample collected between October 1986 (0.63 mg/L) and March 1989 (1.9 mg/L). Substantially higher nitrate levels were detected in the groundwater samples collected in April (335 mg/L) and October 2003 (415 mg/L). It is not clear from the available data if the higher nitrate concentrations are an artifact of the sampling method or if they reflect a substantial increase in nitrate concentrations (and flux) in the groundwater transport/migration pathways intercepted by the monitored interval in the well. The source of the nitrate is the contaminant plume emplaced in the Nolichucky Shale during historical operation of the former S-3 Ponds. Nitrate is chemically stable, does not readily partition to soils, is highly mobile in groundwater, and effectively traces the principal migration pathways followed by other (mobile) components of the plume. The pattern of elevated nitrate levels indicated by the network of wells in the Nolichucky Shale east of the site suggest two principal migration pathways: (1) relatively rapid migration along fairly short, shallow pathways (<30 ft bgs) that typically terminate in storm drains or other utilities, building sumps, and the buried tributaries and original mainstem of Upper East Fork Poplar Creek; and (2) substantially slower migration along much longer strike-parallel pathways deeper in the bedrock toward basement sumps in Bldgs. 9204-4, 9201-5, and 9204-2 (DOE 1998).

5.2 URANIUM

Eight groundwater samples contained uranium concentrations above the applicable analytical reporting limit (Figure 2). Uranium concentrations below the MCL (0.03 mg/L) were reported for six samples obtained with the conventional sampling method between October 1986 (0.008 mg/L) and December 1989 (0.005 mg/L). In contrast, substantially higher uranium concentrations slightly above and below the MCL were reported for the samples obtained with the low-flow sampling method in April (0.0377 mg/L) and October 2003 (0.0295 mg/L). As with the nitrate levels in the well, it is not clear from the available data if the higher uranium concentrations are an artifact of the sampling method or if they reflect a substantial increase in uranium levels (and flux) in the groundwater transport/migration pathways intercepted by the monitored interval in the well.

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for the groundwater samples collected in CY 2003 show non-detect values for all VOCs analyzed.

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity reported for the groundwater samples collected in April and October 2003 does not exceed the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

Gross beta activity reported for the groundwater samples collected in April and October 2003 does not exceed the applicable MDA and corresponding CE.

WELL GW-273

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in June 1986, completed with a screened monitored interval from 22.9 to 33.1 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley near the west end of Y-12, within the south-central section of the Y-12 Salvage Yard, about 750 ft directly east of the former S-3 Ponds, a major source of groundwater contamination at Y-12 that was closed and capped in accordance with a RCRA closure plan in 1988. The S-3 site originally consisted of four unlined and contiguous surface impoundments that were used from 1951 to 1984 primarily for percolation/evaporation of nitric acid effluent (with depleted uranium in solution) discharged into the ponds via a pipeline (the Abandoned Nitric Acid Pipeline) connected to process buildings in the central Y-12 area. Operation of the site emplaced a heterogeneous plume of inorganic, organic, and radiological contaminants into the Conasauga Group (Nolichucky Shale) and created a mound in the water table (which dissipated after disposal of wastes in the ponds ceased) that enabled transport/migration of contaminants into areas that now lie east of the hydrologic divide separating the Bear Creek and Upper East Fork Poplar Creek watersheds. Additionally, the Y-12 Salvage Yard encompasses several former waste management units that are known sources of groundwater contamination (e.g., Salvage Yard Drum Deheader).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Ten groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain eight samples between October 1986 and March 1997, and the low-flow sampling method used to obtain samples in April and October 2003.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Nolichucky Shale). The average static groundwater level in the well is 4.1 ft below ground surface. Presampling depth-to-water measurements for the well indicate minimal (<1 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- low TDS (<150 mg/L), which suggests short groundwater residence time and indicates that the monitored interval in the well intercepts hydraulically active flowpaths;
- pH (field measurements) of 5.3;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Nitrate concentrations above 100 mg/L were detected in each groundwater sample collected between October 1986 (790 mg/L; qualitative) and December 1988 (185 mg/L). The sample collected in December 1997 was not analyzed for nitrate and nitrate was not detected (<0.028 mg/L) in the groundwater samples collected in April and October 2003. It is not clear from the available data if the lower nitrate concentrations are an artifact of the low-flow sampling procedure or if they reflect a substantial decrease in the nitrate levels (and flux) in the groundwater migration/transport pathways intercepted by the monitored interval in the well. Also, the lack of nitrate in the groundwater at this well seems surprising because very high nitrate concentrations (>100 mg/L) are evident in nearby wells to the north (e.g., GW-271), south (e.g., GW-108), east (e.g., GW-274), and west (e.g., GW-105). The source of the nitrate is the contaminant plume emplaced in the Nolichucky Shale during historical operation of the former S-3 Ponds. Nitrate is chemically stable, does not readily partition to soils, is highly mobile in groundwater, and effectively traces the principal migration pathways followed by other (mobile) components of the plume. The pattern of elevated nitrate levels indicated by the network of wells in the Nolichucky Shale east of the site suggest two principal migration pathways: (1) relatively rapid migration along fairly short, shallow pathways (<30 ft bgs) that typically terminate in storm drains or other utilities, building sumps, and the buried tributaries and original mainstem of Upper East Fork Poplar Creek; and (2) substantially slower migration along much longer strike-parallel pathways deeper in the bedrock toward basement sumps in Bldgs. 9204-4, 9201-5, and 9204-2 (DOE 1998).

5.2 URANIUM

None of the groundwater samples had uranium concentrations above the applicable analytical reporting limit.

5.3 VOLATILE ORGANIC COMPOUNDS

As shown below in Table 1, PCE, TCE, 12DCE, and benzene were detected in the groundwater samples, with the highest concentrations of each compound reported for samples obtained with the conventional sampling method.

Table 1. VOC Results for well GW-273

Sampling Date	Concentration (µg/L)			
	PCE	TCE	12DCE	Benzene
10/31/86	**19**	6	2 J	**16**
03/06/87	**43**	4 J	.	**68**
06/02/87	**35**	3 J	4 J	**60**
08/19/87	**46**	**22**	5	**73**
10/28/87	**39**	4 J	5	**72**
03/11/88	**36**	3 J	.	**77**
12/15/88	**27**	4 J	.	**170**
03/17/97	2 J	0.8 J	3 J	**390**
04/29/03	.	.	.	**7**
10/21/03	.	.	.	**6**

Note: Bold typeface denotes results that exceed the MCL; "." = not detected

It is not clear from the data if the lower VOC concentrations evident during CY 2003 are artifacts of the low-flow sampling method or if they reflect an overall decrease in VOC concentrations (and flux) in the groundwater transport/migration pathways intercepted by the monitored interval for the well. In either case, the intermingled plume of dissolved VOCs originating from historical operations of the former S-3 Ponds and several former waste management facilities within in the Y-12 Salvage Yard, including the Salvage Yard Drum Deheader and the Rust Garage Area, is the likely source of the compounds in the groundwater at this well (DOE 1998).

5.4 GROSS ALPHA ACTIVITY

None of the groundwater samples had gross alpha activity above the applicable MDA and corresponding CE.

5.5 GROSS BETA ACTIVITY

None of the groundwater samples had gross beta activity above the applicable MDA and corresponding CE.

WELL GW-274

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during June 1986, completed with a screened monitored interval from 25.8 to 35 ft bgs. The well forms a cluster with well GW-275 and is constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley (BCV) near the west end of Y-12, within the southeastern section of the Y-12 Salvage Yard about 1,200 ft directly east of the former S-3 Ponds. The Y-12 Salvage Yard encompasses several former waste management units that are known sources of groundwater contamination (e.g., Salvage Yard Drum Deheader). The former S-3 Ponds were four unlined surface impoundments that were used from 1951 to 1984 primarily for the percolation/evaporation of nitric acid effluent (with depleted uranium in solution) piped from process buildings in the central section of Y-12. Each pond contains several feet of sludge produced during the neutralization of the liquid wastes prior to RCRA closure of the site in 1988, when the ponds were filled with aggregate and covered with a multilayer low-permeability cap (including an asphalt-paved parking lot).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty groundwater samples have been collected from the well, with the conventional sampling method used to obtain 16 samples between November 1986 and March 1996, and the low-flow sampling method used to obtain four samples between May 2000 and October 2003.

Extremely high levels of total dissolved solids (TDS) is a distinguishing characteristic of the groundwater samples and are a direct consequence of contamination from the former S-3 Ponds (see Section 5.0).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Nolichucky Shale (Conasauga Group). The bulk of the groundwater flow in the Nolichucky Shale occurs within a highly permeable zone (the water table interval) near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992).

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 2 ft bgs and exhibits minimal (<2 ft) seasonal fluctuations. Also, presampling groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are lower in well GW-274 than in well GW-275, which is completed at a greater depth (65.5 ft bgs) in the Nolichucky Shale. Based on the distance (28.9 ft) between the monitored interval midpoint (elevation) in each well, the contemporaneous groundwater elevations indicate upward vertical hydraulic gradients (0.005-0.031) during seasonally high and low flow conditions.

Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-274 indicate southeasterly flow toward the Maynardville Limestone and the Upper East Fork Poplar Creek (UEFPC) drainage system. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and original main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred flow in

directions that parallel geologic strike (i.e., bedding-plane fractures), which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields extremely mineralized, nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 17,500 – 57,684 mg/L;
- pH of 5.3 – 5.98 (field measurements);
- high concentrations of several ions, notably calcium (>3,500 mg/L) and nitrate (>3,000) and;
- low molar proportions of chloride, potassium, and sulfate (<10% of total anions/cations); and
- elevated total concentrations of several trace metals, particularly barium (>20 mg/L), manganese (>80 mg/L), and strontium (>10 mg/L), that substantially exceed the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, the principal contaminants present in the groundwater at this well are nitrate, VOCs, and gross beta activity.

5.1 NITRATE

Each groundwater sample contained nitrate concentrations of at least 1,000 mg/L, including the samples collected most recently (Table 1). The source of the nitrate is the former S-3 Ponds, the historical operation of which emplaced a heterogeneous mixture of inorganic, organic, and radiological contaminants in the Nolichucky Shale and created a mound in the water table that facilitated contaminant transport/migration east of the hydrologic divide separating the Bear Creek and UEFPC watersheds. Nitrate and other inorganic contaminants within the plume were entrained in the wastes disposed at the site, but some of the inorganic contaminants (e.g., barium) were dissolved from bedrock minerals by the acidic seepage from the ponds. With concentrations in excess of 10,000 mg/L, nitrate is the primary inorganic contaminant in the plume. Based on the network of existing monitoring wells completed in the Nolichucky Shale east of the former S-3 Ponds, elevated nitrate concentrations (i.e., >10 mg/L) extend laterally at least 5,000 ft eastward (parallel with geologic strike) and vertically (parallel with geologic dip) at least 150 ft bgs (DOE 1998).

Nitrate concentrations reported for the groundwater samples range between the historical maximum concentration of 15,800 mg/L in October 1986 and the historical minimum concentration of 1,087 mg/L in March 1989 (Table 1). Under the conceptual model for contaminant transport from the former S-3 Ponds, the sampling results for this well are believed to be representative of concentrations within shallow (<30 ft bgs), fairly short groundwater flow/transport pathways that promote relatively rapid flow toward discharge areas in buried storm drains and utilities, building basement sumps, and the buried northern tributaries and original mainstem of UEFPC within about 1,000 ft east of the former S-3 Ponds (DOE 1998). Additionally, as shown by the data summarized below, the nitrate concentrations in the shallow groundwater flow/transport pathways intercepted by the monitored interval in well GW-274 are significantly lower than the nitrate concentrations in the deeper groundwater flow/transport pathways intercepted by the monitored interval in well GW-275.

Well	Nitrate (mg/L)				
	October 1995	May 2000	October 2000	April 2003	October 2003
GW-274	4,270	5,410	3,890	3,010	2,950
GW-275	7,580	7,150	7,160	7,390	6,900

Under the conceptual model for contaminant transport from the former S-3 Ponds, sampling results for well GW-275 are representative of concentrations within long, strike-parallel groundwater flow/transport pathways (e.g., bedding-plane fractures), possibly bound to a relatively narrow band near the middle of the Nolichucky Shale, that promote much slower flow toward operating basement sumps located in Bldgs. 9204-4, 9201-5, 9201-4, and 9204-2, which are up to 4,000 ft east-southeast of the former S-3 Ponds (DOE 1998). Considering the upward hydraulic gradients indicated by presampling groundwater elevations in wells GW-274 and GW-275 (see Section 3.0), the nitrate concentrations in the shallower groundwater flow system are at least partially maintained by nitrate-contaminated groundwater upwelling from deeper in the Nolichucky Shale.

In addition to the lower nitrate concentrations evident in the shallow groundwater at well GW-274, the preceding data summary also illustrates the decreasing long-term nitrate concentration trend (Figure 1), with sampling results for well GW-275 suggesting a much slower decrease in the concentration of nitrate in the deeper groundwater flow/transport pathways. The decreasing nitrate concentrations indicated by the monitoring data for each well are primarily attributable to substantially reduced flux of nitrate (and other contaminants) following closure of the former S-3 Ponds in 1984 and the installation of the low-permeability cap in 1989; reduced flux of contaminants in the deeper bedrock (GW-275) also may be attributable to the continued eastward (strike parallel) migration of the nitrate mass emplaced during historical site operations (DOE 1998). Moreover, the more rapid decrease in nitrate concentrations in the shallow groundwater (GW-274) suggest the influence of natural attenuation processes, including inflow of uncontaminated (or less contaminated) recharge, that are limited to, or are more efficient in, the shallow flow system.

5.2 URANIUM

All of the groundwater samples collected since November 1986 had uranium concentrations above the analytical reporting limit, including results for eight samples that exceed the MCL for uranium (0.03 mg/L). The acidic groundwater in this well and elsewhere immediately downgradient of the former S-3 Ponds contains elevated concentrations of several trace metals, some entrained in the wastes disposed at the site (e.g., uranium) and others dissolved from minerals in the bedrock (Nolichucky Shale) underlying the site (e.g., barium). The uranium in the groundwater probably occurs as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble complexes with a variety of inorganic anions (Fetter 1993). Thus, the distribution of elevated uranium concentrations in the Nolichucky Shale near the former S-3 Ponds is largely confined to the low-pH groundwater within about 500 ft of the site (DOE 1998).

Uranium concentrations reported for the groundwater samples range between the historical minimum value of 0.013 mg/L in October 1995 and the historical maximum value of 0.047 mg/L in November 1988 (Table 1). As with nitrate concentrations in the samples, these uranium results show a decreasing long-term concentration trend, with concentrations below the MCL (0.03 mg/L) reported for each sample collected form the well since January 1990. The decreasing uranium concentrations correspond with the substantially reduced flux of uranium in the shallow groundwater flow system following closure/capping of the former S-3 Ponds (DOE 1998).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, one or more of the following VOCs were detected in the groundwater samples collected since October 1986 (Table 2): benzene, bromoform, chloroform, methylene chloride, PCE, TCE, and 12DCE (c12DCE). Although some of these compounds (e.g., PCE) are confirmed components of the contaminant plume originating from the former S-3 Ponds and the Y-12 Salvage Yard (Drum Deheader), others (e.g., benzene) are not, and their presence in the groundwater at well GW-274 indicates transport/migration from other potential sources of VOCs, such as the Rust Garage, which is a known source of petroleum hydrocarbons located about 500 ft west (hydraulically upgradient, parallel with geologic strike) of the well.

Based on frequency of detection, the primary VOCs in the groundwater samples are PCE and TCE, one or both of which were detected in all but three of the samples (Table 2), although the most recent sampling results (April and October 2003) show PCE concentrations are several orders-of-magnitude higher than TCE concentrations. Secondary compounds in the samples are benzene, bromoform, and 12DCE (c12DCE), with the concentrations of benzene exceeding 100 µg/L and the concentrations of bromoform and 12DCE remaining near 10 µg/L. Also, all of the VOCs have been detected more frequently in the samples collected since October 1995. Benzene, for instance, was detected in two of the 14 samples collected between November 1986 and January 1990, but was detected in all five of the samples collected between October 1995 and October 2003 (Table 2).

As noted in Section 5.1, the nitrate concentrations are substantially higher in the deeper groundwater at well GW-275. Vertically upward hydraulic gradients from well GW-275 to GW-274 suggest upwelling of nitrate-contaminated groundwater from the deeper flow system, which helps maintain the nitrate levels in the shallower groundwater (GW-274). Unlike the nitrate concentrations, however, the concentrations of VOCs in the shallow groundwater at well GW-274 are substantially higher than the concentrations of VOCs in the deeper groundwater at well GW-275, as illustrated by the data summarized below.

VOC	Concentration (µg/L)					
	October 1995		May 2000		October 2000	
	GW-274	GW-275	GW-274	GW-275	GW-274	GW-275
PCE	36	.	500	9	650	.
TCE	6	.	10	.	12	.
12DCE	4	.	5	.	7	.
Bromoform	.	.	6	.	6	.
Chloroform	17	1 J	25	.	28	.
MC	37	3 J	49	.	57	.
Benzene	.	.	35	.	50	.
Note: "." = Not detected; J = Estimated value below analytical reporting limit						

The data for well GW-274 also illustrate the substantial concentration increases evident for PCE and benzene (Table 2), with respective historical maximum values (1,200 µg/L for PCE and 120 µg/L for benzene) reported for the sample collected most recently (October 2003). Also, note the contrast between the increasing concentrations of PCE and benzene and the decreasing concentrations of nitrate. This relationship suggests that the contaminant plume emplaced during operation of the former S-3 Ponds may not be the primary source of the PCE (and other VOCs) in the shallow groundwater at this well, an interpretation supported by the overall lack of PCE (and other VOCs) in the samples of the deeper groundwater from well GW-275. Instead of the S-3 Site, areas in the Y-12 Salvage Yard (e.g., the Drum Deheader) may be the source of the chlorinated solvents. Moreover, the concurrent increase in the concentrations of PCE and benzene in the shallow groundwater at well GW-274 suggest a common source for these compounds, which also discounts the former S-3 Ponds because benzene and other petroleum hydrocarbons were not part of the waste stream disposed at the site. The increasing concentrations of the VOCs suggest a corresponding increase in the relative flux of VOCs along the groundwater flow/transport pathways intercepted by the well.

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity reported for the groundwater samples collected before October 1995 do not meet data quality objectives (the MDA and corresponding CE were not for these results are not available), and gross alpha activity reported for the samples collected since then do not exceed the applicable MDA. However, the apparent lack of gross alpha activity (and associated alpha-emitting radionuclides) may be an artifact of the elevated MDAs reported for the applicable samples (e.g., MDA = 290 pCi/L in October 2003). The elevated MDAs are probably attributable to analytical interference related to the very high TDS of the (unfiltered) groundwater samples.

5.5 GROSS BETA ACTIVITY

Gross beta activity reported for the groundwater samples collected before October 1995 do not meet data quality objectives (the MDA and corresponding CE were not for these results are not available). However, gross beta activity reported for all of the samples collected since then exceed 1,000 pCi/L, with the most recent sampling results (April and October 2003) indicating gross beta activity above 10,000 pCi/L (Table 1). Moreover, all of these results are at least two orders-of-magnitude higher than the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the MCL for gross beta activity). The primary source of the gross beta activity is Tc-99, which is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds (the only site at Y-12 to receive wastes containing Tc-99), and was detected at very high concentrations in the samples collected in May 2000 (15,000 pCi/L) and October 2000 (15,000 pCi/L). Note that both the Tc-99 results substantially exceed the SDWA screening level (3,790 pCi/L) for a 4 mrem/yr dose equivalent from Tc-99. Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-) which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in Nolichucky Shale east of the former S-3 Ponds, the extent of elevated (>50 pCi/L) gross beta activity in the groundwater suggests that the distribution of Tc-99 closely mirrors that of nitrate (see Section 5.1), with the sampling results for well GW-274 being representative of gross beta/Tc-99 activity at shallow depths in relatively short groundwater flow/transport pathways that terminate in buried storm drains and utilities, building basement sumps, and the buried northern tributaries and original mainstem of UEFPC (DOE 1998).

As noted in Section 5.1, nitrate concentrations in the groundwater samples from well GW-274 are substantially lower than evident in the groundwater samples from well GW-275. However, the opposite appears true for gross beta activity (and Tc-99). As shown by the data summarized below, sampling results for well GW-274 show substantially higher gross beta activity than the sampling results for well GW-275, which seems peculiar in light of the very high nitrate concentrations in the groundwater from this well.

Well	Gross Beta Activity (pCi/L)				
	October 1995	**May 2000**	**October 2000**	**April 2003**	**October 2003**
GW-274	4,230	7,800	12,200	13,000	10,000
GW-275	125	<MDA	<MDA	<MDA	<MDA

The preceding data summary also illustrates the increasing long-term trend indicated by the gross beta activity reported for the groundwater samples from well GW-274 (Figure 3). This trend suggests substantially increased flux of Tc-99 along the groundwater flow/transport pathways intercepted by the monitored interval in the well. However, the substantially higher flux of Tc-99 is concurrent with the substantially lower flux of nitrate suggested by a decreasing long-term nitrate concentration trend (see Section 5.1). Divergent concentration trends (and differential flux) for nitrate and Tc-99 seem somewhat surprising considering that both contaminants share a common source (the former S-3 Ponds) and have similar groundwater transport characteristics. Perhaps the apparent differential flux of nitrate and Tc-99 is a consequence of waste disposal operations at the S-3 Ponds, whereby the routine disposal of nitrate wastes essentially emplaced a large contiguous mass of nitrate and the intermittent disposal of Tc-99 wastes emplaced more discontinuous "slugs" of Tc-99 within the mass of nitrate. Thus, the increasing Tc-99 concentrations indicted by the gross beta activity reported for well GW-274 may reflect a temporal "pulse" in the relative flux of Tc-99 emplaced during intermittent disposal of Tc-99 wastes at the site (AJA 2001).

WELL GW-275

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in May 1986, completed with a screened monitored interval from 53.3 to 65.5 ft bgs, and constructed with 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-274 and is located in Bear Creek Valley near the west end of Y-12, within the southeastern section of the Y-12 Salvage Yard, about 1,200 ft directly east of the former S-3 Ponds, a major source of groundwater contamination at Y-12 that was closed and capped in accordance with a RCRA closure plan in 1988. The S-3 site originally consisted of four unlined and contiguous surface impoundments that were used from 1951 to 1984 primarily for percolation/evaporation of nitric acid effluent (with depleted uranium in solution) discharged into the ponds via a pipeline (the Abandoned Nitric Acid Pipeline) connected to process buildings in the central Y-12 area. Operation of the site emplaced a heterogeneous plume of inorganic, organic, and radiological contaminants into the Conasauga Group (Nolichucky Shale) and created a mound in the water table (which dissipated after disposal of wastes in the ponds ceased) that enabled transport/migration of contaminants into areas that now lie east of the hydrologic divide separating the Bear Creek and Upper East Fork Poplar Creek watersheds. Additionally, the Y-12 Salvage Yard encompasses several former waste management units that are known sources of groundwater contamination (e.g., Salvage Yard Drum Deheader).

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Nineteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 15 samples between November 1986 and October 1995, and the low-flow sampling method used to obtain four samples between May 2000 and October 2003.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the shallow bedrock interval (<100 ft bgs) in the Conasauga Group (Nolichucky Shale). The average static groundwater level in the well is 1.4 ft below ground surface. Presampling depth-to-water measurements for the well indicate moderate fluctuations (<4 ft) in seasonal groundwater surface elevations. Also, presampling groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are higher in well GW-275 than in well GW-274, which is completed at a shallower depth (35 ft bgs) in the Nolichucky Shale. Based on the distance (28.9 ft) between the monitored interval midpoint (elevation) in each well, the contemporaneous groundwater elevations indicate upward vertical hydraulic gradients (0.005-0.031) during seasonally high and low flow conditions from the shallow bedrock to the water table interval.

Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-274 indicate southeasterly flow toward the Maynardville Limestone and the Upper East Fork Poplar Creek (UEFPC) drainage system. However, the shallow subsurface throughout the industrialized areas of Y-12 has been extensively reworked and local flow directions may be strongly influenced by subsurface process lines, utilities, and storm sewers, the buried northern tributaries and original main channel of UEFPC, and the intermittent and continuous operation of building basement sumps (DOE 1998). Moreover, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred flow in directions that parallel geologic strike (i.e., bedding-plane fractures), which may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields nitrate-contaminated and highly mineralized calcium-magnesium-bicarbonate groundwater generally characterized by:

- extremely high TDS (>40,000 mg/L);
- pH (field measurements) of 6.4 – 6.7;
- unusually high concentrations of calcium (>8,000 mg/L), magnesium (>1,000 mg/L), chloride (>40 mg/L), potassium (>25 mg/L), and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of several trace metals, notably barium (>100 mg/L) and strontium (>50 mg/L), that substantially exceed the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion, which is based on the analytical results reported for five groundwater samples collected from the well since January 1991.

5.1 NITRATE

Each groundwater sample had nitrate concentrations above 5,000 mg/L, with the highest levels reported for the samples collected in October 1995 (7,580 mg/L) and April 2003 (7,390 mg/L). The source of the nitrate is the former S-3 Ponds, the historical operation of which emplaced a heterogeneous mixture of inorganic, organic, and radiological contaminants in the Nolichucky Shale and created a mound in the water table that facilitated contaminant transport/migration east and west of the hydrologic divide separating the Bear Creek and UEFPC watersheds. Nitrate and other inorganic contaminants within the plume were entrained in the wastes disposed at the site, but some of the inorganic contaminants (e.g., barium) were dissolved from bedrock minerals by the acidic seepage from the ponds. With concentrations in excess of 10,000 mg/L, nitrate is the primary inorganic contaminant in the plume. Based on the network of existing monitoring wells completed in the Nolichucky Shale east of the former S-3 Ponds, elevated nitrate concentrations (i.e., >10 mg/L) extend laterally at least 5,000 ft eastward (parallel with geologic strike) and vertically (parallel with geologic dip) at least 150 ft bgs (DOE 1998).

Under the conceptual model for contaminant transport from the former S-3 Ponds, sampling results for well GW-275 are representative of concentrations within long, strike-parallel groundwater flow/transport pathways (e.g., bedding-plane fractures), possibly bound to a relatively narrow band near the middle of the Nolichucky Shale, that promote much slower flow toward operating basement sumps located in Bldgs. 9204-4, 9201-5, 9201-4, and 9204-2, which are up to 4,000 ft east-southeast of the former S-3 Ponds (DOE 1998). As shown by the data summarized below, the nitrate concentrations in the deeper groundwater flow/transport pathways intercepted by the monitored interval in well GW-275 are significantly higher than the nitrate concentrations in the shallower groundwater flow/transport pathways intercepted by the monitored interval in well GW-274.

Well	Nitrate (mg/L)				
	October 1995	May 2000	October 2000	April 2003	October 2003
GW-274	4,270	5,410	3,890	3,010	2,950
GW-275	7,580	7,150	7,160	7,390	6,900

Little change in the relative flux of nitrate via these flowpaths is suggested by the close similarity between the nitrate concentrations evident in the groundwater samples collected from the well in October 1995 and April 2003, which reflect the indeterminate long-term concentration trend (Figure 1).

5.2 URANIUM

Four groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.00268 mg/L in May 2000) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for three of the five groundwater samples collected since January 1991 had low concentrations of at least one VOC. Tetrachloroethene was detected in samples collected in May 2000 (9 μg/L) and April 2003 (3 μg/L). Low (estimated) concentrations of chloroform (1μg/L) and methylene chloride (3 μg/L) were detected in the groundwater sample collected in October 1995.

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity reported for the sample collected in October 2003 (154 pCi/L) exceeds the applicable MDA and corresponding CE, and is substantially above the MCL for gross alpha activity (15 pCi/L). In contrast, the gross alpha results for the other groundwater samples do not exceed the applicable MDA. The inconsistent detection of gross alpha activity may be related to analytical interference associated with the very high TDS of the (unfiltered) groundwater samples (see Section 4.0), and the elevated result reported for the October 2003 sample is a suspected outlier.

5.5 GROSS BETA ACTIVITY

Gross beta activity reported for the sample collected in October 1995 (125 pCi/L) exceeds the applicable MDA and corresponding CE, and is above the SDWA screening level for gross beta activity (50 pCi/L). In contrast, gross beta results for the other groundwater samples do not exceed the applicable MDA. As for the gross alpha activity, this one elevated result may be an artifact of the very high TDS (>1,000 mg/L) in the samples, and is considered to be an outlier.

As noted in Section 5.1, nitrate concentrations in the groundwater samples from well GW-275 are substantially higher than evident in the groundwater samples from shallower well GW-274. However, the opposite appears true for gross beta activity (and Tc-99). As shown by the data summarized below, sampling results for well GW-274 show substantially higher gross beta activity than the sampling results for well GW-275, which seems peculiar in light of the very high nitrate concentrations in the groundwater from this well.

Well	Gross Beta Activity (pCi/L)				
	October 1995	May 2000	October 2000	April 2003	October 2003
GW-274	4,230	7,800	12,200	13,000	10,000
GW-275	125	<MDA	<MDA	<MDA	<MDA

WELL GW-276

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during July 1986, completed with a screened monitored interval from 11.3 to 18.5 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-277 and is located in Bear Creek Valley (BCV) at the west end of Y-12, near the main headwaters channel of Bear Creek about 200 ft southeast of the former S-3 Ponds. This site consists of four unlined surface impoundments that were filled and covered with a multilayer low-permeability cap (and an asphalt-paved parking lot) during RCRA closure of the site in 1988. The surface impoundments were used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12, which emplaced a large heterogeneous mixture of inorganic, organic, and radiological contaminants in the subsurface that remains one of the primary sources of groundwater and surface water contamination in BCV.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Thirty-six groundwater samples have been collected from the well, with the conventional sampling method used to obtain 22 samples between October 1986 and August 1997 and the low-flow sampling method used to obtain 14 samples between January 1998 and July 2004. The sampling history encompasses a four-year gap (January 1990 – March 1994) as well as almost ten years of uninterrupted semiannual monitoring (March 1994 – January 2004).

High total dissolved solids (TDS) and acidic pH (<5.5) are distinguishing characteristics of the groundwater samples from this well and are a direct consequence of contamination from the former S-3 Ponds (see Section 5.0.).

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Nolichucky Shale (Conasauga Group). The water table interval is a highly permeable zone that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock and transmits the bulk of the groundwater in the Nolichucky Shale. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek, which traverse the Nolichucky Shale from northeast to southwest throughout BCV west of Y-12 and are numbered in ascending order downstream from the headwaters of the creek. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone, a highly permeable (karst) formation that stratigraphically overlies the Nolichucky Shale and subcrops beneath the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements show that the static water level in the well occurs at an average depth of about 3 ft bgs and exhibits moderate (<4 ft) seasonal fluctuations. Also, presampling groundwater elevations recorded during contemporaneous sampling events (i.e., within 24 hours) are lower in well GW-276 than in well GW-277, which is completed at a greater depth (77.4 ft bgs) in the Nolichucky Shale. Based on the distance (54.7 ft) between the monitored interval midpoint (elevation) in each well, the contemporaneous groundwater elevations indicate upward vertical hydraulic gradients (0.005-0.027) during seasonally high and low flow conditions.

Based on contemporaneous depth-to-water measurements for selected monitoring wells in BCV, groundwater elevation isopleths in the vicinity of well GW-276 indicate flow south and west toward the Maynardville Limestone and the main channel of Bear Creek. However, as noted previously, the Nolichucky Shale exhibits strongly anisotropic groundwater flow patterns, with preferred strike-parallel flow directions that may or may not coincide with the flow directions inferred from groundwater elevation isopleths.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields acidic, nitrate-contaminated calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 500 – 2,350 mg/L;
- pH of 2.6 – 5.8 (field measurements);
- concentrations of chloride (>300 mg/L), sodium (>120 mg/L), and sulfate (>50 mg/L) that are substantially higher than typically evident in samples from other wells completed at similarly shallow depths in the Nolichucky Shale;
- nitrate concentrations above 30 mg/L;
- total concentrations of several trace metals, including aluminum, barium, manganese, nickel, and uranium, that substantially exceed the respective range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

The chloride and sodium-enriched geochemistry of the groundwater samples probably reflect contamination resulting from dissolution of bedrock minerals by the acidic seepage from the former S-3 Ponds. However, considering the vertically upward hydraulic gradients indicated by the presampling groundwater elevations in wells GW-276 and GW-277 (see Section 3.0), it is also possible for the geochemistry of the groundwater to reflect upwelling of chloride- and sodium-enriched groundwater from deeper in the Nolichucky Shale. Most of the water table and shallow bedrock wells (i.e., <100 ft bgs) completed in this formation elsewhere in BCV yield calcium-magnesium-bicarbonate groundwater, but a fairly abrupt change to sodium-bicarbonate groundwater occurs at a depth of about 100 ft bgs (in BCV west of Y-12), with another change to sodium-chloride groundwater typically evident more than 400 ft bgs. The sodium- and chloride-enriched geochemistry of the groundwater is interpreted to be a function of longer groundwater residence time related to reduced fracture aperture and increased fracture spacing (Solomon et al. 1992).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, these contaminants are all present at elevated levels in the groundwater at this well.

5.1 NITRATE

Nitrate concentrations above the analytical reporting limit were reported for each groundwater sample collected to date, with 25 samples having had concentrations above 100 mg/L, including eight samples with concentrations above 1,000 (Table 1). The source of the nitrate is the contaminant plume emplaced during historical operations of the former S-3 Ponds. Nitrate is the primary inorganic contaminant in the plume and, based on the existing network of monitoring wells in the Nolichucky Shale west of the former S-3 Ponds, the extent of elevated nitrate concentrations (i.e., >10 mg/L) in the groundwater suggest: (1) transport/migration in the unconsolidated zone (water table interval) directly south toward the headwaters of Bear Creek; (2) westward transport/migration via shallow (<30 ft bgs) strike-parallel flowpaths (i.e., bedding-plane fractures) that terminate in the northern tributaries of Bear Creek located about 1,500 ft

(NT-1) and 2,500 ft (NT-2) west of the former S-3 Ponds; and (2) substantially slower migration deeper in the bedrock via much longer strike-parallel flowpaths, with upward hydraulic gradients promoting upwelling of nitrate-contaminated groundwater into the shallow flow system near NT-1 and NT-2 (DOE 1997).

Nitrate concentrations reported for all of the groundwater samples exceed the MCL (Table 1), with a historical maximum concentration of 1,580 mg/L in October 1986 and a historical minimum concentration of 32 mg/L in January 2004. These "bookend" results illustrate the clearly decreasing long-term concentration trend shown by a time-series plot of the nitrate concentrations (Figure 1). The decreasing nitrate concentrations correspond with the substantially reduced flux of nitrate (and other contaminants) in the shallow groundwater flow system following closure of the former S-3 Ponds in 1984 and the installation of the low-permeability cap in 1989 (DOE 1997). Also, the long-term decreasing trend is punctuated by temporal "peak" nitrate concentrations evident in February 1989 (1,200 mg/L), July 1995 (220 mg/L), July 1998 (138 mg/L), July 2000 (105 mg/L), and July 2002 (73.7 mg/L), most of which correspond with seasonally low groundwater flow conditions. This relationship suggests dilution of the "baseflow" nitrate concentrations during seasonal (and episodic) recharge of uncontaminated (or less nitrate-contaminated) groundwater. Under the conceptual model for contaminant transport from the former S-3 Ponds, recharge in the shallow flow system promotes relatively rapid groundwater transport toward discharge areas in the main channel of Bear Creek and its northern tributaries west of the site (DOE 1997).

5.2 URANIUM

All but one of the groundwater samples collected to date had uranium concentrations at least an order-of-magnitude above the MCL for uranium (0.03 mg/L), with concentrations above 5 mg/L reported for nine samples, including three samples with concentrations above 10 mg/L (Table 1). The acidic groundwater in this well and elsewhere immediately downgradient of the former S-3 Ponds contains elevated concentrations of several trace metals, some entrained in the wastes disposed at the site (e.g., uranium) and others dissolved from minerals in the bedrock (Nolichucky Shale) underlying the site (e.g., barium). The uranium in the groundwater probably occurs as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble complexes with a variety of inorganic anions (Fetter 1993). Thus, the distribution of elevated uranium concentrations in the Nolichucky Shale near the former S-3 Ponds is largely confined to the low-pH groundwater within about 500 ft of the site (DOE 1997).

Excluding the non-detect uranium value reported for the groundwater sample collected in February 1999, which is an obvious outlier compared to the other uranium results and is a likely analytical artifact, the samples had a wide range of uranium concentrations, with the historical minimum value (0.613 mg/L in January 2004) being and order-of-magnitude lower than the historical maximum value (13.45 mg/L in October 1986). As with nitrate, these results illustrate the clearly decreasing long-term concentration trend shown by a time-series plot of the uranium concentrations (Figure 2). The decreasing uranium concentrations correspond with the substantially reduced flux of uranium (and other contaminants) in the shallow groundwater flow system following closure of the former S-3 Ponds in 1984 and the installation of the low-permeability cap in 1989 (DOE 1997). Unlike the nitrate concentrations in the samples, however, the uranium concentrations do not appear to exhibit any clear and consistent relationship with seasonal groundwater flow conditions, although temporal "peak" concentrations are indicated by the uranium results for the samples collected in August 1997 (1.3 mg/L) and July 2001 (1.5 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results, two VOCs were detected in the groundwater samples collected to date: chloroform and PCE (Table 1). Both compounds are known components of the contaminant plume originating from the former S-3 Ponds, but are typically present at substantially lower concentrations compared to other components of the plume (e.g., nitrate). This is because chlorinated solvents were not extensively disposed at the site, with total volumes of organic wastes being substantially less than that of the inorganic wastes disposed at the site (DOE 1997).

The primary VOC in the groundwater samples is PCE, which has been detected in each sample collected from the well (Table 1), all of which had PCE concentrations above the MCL (5 µg/L). In contrast, chloroform has been detected (excluding false positive results) in only eleven samples and all of the results are estimated values below 5 µg/L. A time-series plot of the PCE results spans the four-year gap in the sampling history for the well and shows a clearly decreasing long-term trend (Figure 3). However, the rate of concentration decrease appears to have slowed, as indicated by substantially higher PCE concentration in February 1989 (250 µg/L) compared to February 1999 (11 µg/L), but little if any decrease since then, as indicated by the PCE concentration in July 2004 (10 µg/L). This suggests that the bulk of the dissolved VOCs have been flushed from the shallow flow system south of the former S-3 Ponds.

5.4 GROSS ALPHA ACTIVITY

Gross alpha activity reported for the groundwater samples collected before March 1994 do not meet data quality objectives (the MDA and corresponding CE were not for these results are not available), whereas the gross alpha activity reported for all but two of the samples collected since then not only exceed the applicable MDA and CE, but are more than 100 pCi/L (Table 2). Uranium isotopes (U-234 and U-238) from the contaminant plume emplaced during operation of the former S-3 Ponds are principal source of the gross alpha activity in the groundwater. Twenty of the samples collected since March 1994 were analyzed for U-234 and U-238, with both isotopes detected (i.e., >MDA and CE) in all but one of these samples (Table 2). Note that the historical maximum values for the samples analyzed for U-234 (271 pCi/L in January 1995) and U-238 (603 pCi/L in January 1995) do not correspond with the historical maximum value for gross alpha activity (852 pCi/L in July 1995). This is not surprising considering the inherent variability commonly associated with radiochemical analyses, particularly considering that the high TDS in the samples may cause analytical interferences for gross alpha activity.

Excluding the non-detect gross alpha activity (i.e., <MDA) reported for the groundwater samples collected in February 1996 and July 1998 (Table 2), which are outliers compared to the other results and are likely analytical artifacts, results for the other samples define a wide range of gross alpha activity, with the historical maximum value (852 pCi/L in July 1995) being several-times higher than the historical minimum value (117 pCi/L in January 2000). This may be at least partially attributable to analytical interferences associated with the TDS in the (unfiltered) samples. Also, wide temporal fluctuations tend to dominate the indeterminate long-term trend shown by a time-series plot of the gross alpha activity reported for each sample (Figure 4), which suggests minimal changes in the overall flux of uranium isotopes via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.5 GROSS BETA ACTIVITY

As with gross alpha activity, the results for gross beta activity reported for groundwater samples collected before March 1994 do not meet applicable DQOs, with gross beta activity above the MDA and CE reported for all but two of the samples collected since then (Table 2). Moreover, all of these results substantially exceed the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the MCL for gross beta activity). Uranium isotopes (and related daughter products) contribute to gross beta activity in the groundwater, but the primary source of the gross beta activity is Tc-99, which is a "signature" component of the contaminant plume emplaced during historical operation of the former S-3 Ponds (the only site at Y-12 to receive wastes containing Tc-99). As shown in Table 3, Tc-99 was detected (i.e., >MDA and CE) in all of the samples analyzed for this beta-emitting radionuclide, with the highest value reported for the sample collected in March 1994 (1,570 pCi/L) and the lowest value reported for the sample collected in July 2004 (326.4 pCi/L). Note that all the Tc-99 results are substantially below the SDWA screening level (3,790 pCi/L) for a 4 mrem/yr dose equivalent from Tc-99. Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-) which is soluble and highly mobile in groundwater (Gee et al. 1983). Based on the existing network of monitoring wells in Nolichucky Shale west of the former S-3 Ponds, the extent of elevated (>50 pCi/L) gross beta activity in the groundwater suggests that the distribution of Tc-99 closely mirrors that of nitrate, with transport in the water table interval south toward Bear Creek and more westward (strike-parallel) transport in the bedrock intervals toward discharge areas in NT-1 and NT-2 (DOE 1997).

Aside from the non-detect results (i.e., <MDA) reported for the groundwater samples collected in February 1996 and July 1998, which are both obvious outliers compared to the other results for gross beta activity (and are probably analytical artifacts), each sample collected to date had gross beta activity above 250 pCi/L (Table 2), with a historical maximum value of 1,180 pCi/L in August 1994 and a historical minimum value of 280 pCi/L in January 2004. These results "bookend" the decreasing long-term trend shown by a time-series plot of the gross beta activity reported for each sample except the two samples with results below the applicable MDA (Figure 5). Also, the decreasing long-term trend encompasses the five-year gap in the sampling history for this well (see Section 2.0) and is punctuated by a series of peaks evident in August 1994 (1,180 pCi/L), July 1995 (1,130 pCi/L), August 1997 (790 pCi/L), February 1999 (806 pCi/L), and July 2000 (567 pCi/L).

WELL GW-277

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed during July 1986, completed with a screened monitored interval from 62.2 to 77.4 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-276 and is located in Bear Creek Valley (BCV) west of Y-12, approximately 200 ft east of the southeast corner of the former S-3 Ponds (hereafter referenced as the S-3 Site). Located near the western end of Y-12, directly north of the headwaters of Bear Creek, the S-3 Site consist of four contiguous, above-grade, unlined surface impoundments, each with a surface area of approximately 400 x 400 ft and an average total depth of approximately 15 ft. The ponds were used from 1951 to 1984 for the evaporation/infiltration of several million gallons of nitric acid wastes generated at Y-12, and were closed in 1988 in accordance with requirements of the RCRA regulations applicable to hazardous waste landfills. Closure of the site was completed in 1989 and included the neutralization and removal of liquid wastes and stabilization of neutralization sludge remaining in each pond, which were then filled with crushed limestone and covered with a multilayer low-permeability cap (completed with an asphalt-paved parking lot). Historical operation of the S-3 Site emplaced a heterogeneous mixture of inorganic, organic, and radiological contaminants in the subsurface that remains a primary source of groundwater and surface water contamination in BCV.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Sixteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 14 samples between October 1996 and January 1990 and the low-flow sampling method used to obtain samples in March and August 2005. The sampling history includes quarterly, semiannual, and annual sampling frequencies and, as indicated by the sampling dates noted above, a 15-year period (January 1990 – March 2005); when no groundwater samples were collected from the well.

High total dissolved solids (TDS) is a distinguishing characteristics of the groundwater samples from this well (see Section 4.0), and is a direct consequence of contamination resulting from historical operation of the S-3 Site. Note that the high levels of TDS may cause analytical interferences for some laboratory analytes, including trace metals, gross alpha activity, and gross beta activity.

3.0 HYDROLOGIC CHARACTERISTICS

This well produces groundwater from the water table interval in the Nolichucky Shale (Conasauga Group), which trends northeast-southwest along the northern slope of BCV, dips to the southeast at an angle of 45º - 55º, and is bordered on the southeast by the overlying Maynardville Limestone, a highly permeable karst aquifer that provides the principal pathway for subsurface contaminant migration in BCV. The water table interval is a highly permeable zone that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock and transmits the bulk of the groundwater in the Nolichucky Shale. Moreover, it is suspected that the highly acidic wastes from the S-3 Site dissolved carbonate strata interbedded within the Nolichucky Shale and greatly enhanced the relative permeability of these strata-bound flowpaths within several hundred feet of the site.

Groundwater flow in the water table interval in the Nolichucky Shale is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek, which traverse the formation from northeast to southwest throughout BCV west of Y-12 and are numbered in ascending order downstream from the headwaters of the creek. Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow into the Maynardville Limestone.

The static water level in the well occurs at an average depth of approximately 4 ft bgs and exhibits minor (<1 ft) seasonal fluctuations. As indicated by groundwater elevation isopleths determined from contemporaneous depth-to-water measurements from nearby monitoring wells, directions of groundwater flow near the well are to the west, parallel with the trend (strike) of bedding in Nolichucky Shale, and to the south-southwest, across geologic-strike toward the Maynardville Limestone and the main channel of Bear Creek. However, as noted previously, the Nolichucky Shale exhibits strongly anisotropic flow via strike-parallel flowpaths (i.e., bedding-plane fractures) that may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Also, possible dissolution of carbonate strata by the acidic seepage from the S-3 Site may locally enhance strata-bound groundwater flow/contaminant transport in directions parallel with geologic strike and dip. Additionally, directions of groundwater flow (and contaminant transport) now evident are undoubtedly different from the flow patterns that occurred during historical operations of the S-3 Site, which created a local "mound" in the water table that enabled groundwater flow (and contaminant transport) to the east of the hydrologic divide separating the Bear Creek and Upper East Fork Poplar Creek watersheds.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for the (unfiltered) groundwater samples collected to date show that the well yields acidic, highly contaminated groundwater downgradient of the S-3 Site that is generally characterized by:

- TDS of 2,830 –11,796 mg/L;
- pH (field measurements) of 5.82 – 6.36;
- high concentrations of calcium (>500 mg/L), chloride (>70 mg/L), magnesium (>65 mg/L), nitrate (>300 mg/L), and sodium (>60 mg/L);
- low molar proportions of sulfate and potassium (<10% of total anions/cations);
- slightly elevated concentrations of several trace metals, notably barium (>0.7 mg/L), and strontium (>1 mg/L), that exceed the corresponding background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995)

Note that some of the inorganic compounds and trace metals in the groundwater at this well, such as nitrate, were entrained in the acidic wastes disposed at the S-3 Site, whereas other inorganics, such as calcium and barium, were dissolved from bedrock minerals by the highly acidic seepage from the site. Also, the high levels of TDS may cause analytical interferences for some laboratory analytes, including gross alpha activity and gross beta activity.

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, all of these principal contaminants except gross alpha activity are present in the groundwater at this well. Note, however, that the bulk of the historical the analytical results for VOCs, gross alpha activity, and gross beta activity do not meet all applicable DQOs. The QA/QC sample data needed to identify false positive VOC results are not available for groundwater samples collected before January 1991. Similarly, gross alpha activity and gross beta activity reported for the groundwater samples collected before January 1990 are considered unusable because the sample-specific MDA and CE are not available for these analytes.

5.1 NITRATE

Nitrate concentrations above 1,000 mg/L were reported for all but two of the groundwater samples collected to date (Table 1), with the lowest concentrations reported for the samples collected most recently (March and August 2005). All of the results are at least an order-of-magnitude above the drinking water MCL for nitrate (10 mg/L). The S-3 Site is the source of the nitrate, which is a principal component of the contaminant plume emplaced during historical operations of the site. Nitrate is chemically stable and mobile in groundwater and is believed to effectively trace the groundwater transport pathways followed by other similarly mobile components of the contaminant plume (DOE 1997).

Historical data show that the groundwater concentrations of nitrate in the groundwater from this well fluctuate seasonally, with the highest concentrations typically reported for the groundwater samples collected during seasonally low flow conditions (summer and fall). This apparent relationship with seasonal flow conditions also is mirrored by the most recent sampling results, with the nitrate concentration in the sample collected during August 2005 (406 mg/L) being approximately 30% higher than the concentration in the sample collected during March 2005 (317 mg/L). This relationship suggests that the nitrate concentrations in groundwater samples collected during seasonally (and episodically) high flow conditions (winter and spring) reflect greater relative inflow of uncontaminated (or less contaminated) recharge via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

A time-series plot of the nitrate concentrations reported for the groundwater samples collected to date shows a widely variable trend between the initial sampling date in October 1986 (1,761 mg/L) and the historical maximum concentration in September 1988 (2,720 mg/L), followed by an equally variable but generally decreasing trend through January 1990 (1,690 mg/L). The most recent sampling results, including the historical minimum concentration evident in March 2005 (317 mg/L), demonstrate that the decreasing trend continued through the long gap in the sampling history for the well (Figure 1). The sharp concentration decrease evident after September 1988 is possibly attributable to a corresponding reduction in the relative flux of nitrate in the shallow groundwater flow system as a result of the closure and of the S-3 Site and installation of the low-permeability cap. Also, the most recent sampling results for nitrate indicate that the rate of concentration decrease has slowed considerably. For example, nitrate concentrations decreased at a generalized rate of approximately 2 mg/L per day from September 1988 to January 1990, but only 0.25 mg/L per day from January 1990 to March 2005. This suggests that the most highly contaminated groundwater has been flushed from the most permeable flowpaths at shallow depths in the Nolichucky Shale downgradient of the S-3 Site. Interestingly, although the nitrate concentrations decreased substantially in response to the closure/capping of the site, the acidity of the groundwater has remained relatively unchanged, as illustrated by the field pH measurements obtained during the collection of groundwater samples in August 1987 (6.5), January 1990 (6.1), and August 2005 (6.36).

5.2 URANIUM

All of the groundwater samples collected to date had uranium concentrations above the corresponding reporting limit (Table 1), with the historical maximum value (0.092 mg/L in October 1986) being the only result that exceeds the drinking water MCL for uranium (0.03 mg/L). As noted previously, uranium was entrained in the wastewaters disposed at the S-3 Site, and the uranium in the acidic seepage probably occurred as uranyl cations, which are prone to pH-sensitive sorption reactions and tend to form soluble complexes with a variety of inorganic anions (Fetter 1993). Consequently, elevated concentrations of uranium are generally restricted to the acidic groundwater in the Nolichucky Shale within approximately 500 ft of the S-3 Site (DOE 1987).

Excluding the historical maximum value noted above, which was reported for the initial groundwater sample collected from the well and appears to be an outlier compared to all subsequent sampling results, a time-series plot of the uranium results shows a generally decreasing long-term concentration trend that spans the long gap in the sampling history for the well (Figure 2). This decreasing long-term trend reflects a corresponding reduction in the relative flux of uranium via the groundwater flow/transport pathways intercepted by the monitored interval in the well. As with nitrate in the groundwater, the reduced flux of uranium occurred in direct response to the closure/capping of the S-3 Site. Additionally, it appears that the lower levels of uranium in the groundwater samples collected most recently is not attributable to a concurrent increase in the groundwater pH, which does not appear to have changed appreciably over the long term.

5.3 VOLATILE ORGANIC COMPOUNDS

One or more of the following VOCs was detected in each of the groundwater samples collected to date: acetone, chloroform, MC, PCE, toluene, and 111TCA (Table 2). Chlorinated solvents and organic chemicals were not substantial components of the waste stream for the S-3 Site (DOE 1997). Consequently, VOCs are fairly minor constituents within the contaminant plume emplaced during historical operation of the site, and are typically present at substantially lower concentrations compared to other plume constituents (e.g., nitrate).

Based on the frequency of detection and relative concentrations, the primary VOCs in the groundwater samples collected to date are PCE, chloroform, and MC (Table 2). The highest concentrations were reported for PCE, with the sampling result from March 2005 (30 µg/L) exceeding the historical maximum value (17 µg/L in December 1989) and showing that the PCE levels remain significantly above the drinking water MCL (5 µg/L). In contrast, only trace levels (4 µg/L or less) of chloroform were detected the samples and all of these results are substantially below the MCL for total trihalomethanes (80 µg/L). Similarly low concentrations of methylene chloride were detected in all but three of the samples collected between October 1986 (4 µg/L) and January 1990 (4 µg/L), although this compound was not detected in the samples collected most recently (March and August 2005). Of the other compounds detected in the samples, only acetone was detected at a concentration above 10 µg/L, the results for toluene are estimated values below 5 µg/L, and the results for 111TCA are estimated values below 1 µg/L (Table 2).

A time-series plot of the PCE concentrations detected in the groundwater samples collected to date is dominated by the long gap in the sampling history for the well, and shows a variable but generally increasing long-term concentration trend (Figure 3). This trend shows a modest increase in summed PCE concentrations following installation of the low-permeability cap over the S-3 Site, indicating an increase in the relative flux of PCE along the groundwater flow/transport pathways intercepted by the monitored interval in the well.

5.4 GROSS ALPHA ACTIVITY

As noted in Section 5.0, only the gross alpha activity reported for the groundwater samples since January 1990 meet applicable DQOs, and these results are considered qualitative because of inherent analytical interferences associated with the very high TDS levels in the samples (see Section 4.0). Nevertheless, none of these samples had gross alpha activity above the applicable MDA and/or corresponding CE (Table 1). Low levels of gross alpha activity (i.e., <15 pCi/L drinking water MCL) are supported by analytical results for the primary alpha-emitting radionuclides entrained in the wastes disposed at the S-3 Site, U-234 and U-238, which were detected (i.e., >MDA and CE) at low levels in the groundwater samples collected most recently (Table 1).

5.5 GROSS BETA ACTIVITY

As noted in Section 5.0, only the gross alpha activity reported for the groundwater samples since January 1990 meet applicable DQOs, and these results are considered qualitative because of analytical interferences associated with the high TDS of the samples (see Section 4.0). Although considered qualitative, the gross beta activity detected in the samples collected in January 1990 (2,900 pCi/L), March 2005 (1,200 pCi/L), and August 2005 (1,100 pCi/L) substantially exceed the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

Uranium decay products (e.g., Th-234) and other beta-emitting radionuclides known to be included in the waste stream for the S-3 Site (e.g., Np-237) probably contribute to the high level of gross beta activity in the groundwater from this well. However, Tc-99 is the principal source of beta activity and is the "signature" component of the contaminant plume emplaced during historical operation of the S-3 Site, which is the only site at Y-12 known to have received significant volumes of waste that contained Tc-99 (DOE 1997). Under oxidizing conditions, Tc-99 occurs as the pertechnetate anion (TcO_4^-) which is soluble and highly mobile in groundwater (Gee et al. 1983). Consequently, the distribution of Tc-99 in the groundwater downgradient of the S-3 Site, as indicated by the extent of elevated gross beta activity (>50 pCi/L) defined by the network of wells to the south and west (and east) of the site, closely mirrors that of nitrate from the site, which is also highly mobile in groundwater.

The Tc-99 activity reported for the groundwater samples collected in March 2005 (2,000 pCi/L) and August 2005 (1,700 pCi/L), which are the only samples collected to date that were analyzed for Tc-99, substantially exceed the SDWA screening level (900 pCi/L) for a 4 mrem/yr dose equivalent from Tc-99. There are insufficient data to adequately characterize the long-term trend for Tc-99 activity. However, considering that the mobility of Tc-99 is similar to that of nitrate and the substantially reduced nitrate concentrations in the well reflect a corresponding reduction in the overall flux of nitrate after the S-3 Site was closed and capped, the levels of Tc-99 now evident in the groundwater from this well likewise probably reflect a corresponding decrease in the relative flux of Tc-99 via the groundwater flow/transport pathways intercepted by the monitored interval in the well.

WELL GW-281

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in August 1986, completed with a screened monitored interval from 4 to 15 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well is located in Bear Creek Valley at the Bldg. 9754-2 Fuel Facility, which is near the east end of Y-12.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-two groundwater samples have been collected from the well to date using the conventional sampling method with a peristaltic pump and bailer.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Nolichucky Shale). Note that the large monitored (screened) interval in the well is intended to straddle the water table during seasonally high and low flow conditions and facilitate detection of light non-aqueous phase liquids (LNAPL). The average static groundwater level in the well is 7 ft bgs. Presampling depth-to-water measurements for the well indicate minor (<5 ft) water-level fluctuations.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 214 mg/L – 386 mg/L;
- pH of 6.1 – 7.2 (field measurements);
- low molar proportions of chloride, potassium, sodium, and sulfate (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion, which is based on the analytical results reported for the groundwater samples collected from the well since January 1991.

5.1 NITRATE

Twelve of the groundwater samples were analyzed for nitrate, and concentrations above the applicable analytical reporting limit were reported for the three samples, with the highest value (3.2 mg/L in April 1992) being substantially below the MCL for nitrate (10 mg/L).

5.2 URANIUM

Twelve groundwater samples had uranium concentrations above the applicable analytical reporting limit, with the highest concentration (0.005 mg/L) being substantially below the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Analytical results for each groundwater sample show non-detect values or false positive results for all of the VOCs analyzed.

5.4 GROSS ALPHA ACTIVITY

Seven groundwater samples had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (8.17 pCi/L in January 1992) being less than the MCL for gross alpha activity (15 pCi/L)

5.5 GROSS BETA ACTIVITY

Seven groundwater samples had gross beta activity above the applicable MDA and corresponding CE, with the highest value (16 pCi/L in January 1992) being less than the SDWA screening level for gross beta activity (50 pCi/L).

WELL GW-286

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in November 1986, completed with a screened monitored interval from 19.5 to 32.3 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-287 and is located on the southern flank of Pine Ridge west of Y-12, about 600 ft west of the central section of the Bear Creek Burial Grounds (BCBG) waste management area. The BCBG includes numerous hazardous and nonhazardous waste disposal units that received a mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. Liquid wastes included oils, machine coolants, and borax waste water, all or most of which may have contained varying amounts of radioisotopes (primarily uranium isotopes). In 1989, most of the waste-disposal units in the BCBG waste-management area were covered with multi-layer, low-permeability caps installed during RCRA closure of the site.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Twenty-seven groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 25 samples between March 1987 and October 1993, and the low-flow sampling method used to obtain samples in June and October 2005. This sampling history includes an extended period (12 years) when no groundwater samples were collected from the well.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the shallow bedrock interval (<100 ft bgs) in the Conasauga Group (Maryville Limestone). The bulk of the groundwater flow in the Maryville Limestone occurs in the water table interval, which is a highly permeable zone that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek that traverse the Maryville Limestone and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow toward the Maynardville Limestone, a highly permeable (karst) formation that statigraphically overlies the Maryville Limestone (and Nolichucky Shale) and subcrops along the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 7 ft bgs, with seasonal fluctuations of about 1 ft. Moreover, measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in well GW-286 are typically lower than evident in well GW-287, which is completed at a shallower depth (12.5 ft bgs) in the Maryville Limestone. Based on the distance between the monitored interval midpoint (elevation) in each well (16.9 ft), the contemporaneous groundwater elevations indicate downward vertical hydraulic gradients (0.024–0.061) from the water table interval (GW-287) to the shallow bedrock interval (GW-286).

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-286 indicate flow to the south and southwest toward the Maynardville Limestone and the main channel of Bear Creek. However, groundwater flow in the Maryville Limestone is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Consequently, the direction(s) of groundwater flow in the vicinity of well GW-286 may be primarily westward (parallel with geologic strike) toward discharge areas in NT-8.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 128 – 248 mg/L;
- pH (field measurements) of 7.5 – 8.5;
- low molar proportions of chloride, potassium, sulfate, and sodium (<10% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, none of the principal contaminants are present at elevated concentrations in the groundwater at this well.

5.1 NITRATE

None of the groundwater samples had nitrate concentrations above the analytical reporting limit.

5.2 URANIUM

Six groundwater samples had uranium concentrations that exceeded the analytical reporting limit, with the maximum value (0.006 mg/L in August 1988) being below the drinking water MCL for uranium (0.03 mg/L). Uranium concentrations have been at or below the reporting limit since August 1989.

5.3 VOLATILE ORGANIC COMPOUNDS

Several common laboratory reagents (acetone, chloroform, toluene, xylene, and MC) were detected in most of the samples collected from the well before March 1989. Excluding false positive results, only a trace (3 µg/L) of TCE was detected in one (April 1993) of the 12 groundwater samples collected from the well since September 1991.

5.4 GROSS ALPHA ACTIVITY

Three groundwater samples collected from the well since February 1990 had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (4.59 pCi/L in October 1993) being substantially below the MCL for gross alpha activity (15 pCi/L). Results obtained before January 1990 do not meet applicable data quality objectives because the sample specific MDA and/or CE are not available for these samples.

5.5 GROSS BETA ACTIVITY

One groundwater sample collected from the well since February 1990 had gross beta activity above the applicable MDA and corresponding CE limits, with that result (7.39 pCi/L in October 1993) being substantially less than the SDWA screening level (50 pCi/L) for a

4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity). Results obtained before January 1990 do not meet applicable data quality objectives because the sample specific MDA and/or CE are not available for these samples.

WELL GW-287

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in November 1986, completed with a screened monitored interval from 5.6 to 12.5 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-286 and is located on the southern flank of Pine Ridge west of Y-12, about 600 ft west of the central section of the Bear Creek Burial Grounds (BCBG) waste management area. The BCBG includes numerous hazardous and nonhazardous waste disposal units that received a mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. Liquid wastes included oils, machine coolants, and borax waste water, all or most of which may have contained varying amounts of radioisotopes (primarily uranium isotopes). In 1989, most of the waste-disposal units in the BCBG waste-management area were covered with multi-layer, low-permeability caps installed during RCRA closure of the site.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Forty-five groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 37 samples between March 1987 and September 1997, and the low-flow sampling method used to obtain eight samples between March 1998 and October 2005.

Unusually low levels of TDS (<150 mg/L) are a distinguishing characteristic of the groundwater samples from this well (see Section 4.0). The low TDS of the samples suggests relatively low residence time for the groundwater in the well, which indicates that the monitored interval for the well intercepts highly permeable groundwater flowpaths.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the water table interval in the Conasauga Group (Maryville Limestone). The bulk of the groundwater flow in the Maryville Limestone occurs within the water table interval, which is a highly permeable zone that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek that traverse the Maryville Limestone and are probably the surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow toward the Maynardville Limestone, a highly permeable (karst) formation that statigraphically overlies the Maryville Limestone (and Nolichucky Shale) and subcrops along the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 7 ft bgs and exhibits seasonal fluctuations of about 2 ft. Moreover, measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in well GW-287 are typically higher than evident in well GW-286, which is completed at a deeper depth (32.3 ft bgs) in the Maryville Limestone. Based on the distance between the monitored interval midpoint (elevation) in each well (16.9 ft), the contemporaneous groundwater elevations indicate downward vertical hydraulic gradients (0.024 – 0.061) from the water table interval (GW-287) to the shallow bedrock interval (GW-286).

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-288 indicate flow to the south and southwest toward the Maynardville Limestone and the main channel of Bear Creek. However, groundwater flow in the Maryville Limestone is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Consequently, the direction(s) of groundwater flow in the vicinity of well GW-288 may be primarily westward (parallel with geologic strike) toward discharge areas in NT-8.

4.0 GEOCHEMICAL CHARACTERISTICS

The well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 39 – 288 mg/L, excluding a suspected outlier (404 mg/L) in March 1995;
- pH (field measurements) of 5.22 – 7.8;
- low molar proportions of chloride, sulfate, potassium, and sodium (<15% of total anions/cations); and
- total (unfiltered sample) concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12 and are the focus of the following discussion.

5.1 NITRATE

Eight groundwater samples collected to date had nitrate concentrations that exceeded the analytical reporting limit, with the highest value (0.42 mg/L in March 1995) being substantially less than the MCL for nitrate (10 mg/L).

5.2 URANIUM

Thirteen groundwater samples had uranium concentrations that exceeded the analytical reporting limit, with the highest value (0.004 mg/L in March 1995) being substantially less than the MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false-positive results, 12 of the 30 groundwater samples collected from the well since September 1991 had very low concentrations of PCE, with the highest value (5 µg/L in February 1997 and March 1998) equal to the drinking water MCL for PCE (5 µg/L). The sporadic detection of PCE in groundwater at the well probably reflects limited westward (along geologic strike) transport from the Walk-In Pits in the BCBG. A time-series plot of the PCE results (Figure 1) shows a slightly increasing long-term trend, however the significance of this trend is questionable because the values are very low and PCE is not detected in most (18) of the samples from the well during this time period.

5.4 GROSS ALPHA ACTIVITY

Six of the 31 groundwater samples collected from the well since February 1990 had gross alpha activity above the applicable MDA and corresponding CE, with the highest value (7.12 pCi/L in June 1995) being substantially below the MCL for gross alpha activity (15 pCi/L).

5.5 GROSS BETA ACTIVITY

Five of the 31 groundwater samples collected from the well since February 1990 had gross beta activity above the applicable MDA and corresponding CE, with the highest value (9.9 pCi/L in February 1997) being substantially below the SDWA screening level (50 pCi/L) for a 4 millirem per year (mrem/yr) dose equivalent (the drinking water MCL for gross beta activity).

WELL GW-288

1.0 INSTALLATION, CONSTRUCTION, AND LOCATION

This well was installed in November 1986, completed with a screened monitored interval from 46 to 60 ft bgs, and constructed with nominal 4.5-inch diameter stainless steel (Type 304) riser casing and well screen (0.01 slot wire-wound). The well forms a cluster with well GW-289 and is located in Bear Creek Valley (BCV), immediately west of the central part of the Bear Creek Burial Grounds (BCBG) waste management area. The BCBG includes numerous hazardous and nonhazardous waste disposal units that received a mixture of solid wastes (1955 to 1993) and liquid wastes (1959 to 1979) generated at Y-12. Liquid wastes included oils, machine coolants, and borax waste water, all or most of which may have contained varying amounts of radioisotopes (primarily uranium isotopes). In 1989, most of the waste-disposal units in the BCBG waste management area were covered with multi-layer, low-permeability caps installed during RCRA closure of the site.

2.0 SAMPLING HISTORY AND CHARACTERISTICS

Fifteen groundwater samples have been collected from the well to date, with the conventional sampling method used to obtain 11 samples between February 1988 and August 1995, and the low-flow sampling method used to obtain four samples between March 2002 and October 2005.

The well does not exhibit conspicuous sampling characteristics.

3.0 HYDROLOGIC CHARACTERISTICS

This well yields groundwater from the shallow bedrock interval (<100 ft bgs) in the Conasauga Group (Maryville Limestone). The bulk of the groundwater flow in the Maryville Limestone occurs within the water table interval, which is a highly permeable zone that occurs near the transition between unconsolidated material (residuum and weathered bedrock) and bedrock. Groundwater flow in the water table interval is relatively rapid and primarily occurs via flowpaths that discharge into nearby northern tributaries of Bear Creek that traverse the Maryville Limestone and are probably the ground surface expression of large-scale cross-strike fractures (or fracture zones) in the bedrock (DOE 1997). Relatively little recharge (about 1% of available groundwater) occurs in the much less permeable, fracture-dominated flow system deeper in the bedrock, where groundwater flux decreases with depth as a result of reduced fracture aperture and increased fracture spacing (Solomon et. al. 1992). Groundwater flow in the bedrock intervals (shallow, intermediate, and deep) primarily occurs in directions parallel with geologic strike (i.e., bedding plane fractures) until a cross-strike fracture is encountered, which may promote upward discharge into the water table interval or lateral inflow toward the Maynardville Limestone, a highly permeable (karst) formation that statigraphically overlies the Maryville Limestone (and Nolichucky Shale) and subcrops along the axis of BCV and the main channel of Bear Creek.

Presampling depth-to-water measurements for the well show that the static water level in the well occurs at an average depth of about 16 ft bgs and exhibits seasonal fluctuations of about 3 ft. Moreover, measurements recorded during contemporaneous sampling events (i.e., within 24 hours) show that presampling groundwater elevations in well GW-288 are typically lower than evident in well GW-289, which is completed at a shallower depth (40.8 ft bgs) in the Maryville Limestone. Based on the distance between the monitored interval midpoint (elevation) in each well (18.4 ft), the contemporaneous groundwater elevations indicate upward vertical hydraulic gradients (0.001 –0.03) from the shallow bedrock interval (GW-288) to the water table interval (GW-289).

Groundwater elevation isopleths determined from contemporaneous depth-to-water measurements for selected monitoring wells in the vicinity of well GW-288 indicate flow to the south and southwest toward the Maynardville Limestone and the main channel of Bear Creek. However, groundwater flow in the Maryville Limestone is strongly anisotropic, with preferred flow in directions that parallel geologic strike, which may or may not coincide with the flow directions inferred from groundwater elevation isopleths. Consequently, the direction(s) of groundwater flow in the vicinity of well GW-288 may be primarily westward (parallel with geologic strike) toward discharge areas in NT-8.

4.0 GEOCHEMICAL CHARACTERISTICS

Analytical results for unfiltered groundwater samples show that the well yields calcium-magnesium-bicarbonate groundwater generally characterized by:

- TDS of 183 – 199 mg/L, excluding a suspected outlier (96 mg/L) in February 1990;
- pH of 6.8 – 7.53 (field measurements);
- low molar proportions of chloride, sulfate, potassium, and sodium (<10% of total anions/cations);
- total concentrations of trace metals that are either below respective analytical reporting limits or are within the range of background levels in groundwater at Y-12, as defined by the respective upper tolerance limit (UTL) reported in: *Determination of Reference Concentrations for Inorganic Analytes in Groundwater at the Department of Energy Y-12 Plant, Oak Ridge, Tennessee* (HSW 1995).

5.0 CONTAMINATION

Nitrate, uranium, VOCs, gross alpha activity, and gross beta activity are the primary groundwater contaminants at Y-12. As discussed in the following sections, monitoring data obtained to date show that VOCs are the principal contaminants present in the groundwater at this well.

5.1 NITRATE

Five groundwater samples had nitrate concentrations above the analytical reporting limit, with the highest value (0.25 mg/L in August 1995) being substantially below the drinking water MCL for nitrate (10 mg/L).

5.2 URANIUM

Two groundwater samples had uranium concentrations that exceeded the analytical reporting limit, the highest value (0.002 mg/L in April 1988) being substantially less than the drinking water MCL for uranium (0.03 mg/L).

5.3 VOLATILE ORGANIC COMPOUNDS

Excluding false positive results and detection of common laboratory reagents (e.g., acetone) in samples collected from the well before February 1990, one or more of the following VOCs were detected in the groundwater samples: PCE, TCE, 12DCE, 11DCE, and VC (Table 1). The Walk-In Pits (WIP) are the likely the source of the dissolved VOCs in the shallow groundwater at this well. Groundwater near the WIP contains a distinct plume of dissolved VOCs dominated by PCE, with concentrations in some areas exceeding 2000 µg/L, which is about 1% of the maximum PCE solubility and possibly indicates DNAPLs in the subsurface (DOE 1997).

The primary contaminant in the groundwater samples is PCE, which has been detected in all but one of the samples and has a historical maximum concentration of 1,600 µg/L (May 1988). The non-detected result (August 1989) is a suspected outlier (Table 1). Secondary VOCs are TCE, VC, and c12DCE which have historical maximum concentrations below 20 µg/L. Recent sampling results show that concentrations of PCE, TCE, and VC continue to exceed respective drinking water MCLs (Table 1).

As shown by the data summarized below, the PCE concentrations are lower in the groundwater flow/transport pathways intercepted by the monitored interval in well GW-288 than the PCE concentrations in the shallower groundwater flow/transport pathways intercepted by the monitored interval in well GW-289.

Well	PCE Concentration (µg/L)							
	Conventional Sampling				Low-Flow Sampling			
	May 1988	Oct. 1988	Feb. 1990	Aug. 1995	Mar. 2002	Aug. 2002	June 2005	Oct. 2005
GW-288	1,600	1,400	1,200	690	180	250	65	110
GW-289	800	880	590	930	670	690	590	940

These results may reflect the influence of the upward vertical hydraulic gradient from the shallow bedrock interval (GW-288) to the water table interval (GW-289) in the vicinity of these wells (see Section 3.0). The PCE concentrations in the shallower groundwater flow system are at least partially maintained by PCE-contaminated groundwater upwelling from deeper in the Maryville Limestone.

The preceding data summary also suggests a decreasing trend in PCE concentrations at well GW-288, which is clearly illustrated by a time-series plot (Figure 1). These sampling results suggest a reduction in the relative flux of PCE via the groundwater flow/transport pathways intercepted by the monitored interval in the well. Moreover, the persistent low concentrations of TCE and other PCE degradation products in the samples (Table 1) suggest that there is minimal biotic or abiotic degradation of the PCE in the groundwater at this well. Conversely, data for other wells that monitor VOC-contaminated groundwater with similar geochemical characteristics elsewhere at the BCBG indicate active biotic degradation of PCE and related degradation products. It is unclear from the available data why active biotic degradation of PCE apparently does not occur in the groundwater at this well.

5.4 GROSS ALPHA ACTIVITY

None of the six groundwater samples collected from the well since February 1990 had gross alpha activity above the applicable MDA and corresponding CE. Results obtained before January 1990 do not meet applicable data quality objectives because the sample specific MDA and/or CE are not available for these samples.

5.5 GROSS BETA ACTIVITY

None of the six groundwater samples collected from the well since February 1990 had gross beta activity above the MDA and corresponding CE limits. Results obtained before January 1990 do not meet applicable data quality objectives because the sample specific MDA and/or CE are not available for these samples.
